

Springer  
Handbook *of*

Power  
Systems

*Papailiou*  
*Editor*

---

**Springer Handbook  
of Power Systems**

---

**Springer Handbooks** provide a concise compilation of approved key information on methods of research, general principles, and functional relationships in physical and applied sciences. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of scientific and technical information.

The volumes are designed to be useful as readable desk book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

## Foreword

It is a great honor to compile the Foreword for this esteemed book on power systems. It is not common to find most of the topics relating to power systems in one book. This book is also unique in that, in spite of the very diverse topics, many authors are well revered and respected members of the CIGRE community. This means that they are respected leaders in their particular fields and recognized by fellow experts.

The book, which is, in fact, a series of books within a book, covers all aspects of electrical power provision from the generator to the meter. Each chapter can be read on its own, and the reader can access all the relevant information on the topic from the particular chapter without necessarily having to refer to other chapters or sections. It is not exclusively a high-voltage or transmission-based book but can be applied to all voltage levels. It can be of value to experienced engineers, as well as to newly graduated engineers, or as a textbook for undergraduates. The chapters themselves provide detailed equations for the design, operation, and maintenance of the grid and the components. The references provided will allow the reader to delve in more depth into a specific topic where necessary.

In order to understand power systems, you need to understand the basics of high-voltage engineering. The chapter on high-voltage engineering covers the theory as well as the application of the theory to power delivery. This provides a well-rounded document for the reader. As mentioned in the chapter “High-voltage engineering is knowledge about power transmission at high voltage and about stress on equipment used in high-voltage transmission systems. The basis for the design of high-voltage equipment is the stress of the insulation by the electric field, whereby the stress magnitude depends on the voltage type. Electric field distribution is given by relative permittivity for AC and by conductivity for DC and homogeneity of the electrode arrangement.” The chapter covers the mathematics and application of the theory to the components of the power grid, such as cables and conductors. The behavior of gases such as air and SF<sub>6</sub>, which are very pertinent to the equipment used on the grid, is given.

The basics of power system analysis cover power flow analysis, short-circuit analysis, stability, power system control, electromagnetic transients, and future network trends covering inverter-based resources. This provides the reader with an in-depth knowledge of all aspects of how the power system behaves under fault

conditions and under certain power system disturbances.

The chapter on switching equipment deals with various HVAC switching equipment. Fundamental interrupting phenomena and switching phenomena related to switching equipment used in power systems are explained. The chapter is very detailed and allows the reader, even one with little experience, to fully understand the components comprising a substation. The latest information on HVDC breakers is also included.

Transformers are explained in great detail from fundamentals, design equations as well as the materials used in construction. The construction of transformers is covered. Different types of transformers are explained. This includes HVDC applications, furnace, traction, and other types. This chapter covers more than most textbooks on the subject of transformer design and theory and will provide the reader with the ability to understand the design, construction, and operation of many types of transformers.

The section on cables covers the history of cables, the involvement of CIGRE in sharing knowledge of cables, as well as the theory, design, maintenance, and operation of cable systems. All cable types are covered, as well as the theory for design of cables. The topic of the upgrading of cable systems is also discussed. The chapter also explains the design and use of superconducting cables and gas-insulated lines (GIL). The reader can also expand their knowledge by studying the additional reading material provided in the last of the 14 sections. Once again, this chapter is a book in its own right, as are most of the other chapters.

The chapter on overhead lines covers all aspects required to understand the design, construction, and maintenance of overhead lines. It covers towers, foundations, insulators, as well as conductor selection and when to use certain tower, foundation, and conductor configurations. The reader can obtain a clear grasp of the concepts of line design, as well as where to apply them. The history of overhead lines and the use of compact line versus conventional line design are covered. The chapter covers the function of the line on the power grid. This relates to the selection of the optimum tower, foundation, and conductor combination. An objective

**Rob Stephen**  
President of CIGRE  
2016–2020

indicator whereby the designer can assess different design options is provided. The design of components from a mechanical and electrical point of view is also discussed. This includes the detailed design of insulators, hardware, towers, and foundations. Construction techniques, foundation testing, and asset management of transmission lines are also explained. Once read, this chapter provides the reader with a full overview of the function, design, construction, and maintenance of overhead transmission lines.

The chapter on substations is, once again, a detailed book in its own right. It covers the concept of substation design, layouts, philosophy, theory, clearances, maintenance, and so on. It provides the reader with a full understanding of the purpose of the substation, as well as which layout or configuration is best suited under which condition. It also includes safety, insulation coordination, surge arrester selection, earth mat design, and other important factors indirectly related to substation design. The chapter is written, as are the others, in such a way that the reader can understand the concepts with little or no prior experience.

The book also covers the generation side of power systems. Types of generation are explained in detail from hydrogeneration and pumped storage to nuclear, thermal, and renewable types. The chapter not only describes the generation type but also includes the equations governing the behavior of the generation. A chapter on rotating machines is also included, covering generator and large motor designs and usage in the power system.

Having read the above chapters, the reader will have an in-depth knowledge of the components and systems relating to the power system generation and delivery of power. The book then includes power system protection and power quality theory and application. The concept and philosophy of power system protection is covered, as well as the types of protection and where to apply them. The chapter on power quality covers the required quality, how to determine power quality, and the issues related to the source of power quality deviations. The reader can then broadly understand the concept of protection, as well as power quality. Optimization of the protection schemes and mitigation power quality issues can also be understood.

The above-mentioned chapters mainly deal with AC transmission. The book would not be complete, however, without a chapter on DC transmission. This chapter explains the purpose and benefits of DC transmission and goes into great detail about the types of pole configuration. Line commutated converters are explained with regard to operation and harmonics. Thyristor operation, characteristics, and valve design are explained. The chapter then looks at different tech-

nologies for converters, such as IGBTs (insulated gate bipolar transistors), VSC (voltage sourced converters), and MMC (modular multilevel converters). The chapter ends with a discussion on the HVDC grid, which was particularly pertinent at the time of writing. Future trends, including cables above 500 kV, power electronic DC circuit breakers, and off-shore DC grids are also covered. The application of DC is growing at all voltages, as the cost of the converter stations is dropping. The ability of VSC technology to allow tap offs provides the benefits of DC to be expanded to areas not possible before. At the time of writing CIGRE was investigating the development of MV and LV DC systems.

The issue of energy is then explained in great detail. This is the content of two chapters. The first deals with the energy fundamentals and covers types of traditional fossil fuels, as well as renewables, such as solar and wind energy. The global use of different types of energy used is also given, as well as emissions of CO<sub>2</sub> per country. The second chapter relating to energy deals with energy storage. The different types of storage are given, from pumped storage and batteries, to flywheels and superconducting magnetic energy storage devices. The uses of each type, as well as where to apply the different types of storage are discussed. This includes fuel cell technologies, as well as the conversion of water to hydrogen and the use of hydrogen in fuel cells. This is important as it could be the next major disruptor in the energy provision field. The reader will have enough information to determine which battery or energy storage device to use in which application.

The issue of markets is then discussed. The concept of markets has been in place for over 20 years at the time of writing this book. The chapter discusses the concept and purpose of markets, the different types of markets, and the application of markets around the world. The case studies of market success and otherwise from different continents and countries, provide the reader with a clear understanding of the pitfalls and successes of markets over the past two decades. Markets distort the power flow, as they affect the generation and use of electrical energy at all voltages. They also determine investment in different generation capacities, ancillary services, and energy provision. Note that inverter-based renewables, such as wind and solar energy provide mainly energy at a very competitive cost. The power grid needs many other components to operate successfully. This includes fault level, frequency support, voltage support, black start capability, and other factors. Markets need to ensure that these can be purchased and put in place when required by the system operator.

The book can be of immense use, not only to university students but also to professionals who have been

in the business of power delivery for a number of years. It provides an excellent overview of the entire industry in one place, which is unique. It is not possible for engineers to be aware of all aspects from markets to transformer design; this book provides a source of valuable information, which can be rapidly referenced and studied.

A further major benefit of the book is that all royalties will be channeled to the development of young engineers via the CIGRE organization ([www.cigre.org](http://www.cigre.org)). This will provide young engineers with the means to meet and discuss with international experts within the CIGRE organization.

I would encourage the reader to study the book and follow up with an in-depth study of the topics covered in

the CIGRE brochures to be found at [www.e-cigre.org](http://www.e-cigre.org). In addition, it is with great pleasure that I can announce that a CIGRE “Green Book”, entitled “Electrical Supply System of the Future” is now available. This book is authored by each of the 16 Study Committees of CIGRE and provides the best possible solutions to enable stakeholders to fully understand the new trends and developments of all components and systems, including markets and regulations that comprise the future grid. This Green Book is an excellent complementary addition to this handbook, and I highly recommend it.

12 August 2020

Rob Stephen  
President CIGRE

## Preface

There is no doubt that writing a book is a stressful endeavor that requires a lot of effort. However, I like comparing the experience of holding a printed copy of the book for the very first time to holding your newborn baby. Being the Editor of a big work like this handbook is at least one level up. Firstly, the work involved takes a considerably longer time than writing a monograph – in our case 5 years – and, secondly, the stress and effort are not limited to birth labor but includes the teething and all the other problems of having a toddler, too. Thankfully, also the pleasure and the proudness of the achievement grow accordingly. In this sense, I am extremely happy and honored to write these lines today, as, evidently, the preface is written a posteriori, i.e., when all the hard work has been done.

I recall the day when Dr Christoph Baumann from Springer asked to have a meeting, during which he placed a heavy, bulky book of the typical Springer red color in front of me. He explained that this was a *Springer Handbook* and asked if I would be interested in becoming the Editor of a new *Springer Handbook of Electrical Power Systems*. My Greek spontaneity took over, and within seconds I agreed. To be honest, despite all imaginable and unimaginable issues that arose during the production of such a major work, and despite my Swiss tendency for perfection, which did not make things easier, I never regretted this decision.

The simplest part was finding the chapter authors. I am extremely proud that my colleagues from academia and industry, the great majority strongly involved in CIGRE, and all of them undisputed leaders in their field, responded positively to my request to become part of this great task. I cordially thank all of them for their strong engagement, which is not self-evident, considering that the writing of the book had to take place in parallel and in addition to their day-to-day work and other important responsibilities. That all authors spontaneously agreed to offer their book royalties to CIGRE in order to support its activities for young engineers is such a clear sign of goodness and generosity for which I can only say: *Chapeau*.

The writing itself proved to be more demanding. To start with, it took some time to decide on the final number, title, and content of the individual chapters, as these should reflect the nature of a Handbook, i.e., the all-embracing coverage of its subject, in this case, electrical power systems. I am confident that the final selection will satisfy our readers.

Then, being a chapter author myself, I realized quite early on that writing a chapter for a handbook is very different from writing a paper or a monograph. While the latter often present new research results, a handbook chapter summarizes established and accepted knowledge for the benefit of the reader. The fact that, by nature, the available space is limited does not make writing any easier – or faster – as the author is continuously trying to find the balance between actuality and tradition, and this as succinctly as possible.

It goes without saying that the high standards of Springer, and also of all authors and the editor, entailed a thorough, strenuous review of each chapter. This would not have been possible if a high number of internationally acclaimed experts had not offered to undertake the task. From my heart, I also thank them for adding immense value to this publication.

To continue in the same vein, unlimited thanks are offered to Dr Christoph Baumann, the initiator of this project, Dr Judith Hinterberg, and her maternity cover, Heather King, for their masterful coordination and management of such a complex undertaking, Dr Werner Skolaut for the skillful language and content editing, Jeanette Krause for the very attractive layout, and all other people involved in the production of this book, in particular those responsible for redrawing all figures and diagrams with such unprecedented quality.

Last, but definitely not least, I would like to thank CIGRE, the great organization that has fostered my scientific and engineering activities, actually my life for the last 45 years, and in particular my good friend Dr Rob Stephen, the CIGRE President, who was kind enough to write the Foreword, and the Secretary General of CIGRE, Philippe Adam, for arranging that CIGRE endorses this Handbook, which I consider a major distinction. And it is a very exciting coincidence that our Handbook will be published in 2021, the centennial year of CIGRE!

No list of thanks would be complete without mentioning my family and, in particular, my wife Margarita, who incidentally I met many, many years back at a CIGRE venue, for always encouraging and supporting my work.

It has been an unforgettable time, *merci!*

Athens, Greece  
July 2020

Konstantin O. Papailiou

---

## About the Editor

**Konstantin O. Papailiou** has spent his entire career of more than 45 years working in the field of power systems and, in particular, overhead lines. He received his doctorate from the Swiss Federal Institute of Technology (ETH) Zurich and his postdoctoral qualification as lecturer (Dr.-Ing. habil.) from the Technical University of Dresden, where he is also Honorary Professor. Until his retirement, he was the CEO of the Pfisterer Group, a company he served for over 25 years. He has held leading positions in various international technical societies and standardization bodies and has authored a number of books and more than 100 papers.

Professor Papailiou is active in power engineering education, teaching courses on high-voltage overhead lines at the University of Stuttgart and the Technical University of Dresden. Since 1976 he has been strongly involved with CIGRE; he has served as Chairman of the CIGRE Study Committee “Overhead Lines” and is the founding Editor-in-Chief of the CIGRE Science and Engineering Journal. In 2020, he was awarded the CIGRE Medal, the organization’s highest distinction.

## List of Abbreviations

1-D	one-dimensional
2-D	two-dimensional
3-D	three-dimensional

### A

AAAC	all aluminum alloy conductor
AAC	all aluminum conductor
AAS	atomic absorption spectrometry
AC	alternating current
ACAR	aluminum conductor alloy reinforced
ACCC	aluminum conductor composite core
ACCR	aluminum conductor composite reinforced
ACE	area control error
ACIM	automated continuous injection molding
ACSE	association control service element
ACSI	abstract communications service interface
ACSR	aluminum conductor steel-reinforced
ACSS	aluminum conductor steel-supported
ADC	analogue-to-digital converter
ADM	add-drop multiplexer
ADMS	advanced distribution management system
ADN	active distribution network
ADNR	active distribution network reconfiguration
ADSS	all-dielectric self-supporting
AFC	alkaline fuel cell
AGC	aerodynamic galloping controller
AGC	automatic generation control
AGM	absorbent glass mat
AGR	advanced gas cooled reactor
AGS	Armor-Grip Suspension
AIS	air-insulated switchgear
Al	aluminum
ALARP	as low as reasonably practicable
AM	accounting management
AMF	axial magnetic field
AMI	advanced metering infrastructure
AMR	automated meter reading
AN	acoustic noise
ANM	active network management
APC	active power curtailment
API	application programming interface
API	arc plasma injector
AR	automatic reclosing
ARP	address resolution protocol
ASE	application service elements
ATCC	automatic tap-change control
ATH	aluminum trihydrate
ATI	appropriate technology index
AVR	automatic voltage regulator
AWM	aircraft warning marker

### B

BAP	basic application profiles
-----	----------------------------

BCM	business continuity management
BCP	business continuity planning
BEM	boundary element method
BER	basic encoding rules
BESS	battery energy storage system
BF	breadth-first
BGP	border gateway protocol
BI	business impact
BIL	basic insulation level
BM	balancing mechanism
BML	business management layer
BMS	battery management system
BO	blocking overreach
BOD	breakover diode protection
BPL	broadband power-line
BPS	bypass switch
BTF	bus terminal fault
BWR	boiling water reactor

### C

C/S	converter station
CAES	compressed-air energy storage
CAIDI	customer average interruption duration index
CAPEX	capital expenditure
CAS	corrugated aluminum sheath
CB	circuit breaker
CBFP	circuit-breaker failure protection
CBM	condition-based maintenance
CC	core clamping
CCC	capacitor commutated converter
CCS	carbon capture and storage
CCUS	CO <sub>2</sub> capture utilisation and storage
CD	combined design
CDC	common data class
CEP	Clean Energy Package
CET	Central European Time
CF	creepage factor
CFC	chlorinated fluorocarbon
CFL	cantilever failing load
CGIC	compressed gas-insulated cable
CGMES	common grid model exchange specification
CHP	combined heat and power plant
CIM	common information model
CIS	component interface specification
CL	corona loss
CL	core lamination
CM	configuration management
COI	center of inertia
CORBA	common object request broker architecture
CPT	cone penetration test
CRM	customer relationship management
CRM	condition reliability maintenance
CSI	current source inverter
CSS	controlled switching systems

CT	current transformer
CUR	contamination uniformity ratio
CVD	capacitive voltage divider
CVM	collection volume method
CVT	capacitive voltage transformer
CWDM	coarse-wavelength division multiplexing

**D**

DAC	damped AC
DC	direct current
DCUB	directional comparison unblocking
DER	distributed energy resources
DFIMG	doubly-fed induction motor generator
DFT	discrete Fourier transform
DG	distributed generation
DGA	dissolved gas analysis
DIL	design insulation level
DL	pressure line
DLL	damage limit load
DM	degraded minute
DMFC	direct methanol fuel cell
DMR	dedicated metallic return
DMS	distribution management system
DNP	distribution network planning
DoD	state of discharge
DP	digital position
DPF	distribution power flow
DR	demand response
DRP	Deutsches Reichspatent
DRS	dynamic rating system
DS	disconnecting switch
DSC	differential scanning calorimetry
DSE	distribution state estimation
DSO	distribution system operator
DSSE	distribution system state estimator
DT	diagnostic test
DTC	distribution transformer controller
DTC	direct torque control
DTOC	definite time overcurrent
DTS	distributed temperature sensing
DTT	direct transfer tripping
DUT	device under test
DVR	dynamic voltage restorer
DWDM	dense-wavelength division multiplexer
DZ	discriminating zone

**E**

EBP	energy balance principle
ECC	earth continuity conductor
ECT	electronic current transformer
EDS	everyday stress
EF	electric field
EGM	electro-geometric model
EHV	extrahigh voltage
EIA	environmental impact assessment
EMC	electromagnetic compatibility
EMF	electromagnetic field

EMF	electromotive force
EMI	electromagnetic interference
EML	element management layer
EMS	energy management system
EMTP	electromagnetic transient
EMTP-RV	electromagnetic transient program
EMU	electromagnetic unit
EP	equilibrium point
EPDM	ethylene propylene diene monomer
EPE	experimental plastic elongation
EPM	ethylene propylene monomer
EPR	ethylene propylene rubber
EPR	European pressurized reactor
ERP	enterprise resource planning
ES	errored second
ES	elastomeric suspension
ES	earthing switch
ESCR	effective short-circuit ratio
ESD	energy storage device
ESDD	equivalent salt deposit density
ESS	energy storage system
ETT	electrically triggered thyristor
EV	electric vehicle
EVT	electronic voltage transformer

**F**

FACTS	flexible alternating current transmission system
FAT	final acceptance test
FC	functional constraint
FC	fast contact
FCAPS	fault, configuration, accounting, performance, and security model
FDM	frequency division multiplexing
FDR	frequency-domain reflectometry
FDS	frequency-domain spectroscopy
FEC	forwarding equivalence class
FEM	finite element method
FEP	tetrafluoroethylen-hexafluoropropylene
FES	flywheel energy storage
FF	fluid-filled
FFT	fast Fourier transformation
FLISR	fault location, isolation, and service restoration
FM	fault management
FMEA	failure mode and effects analysis
FPD	fast protective device
FPI	fault passage indicator
FRA	frequency-response analysis
FRP	fiber reinforced plastic
FTIR	Fourier-transform infrared
FTR	financial transmission rights

**G**

GAMS	general algebraic modeling system
GCD	galloping control device
GDP	gross domestic product

GES	generic eventing and subscription	IE	international efficiency
GF	gas-filled	IEC TS	IEC Technical Specification
GFD	ground flash density	IED	intelligent electronic device
GFP	generic framing protocol	IETF	internet engineering task force
GIC	geomagnetically induced current	IGBT	insulated-gate bipolar transistor
GIL	gas-insulated line	IGCT	integrated gate commuted thyristor
GIS	gas-insulated switchgear	IOP	internet inter-ORB protocol
GITL	gas-insulated transmission line	IMP	intermetallic phase
GOOSE	generic object-oriented substation event	INMR	Insulator News and Market Report
GPR	grid potential rise	IOA	information object addresses
GPS	global positioning system	IOC	instantaneous overcurrent
GRP	glass reinforced plastic	IP	interior point
GRTS	ground return transfer switch	IP	internet protocol
GSSE	generic substation status event	IPS	interphase spacer
GSU	generator step-up	IR	infrared
GtL	gas-to-liquid	IR	insulation resistance
GTO	gate turn-off thyristor	IRLS	iteratively reweighted least squares
GWP	global warming potential	ISWR	inverse standing wave ratio
<hr/>			
<b>H</b>			
<hr/>			
HAES	helically attached elastomeric suspension	ITP	inspection and test plans
HAN	home-area network	ITRV	initial transient recovery voltage
HDD	horizontal directional drilling	ITU-T	International Telecommunication Union telecommunication standardization sector
HDPE	high-density polyethylene	IVT	inductive voltage transformer
HF	high-frequency	<hr/>	
HHPSA	hexahydrophthalic anhydride	<b>J</b>	
HIL	hardware in the loop	<hr/>	
HIS	hybrid-insulated switchgear	JBD	jitter buffer delay
HMI	human-machine interface	<hr/>	
HP	horsepower	<b>K</b>	
HP	high-pressure	<hr/>	
HPFF	high-pressure fluid-filled	KPI	key performance indicators
HPGF	high-pressure gas-filled	KPT	knee-point temperature
HPOF	high-pressure oil-filled	<hr/>	
HSDA	high-speed data access	<b>L</b>	
HSEQ	health safety, environment and quality	<hr/>	
HSGS	high-speed grounding switch	LA	light angle
HT	Hydrophobicity transfer	LAN	local area network
HTLS	high-temperature low-sag	LC	induction-capacitance
HTM	hydrophobicity transfer material	LCA	life cycle assessment
HTR	high-temperature reactor	LCAS	link capacity adjustment scheme
HTS	high-temperature superconductor	LCC	life cycle cost
HTV	high-temperature vulcanized	LCC	line-commutated converter
HV	high voltage	LCD	load control device
HVAC	high-voltage alternating current	LD	logical devices
HVDC	high-voltage direct current	LDAP	lightweight directory access protocol
HVHS	high-voltage, high-speed switches	LDC	line-drop compensation
HVIGBT	high-voltage insulated gate bipolar transistor	LDP	label distribution protocol
HWR	heavy water reactor	LDPE	low-density polyethylene
<hr/>			
<b>I</b>			
<hr/>			
IC	initial cost	LE	linear elastic
ICE	internal combustion engine	LEC	local energy community
ICM	impulse current method	LED	light emitting diode
ICT	information and communications technology	LFP	lithium-iron phosphate
IDL	interface definition language	LI	lightning impulse
IDMT	inverse definite minimum time	Li-Po	lithium-ion polymer
		lidar	light detection and ranging
		LIM	linear induction motor
		LIPL	lightning impulse protection level
		LIWV	lightning impulse withstand voltage
		LLF	long line faults

LLW	live line work
LMR	land mobile radio
LMW	low molecular weight
LN	logical node
LOLP	loss of load probability
LP	linear programming
LP	low-pressure
LPC	last point of contact
LPIT	low-power instrument transformer
LPOF	low-pressure oil-filled
LSA	load shed application
LSP	label-switched path
LSPM	line start permanent magnet
LSR	label switch router
LSR	liquid silicone rubber
LTO	lithium titanate oxide
LTS	low-temperature superconducting
LTT	light-triggered thyristor
LV	low voltage
LVAC	low-voltage AC
LWC	low-weight conductor

**M**

MAP	maximum available power
MCA	maximum credible accident
MCCB	molded case circuit breaker
MCFC	molten carbonate fuel cell
MDCL	maximum design cantilever load
MF	magnetic field
MG	motor generator
MHHPASA	methylhexahydrophthalic anhydride
MI	mass-impregnated
MIF	multi-infeed factor
MIM	multiple impulse method
MJ	megajoule
MM	multimode
MMC	modular multilevel converter
MMF	magnetomotive force
MMI	man-machine interface
MMS	manufacturing message specification
MO	metal oxide
MOS	metal oxide semiconductor
MOSA	metal-oxide surge arrester
MOSFET	metal-oxide-semiconductor field effect transistor
MP	medium-pressure
MPLS	multiprotocol label switching
MPP	maximum power point
MPPT	maximum power-point tracking
MRTB	metallic return transfer breaker
MTBF	mean time between failure
MTBM	microtunnel boring machine
MTS	mixed-technology switchgear
MTTR	mean time to repair
MV	medium voltage
MVA	megavolt ampere
MW	active power

**N**

NBR	nitrile butadiene rubber
NCA	network connectivity analysis
NCI	nonceramic insulator
NCIT	nonconventional instrument transformer
ND	network delay
NE	normal equation
NFB	no-fuse breaker
NIMBY	not in my backyard
NLP	nonlinear programming
NMC	network management center
NMC	nickel mangan cobalt
NML	network management layer
NMS	network management system
NPP	nuclear power plant
NPV	net present value
NS	North and South
NSDD	non soluble deposit density
NSP	nonsalient pole
NSPG	nonsalient-pole generator
NSPL	nonsalient pole
NSPM	nonsalient-pole machine

**O**

OAM	operation, administration, and maintenance
OC	open circuit
OCC	open-circuit characteristic
OD	oil-directed
ODP	open drip-proof
OEE	overall equipment effectiveness
OEL	overexcitation limiter
OF	oil-filled
OF	oil-forced
OHL	overhead line
OHLCD	overhead line corrosion detector
OHS	occupational safety and health
OHVS	offshore high-voltage substation
OIP	oil-impregnated paper
OLTC	on-load tap changer
OMG	object management group
OMS	outage management system
ON	oil-natural
OP	out-of-phase
OPEX	operational expenditure
OPF	optimal load flow
OPGW	optical ground wire
ORB	object request broker
OSI	open system interconnection
OTDR	optical time-domain reflectometry
OV	overvoltage
OW	headwater
OWS	oscillating wave system

**P**

PA	polyamide
PAFC	phosphoric acid fuel cell

PAR	phase-angle regulator
PCB	polychlorinated biphenyl
PCC	point of common coupling
PCE	path computation element
PCI	protocol control information
PCR	price coupling of regions
PD	partial discharge
PD	packetization delay
PDH	plesiochronous digital hierarchy
PDIV	partial discharge inception voltage
PDMS	polydimethylsiloxane
PDU	protocol data units
PE	polyethylene
PED	portable earthing device
PEFC	polymer electrolyte fuel cell
PEM	polymer electrolyte membrane
PF	power frequency
PF	power factor
PFA	perfluoroalkoxy
PFC	power factor corrected
PI	polyimide
PI	polarization index
PI	proportional integral
PICOM	piece of information for communication
PLC	programmable logic controller
PLC	power line carrier
PM	performance management
PM	permanent magnet
PMG	permanent magnet generator
PMR	private mobile radio
PMU	phasor measurement unit
POE	polyoxide ethylene
POTT	permissive overreaching transfer trip
PPA	power purchase agreement
PPA	purchasing-power adjusted
PPL	polypropylene paper laminate
PPL-MI	polypropylene laminate, mass impregnated
PPP	purchasing power parity
PSA	phthalic anhydride
PSS	power system stabilizer
PT	potential transformer
PT	pump turbine
PTFE	polytetrafluoroethylene
PtG	power to gas
PTP	precision time protocol
PU	polyurethane
PUP	permissive underreach transfer tripping scheme
PUTT	permissive underreach transfer tripping scheme
PV	power voltage
PV	photovoltaic
PVC	polyvinyl chloride
PVGIS	photovoltaic geographical information system
PW	pseudowire
PWM	pulse width modulation
PWM-VSI	pulse width modulated voltage source inverter
PWR	pressurized water reactor

# Energy Fundamentals

Valentin Crastan

Fundamentals and the structure of energy supply with primary energy, final energy, energy carriers, reserves and resources, and the potential and use of renewable energy are presented in this chapter.

Past energy demand and CO<sub>2</sub> emissions are illustrated for all regions of the world and for the most important countries. The desired future development with regard to climate protection is discussed and illustrated with the aid of the most important indicators.

## 1.1 Basic Terms, Historical Review

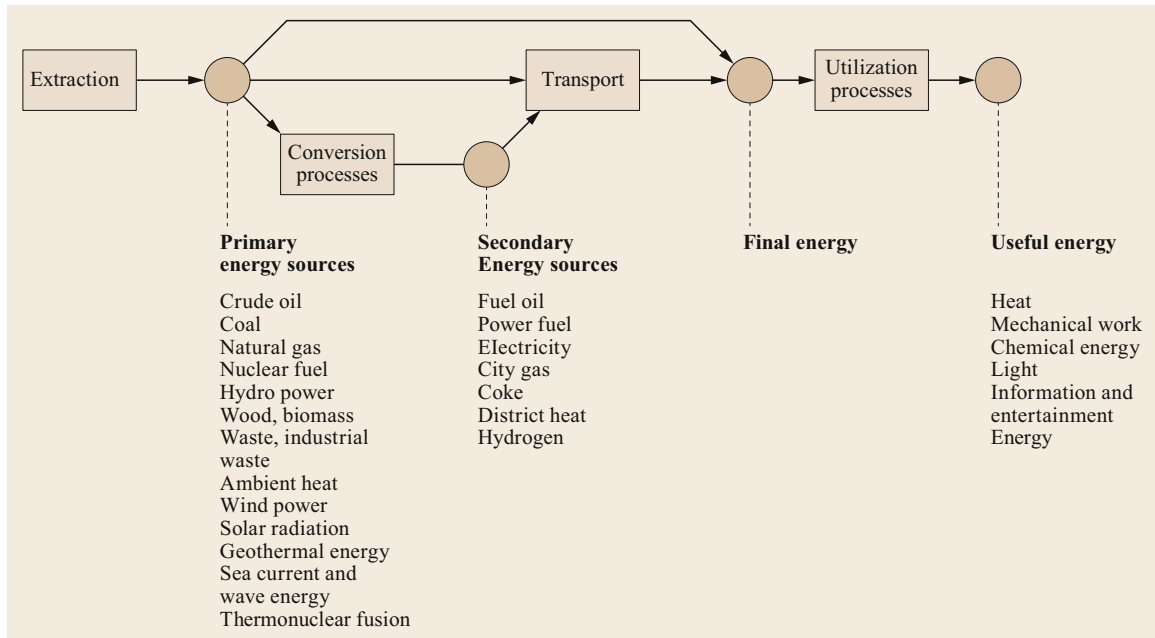

Figure 1.1 represents the structure of the energy industry, showing the energy carriers in use today and the possible future of energy carriers. We distinguish between four energy conversion stages: *Primary energy*, *secondary energy*, *final energy* and *useful energy*.

Companies with activities in the *extraction*, *conversion* and *transport* of energy carriers, form the *energy sector of the economy*. Their task is to provide the *end-*

*user* with energy in the desired form of energy carrier (*final energy*) The consumer converts the *final energy* by means of *usage processes* into *useful energy*.

### 1.1.1 The Energy Sector

*Primary energy carriers* are sources of energy that occur naturally. For the most part, they are not used at

**Fig. 1.1** Forms of energy, and energy conversion stages

the places where they occur, but are first extracted (e.g., mined), then transported and, if necessary, converted into another more suitable form of energy (secondary energy carriers). Coal and natural gas are usually simply extracted and transported to the place of use; oil, on the other hand, is converted into heating oil and motor fuel in refineries; naturally occurring uranium is converted into nuclear fuel; coal, oil, natural gas, water power, wind power, nuclear fuels, solar heat and refuse, generate electricity in power stations.

Fossil fuels, nuclear fuels, hydropower, wind power, solar radiation, geothermal energy, biomass and waste generate electricity and district heating in power plants and combined heat and power plants. A few energy sources, such as solar radiation and ambient heat, but also geothermal heat and wind, can be used in a decentralized way as heat or to generate electricity directly at the place where they arise.

In addition to the most important *secondary energy carriers* that have already been mentioned such as heating oil, motor fuel, electricity and district heat, Fig. 1.1 also shows hydrogen as a secondary energy carrier that could be important in the future (for more details, see [1.1]).

*Extraction*, *transformation* and *transport* are associated with costs, losses and environmental impact.

Under normal conditions and when dealt with correctly and competently, the processes of *mining* and *transport* have only a small adverse environmental impact, but in wartime situations and when there are

accidents with fossil and nuclear fuels, they can have very serious environmental consequences. Some examples are: accidents with tankers, sabotage and fires in conveyor equipment and oil and gas pipelines, accidents in the transport of radioactive fuel elements.

In the *conversion* processes the harm is, above all, the constant environmental pollution from the *burning of fossil fuels* (combustion products, CO<sub>2</sub> that damages the climate). Further localized sources of environmental pollution can be accidents in nuclear power stations, oil storage tanks and refineries.

In addition, the *conversion* of thermal energy from fossil and nuclear fuels into mechanical or electrical energy always produces a high level of *waste heat* for thermodynamic reasons. With appropriate investments, it is possible to use part of this heat (combined heat and power, Chap. 2).

*Final energy* or *final consumption* is the energy actually available to the consumer. *National energy statistics* generally refer to final consumption and/or primary energy, or *gross consumption* (annual consumption of indigenous primary energy carriers plus the import–export difference in primary and secondary energy carriers). The figures differ considerably because of the losses arising in conversion and transport, which includes the energy consumption of the energy sector itself. The *conversion losses* are very high. *Transport losses* arise primarily in the transmission and distribution of electrical energy which, for example in Switzerland, has an overall efficiency of 93%, with the

greatest part of the losses occurring in the distribution network.

### 1.1.2 Energy-Usage Processes

Final energy is converted by the energy-usage processes of energy consumers (households, industry, services, commerce, agriculture, traffic) into *useful energy*, mainly *heat*, *mechanical work* and *light* (Fig. 1.1). A small part is stored in the form of *chemical energy* in end products (steel, aluminum etc.). The amount of this is insignificant, at least in Switzerland. Another small part, but this is likely to increase in the future, is the energy used in *information technology* and *entertainment* (for computers, leisure electronics and communication).

*Energy-usage processes* have very different efficiencies. Whereas, for example, in an electrical heater the electricity is 100% converted into heat, on average only about 20% of the energy in the fuel of a present-day automobile is converted into mechanical energy and a conventional incandescent light bulb converts only about 5% of the electrical energy into light (but at least in winter, the rest of the energy is not lost but contributes to heating the buildings). The energy-usage processes are therefore in some cases associated with large losses of energy; the average efficiency has been estimated, for example for Switzerland in 1997, as 56% [1.2]. Burning fossil heating fuels and motor fuels produces gas emissions, which are *locally* and *globally* (generation of CO<sub>2</sub>) a considerable source of *environmental pollution* (Sect. 1.7).

### 1.1.3 Historical Review

The *uses made* of final energy have changed only little and slowly since the beginnings of human history. Only the range of available energy carriers is much wider, and the technologies of energy conversion and usage have become more varied, efficient and convenient.

#### Mechanical Work

Today, as in previous times, *mechanical work* is used for acquiring and creating goods, for providing services and for transporting goods and people. The muscular efforts of humans and animals were prerequisites for survival in almost all early societies, both for the hunter-gatherers and even more so for the farmers. In ancient times, urban societies could only exist and develop thanks to slave workers. Over the course of time it became possible to make more effective use of muscle power and increase productivity through many mechanical inventions such as the wheel and the lever and, later, all kinds of mechanical devices, and also making use of the natural forces of

water and wind (water-wheel, windmill, sailing ships), in other words to exploit new sources of energy. Much later, starting in the eighteenth century, was the beginning of replacing muscle power by more powerful steam machines. From the end of the nineteenth century, electric motors enabled a big increase in productivity and in the twentieth century, internal combustion engines resulted in greatly increased mobility.

#### Heat and Light

Today, as in earlier times, *heat* and *light* serve to protect from the cold, in the provision of food, increasing security, improving conditions of work, human well-being and thus the development of cultural activities. Energy sources were originally wood, plant waste and dried dung. Hot springs were already in use in ancient times. Coal first came gradually at the end of the seventeenth century and then mineral oil, natural gas and electricity which were not in widespread use for generating heat until the twentieth century.

Heat, mostly at high temperature, was also used for producing various kinds of goods (metals, earthenware, jewelry and art objects). In this connection, we speak today of industrial and commercial *process heat* (in contrast to *heat for cooking and comfort*).

#### Summary

The *structure of making energy available and using it* changed but little for millennia until developments in science from the end of the eighteenth century led to the *age of technology*. The beginnings of this were already present in antiquity and in the Middle Ages. But only in recent times were revolutionary technical means invented for the mechanical use of the heat energy of fuels (steam engines, and later, combustion engines). Success was achieved in creating new (secondary) energy carriers such as town gas and electricity and in distributing them to small-scale consumers. *Electricity* in particular simplified and encouraged the use of energy on a scale previously unknown and, together with *coal*, made the industrial revolution possible. In many countries *water power* gained great significance in generating electricity. Coal, initially the most important primary energy carrier, was to an increasing extent replaced by *mineral oil* after the 2nd World War, i.e., in the 2nd half of the twentieth century, but in many countries it retains a primary position in the generation of electricity. Finally, new primary energy sources were successfully exploited such as *natural gas* and *nuclear fission*.

The structure of the energy industry underwent a fundamental change in the course of a century. The muscle power of humans and animals is still used today (e.g., the bicycle as a means of transport) but is not included in the energy statistics. Wind and water power

are only taken into account to the extent that they contribute to the production of electricity.

### 1.1.4 Perspectives and Problems

The progress of civilization in the twentieth century would have been considerably slower without cheap energy. The *use of energy* in industrialized societies increased by a factor of more than ten in the course of that century. It freed humanity from the burden of heavy manual work and made a decisive contribution to a previously unimaginable mass prosperity. Although this process initially only affected a part of the world, it was the basis for a world-encompassing improvement in the material conditions of life.

An important element of this *progress* was firstly the mechanization of manual labor, and later its replacement by automation. Connected to this are rapid

changes in social structures and a progressive intellectualization of work in general. The social problems that arise from this are a challenge for the socio-economic order, also in the developed world, and cannot be solved simply by an often inadequately thought-out globalization. More of the dark sides of this development became manifest in recent decades with *overloading and poisoning of the biosphere* and *threats to the stability of the climate*.

Attempts are being made to rectify this through political demands for *social and ecological sustainability*. The contribution of the energy industry lies in the implementation of making energy available with the *least possible damage to the environment* and in *environmentally sustainable* usage of energy (Sects. 1.6 and 1.7). In this context, the *rational use* of energy is very important, i.e., the improvement of the efficiency levels of all processes.

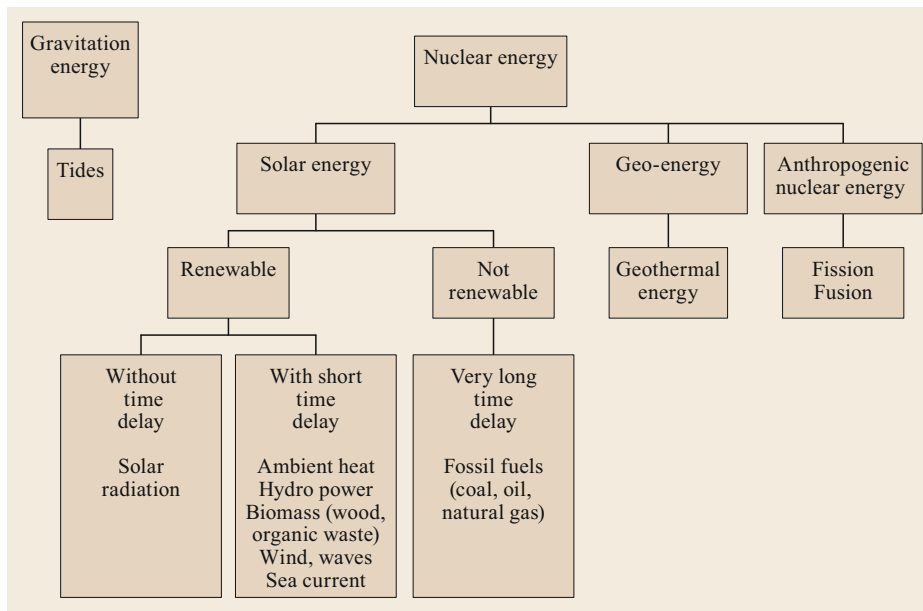

## 1.2 Availability of Primary Energy

All the primary energy carriers listed in Fig. 1.1 can ultimately be traced back to the two principal forms that occur in the universe, *gravitational* and *nuclear energy*, as is shown in Fig. 1.2, with the second being much more significant.

The primary energy carriers can be divided into two large classes that are discussed below:

- *Non-renewable energies*: fossil and nuclear energy carriers
- *Renewable energies*: tidal energy, geothermal energy and above all, direct and indirect solar energy.

Table 1.1 lists and estimates the *energy content* of important energy carriers. Since various units are used in the literature, conversion factors are indicated.

**Fig. 1.2** Origins of available primary energy types

**Table 1.1** Energy content of energy carriers (mean values [1.3]) and conversion factors

Energy carriers		Conversion factors
Oil	10 000 kcal/kg	860 kcal/kWh
Hard coal	6700 kcal/kg	4.19 kJ/kcal
Lignite	4800 kcal/kg	3.6 MJ/kWh
Wood	3600 kcal/kg	31.54 GJ/kWa
Waste	2840 kcal/kg	0.753 toe/kWa
Natural gas	8660 kcal/m <sup>3</sup>	1.12 tce/kWa
Gas from coal and oil (town gas)	4200 kcal/m <sup>3</sup>	1 kWa = 8760 kWh
Uranium 235	20 Tcal/kg	

## 1.2.1 Non-Renewable Energies

### Future Demand

Coal, mineral oil, natural gas, fissile materials (uranium, thorium) are not renewable energy sources. The fusion process has not yet been implemented [1.1, Chap. 11]. In 2016, about 86% of primary energy demand were met from non-renewable energies. According to the older IEA scenarios (International Energy Agency), this share will decline only slightly by 2030 to 86% according to the reference scenario of 2004 and to 83% according to the alternative scenario of 2004; slightly more, namely to around 75%, with the newer 450 scenario of the IEA of 2009 [1.4, Special excerpt] (Fig. 1.3, more details in Sect. 1.6). Less optimistic are the New Policies and Gas Scenario scenarios from

2011, which focus more on CCS (carbon capture and storage). The INDC scenario of 2015 corresponds to the declared contributions of the countries (worldwide); the Bridge scenario of 2015 [1.5] tries to approach the 450 scenario more, but with a lower share of renewable energies (about 15%). The last IEA statistic gives for 2016 a worldwide energy demand of 18.3 TW.

Assuming, for example, that the average energy demand of about 17 TW in 2014 would increase linearly to 20 TW (approx. 15 Gtoe/a) by 2030 and then stabilize by 2050, the cumulative energy demand during this period would be about 710 TWa. The question arises about the *reserves* and *resources* of exhaustible energy sources, whether and how they are able to cover about 80% of this demand, i.e., around 570 TWa. According to the bridge scenario of the IEA (Fig. 1.3), for example, this quantity would be distributed as follows: coal (160 TWa), petroleum (200 TWa), natural gas (160 TWa), uranium (50 TWa).

### Reserves and Resources

*Reserves* are verifiable deposits that can be used at today's market prices and by means of today's technologies. *Resources* are deposits that are known to exist but at present cannot be economically extracted, or those that are assumed and

[...] probably discovered in the future and/or used with technologies yet to be developed and sold at what will then be usual prices. [1.13]

**Fig. 1.3** IEA: World energy demand 2009 and scenarios for 2030 (or 2035), 1 TW = 753 Mtoe/a = 31,54 EJ/a [1.4–7] (Alt: alternative IEA scenario of 2004; New Pol. = New Policies IEA scenario of 2011; INDC = IEA scenario of 2015, corresponds to the declared contributions of countries (worldwide))

**Table 1.2** Reserves and resources of fossil and nuclear energy sources. The duration of the reserves is based on conventional reserves in 2006 [1.8, 9] and on the average consumption of the period 2004–2030 (average forecast IEA)

	Reserves 1980 <sup>a</sup> (TWa)	Reserves 1990 <sup>a</sup> (TWa)	Reserves 1998 <sup>a</sup> 1997 <sup>b</sup> 1996 <sup>c</sup> (TWa)	Reserves 2006 <sup>d</sup> (TWa)	Resources 2006 <sup>d</sup> (TWa)	Range in years of conv. reserves
Petroleum conventional	118	181	185 <sup>a</sup> /203 <sup>b</sup>	216	109	36
Petroleum unconventional	19	68	180 <sup>b</sup>	88	332	–
Natural-gas conventional	89	142	170 <sup>a</sup> /161 <sup>b</sup>	219	250	48
Natural-gas unconventional	–	–	4 <sup>b</sup>	–	1852	–
Coal	647	1005	878 <sup>c</sup>	842 <sup>b</sup> /676	8101	135
Uranium	39	61	63 <sup>c</sup>	85 <sup>e</sup>	98	65

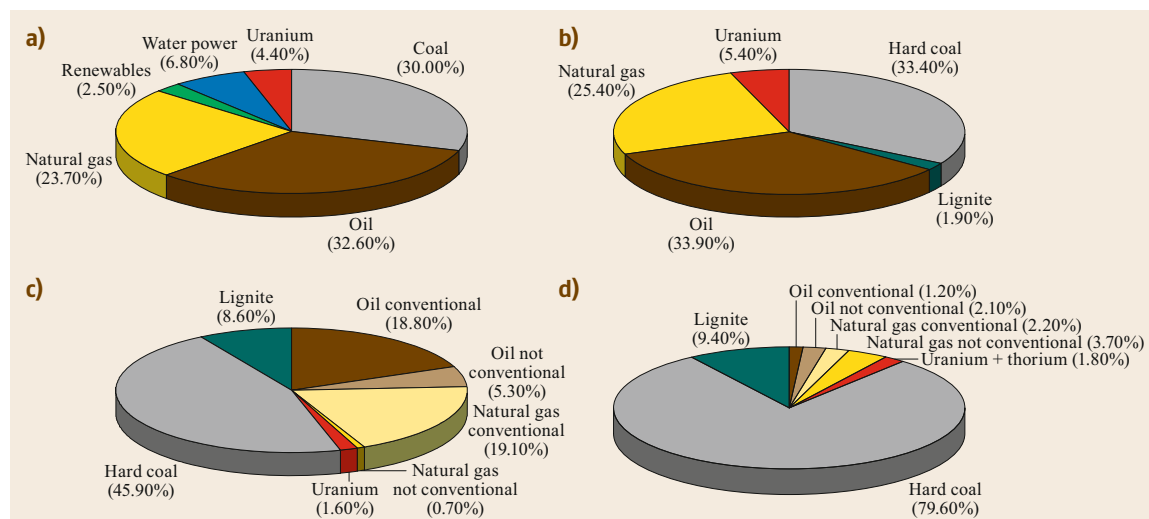

<sup>a</sup> [1.8, 10]; <sup>b</sup> [1.11]; <sup>c</sup> [1.12]; <sup>d</sup> [1.12]; <sup>e</sup> (OECD/IAEA)

The sizes of the reserves and resources are often re-vised upwards, but with differences depending on who collects the statistics, and when (Table 1.2). Resources increase as a result of research and prospecting, that lead to a better understanding of our planet. Resources become reserves when new economically exploitable deposits are discovered, and also as a result of technological progress or higher market prices.

The status of reserves and resources at the end of 2014, as reported by the BGR [1.9], is shown in Fig. 1.4.

The figures of Table 1.2 and Fig. 1.4 show that, thanks to coal, there is no threat of a global shortage in the medium term. The critical energy carrier is mineral oil. The so-called *mid depletion point* (that follows the maximum production point and after which no fur-

ther increase of production is possible) is the date when half the reserves have been used and is estimated by most experts to be 2030–2035. From this date, a large price increase can be expected. The situation is similar for natural gas, with the difference that the reserves are larger and the critical point will not be reached until 2050–2060. There is the possibility of converting coal into liquid and gaseous fuels and of the technology of separating and storing (sequestration) the resulting CO<sub>2</sub>. However, the required industrial processes are still at the stage of development and testing. The outlook as regards technical, economic and ecological aspects is therefore still uncertain. Overall, it seems sensible and sustainable, including from the point of view of the reserves, to reduce the worldwide consumption of fossil energy sources more quickly than the IEA studies

**Fig. 1.4a–d** Worldwide shares of all energy sources in consumption and non-renewable energy raw materials in production, reserves and resources for the end of 2014; (a) Energy consumption: 540 EJ = 17.1 TWa = 12 890 Mtoe; (b) Energy production with non-renewable energy sources: 522 EJ = 16.5 TWa = 12 460 Mtoe; (c) Reserves of non-renewable energy sources: 37 934 EJ = 1202 TWa; (d) Resources of non-renewable energy sources: 551 813 EJ = 17 490 TWa (Source: [1.9])

of 2011 foresee for 2035. The IEA–450 scenario of 2009 and the Bridge scenario of 2015 correspond quite well to this circumstance (Fig. 1.3, see also Sects. 1.6–1.7).

The uranium reserves have been calculated for a marginal price of 130 \$/kg. This is, however, somewhat elastic, as the cost of uranium has little influence on the price of electrical energy supplied by a nuclear power station. With the occurrence of the modest global increase in nuclear power station capacity expected by the IEA, the critical point is likely to occur relatively late towards the end of the century. There is however, no scope for a large-scale substitution of fossil fuels unless alternative concepts are introduced (4th generation breeder technology, high-temperature reactors and thorium – [1.1, Chap. 5.6]). Nuclear fusion is unlikely to play a role until 2050.

#### Ethical Aspects and Environmental Protection

The question of the rate at which these reserves can be allowed to be consumed can be given a good answer from purely economic points of view (Hotelling’s rule and other aspects, e.g., see [1.10]). In addition to these there are ethical considerations and environmental aspects:

- From an ethical viewpoint one must ask whether it is acceptable to extract virtually the whole of this within two or three centuries, the human race’s store of energy, that future generations might be dependent on (emergency supplies, raw materials). This aspect should be relativized to the extent that we do not know today whether future generations will in fact be dependent on this energy. But, is this behavior really responsible?
- The harmful effects of CO<sub>2</sub> emissions on the climate, corroborated by scientific studies (e.g., IPCC), justify political action on a global scale in order to produce a drastic reduction in the output of CO<sub>2</sub> (Sect. 1.7).

*As seen today, it is particularly the second aspect that makes it clearly urgent to correct the economic viewpoint by internalizing the external costs of present and future damage to the climate.*

### 1.2.2 Renewable Energies

Renewable energies (Fig. 1.2) are *natural* energy flows of a certain magnitude that can be tapped using technical means and with a certain economic cost. Most energies are not everywhere, but only available or economically exploitable at favorable locations. The vari-

ous sources will now be considered in respect of their availability.

#### Tidal Energy

Gravitational energy is available to us in the form of *tidal energy*. Tidal friction amounts to about 2.5 TW (i.e., the earth’s rotational energy is reduced by 2.5 TWa each year). It is estimated that only about 9% of this is economically usable [1.12]. For economical use, the tidal range must be at least 6 m. Consequently, in relation to future global energy demands (> 25 TW), tidal energy is of very little significance. For more, details see *Kleemann and Meliss* [1.14], *Kugeler and Philippen* [1.15] and World Energy Council [1.12].

#### Geothermal Energy

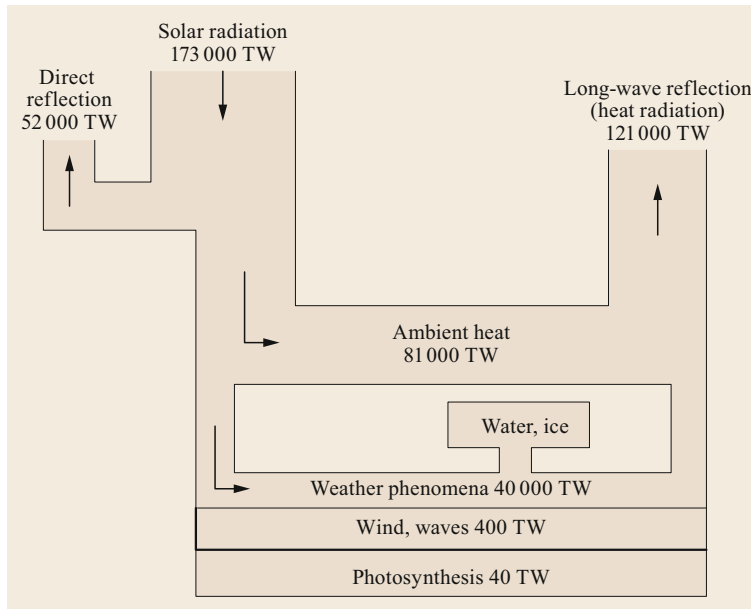

The mean natural flow of heat is very small (about 0.06 W/m<sup>2</sup>). Of this, 30% is from the residual heat of the Earth’s core and 70% from the decay of radioactive isotopes in the earth’s crust. The thermal gradient has a mean value of 1 °C per 30 m. Therefore, it is above all the geothermal anomalies (volcanoes, geysers) that can be economically exploited. In 2005 the world total installed power was about 28 GW, of which 17 GW was *thermal* (main countries: China, USA, Sweden, Iceland) and 9 GW was *electrical* (main countries: USA, Philippines, Indonesia, Mexico, Italy) with annual production rates (mean power) of 6.6 and 6.5 GW. These are almost all *hydrothermal* uses (hot springs). In the future, the *hot dry rock* process may become more significant [1.16–18].

Geothermal energy is a renewable energy, although over relatively long periods (decades to centuries), so *resources* usable in the short to medium term are indicated. The hydrothermal *resources* with high enthalpy levels, > 150 °C, that can be used for generating electricity, amount to about 30 TWa, and the low-enthalpy stocks suitable for heating, about 3200 TWa. How much of this can be called reserves cannot be quantified at present [1.9]. The global installed capacity can presumably be increased to 2 TW (about 100 times the present value), which would cover 5–10% of the future global energy requirement. However, by using the heat pump, this could be significantly greater. In some countries the contribution of geothermal energy is very significant.

#### Solar Energy

Solar is the only renewable energy that is already making a significant contribution to meeting global energy requirements, in the form of water power and biomass (in 2016 about 2.5 TWa).

The supply of solar energy is more than 10 000 times the current global energy demand and it is the

**Fig. 1.5** Solar energy balance of the world

only energy source, possibly together with nuclear fusion, that can meet mankind's energy requirements in the post-fossil age. The problems around the direct use of solar radiation are related to economics and its low density.

As is shown in Fig. 1.5, the flow of solar energy is around 173 000 TW. Of this energy, 52 000 TW are directly reflected back into space as short-wave radiation, while 121 000 TW are absorbed, converted and finally, since the earth is in thermal equilibrium, returned into space as long-wave thermal radiation.

About two thirds of the absorbed radiation is stored in air, water and the ground as *low-temperature heat* and, as such, it can be made use of, e.g., by means of heat pumps.

The remaining third drives the world's weather by evaporating water and creating differences of pressure and temperature; this energy occurs as *potential energy* (water content of clouds, flowing water and glaciers) and as *kinetic energy* (wind, ocean currents, waves).

Only a fraction, about 40 TW, is absorbed by photosynthesis that creates *biomass* and makes life on earth possible.

In view of its importance, the potential and exploitation of solar energy will now be discussed further.

### 1.2.3 Potential and Use of the Main Types of Solar Energy

We distinguish between indirect (delayed) exploitation of:

- Ambient heat (particularly through use of the heat pump)
- Water power (via hydro-electric power stations)
- Wind power, wave power and ocean currents (especially wind turbines)
- Biomass (wood, plants, organic waste) and

direct (immediate) exploitation of:

- Solar radiation (solar architecture, collectors, thermal solar power plants, photovoltaics).

#### Heat Pumps

Heat pumps are a mature technology for making use of low-temperature heat. It enables the temperature to be raised to values suitable for use in space heating and providing hot water. The possible sources of thermal energy are air, ground water, surface water and the interior of the ground. The heat pump makes it possible to use heat from the environment, from waste, and geothermal heat when the source is at least 100–150 m below ground level.

It is the most mature technology for low-temperature applications for substituting fossil fuels with solar heat and geothermal heat. The potential for ambient heat is enormous, as Fig. 1.5 shows. Increased use of heat pumps is being impeded in particular by cheap fossil fuels. Also, the fact that about one third of the generated heat must be obtained from high-value energy carriers (electricity, gas) has an inhibiting effect in countries where a high proportion of electricity pro-

duction is from fossil fuels. For more information about heat pumps, see Sect. 1.7.4 and [1.1, Chap. 6].

### Water Power

The potential of all flowing water in the world is estimated at 6 TWa (average power), of which about 1–1.5 TWa is economically accessible [1.12]. In 2005, 0.334 TWa (hydroelectricity) was used. The development potential is primarily in the developing countries but also in the north (Greenland, Canada). The contribution of water power to *meeting the demand for electricity* was, in 2012, 16.5% worldwide, 13.4% in OECD countries, 61% in South America, 17% in China, 11% in India, 7% in the USA, 11% in the EU-27, 4.4% in Germany, 66% in Austria, 58% in Switzerland and 97% in Norway (more details in Chap. 4, where the use of hydropower is discussed in detail).

### Wind and Ocean Power

The use of wind power has made considerable progress in some countries with favorable wind conditions (Germany, Spain, USA, Denmark) and the associated technology has matured. The economic viability is dependent on the strength and reliability of the wind. Mean wind speeds of at least 5–6 m/s are necessary. These are mainly to be found in coastal regions and some mountainous regions. If it is assumed that 2–5% of wind and wave energy (400 TWa according to Fig. 1.4) can be used economically worldwide, 1–2 TWa are obtained; probably more can be used. In 1996, the installed wind-power capacity worldwide was 6 GW [1.2], but it increased to 20 GW by 2001 and reached 59 GW at the end of 2005 (corresponding to a growth rate of 30%/a). In 2006, the power had reached 75 GW (of which 20 GW was in Germany), which corresponds to an energy output of around 12 GWa (usage factor 0.16). The *offshore* installations (use of wind energy in the sea) have a significantly better utilization factor. At the end of 2014, 370 GW of installed capacity or 86 GWa of generated energy had already been reached worldwide. In Denmark, 1.2 GWa of electricity was already generated by wind in 2012, a third of its total electrical energy consumption, and it is planned to increase this figure to one half by 2030, mainly offshore. In France, 23 GWa of wind energy is expected to be generated in 2040.

If there is a big increase in the energy generated by wind, however, the storage problem must also be solved due to the substantial variability of this form of energy (similar to the somewhat milder variability of hydropower). The corresponding costs must be taken into account when evaluating wind energy.

More information on the technology of using wind energy to generate electrical energy can be found in

Sect. 2.8. For the possible use of waves and ocean currents, see: [1.19, 20].

### Biomass

**Definition.** Biomass consists of materials of organic origin, in other words the material from living beings and organic waste materials (excluding fossil fuels).

**Potential.** The energy in the total biomass of the world is estimated at about 450 TWa [1.18, 21] (1 TWa = 31.5 EJ), with a mean calorific value of about 3500 kcal/kg (referring to fully dry biomass). The growth rate is of particular importance, around 60 TWa/a. The conversion efficiency for solar radiation is, on average, about 0.14%, but higher for forests and fresh water (about 0.5%) and highest of all for tropical forests (up to 0.8%). From the chemical point of view, biomass consists of 82% polysaccharides (cellulose and hemicellulose) and 17% lignin (wood pulp) [1.14].

**Usage.** The technologically exploitable energy potential of biomass in the form of fuels for heating and transport is estimated to be about 6 TW. With a world population of 10 billion people, around 2 TW of this could be obtained from waste. Biomass is thus one of humanity's most significant energy reserves, that could provide about 25% of future demand. Current usage (mainly non-commercial energy) may be (2005) around 1.6 TW. The burning of biomass is CO<sub>2</sub>-neutral only if reforestation is also undertaken.

Technical procedures for use (see details, e.g., in [1.18]):

- **Physical bioconversion:** This includes the *compaction* to biofuels (peat, straw, wood waste → briquettes) and the *extraction* of oils (rape, special oil plants → diesel fuel). If oil plants are cultivated on a large scale, biodiversity is endangered by monocultures.
- **Thermochemical bioconversion:** Methods to mention include in particular: *direct burning* (especially wood) open or in stoves, *gasification/liquefaction* by *pyrolysis*, i.e., the thermal decomposition of high-molecular-weight substances (including used materials, such as waste, old tyres, plastics etc) into smaller molecules, and *methanol synthesis* (for obtaining fuel).
- **Biological conversion:** These are low-temperature processes that use micro-organisms (fermentation). They include *biogas production* and the production of *ethanol* from plants containing sugar (sugar cane), that is used on a large scale for fuel production in Brazil, for example.

### Solar Radiation

**Specific Availability of Solar Energy.** If the 121 000 TW that reaches the earth (Fig. 1.5) is distributed uniformly over the earth's surface, the result for a *horizontal surface* is

$$\begin{aligned}\text{Mean annual power} &= \frac{121\,000\text{ TW}}{510 \times 10^6 \text{ km}^2} \\ &= 237 \frac{\text{W}}{\text{m}^2}.\end{aligned}$$

If we consider only daylight hours (12 instead of 24 h), the result is a doubled mean annual daytime power of 474 W/m<sup>2</sup>. These figures apply to an average latitude, clear weather and at sea level. The effective mean value depends not only on the latitude but also on the climate. In central Europe (often cloudy or foggy), half this figure can be expected, namely 120 W/m<sup>2</sup>.

If we multiply the annual mean power by 8760 h/a, the result is

$$\begin{aligned}\text{Annual mean energy} &= 237 \frac{\text{W}^2}{\text{m}} \cdot 8760 \frac{\text{h}}{\text{a}} \\ &= 2076 \frac{\text{kWh}}{\text{a m}^2}.\end{aligned}$$

For the reasons stated, this annual energy is not achievable at moderate latitudes because it assumes constant sunshine. The value is exceeded (up to over 2200 kWh/(am<sup>2</sup>)) near the equator and in desert climates (Sahara, Arizona, Australia etc.).

**Density of Solar Radiation (Global Radiation).** The earth's cross-section is about 127 × 10<sup>6</sup> km<sup>2</sup>. Outside the atmosphere this gives

$$\begin{aligned}\text{Extraterrestrial radiation density} &= \frac{173\,000\text{ TW}}{127 \times 10^6 \text{ km}^2} \\ &= 1360 \frac{\text{W}}{\text{m}^2}.\end{aligned}$$

This quantity is also known as the *solar constant*. On the earth's surface (sea level) the radiation density (without reflections!) is, on a *surface perpendicular to the rays*

$$\begin{aligned}\text{Radiation density at sea level} &= \frac{121\,000\text{ TW}}{127 \times 10^6 \text{ km}^2} \\ &= 950 \frac{\text{W}^2}{\text{m}}.\end{aligned}$$

In Switzerland the figure of 1000 W/m<sup>2</sup> is usually used. This global radiation contains both a *direct* and a *diffuse* component (diffuse sky radiation). Under the climate conditions of central Europe, the diffuse component is important (Sect. 2.9).

These figures show, on the one hand, that solar radiation has practically unlimited potential, but also make clear the problems that an economical exploitation of solar radiation encounters. The most important methods of use are listed here:

**Solar Architecture.** Designing buildings to exploit solar energy can result in a large reduction in the demand for heating energy. This is an option that should be used and promoted much more than at present. For more information, refer to the special literature and to [1.17, 22].

**Flat Collectors.** Flat collectors can use direct and diffuse radiation. The heat is transferred to a heat carrier (usually water with anti-freeze). High efficiency levels are achieved in low-temperature applications (up to 70% for heating open-air swimming baths, up to 60% for water heating, but only 40–50% for space heating); i.e., the efficiency is strongly dependent on the temperature at which the energy is used. These efficiencies are, however, only achieved for the full irradiation levels and are reduced more than proportionally at lower levels. Collectors are economical at present for heating swimming baths and water heating (especially in summer) (for details see [1.17, 22, 23]).

**Concentrating Collectors.** *Parabolic mirrors* (parabolic cylinders or paraboloids) can be used to concentrate direct radiation (diffuse radiation cannot be used this way). This generates high temperatures that can be used for producing process heat and electricity. The mirrors do need to be moved to track the sun. The heat carrier is usually a special oil. Examples of applications are solar cookers for developing countries, solar farms for producing industrial heat and electricity (solar thermal power stations) by using the usual steam process, see [1.21].

With parabolic cylinders (parabolic troughs) temperatures of 100–400 °C are achieved. The water is heated in a tube placed at the focus of the parabola. For higher temperatures, expensive *paraboloids* or *heliostats* are used, which serve both for generating electricity and for carrying out chemical processes [1.18].

**Solar Thermal Power Stations.** For the production of electricity, one can use *parabolic trough collectors* which concentrate the sunlight on an absorber tube running along the focal axis, or *solar tower systems*; in the latter case, the sun is tracked with the aid of flat mirrors that follow the sun biaxially (the so-called *heliostats*), which concentrates radiation on the top of a tower. A radiation receiver is located here. The heat is transferred to a working medium (e.g., steam, helium, liquid sodium). Temperatures between 500 and 1200 °C can

be reached. This can drive steam or gas turbines that generate electricity in the conventional way.

Solar thermal power plants are particularly suitable for regions with long periods of sunshine and clear skies, as they cannot make use of diffuse radiation. Various pilot plants are in operation worldwide. Three 50 MW parabolic trough power plants have been built in Spain, 100 MW in Abu Dhabi and a total of 350 MW in California; further large-scale plants are planned. Efficiencies of approx. 15% have been estimated. The energy costs for plants of 100 MW are around 20 ct/kWh.

Projects with large installations in the Sahara that could be connected to the European grid by means of HVDC (high-voltage direct current transmission), see [1.24] have been under discussion (Desertec).

### Photovoltaics

Photovoltaics enable the direct conversion of solar radiation into electricity by means of *solar cells*. With *polycrystalline silicon cells*, commercial efficiencies of 15% are achievable today with *monocrystalline*, even as high as around 20%. Crystalline cells have become significantly cheaper in recent years, and the energy-harvest factor (ratio of energy generated to energy required for fabrication) has improved significantly. The technology is quite advanced and the operational experience is good.

Commercial grid-connected photovoltaic plants of over 100 kW output using crystalline cells can today produce electricity at a price of 15 ct/kWh or much less, which approaches or falls below grid parity in terms of household electricity prices in many countries. However, it is often ignored that the fluctuations in the feed-in must also be compensated, as is done with hydroelectrically generated energy with appropriate storage facilities.

For more information on photovoltaics and photovoltaic power plants, Chap. 8.

## 1.2.4 Ecological Problems

The energy industry, together with chemistry and agriculture, is one of the main contributors to the contamination of the biosphere with pollutants. Energy supply and energy use lead to *pollution of the atmosphere* by emissions from the combustion of fossil fuels and biomass and by natural gas losses. Pollution of the sea from tanker accidents is also not negligible. The *main emissions* are:

- Oxides of carbon (CO, CO<sub>2</sub>);
- Oxides of nitrogen;
- Sulfur compounds;

- Methane;
- Ozone.

### Predominantly Localized Effects

Nitrogen oxides, sulfur compounds, CO and tropospheric ozone mainly have regional impacts on health, plant ecosystems and cultural assets, but are sometimes transported over long distances by winds. The harmful effects have been effectively minimized in recent decades in advanced countries through desulphurization and nitrification measures and catalysts.

Stratospheric ozone depletion (the ozone hole) is rather different, and is mainly caused by emissions of chlorinated fluorocarbons (CFCs) and only marginally connected with energy use (for more details see, for example, [1.18]).

### Increasing the Greenhouse Effect

Much more serious consequences for the climate derive from so-called *greenhouse-gas emissions*, and there is an extensive literature on this subject. The fifth IPCC report (Intergovernmental Panel on Climate Change) of 2013/2014 (IPCC 2014) provides a good summary, while other research and reports also support its findings. The report concludes, even more emphatically than earlier reports, that the observed global warming is very probably caused by humans. The most important greenhouse gas is CO<sub>2</sub> which contributes 77% to the strengthening of the greenhouse effect. Further contributions are from methane (15%), CFCs (1%) and N<sub>2</sub>O (7%). The CO<sub>2</sub> concentration in the atmosphere is 380 ppm, i.e., 36% higher than the pre-industrial concentration (280 ppm, practically unchanged over the previous 10 000 a). It increases annually by 1.5–2 ppm. Simulations for the year 2100 give, assuming a doubling of the pre-industrial concentration, and depending on the scenario, an increase in the mean temperature of 2–6 °C (with a probability of 66% for an increase between 2.4 and 4.1 °C). In addition, sea levels could rise by 50 cm or significantly more by 2100 (according to recent studies), and the number and intensity of extreme climatic events could increase. Although the existing uncertainties could have a positive effect, they could also have a much more negative effect, e.g., as a consequence of non-linear feedback. A mean temperature increase of 2 °C corresponds for medium latitudes to a shift of the isotherms about 350 km northwards or of the apparent height above sea of about 350 m, with the possibility of very great regional differences.

The consequences could be even more dramatic in the case of a *tipping point of the climate*. A deflection or slowdown or even a long-term interruption of the Gulf Stream would, for example, have catastrophic consequences for Western Europe.

The consequences of this, in the geological time scale, extremely rapid climate change would undoubtedly be further stress for the already heavily damaged ecosystems (extinction of species, forests). The distribution of water resources and agricultural productivity could be adversely affected world-wide, with increased stress on socio-economic systems, and with particularly great suffering in the regions that are weak and can only adapt slowly or not at all to the changed conditions. Although there may also be winners, the global balance is very negative.

### Sustainable Development

The term *sustainability* has assumed political contours, in particular through the Brundtland Commission's 1987 report, which defined sustainable development as *one that meets current needs without compromising the ability of future generations to meet their own needs* and called for growth that integrates social and environmental aspects into economic considerations, both spatially and temporally.

It is thus a matter of optimizing development in the triangle of economy, society and ecology (the *triple bottom line* of people, planet, profit) and of global and intertemporal solidarity. The main difficulty in implementing this goal is the fact that economic, but also sociopolitical thinking, is too often short-to-medium term, while the ecological requirements, especially in connection with the climate problem, require long-term optimization.

The above paragraph has highlighted the need to vigorously reduce greenhouse-gas emissions world-wide, in particular CO<sub>2</sub> emissions. The costs of this energetic transformation are quite high, but even higher would be the cost of a *laissez-faire* approach. It is not a matter of (purely selfish) adaptation to the consequences of climate warming, but above all, of putting a brake on climate warming, reducing it to the extent that is possible and avoiding the enormous costs of social and infrastructural adaptations, that would linearly increase faster than the increase in mean temperature.

## 1.3 Energy Demand, CO<sub>2</sub> Emissions, Indicators

### 1.3.1 General Information

Prior to a detailed analysis of the energy situation in Europe (Sect. 1.4), in the world (Sect. 1.5) and the prospects in relation to climate-protection requirements (Sects. 1.6–1.7), some basic aspects of energy demand should be presented and indicators defined that are particularly relevant for climate change.

Fig. 1.6 Sustainable investments

Political initiatives are required that aim to internalize current and future external costs, a recipe well compatible with the market economy. In the fight against global environmental damage, it is right in theory to apply capital and knowledge in those areas where the contribution to improving energy efficiency and reduction of CO<sub>2</sub> intensity will be maximized (e.g., via the trading of emission certificates). International co-operation in putting this sensible theory into practice is all too often made problematic by the absence of boundary conditions that steer market forces in the right socio-ecological directions, and by political differences. Sometimes this argument is rather an excuse for doing nothing in one's own region. Both kinds of effort, global and local (Fig. 1.6) are necessary. Although rationalization is suboptimal in terms of global capital spending in the short term, it nevertheless promotes regional innovation in the environmental sector, which will probably pay off globally in the medium and long term (for actions in energy economics see Sect. 1.7).

The results of the UN climate conference COP21 in Paris, December 2015, where for the first time a large number of countries committed to take measures to limit the mean temperature rise of the Earth compared to pre-industrial times to at most 2 °C, and if possible aim for 1.5 °C, provide some hope. See Sect. 1.7 for more details.

Especially for readers unfamiliar with energy demand issues, it can also be useful to review the case of Switzerland's energy demand as an example of a highly industrialized country [1.1, Appendix C]. In particular, the structural aspects of energy demand are illustrated with concrete figures, and the factors that determine their evolution are presented.

**Fig. 1.7** Final energy and energy sector losses worldwide in 2016 (100%  $\hat{=}$  final energy = 8686 Mtoe, together = gross energy consumption = about 150% of final energy)

### 1.3.2 Final Energy and Losses in the Energy Sector

For further considerations, it is useful to distinguish between three areas of the use of final energy [1.25, 26]:

- *Comfort heating and process heat*, predominantly obtained from fossil fuels and partly from renewable energies (geothermal energy, biomass, solar radiation, ambient heat). Heating by electricity is excluded.
- *Propellants* (fuels for transport), mainly fossil, some biomass.
- *Electricity*, all uses, including heating.

Figure 1.7 shows the global importance of each of the three areas as a percent of final energy for 2016 (i.e., heat + district heating: 45% + 3%; transport fuels (motor fuels): 31%; electricity: 21%). The three areas are subdivided into the primary energy carriers.

The bar for final energy (100% = 8686 Mtoe in 2016) also shows the subdivision into the three energy-consuming sectors: industry (32%), traffic (32%) and others (36% residential, services + agriculture).

Finally, the *losses in the energy sector* are shown, attributable to heat losses in power plants and the energy sector's own consumption of energy. The representation of these losses corresponds to the statistics of the IEA (international energy agency), in which hydroelectricity is recorded but not water power. Worldwide,

there are losses of 49% of the final energy. Global gross energy consumption thus amounts to almost 150% of final energy demand or exactly 12 892 Mtoe in 2016.

### 1.3.3 Global Gross Energy Demand, Energy Sector

For further analysis, it makes sense to define the *energy sector* as [1.25]:

- The electricity and district heating produced, and
- All losses associated with the conversion of gross energy into final energy.

The global demand for primary energy in 2016 can then be illustrated by Fig. 1.8. It is composed of the energy consumed in the *transport sector* (fuels, excluding electricity), of *heating and process heat energy* (excluding electricity and district heating) required by industry and the other sectors (households, commerce, services, etc.) and of the *energy needs of the energy sector*, which is primarily used for the production and transmission of electricity and district heating, with large losses.

The energy sources with which this total consumption was supplied in the past and will probably be supplied in the future have already been illustrated in Fig. 1.3 (Sect. 1.2); Fig. 1.7 shows the situation in 2016.

**Fig. 1.8** Worldwide consumption of gross energy in 2016 (total 12 892 Mtoe, 1.37 KWh/\$), divided into: transport, heat consumption and energy sector (electricity + district heating + losses)

With 49% of the gross energy consumed worldwide, i.e., around 6300 Mtoe in 2016, the energy sector plays a decisive role for climate protection aims.

The energy demand of the energy sector can be broken down according to Fig. 1.9. The final energies produced by the energy sector – electricity and district heating – account for 33%. The remaining 67%, corresponding to about 4200 Mtoe, are energy losses or own consumption (difference between the gross consumption of 12 900 Mtoe and the final consumption of 8700 Mtoe). The largest part of these losses are thermal losses in power plants and combined heat and power plants (broken down by type of energy carrier in the figure). Further losses are the electrical transmission losses (in the transmission and distribution networks). Finally, the own consumption and residual losses in pure heating plants and gas works, in refineries and other conversion plants (gasification and liquefaction processes) and in the mine extraction of energy carri-

**Fig. 1.9a,b** World 2016, energy shares of the energy sector (a) Energy sector = final energies electricity and district heating + losses (6283 Mtoe), and corresponding CO<sub>2</sub> emissions, (b) CO<sub>2</sub> emissions = 15 815 Mt

**Table 1.3** Worldwide indicators for 2016 in international dollars from 2010, 1 kW<sub>a</sub> = 8760 kWh = 0.753 toe = 31 540 MJ

2016	$y$ (10 <sup>4</sup> \$/(a capita))	$e$ (kW <sub>a</sub> /(10 <sup>4</sup> \$)) = 1.37 kWh/\$	$k$ (t CO <sub>2</sub> /W <sub>A</sub> ) = 215 g CO <sub>2</sub> /kWh	$\eta$ (t CO <sub>2</sub> /(10 <sup>4</sup> \$)) = 296 g CO <sub>2</sub> /\$	$\alpha$ (t CO <sub>2</sub> /(a capita))
World	1.47	1.56	1.88	2.96	4–35

**Fig. 1.10** Worldwide CO<sub>2</sub> emissions and polluters. 2016, CO<sub>2</sub> emissions = 32.316 Mt, 4.4 t/capita, 296 g/\$ (GDP PPP \$ of 2019)

ers must be taken into account. High residual losses are often a sign of a lack of efficiency in the energy sector.

### 1.3.4 CO<sub>2</sub> Emissions and Indicators

Global CO<sub>2</sub> emissions resulting from the combustion of fossil fuels for 2016 are shown in Fig. 1.10. They amount to a total of 4.4 t/(a capita), and almost 50% comes from the energy sector, with electricity generation from coal being the main polluter.

For further analysis, we introduce the following relationships [1.25, 26]

$$\alpha \left[ \frac{\text{t CO}_2}{\text{a capita}} \right] = k \left[ \frac{\text{t CO}_2}{\text{kW}_a} \right] \times e \left[ \frac{\text{kW}}{\text{capita}} \right], \quad (1.1)$$

where  $\alpha$  = CO<sub>2</sub> emissions per year, per capita,  $k$  = CO<sub>2</sub>

intensity of gross energy,  $e$  = gross energy consumption per capita.

Specific energy consumption  $e$  correlates primarily with gross domestic product (GDP), whereby it is useful for international comparisons to refer to GDP at purchasing power parity (GDP PPP). That's why we can write

$$e \left[ \frac{\text{kW}}{\text{capita}} \right] = y \left[ \frac{10\,000\ \$}{\text{a, capita}} \right] \times \varepsilon \left[ \frac{\text{kW}_a}{10\,000\ \$} \right], \quad (1.2)$$

where  $y$  = specif. gross domestic power (adjusted for purchasing power),  $\varepsilon$  = gross energy intensity.

The CO<sub>2</sub> emissions can then be expressed as

$$\alpha = ke = k\varepsilon y = \eta y$$

$$\begin{aligned} \text{with } \eta \left[ \frac{\text{t CO}_2}{10\,000\ \$} \right] &= k\varepsilon \\ &= \text{CO}_2 \text{ sustainability of energy supply} \end{aligned} \quad (1.3)$$

as a product of *prosperity indicator*  $y$ , energy intensity  $\varepsilon$  and CO<sub>2</sub> intensity of energy  $k$ .

In order to reduce the specific CO<sub>2</sub> emissions per year per capita  $\alpha$ , we must be able to achieve the desired increase of  $y$  (GDP/capita) and compensate it with a considerable reduction of *energy intensity*  $\varepsilon$  and CO<sub>2</sub> *intensity of the energy*  $k$ . The product of these two quantities is defined as the CO<sub>2</sub>-*sustainability indicator*  $\eta$ . The corresponding figures worldwide for 2016 are summarized in Table 1.3. The GDP PPP is expressed in international dollars as of 2010 (sources: IMF, see also [1.25, 27, 28]); we get a worldwide  $\eta = 3.49 \text{ t CO}_2/\$10\,000$  or  $349 \text{ g CO}_2/\$$ . 8

## 1.4 Energy Consumption and CO<sub>2</sub> Emissions in Europe

We refer here to Europe as the EU-28 plus the three Western European countries that are not members of the EU: Iceland, Norway and Switzerland.

### 1.4.1 Population and Gross Domestic Product

The EU-15 comprises all Western European EU members. Figure 1.11 shows the percentage distribution of the population in 2015. Figure 1.12 shows the

purchasing-power adjusted (PPA) gross domestic product (GDP) per capita of the European countries.

### 1.4.2 Energy Consumption per Capita

Energy consumption per capita depends on the one hand on the level of economic development (measured by GDP/capita, Fig. 1.12) and on the other hand on the efficiency of energy use (measured by energy intensity). Consumption is also influenced

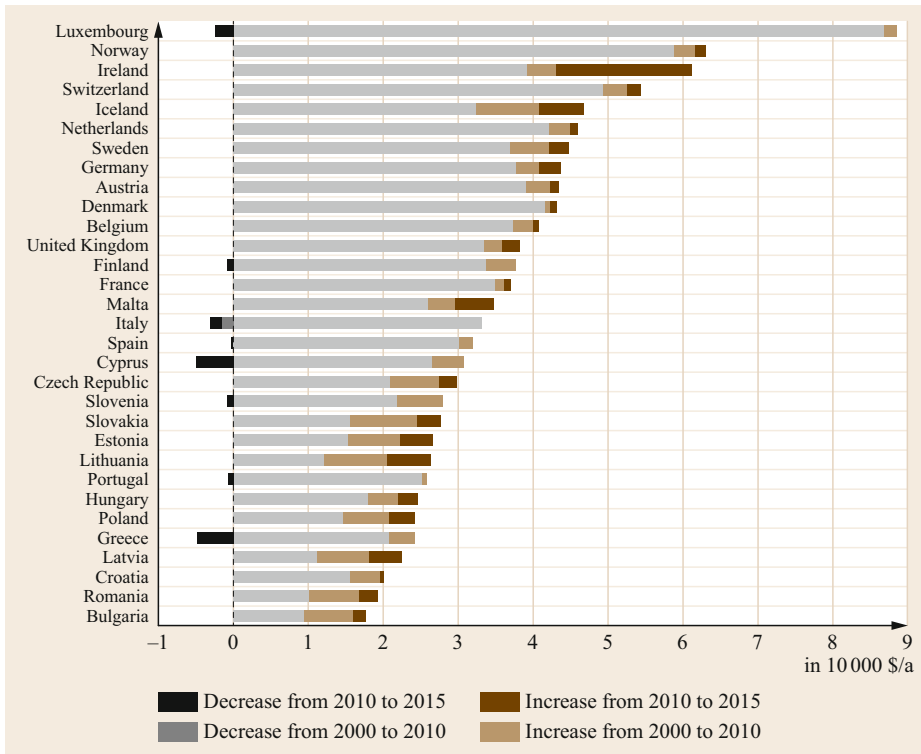

**Fig. 1.11** Percentage distribution of the population of Europe in 2015 (total 524 million): EU-28 + Iceland, Norway, Switzerland

by the climate and depends on the characteristics of the economy of the country in question. Figure 1.13 shows gross energy consumption per capita in 2015 for Western Europe and Eastern Europe (EU 13, only EU members). One notes significant differences. Southern European countries consume less energy than the Scandinavian countries, which is due to climatic conditions and, in some cases, to weaker economic development (Fig. 1.13a). Accord-

ingly, the figures for Eastern Europe are generally lower (Fig. 1.13b).

Iceland is not included because of the extremely high value of 22 kW/capita, which can be explained by the heavy use of (non-polluting) geothermal energy. For Luxembourg, both in terms of GDP and energy consumption, the distortion caused by the very high proportion of cross-frontier workers must be taken into account (Figs. 1.12 and 1.13a).

**Fig. 1.12** Per capita GDP (PPP) of the European countries in 2015, in 10 000 \$ (US\$ of 2010)

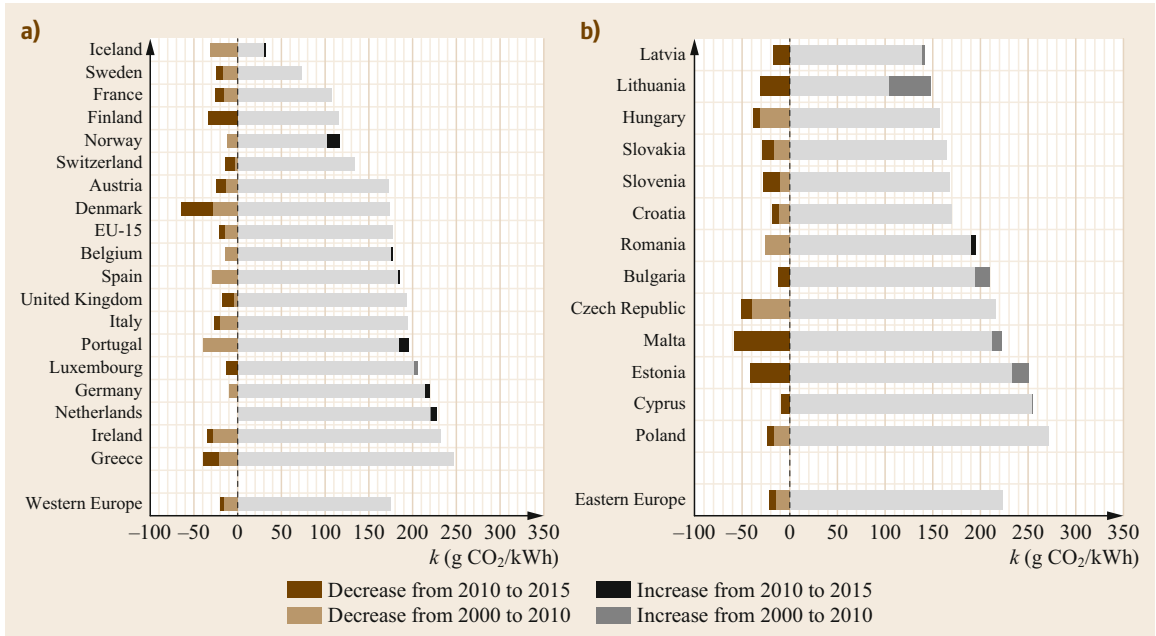

**Fig. 1.13a,b** Per capita energy consumption in Europe [1.5]: (a) Western Europe (EU-15 + Iceland, Norway, Switzerland, all OECD members), (b) Eastern Europe and Malta (only EU-28 members)

**Fig. 1.14a,b** Energy intensity  $\epsilon$  of the countries of Europe in 2015: (a) Western Europe; (b) Eastern Europe and Malta (GDP PPP in \$ of 2010)

**Fig. 1.15a,b** CO<sub>2</sub> intensity of energy  $k$  of the countries of Europe in 2015: (a) Western Europe; (b) Eastern Europe and Malta

**Fig. 1.16a,b** Indicator of CO<sub>2</sub> sustainability  $\eta$  of the countries of Europe in 2015: (a) Western Europe; (b) Eastern Europe and Malta (GDP PPP in \$ 2010)

**Fig. 1.17** Final energy and losses of the energy sector in the EU-15, 2015. 100%  $\hat{=}$  total final energy = 852 Mtoe (source: IEA statistics)

### 1.4.3 Energy Intensity and CO<sub>2</sub> Emissions, Sustainability

The *energy intensity*  $\varepsilon$  of the countries of Europe is shown in Fig. 1.14 for 2015. A low energy intensity basically indicates a rational use of energy. Various factors, such as climate or type of economic performance (services instead of heavy industry) or of electricity generation, also have an impact. Multiplying the energy intensity by the *CO<sub>2</sub> intensity of the energy*  $k$  as shown in Fig. 1.15, gives the *CO<sub>2</sub> sustainability*  $\eta$  of Fig. 1.16 ((1.1)–(1.3)).

Four countries in Western Europe have a *CO<sub>2</sub> sustainability indicator*  $\eta$  below 120 g CO<sub>2</sub>/\$ (Fig. 1.16). These are the countries whose electricity production is predominantly CO<sub>2</sub>-free: Switzerland and Sweden with a mix of hydropower and nuclear energy, Norway with pure hydropower, and France with, in addition to hydropower, predominantly nuclear energy. The remaining EU-15 countries are between 125 and 250 g CO<sub>2</sub>/\$. The countries of Eastern Europe (only EU-28 members) have an average of around 250 g CO<sub>2</sub>/\$ and thus have a clear need to catch up.

#### 1.4.4 Final Energy and Losses of the Energy Sector in the EU-15

The EU-15 comprises the economically strongest countries in Europe. In terms of population, they account for about 400 million inhabitants or almost one third of the population of the OECD-34. Their energy con-

**Fig. 1.18** CO<sub>2</sub> emissions of the EU-15 in 2015 and their distribution. Total emissions = 2517 Mt, 6.2 t/capita, 164 g CO<sub>2</sub>/\$ (GDP PPP in \$ of 2010; Data-source: IEA)

sumption and the associated CO<sub>2</sub> emissions are illustrated in Figs. 1.17 and 1.18, and the characteristic indicators are compared in Table 1.4 with those of Switzerland and Norway. The main difference lies in the energy sector, which has a 40% share of CO<sub>2</sub> emissions (Fig. 1.18).

The electricity production in many EU countries is based mainly on fossil fuels (e.g., in Germany, Italy, Great Britain, Benelux and Denmark). But there are big differences within the EU-15. France and Sweden are structurally similar to Switzerland, thanks to their electricity generation also based on hydro and nuclear power. The structure of the energy sector is shown in Fig. 1.19.

**Table 1.4** Indicators for 2015 for Switzerland, Norway and EU-15.  $\eta = k\varepsilon$ ,  $\alpha = \eta y/100$ 

	$y$ ( $10^4$ \$/(a capita))	$\varepsilon$ (kWh/\$)	$k$ (g CO <sub>2</sub> /kWh)	$\eta$ (g CO <sub>2</sub> /\\$)	$\alpha$ (t CO <sub>2</sub> /(a capita))
Switzerland 2015	5.43	0.62	134	83	4.5
Norway 2015	6.30	0.96	116	112	7.1
EU-15 2015	3.80	0.94	178	167	6.3

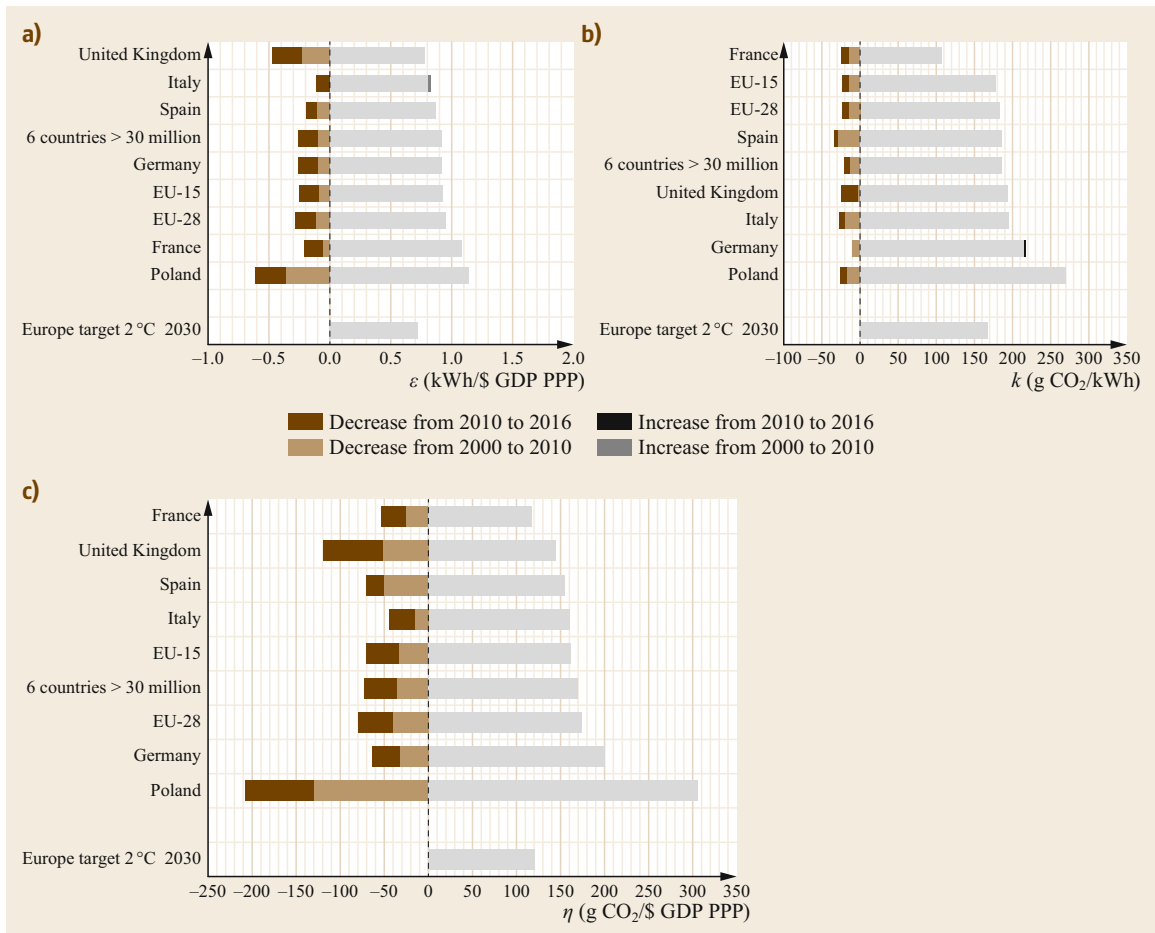

**Fig. 1.19** (a) Structure of the energy sector for the EU-15 in 2015 (627 Mtoe in total): electricity generated and district heating, thermal losses in power stations and cogeneration plants (broken down by type of energy source), electrical transmission losses, residual losses including the sector's own consumption (b) The corresponding CO<sub>2</sub> emissions (1000 Mt in total)

### 1.4.5 Countries With More Than 30 Million Inhabitants

The six European countries with more than 30 million inhabitants: Germany, France, the United Kingdom, Italy, Spain and Poland, accounted for a total of 358 million inhabitants in 2015, and achieved 70% of Europe-wide GDP (PPP). The corresponding energy gross demand was 1100 Mtoe. The detailed energy and emission diagrams of the six countries are given in [1.1,

Annex D] for 2013. Energy intensity, CO<sub>2</sub> intensity of energy and the index of CO<sub>2</sub> sustainability are shown in Fig. 1.20 and compared with the climate protection 2 °C target for 2030 of Europe [1.27, 28]. Thanks to the production of electricity from nuclear energy and thus a low CO<sub>2</sub> intensity of energy, France is closest to this goal at present. Poland has the most catching up to do in terms of both energy intensity and CO<sub>2</sub> intensity. Germany occupies the second-last place.

**Fig. 1.20** (a) Energy intensity  $\varepsilon$ , (b) CO<sub>2</sub> intensity of energy  $k$ , and (c) CO<sub>2</sub> sustainability  $\eta = \varepsilon k$  of the six largest European countries (population > 30 million), for 2016 (GDP PPP in \$ 2010); also given are the average values of the EU-15 and EU-28 in 2016 and the European averages necessary in 2030 for climate protection (2°C target)

## 1.5 Global Energy Demand

### 1.5.1 Energy Consumption in the Past

Figure 1.21 compares Switzerland's primary energy use and its distribution among energy sources with that of two other countries (the Federal Republic of Germany and Egypt) and the world as a whole [1.29]. The thickness of the column corresponds to the size of the per capita energy consumption.

Per-capita energy demand depends primarily on a country's level of economic development, but it is also influenced by the structural characteristics of the economy and the climate. According to official statistics, Switzerland has a slightly lower specific consumption than Germany, despite a higher gross national prod-

uct per inhabitant. It should be noted, however, that the statistics do not include the so-called gray energy. This is the balance of the energy expenditure for the production of imported minus exported goods or the provision of corresponding services. This import balance was estimated at 23% of gross energy for Switzerland [1.5]. A contrary example is Luxembourg, which has a considerable export balance. For large countries, gray energy is generally not too important.

Figure 1.21 shows Egypt as an example of a developing country. Per-capita consumption in 1980 was about one eighth of that of the developed Western European countries. The degree of utilization of this energy

**Fig. 1.21** Comparison of the primary energy consumption of some countries and the world. *Other* = wood and non-commercial energy sources [1.29]

(useful energy) is also lower. Not to be neglected are the non-commercial energy sources, which still cover a large part of the energy demand in developing countries. They include non-commercial biomass such as wood, vegetable waste, dried manure, etc.

At the end of the century, global specific energy consumption, including non-commercial energy, was still 2.2 kW/capita (thanks to the collapse of the Soviet Union). In Egypt, it increased from 0.65 to 0.95 kW/capita. But there was still a gap between OECD and non-OECD countries. While the former claimed a good 6 kW/capita, the latter had to make do with an average of around 1.4 kW/capita.

Before fire was used, man needed on average 100 W of energy, which he took by means of food. With the use of fire, the amount of energy consumed increased to about 250 W. A sedentary farmer, who performs field work with the help of animals and primitive devices, already needs energy of the order of

0.5 kW, the climate having a considerable influence on this figure. In Switzerland, per-capita energy consumption of commercial energy amounted to 1 kW in 1910. Due to the mechanization and industrialization process, the increased mobility and the increased demands on comfort, the specific energy consumption rose progressively by 2008 to around 10 kW primary energy in the USA and Canada, and to approx. 4.6 kW gross energy without and 5.6 kW with gray energy in Switzerland, which roughly corresponds to the OECD average and is not far from the Western European average.

### 1.5.2 Energy Demand, Population and GDP in 2016

Figures 1.22–1.24 show the distribution of the global gross energy demand (gross domestic consumption) and the two most important influencing factors: popula-

**Fig. 1.22** Worldwide distribution of gross energy consumption 2016; \* without China, India and OECD members, \*\* OECD without USA, Japan and EU-15, \*\*\* without Chile (OECD member)

**Fig. 1.23** World-wide distribution of the world population 2016; \* without China, India and OECD members, \*\* OECD without USA, Japan and EU-15, \*\*\* without Chile (OECD member)

**Fig. 1.24** Worldwide distribution of gross domestic product (adjusted for purchasing power), \$ of 2010; \* without China, India and OECD members, \*\* OECD without USA, Japan and EU-15, \*\*\* without Chile (OECD member)

**Fig. 1.25** Gross energy consumption per capita in the world zones, 2000 and 2016, (1 kW/capita = 0.753 toe/(a capita)); \* Asia/Oceania without China, India and OECD members

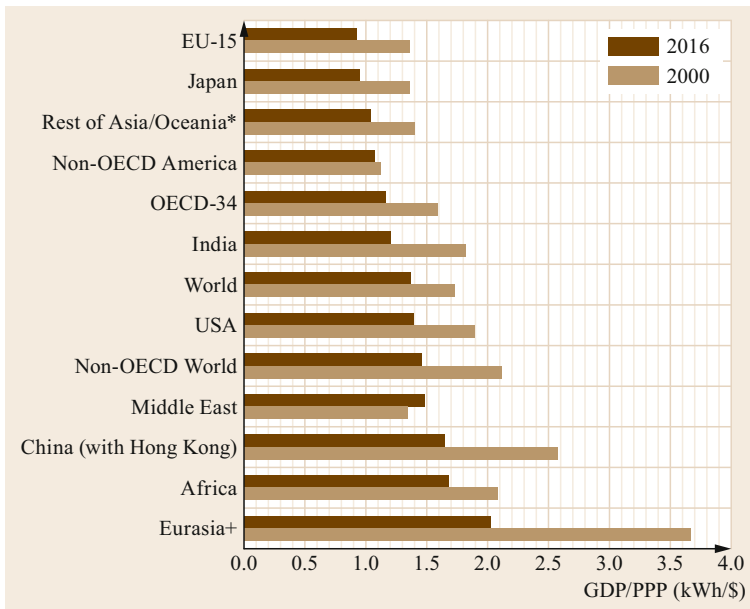

tion and GDP (the latter taking into account purchasing power parity). Figures 1.25–1.29 illustrate, for a number of countries or groups of countries, gross energy consumption per capita, GDP per capita, intensity of gross energy consumption, CO<sub>2</sub> intensity of energy and the CO<sub>2</sub> sustainability indicator.

The world zones considered are:

- EU-15: Germany, France, United Kingdom, Italy, Belgium, the Netherlands, Luxembourg, Austria, Ireland, Spain, Portugal, Greece, Sweden, Denmark and Finland

**Fig. 1.26** Gross domestic product per capita, 2000 and 2016 (PPP = purchasing power parity, US\$ of 2010); \* Asia/Oceania without China, India and OECD members

**Fig. 1.27** Energy intensity of GDP PPP (gross energy), 2000 and 2016 (US\$ of 2010); \* Asia/Oceania without China, India and OECD members

- OECD-34: EU-15, Slovenia, Czech Republic, Slovakia, Poland, Hungary, Switzerland, Norway, Iceland, Estonia, Turkey, USA, Canada, Mexico, Chile, Israel, Australia, New Zealand, Japan and South Korea
- Eurasia+: Eurasia (Russia, Ukraine, Belarus, Armenia, Georgia, Kazakhstan, Azerbaijan, Kyrgyzstan, Tajikistan and Turkmenistan and Uzbekistan) and non-OECD Europe (Lithuania, Latvia, Bosnia and Herzegovina, Croatia, Serbia, Kosovo, Montenegro, FYR Macedonia, Romania, Bulgaria, Albania, Cyprus, Malta and Gibraltar)
- China
- India
- Middle East
- Rest of Asia/Oceania (Asia excluding India, China and OECD Asia)
- Non-OECD America (Central and South America excluding Chile)
- Africa.

**Fig. 1.28** Worldwide CO<sub>2</sub> intensity of gross energy, 2000 and 2016; \* Asia/Oceania without China, India and OECD members

**Fig. 1.29** CO<sub>2</sub>-sustainability indicator  $\eta$  (adjusted for purchasing power), 2000 and 2016 (US\$ of 2010); \* Asia/Oceania without China, India and OECD members

The data sources are the reports of the IEA (International Energy Agency) and the IMF (International Monetary Fund) [1.30, 31]. The international \$2010 used corresponds to  $0.895 \times \$2005$  or  $1.087 \times \$2015$ .

### 1.5.3 Primary and Final Energy and its Distribution 2016

Given the gap that separates the OECD countries from the rest of the world in terms of GDP per capita (Fig. 1.26), it makes sense to analyze the OECD world

and the non-OECD world separately. In addition to the EU-15 already analyzed, other countries or groups of countries within these groups are particularly important and interesting, such as the USA, India, China, the Middle East, Eurasia and Central and South America, which is why we also examine them closely.

#### The OECD Countries as a Whole

The OECD countries accounted for 17% of the world population in 2016 (Fig. 1.23), and consumed 38% of the primary energy (Fig. 1.22). Figure 1.30 illustrates

**Fig. 1.30a–c** OECD-34 in 2016: (a) Gross energy as the sum of final energy and losses of the energy sector (100% = final energy = 3303 Mtoe), (b) CO<sub>2</sub> emissions (11 591 Mt in total, 9.0 t/capita, 235 g CO<sub>2</sub>/\$ GDP PPP, US\$ of 2010), (c) Structure of the energy sector (2484 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (5287 Mt in total)

the energy structure and CO<sub>2</sub> emissions of the OECD area for the year 2016. Figure 1.31 shows the same for the USA (the most important OECD economy).

The structure of energy consumption in the OECD area is comparable to that of the EU 15 (Figs. 1.17–1.19). But although the share of electricity is about the same (just under 25%), it is even more coal-based and

has a lower share of renewable energies; this thus leads to larger coal-heavy losses in the energy sector and is primarily responsible for the poorer CO<sub>2</sub> balance sheet.

**USA.** Since the USA accounts for about 41% of the OECD’s primary energy (and thus just under 16% of the world’s energy demand), its behavior in connection

**Fig. 1.31a–c** USA in 2016: **(a)** Gross energy as the sum of final energy and losses of the energy sector (100% = final energy = 1379 Mtoe), **(b)** CO<sub>2</sub> emissions (4833 Mt in total, 14.9 t/capita, 284 g CO<sub>2</sub>/\$ GDP PPP, US\$ of 2010), **(c)** structure of the energy sector (986 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (2158 Mt in total)

with climate-protection requirements is of paramount importance.

Figure 1.31 shows the structure of energy consumption and the corresponding CO<sub>2</sub> balance sheet. CO<sub>2</sub> emissions per capita are 66% higher than the OECD average; the reasons in 2016 are: 38% higher GDP

per capita (PPP); 20% higher energy intensity; and 1% higher CO<sub>2</sub> intensity of gross energy (Table 1.8). This result is due to the transport sector (with more than 40% of the final energy being more important than the heating sector) and to electricity production, which is still strongly influenced by coal.

**Fig. 1.32a-c** Non-OECD world in 2016: **(a)** Gross energy as the sum of final energy and losses of the energy sector (100%  $\hat{=}$  final energy = 4985 Mtoe), **(b)** CO<sub>2</sub> emissions (19 485 Mt in total, 3.2 t/capita, 323 g CO<sub>2</sub>/\$ GDP PPP, US\$ of 2010), **(c)** Structure of the energy sector (3800 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (11 105 Mt in total)

### Non-OECD Countries

The non-OECD countries with a population of 6.15 billion (2016) consume only 51% more energy in total than the OECD countries (1.28 billion inhabitants). The energy structure is completely different, as the comparison between Figs. 1.30 and 1.32 illustrates.

About 55% of the final energy in the non-OECD world is consumed by heat applications. The corresponding CO<sub>2</sub> emissions are relatively small thanks to the high proportion of biomass. This is likely to change unfavourably in the future.

**Fig. 1.33a–c** China (with Hong Kong) in 2016: **(a)** Gross energy as the sum of final energy and losses of the energy sector (100% = final energy = 1816 Mtoe), **(b)** CO<sub>2</sub> emissions (9102 Mt in total, 6.6 t/capita, 461 g CO<sub>2</sub>/US\$ GDP PPP, US\$ of 2010), **(c)** Structure of the energy sector (1533 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (5084 Mt in total)

The same applies to fuels because mobility is subject to strong growth. The energy sector is coal-heavy, extremely inefficient and responsible for 55% of CO<sub>2</sub> emissions, although electricity accounts for only 21% of final energy.

Figures 1.33–1.35 illustrate in detail the energy consumption structure of the individual non-OECD world regions and the corresponding CO<sub>2</sub> emissions.

*China.* The structure of energy supply and the associated CO<sub>2</sub> emissions are illustrated in Fig. 1.33. China's

**Fig. 1.34a-c** Non-OECD America in 2016: **(a)** Gross energy as the sum of final energy and losses of the energy sector (100% = final energy = 430 Mtoe), **(b)** CO<sub>2</sub> emissions (1099 Mt in total, 2.2 t/capita, 173 g CO<sub>2</sub>/\$ GDP PPP, US\$ of 2010), **(c)** Structure of the energy sector (240 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (366 Mt in total)

gross energy demand in 2016 was about 22% of world demand, or 38% of that of non-OECD countries.

The heating requirement in 2016 is 60% of the final energy. The losses of the energy sector are very high and also reach 60% of the final energy demand. The relatively high CO<sub>2</sub> emissions are attributable to the high

consumption of coal (used to produce more than 80% of heat and 68% of electricity).

China ranks last in the CO<sub>2</sub> sustainability list (Fig. 1.29), with around 450 g CO<sub>2</sub>/\$, and is a key factor in the fight against climate change, given its size and increasing economic importance. Efficiency has

**Fig. 1.35a–c** Rest of Asia/Oceania in 2016: **(a)** Gross energy as the sum of final energy and losses of the energy sector (100% = final energy = 606 Mtoe), **(b)** CO<sub>2</sub> emissions (1910 Mt in total, 1.7 t/capita, 195 g CO<sub>2</sub>/\$ GDP PPP, US\$ of 2010), **(c)** Structure of the energy sector (383 Mtoe in total) and CO<sub>2</sub> emissions of the energy sector (922 Mt in total)

improved (Fig. 1.27) but strong efforts are needed to improve and to differentiate the energy sector, which today focuses almost exclusively on a conventional coal economy (Figs. 1.28, 1.29 and 1.33).

#### Characteristic Indicators

The main energy indicators, as defined in Sect. 1.3, are summarized and compared in Tables 1.5 and 1.6 for all groups of countries or countries analyzed and for the world as a whole.

**Table 1.5** Final energy consumption per capita ( $e_f$ ) and gross energy ( $e$ ) as well as total CO<sub>2</sub> emissions for country groups and countries, CO<sub>2</sub> emissions share of the energy sector in %, ordered by increasing  $e$ -value

## 1.6 Future Development of World Energy Demand

Predictions in this area are, as the past has shown, difficult and often misleading, even using sophisticated econometric methods [1.10]. However, on the basis of the easily predictable development of the population and certain assumptions about the further development of the economy and the energy intensity of the individual regions of the world, scenarios can be generated that provide an overall picture of possible developments in world energy demand. These scenarios are options that society can choose by means of energy policy, taking into account economic, social and environmental constraints.

Let's start with a few simple considerations. At the turn of the millennium, world energy consumption (primary energy) was 2.2 kW/capita  $\times$  6 billion people  $\approx$  13 TW. During the last 20 years of the previous century, specific consumption has remained almost stable at around 2.2 kW/capita, a level which is mainly due to the collapse of the former Soviet Union in 1989. In 2007, the world energy demand, according to IEA, reached 2.26 kW/capita (with a world popula-

tion of 6.6 billion people, i.e., 15 TW) and increased to 18.2 TW or 2.45 kW/capita by 2016.

In the future, it will not be easy to maintain a value of 2–2.5 kW/capita or even to reduce it to 2 kW/capita (*2000 W-Society*). It is difficult to compensate the strong need to catch up in terms of GDP (PPP) of the developing countries by reducing the energy intensity of the already industrialized world. Scenarios promoting a specific consumption of 2 kW per capita were discussed in the 1980s within the framework of the WEC (then the *World Energy Conference*) in view of the CO<sub>2</sub> problem that was already becoming known [1.29]. In 1996 the World Energy Council predicted a global energy demand of around 3 kW/capita for 2020 [1.2], which would already correspond to a primary energy demand of 24 TW at this point in time for the expected world population of around 7.5 billion people.

The WEO 2006 of the IEA [1.7] envisaged two scenarios for 2030, which have already been mentioned in Sect. 1.2.1 *Future Demand*. The reference scenario, which corresponds to current trends, leads to a global

energy demand of 22 TW or 2.7 kW/capita. The alternative scenario, which requires the political will to reduce CO<sub>2</sub> emissions, leads to a total demand of almost 20 TW or 2.5 kW/capita (Fig. 1.3). Extrapolating this scenario up to 2050, for a world population of 9 billion people, a specific consumption of 2.75 kW/capita and a total consumption of 25 TW are obtained. However, this figure is hardly compatible with climate protection (for a more detailed analysis see Sect. 1.7). This is also the reason why the IEA, in the *Scenario 450* of 2009 for 2030, requires a total global consumption of 19 TW, which corresponds to 2.3 kW/capita. The latest 2015 Bridge scenario is similar, with a good 20 TWa. We start our study with assumptions about the two most important factors influencing the future world energy demand: population and GDP (PPP).

### 1.6.1 Development of the World Population

At the turn of the millennium, the world population was about 6 billion people. This is a doubling since 1960. Of these, approximately 1.5–2 billion people are materially privileged, while the remaining 4–4.5 billion have a long way to go to catch up. Demographic studies are largely in agreement that the world population, as in Fig. 1.36, will increase to at least 8 billion by 2030, and to about 9 billion people by 2050. By 2100, a progressive stabilization to about 10–11 billion people is predicted [1.32]. The population of today’s industrialized countries will grow relatively little, mainly through immigration, and that of the developing countries will increase considerably, even though the current war situation in the Middle-East/Africa shows a different picture.

### 1.6.2 Increase in GDP (PPP) and Energy Demand

Table 1.7 compares GDP for the year 2030 in the OECD, non-OECD countries and the world as a whole, as well as for the US and China: GDP per capita  $y$  (purchasing power adjusted (PPA), in \$ of 2010), intensity  $\varepsilon$  of the gross inland energy demand and the resulting per capita consumption of final and gross energy  $e_c$  or  $e$ . The figures are based on the indicator values required to meet the 2 °C climate target [1.29, 33, 34]. The lower value corresponds to a scenario with a lower CCS input, the upper value to a scenario with a higher CCS input. Both assume the same GDP (PPP), so they assume that the chosen energy policy will not have a major impact on overall economic development. The scenarios demand for coming years a *significant decrease in energy intensity* relative to 2016, anywhere in the world (Fig. 1.27).

Fig. 1.36 World population growth since 1950 and forecast, IC = today’s industrialized countries (essentially OECD-34), RW rest of the world [1.29]

Table 1.7 Comparison of GDP (PPP)  $y$ , gross energy intensity  $\varepsilon$  and gross energy consumption per capita  $e$  for 2030 according to 2 °C target [1.27]

2030	$y$ ( $\times 10^4$ \$/(a capita))	$\varepsilon$ (kWh/\$)	$e$ (kW/capita)
OECD-34	4.2	0.9–1.0	4.5–4.7
Non-OECD	1.5	1.1–1.2	1.9–2.2
World	1.9	1.0–1.2	2.3–2.6
USA	5.7	1.0–1.1	6.5–7.2
China	2.6	0.9–1.2	2.7–3.2

Fig. 1.37 Increase of the world population since the year zero of our time calculation and forecast of further development [1.29]

In the OECD countries, GDP/capita adjusted for purchasing power increases by 9% relative to 2016 and energy intensity decreases by an average of 20%, which essentially suggests a slight decrease in gross energy consumption per capita (−12% on average).

In the rest of the world (non-OECD countries), GDP/capita adjusted for purchasing power increased

by 80% relative to 2016 and an energy intensity decrease by 30%. So the gross energy demand per capita increased by an average of about 10%.

Worldwide, there is an average increase in GDP per capita of 50% and a decrease in energy intensity of just under 25%. The gross energy demand per capita is increasing on average by around 1%.

## 1.7 CO<sub>2</sub> Emissions and Climate Protection

Various climatological studies [1.35, 36] show that for climate protection, the increase in the earth's mean temperature relative to the pre-industrial era must be limited to 2 °C, or even better to 1.5 °C. The emissions reduction by 2100 necessary to reach the 2 and the 1.5 °C targets are shown in Fig. 1.38 [1.27]. To achieve the 2 °C goal, it is necessary to bring CO<sub>2</sub> emissions back to 2010 levels by 2030 (± 10%) and halve them by 2050. The variant *a* is primarily to be aimed at and would also allow a target of 1.5 °C, by a strong decrease gradient from 2030 to zero in 2050.

### 1.7.1 Climate Protection, Medium and Long-Term Measures

The most important measure for most OECD and also non-OECD countries, is the reduction of CO<sub>2</sub>-

emissions in the energy sector, which in 2016 accounts for around 50% of total global emissions (Table 1.5) and primarily concerns the generation of electricity. Exceptions are some European countries (France, Norway, Iceland, Sweden and Switzerland) as well as many Central and South American countries with a near CO<sub>2</sub>-free electricity generation. In 2016 their emission of CO<sub>2</sub> was already at or below 120 g CO<sub>2</sub>/\$ (Fig. 1.16). If this advantage is maintained, the efforts of these countries can focus on fuels for heating and transport.

#### Specific Energy Consumption and CO<sub>2</sub> Intensity

The CO<sub>2</sub> emissions per capita and year  $\alpha$  can be expressed as the product of specific energy consumption  $e$  and CO<sub>2</sub> intensity of gross energy  $k$  (Sect. 1.3.4). The gross world consumption in 2016 was around

**Fig. 1.38** Worldwide CO<sub>2</sub> emissions 1970–2016 and climate protection scenarios up to 2100 for 2 and 1.5 °C (cumulative emissions until 2100: 2 °C (< 800 GtC), 1.5 °C (< 550 GtC)); 2 °C scenario with variants *a* and *b*, 1.5 °C scenario with soft variant and hard variant starting 2030 from 2 °C scenario variant *a* [1.27, 28, 34]

**Table 1.8** Target values for gross energy intensity  $\varepsilon$ , CO<sub>2</sub> intensity  $k$  and CO<sub>2</sub> sustainability indicator  $\eta$  for 2030 Var.  $a$  of Fig. 1.38, [1.34]

2030	$\varepsilon$ (kWh/\$)	$k$ (g CO <sub>2</sub> /kWh)	$\eta$ (g CO <sub>2</sub> /)\$)
OECD	0.95	170	160
World	1.05	165	160
Non-OECD	1.1	160	175

2.3 kW/capita, with a factor of around three between the OECD and the non-OECD countries. If the global value is not to exceed 2.3 kW/capita by 2030, an emphatic reduction in the specific value of the OECD countries (2016: 5.1 kW/capita) is required in order to compensate the inevitable increase in that of the non-OECD countries (1.7 kW/capita), which is mainly associated with the expected strong increase in the GDP of this part of the world. An important step towards this is to increase the energy efficiency (reduce energy intensity) in the industrialized countries, but at the same time to make available to the developing and emerging countries, technologies for increasing energy efficiency.

Table 1.8 also shows, however, that increasing the efficiency is not enough for reaching the goals of climate protection set out in Fig. 1.38. It is equally important to achieve a large reduction in CO<sub>2</sub> intensity, that applies equally to OECD and non-OECD countries (Fig. 1.28).

#### The Life-Cycle Cost-Benefit and Grey Energy

These aspects are often brought into the CO<sub>2</sub> balance, making some CO<sub>2</sub>-free energies or energy uses appear to be less favorable. However, as regards the medium and long-term climate protection goals, this is, for the following reasons, not defensible:

**Life-Cycle Cost-Benefit Ratio.** A poor life-cycle cost-benefit factor does have a negative effect on the energy balance (and thus on the economic viability), but not on medium-term climate protection, provided that the energy required for manufacture and transport is also CO<sub>2</sub>-free, which is required in any case for the medium and long-term target.

**Grey Energy.** If the energy used in the manufacture of imported products causes greater emissions of CO<sub>2</sub> than that used for producing exported goods, the CO<sub>2</sub> balance of a country is in theory worsened. However, it does not make sense to include this in the sustainability balance. Each country is ultimately responsible for the energy used in the production of its goods and should

put the required climate protection measures in place using its own efforts or in the context of international agreements or emissions trading. But emissions trading should primarily be seen as development aid.

### 1.7.2 Electricity Consumption and Climate Protection

It has already been pointed out several times that the energy sector (which is largely determined by electricity production) has the main responsibility for global CO<sub>2</sub> emissions (around 50%). The objectives of climate protection can only be achieved if effective measures for CO<sub>2</sub>-free electricity production are brought in.

Figure 1.39 illustrates which energy sources have been used in 2016 to meet global electricity demand. Above all, the large proportion of coal (still 38%) is devastating for the CO<sub>2</sub> balance.

#### Countries With CO<sub>2</sub>-Intense Electricity Production

The most important countries in this group are the USA, China, India, Russia, Japan and in Europe Germany, the UK, Poland, Spain and Italy. Their electricity production is essentially dependent on coal (China and India) or heavily on coal and/or oil + natural gas (see also Figs. 1.30–1.35).

Figure 1.40 shows the structure of electricity production in three major countries: the USA, China and Germany.

Turning away from coal and oil as fast as possible or at least from the current way of using them is the *imperative basic requirement for effective climate protection*. The countries of the OECD should be able to achieve this, given the political will, using their own efforts, the emerging economies too with political support, and the developing countries presumably only with international support. This is made more difficult by the fact that the world demand for electrical energy is expected to increase by around 20% between 2016 and 2030.

The possible measures and substitutions are as follows (a–h). It should be noted that it makes no sense to play one possibility off against the other in a fundamentalist way. All are necessary and must find their place within the framework of an economic, ecological and also political balance, which can vary from country to country and from continent to continent:

- a) Large reductions in losses in the energy sector by significantly increasing the efficiency of thermal power stations (combined heat and power, combined cycle generation).

**Fig. 1.39** Energy sources used for electricity production worldwide in 2016 (25 0852 TWh in total)

- b) CO<sub>2</sub> capture utilisation and storage (CCUS) in coal and oil-fired power stations; with a significant limitation: The CCS technology is not yet mature, is probably expensive and is not yet fully tested for environmental sustainability. Better is CCU, which allows to produce carbon neutral fuels by hydrogenating carbon exhaust gases with the help of renewables energies. Without CCUS, the 2-degree target, and even more the 1.5-degree target is difficult to achieve.
- c) Use of natural-gas power stations, substitution of coal and oil with natural gas: CO<sub>2</sub> emissions, compared to coal, are reduced to about 55% (compared to oil, to about 75%), with a restriction: worldwide gas reserves are limited. Fracking increases reserves, but its environmental risks have not yet been sufficiently clarified.
- d) Use of nuclear energy: the power stations do not emit CO<sub>2</sub>; restriction: reserves of uranium, used in 3rd-generation reactors, are also limited. Use of fourth generation reactors is possible, but must be well thought out, technically and politically. Nuclear fusion can only be considered in the second half of the century.
- e) Use of all opportunities to generate electricity from water power; restriction: the potential for this is limited.
- f) Use of wind energy: the technology is mature and, where the wind conditions are favorable, cost-efficient. The potential for this is very great. Restrictions: Networks and energy storage require considerable adjustments.
- g) Use of geothermal and biomass energy.  
Limitations: geothermal power stations are only suitable in locations with geothermal anomalies. In several parts of the world, however, the geothermal potential is very high.  
The potential of biomass is limited. Biomass including waste should therefore be used primarily, and provided its use is ecologically acceptable, for fuel in transport and heating, with the exception of local combined heat and power. The production of bio-fuels is often anything but CO<sub>2</sub> neutral
- h) Use of solar thermal energy and photovoltaics. Solar thermal power plants are appropriate only for countries with a low proportion of diffuse light. However, its potential in desert regions (e.g., the Sahara) is very great. HVDC (high-voltage direct-current transmission, see [1.24]) enables connection to consumption centres. Due to its unlimited and capillary exploitable potential, photovoltaics should continue to be promoted purposefully as long as necessary and economically justifiable, including through feed-in tariffs. Here, too, adjustments to the transmission and distribution grids are necessary, as is energy storage (partly also through load control).

**Fig. 1.40a–c** Structure of electricity production **(a)** in the USA (4322 TWh in total), **(b)** China (with Hong Kong) (6256 TWh in total) and **(c)** Germany (649 TWh in total) in 2016

**Remarks.** The great increase in electricity demand expected worldwide by 2030 can hardly be avoided, even by improving efficiency, for various reasons listed below. It is therefore unreasonable to rely only on the latter, however indispensable they may be. The use of natural gas and third-generation nuclear power plants is necessary, but at best does not enable much

more than the maintenance of their percentage shares (Fig. 1.40, worldwide 2016: natural gas 23%, nuclear energy 10%), but hardly the complete replacement of coal and oil-fired power plants (shares 41% and 4% respectively). The same applies to hydropower (17% share). The use of b) must therefore be examined; that of the remaining renewable energies f) to h) is indis-

Fig. 1.40 (continued)

pensable and must be greatly increased (share 2016: 6%!). Although electricity from wind energy has multiplied worldwide, at 3.8% it is still a long way from being a significant source of energy.

#### Countries With Nearly CO<sub>2</sub>-Free Electricity Production

These countries have the great advantage of already having solved the most important emissions problem: Switzerland and Sweden with a mix of water power and nuclear energy, Norway with water power, Iceland with water power and geothermal power, France with mainly nuclear energy and Latin America mainly with water power. The first priority is naturally given to maintaining the freedom from CO<sub>2</sub> in the electrical energy sector, which can only be achieved by the measures d) to h). These countries already have the basic prerequisite and so they can be pioneers in the development and application of new technologies for limiting emissions in the areas of transport and heating. The areas will now be analyzed.

### 1.7.3 Transport

Emissions are almost entirely caused by the use of fuels obtained from mineral oil, which accounted for around 22% of world CO<sub>2</sub> emissions in 2016, and is steadily increasing (OECD 23%, non-OECD 15%). In the short

term the increase can be kept within bounds by improvements in efficiency (and the associated reduction of CO<sub>2</sub> emissions per km travelled), by electrification of traffic (electric and hybrid cars) and by partial substitution of petrol and diesel by natural gas and biofuels (for the latter ecological considerations are important and require further examination).

However, in the medium and long term, protection of the climate is possible only with a paradigm shift. The future is likely to belong to electromobility, the *pure electric motor* and the *hybrid solution* with the *electric motor as the primary drive* and an *internal-combustion engine as serial or parallel secondary module* to improve the range before recharging. The latter may, except with petrol or natural gas, be at least partially combined with *biofuels* provided that their production has a good CO<sub>2</sub> balance and is compatible with the food production required worldwide. Secondary operation with *solar gas* (fuel derived from syngas generated with solar energy) is also conceivable.

At least 75% of vehicles are driven for less than 50 km/day. The battery supplying the electric motor can then be charged overnight, which will at least enable urban traffic to be largely CO<sub>2</sub> free. The production of electrical energy in sufficient quantity and as far as possible free of CO<sub>2</sub> together with powerful batteries are the prerequisites for this change which will

therefore not happen immediately, at least not globally.

Using a *fuel cell* to supply the electric motor could also make a significant contribution in the long term; for this, however, hydrogen made using CO<sub>2</sub> free energy is required (Chap. 8).

The change is also imperative from purely economic considerations. The fuel for an efficient mid-range car with a consumption of, for example 6l petrol per 100 km (46 mpg, emissions of about 140 g CO<sub>2</sub>/km) currently costs about 8.4 €/100 km at a price of 1.4 €/l. The energy content of 6l petrol is 52.6 kWh and with an average efficiency of 20% this gives a mechanical power (useful energy) of about 10.5 kWh/100 km. The price of the mechanical drive energy is therefore today already (in Europe) at least 0.8 €/kWh and rising. With an electric motor and including the battery and the power electronics, an average efficiency of at least 65% can be achieved, giving, for the same useful mechanical energy of 10.5 kWh, an electricity consumption of at most 16 kWh/100 km. To achieve the same energy costs as with the combustion engine, the electrical energy from the mains socket for recharging the battery can cost 0.5 €/kWh or more. The corresponding comparison with diesel fuel gives 0.45 €/kWh. Consequently, the mains electricity *fuel* is already much cheaper in most countries than petrol or diesel and the time is not far off when photovoltaic electricity will be cheaper, even from small installations. Even when the extra power required for the heavier vehicle (because of the battery) is allowed for, there is a clear advantage in the energy costs.

The change is also necessary for purely economic reasons. The fuel for a very efficient mid-range car with a consumption of, e.g., 6l of petrol per 100 km (emissions approx. 140 g CO<sub>2</sub>/km) costs, at a price of 1.4 €/l, about 8.4 €/100 km. The energy content of 6l of petrol is 52.6 kWh and, with an average efficiency of 20%, results in a mechanical drive power (useful energy) of 10.5 kWh/100 km. The price of mechanical drive energy is therefore already today (at least in the European environment) at least 80 ct/kWh and is rising.

With the electric motor, together with the battery and power electronics, an average efficiency of more than 65% can be achieved, resulting in an electricity consumption of at most 16 kWh/100 km for the same mechanical drive energy of 10.5 kWh. In order to be on a par with the combustion engine in terms of energy costs, the electrical energy from the socket for charging the battery may therefore cost 50 ct/kWh or more. The analogous comparison with diesel fuel leads to at least 45 ct/kWh. As a result, in most OECD countries

(except the USA), the *fuel* electricity from the grid is already significantly cheaper than petrol or diesel, and the time is not far off when even electricity generated by photovoltaics in small systems will be cheaper. Even taking into account a power supplement for the greater weight of the electric car (battery), there is a clear advantage in terms of energy costs. Although the vehicle price is higher, it can be assumed that technical progress (Chap. 9) and mass production will reduce the price differential.

Whether a primary drive with solar gasoline or solar hydrogen will result in an economically better solution in the medium term is an open question, but is unlikely, due to the following disadvantages:

- The expected high fuel price, probably significantly higher than today's European gasoline price
- The low energy efficiency of the production chain solar energy–mechanical drive power, which will by far not reach that of the mains-operated electric drive.

#### 1.7.4 Heating

Energy for heating (excluding electricity) accounts for 27% of global CO<sub>2</sub> emissions. This applies almost equally to OECD countries (24%) and the rest of the world (30%).

*Heating for comfort* with the lowest emissions possible should not cause particular difficulties, given the appropriate promotion. Suitable means are: solar architecture and good insulation, solar collectors, biomass (wood) and, not least, district heating (combined heat and power) and, above all, the *heat pump* (for using environmental and geothermal heat). For the latter, the restriction applies that the most CO<sub>2</sub>-free electricity possible should be used (in Switzerland, Sweden, Norway and France conditions are almost ideal for this). This gives a new dimension to the importance of an adequate and low-CO<sub>2</sub> production of electricity. With a modern heat pump 25–30% of the heating energy is supplied by the electricity. The importance of the heat pump for heating is explained in more detail in Sect. 1.7.4 *Heat-Pump*.

For *process heat* the contribution from fuels should be reduced in favour of electricity (the most CO<sub>2</sub>-free possible) and the most emissions-free possible in industry by more efficient processes and the use of biomass, above all in the form of waste.

Let it be emphasized again that in the use of biomass, this is not CO<sub>2</sub>-neutral unless woodland clearance is compensated by new growth (preservation of forests and the rain forests in particular).

### Heat-Pump

Technical methods have been known for about 150 a to *pump up* heat by means of work from a low to a higher temperature level. The refrigeration machine has been using these methods for a long time: it extracts heat from the object to be cooled and pumps it up to a temperature slightly above the ambient temperature. Similarly, the heat pump removes heat from the environment and brings it to a temperature necessary for heating purposes.

The refrigeration machine quickly became popular as no other processes were available. The heat pump as a heating system, however, could not compete with conventional heating. Pioneering systems were, in the 1930s, built mainly in the USA and during the Second World War in Switzerland because of the shortage of coal. After the war, however, the heat pump was almost forgotten due to the onset of the oil boom. Only in the USA did it experience a renaissance in the 1950s and 1960s as a year-round air-conditioning unit (about 300 000 in use in 1963).

As a result of the 1973 oil crisis, interest in the heat pump returned everywhere in the second half of the 1970s, and it gradually began to become an alternative heating system.

From an exergy point of view, as well as in terms of energy efficiency, the heat pump clearly has advantages over other heating methods. In terms of sustainability, it is by far the best heating system. The relatively high installation costs compared to a boiler plant and cheap fossil fuels have so far worked against their use. The latter disadvantage should diminish more and more in the future.

**Exergy Comparison.** The heat energy of a medium is expressed by the following relationship

$$Q = c_m m T \text{ (kJ)} \quad (1.4)$$

with  $c_m$  = average specific heat (KJ/(kg K)),  $m$  = mass (kg),  $T$  = absolute temperature (K).

The heat energy is represented by a rectangle in the  $(c_m m, T)$  diagram (Fig. 1.41), which clearly shows the exergy and anergy components [1.1, in Annex A, Sect. A.2.2] when the ambient temperature is entered. The exergy levels at combustion temperature and at low temperature applications are very different. At low-temperature, a larger mass or greater specific heat is necessary to store the same amount of heat.

In a conventional heating system (Fig. 1.42a), the large exergy content of the fuel is uselessly destroyed during the transition from A to B. The use of fuels

**Fig. 1.41** Heat content at combustion temperature and low temperature

(which have a high potential exergy content) to produce low-temperature heat is thermodynamically very wasteful.

If, for example, the following values are assumed:  $T_0 = 1300$  K,  $T_v = 340$  K and  $T_u = 280$  K and a conversion efficiency of  $\eta = 0.95$  in combustion and heat emission, the following exergy efficiency results

$$\eta_{ex} = \eta \frac{T_v - T_u}{T_v} \frac{T_0}{T_0 - T_u} = 0.21, \quad (1.5)$$

see also the energy flow diagram in Fig. 1.42b.

Heating with a heat pump is quite different. The analogous representation in Fig. 1.43a shows that only that exergy in the form of work is used, that is required for reaching the heating inlet temperature. The energy is supplied by the environment. With reference, e.g., to Fig. 1.43b, the thermodynamically much more favorable characteristic figures result (COP = coefficient of performance),

$$\text{exergetic efficiency: } \eta_{ex} = \frac{\text{useful exergy}}{\text{exergy}} \approx 0.55$$

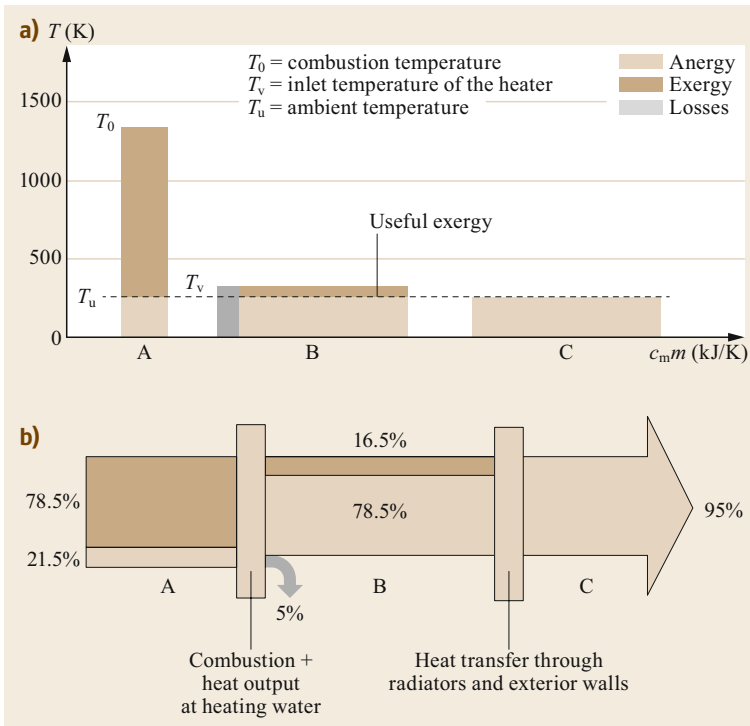

$$\text{COP of heat pump: } \beta = \frac{\text{useful energy}}{\text{work}} \approx 3. \quad (1.6)$$

**Comparison of Energy Utilization Degrees.** To assess the energy utilization degree, assumptions must be made about the origin of the work required to operate the heat pump. The degree of utilization is defined as

$$\eta_{use} = \frac{\text{useful energy}}{\text{required energy}}. \quad (1.7)$$

In the case of conventional heating, the degree of utilization is always  $< 100\%$  (for example, 95% in

**Fig. 1.42** (a) Heat content, (b) Energy flow in conventional heating. A energy content of the fuel, B heat supplied to the heating system (useful energy), C final state of energy (pure energy)

**Fig. 1.43** (a) Heat rectangle, (b) energy flow of the heat pump heating

**Fig. 1.44** Utilization degree of the heat pump heating with hydroelectric energy supply

**Fig. 1.45** Utilization degree of heat-pump heating with energy supply from a thermal power plant

**Fig. 1.46** Utilization degree of heat pump + CHP plant with power balance

Fig. 1.42). In the case of the heat pump, however, utilization rates much greater than 100% are the rule. Here are some examples:

- The electric drive energy comes from a hydroelectric power plant, which works with an efficiency of 85%. Figure 1.44 shows the flow diagram of Fig. 1.43b with a utilization rate of about 250%.
- The drive energy comes from a thermal power plant with an efficiency of 35%. Figure 1.45 then follows with a utilization rate of 105%. If the transmission losses in the network are taken into account, there is no significant advantage over conventional boiler heating.
- The heat pump is operated together with a heat-power cogeneration plant (CHP). Particularly interesting is the case of the *power balance*, in which

the CHP plant generates exactly as much electricity as is required to drive the heat pump. Assuming that the combined heat and power plant has an overall efficiency of 90% and generates 35% electricity, this results in a utilization rate of 160% (Fig. 1.46). With modern gas turbines and combined with district heating the utilization rate can reach 180% [1.1, Sect. 6.1.2])

**Conclusions.** The highest energy utilization degree is achieved with the combination hydropower-heat pump (e.g., small hydro powerplant and heat pump), which is also a very sustainable solution because it is CO<sub>2</sub>-

free. The same applies to the combination: power from another renewable energy (sun, wind)-heat pump.

The combination of heat pumps with conventional thermal power plants operated with fossil energies is pointless. In the case of nuclear energy or biomass, the utilization degree is not higher than that of conventional boiler heating, but the heat produced is CO<sub>2</sub>-free and the contribution to sustainability therefore considerable.

The combination of the heat pump with CHP plants has utilization degrees of well over 150% and therefore, even if it is not CO<sub>2</sub>-free, has a considerable potential for saving CO<sub>2</sub> (but only for countries with a high share of electricity production from fossil energy).

Dr-Ing Valentin Crastan is professor emeritus. After practical and managerial work in energy technology companies (Brown Boveri/ABB, Baden, Swiss electricity and transport company (Suisselectra), Basel), he has been appointed professor of energy systems and control engineering at the Bern University of Applied Sciences, Engineering and Computer Science, Biel. He also served as the Dean of the Department of Electrical Engineering/Communications for nine years.

# Power Generation

## 2. Power Generation

Valentin Crastan

The 1.5 °C climate target calls for rapid elimination of coal and oil for electricity production and the progressive reduction of the contribution of natural gas. This demands an enormous effort in the energy sector for the production of electricity using CO<sub>2</sub>-free energy sources. This chapter discusses five ways to generate electrical energy as sustainably as possible. The resulting grid stability problems are briefly outlined.

Hydropower (Sects. 2.1–2.6) is one of the most important sources of energy for generating electricity. It is also ecologically sound (no CO<sub>2</sub> emissions) if the plant construction (river dams, reservoirs) respects nature and human settlements appropriately. In 2016, hydropower installations accounted for 16.6% of global electricity production. This section provides an overview of the planning, engineering and modeling of hydraulic power stations.

The efficiency of power generation from fossil fuels in thermal power plants has risen considerably over time and today reaches almost 60% in natural gas-powered, combined cycle power plants (Sect. 2.7). Nevertheless over 40% of the energy is still lost as waste heat. In *combined heat and power* (CHP), useful heat is produced in addition to electrical energy, thus further increasing overall energy efficiency.

The potential of wind energy (Sect. 2.8) and the prerequisites for its economic use have already been briefly discussed in Sect. 1.2.3. This section deals in more detail with the technical and economic aspects of wind-energy use.

In Sect. 2.9 the basics of photovoltaics (photoelectric effect) and solar cells (structure, types, characteristics, efficiencies) are given. To use them optimally requires knowledge of the radiation intensity and thus the calculation of the apparent movement of the sun relative to the Earth. Photovoltaic is the renewable energy with the highest potential worldwide.

Fuel cells (Sect. 2.10) can be used to convert hydrogen as well as natural gas and other hydrocarbons (e.g., petrol, methanol) or biogas

electrochemically directly into electrical energy. It is predictable that in the course of the next decades this technology will open up a wide range of applications for *mobile* and *stationary* applications.

The 1.5°C climate target calls for rapid elimination of coal and oil for electricity production and the progressive reduction of the contribution of natural gas. However, the demand for electricity will continue to increase worldwide, not only because of economic growth, but also because of the increased use of heat pumps for heating buildings, the progressive electrification of mobility and the increasing use of synthetic power to gas (PtG) generation as a natural gas replacement. This requires an enormous effort in the energy sector for the production of electricity using CO<sub>2</sub>-free energy sources. This chapter discusses ways to generate electrical energy as sustainably as possible.

Figure 2.1 shows the current distribution of energy sources used worldwide for electricity production. Due to the high proportion of fossil fuels, electricity production accounts for nearly half of global CO<sub>2</sub> emissions (Fig. 2.2).

In view of the climate problem, the sections on *hydropower, wind energy and photovoltaics* are paramount. Wind energy and, above all, photovoltaics have enormous potential, but also a temporal *variability*, that represents a big challenge to the control systems for frequency maintenance and grid stability. Because of the bi-directionality of the energy flows, this variability also requires general strengthening of local and transmission grids. *Hydroelectricity* has a very good growth potential in many developing countries and is

indispensable there for primary and secondary regulation of the electricity grid. *Pumped-storage plants* are being used less and less to convert inexpensive nighttime energy into expensive peak energy, as the rising solar energy share reduces the cost of daytime energy, but they remain an essential element for rapid compensation of the variability of wind and solar energy.

Fossil-based *thermal power plants* will be less and less able to take over this work, as their share is likely to be reduced as quickly as possible if climate goals are to be achieved, even if CCS (carbon capture and storage) technology can bring some relief. Combined heat and power generation (CHP) plays an indispensable role in improving efficiency. Although *geothermal or biomass* (wood from forests, waste, landscape maintenance and industrial residues) *power stations* are, or can be, CO<sub>2</sub>-neutral, their capacity is limited, with the exception of certain parts of the world (with big geothermal resources such as Indonesia and certain areas of America). The *power to gas* (PtG) processes for the *synthetic production of CO<sub>2</sub>-free hydrogen or gas* are very interesting for the decarbonization of the transport sector (hybrid long-distance vehicles and air traffic), but also require, due to poor conversion efficiencies, large amounts of electricity that worldwide can only be generated with big photovoltaic systems in sunny regions (e.g., Sahara, Middle East) and require, if local gas production is not appropriate, suitable transmission grids.

**Fig. 2.1** Energy sources used for electricity production worldwide in 2016, 25 082 TWh in total (see Chap. 1)

**Fig. 2.2** Energy flow in the energy sector and total CO<sub>2</sub> emissions from fossil fuels (with marine and aviation bunkers), worldwide in 2016. PP: power plants; CHP: combined heat and power; HP: heat plants; *Heat*: heating and process heat of non-electrical origin, without district heat (may contain non-electrical stationary work, in developed countries usually minimal) (adapted from [2.1, 2])

Since the decreasing use of thermal power stations will reduce their grid control ability, other methods of grid control will be needed. Thus, the importance of the *flexibilization of the load* is constantly increasing. Through appropriate digital controls and intelligent use of storage, the demand for electricity in the field of industry, building technology and mobility can be adjusted in terms of time and be frequency dependent, thus making a contribution to grid stability. Similarly, the supply from *photovoltaic systems and wind turbines* can be adjusted to the grid requirements (smart and micro grids). Above all, *medium and large photovoltaic power plants* (more and more are needed in the evolution to a CO<sub>2</sub>-free en-

ergy supply) can and must replace the inertia of the generators of thermal power plants with a virtual inertia of inverter-to-grid coupling, with *appropriate controllable storage units*, and thus make an important contribution to the primary and secondary regulation of the grid [2.3].

Regulation through *nuclear power plants* has been enforced in France with a flexibilization of the power output (inevitably, because of the very large share of NPPs in power generation), but in principle light-water reactors have, for physical and economic reasons, only limited suitability for primary control within seconds; their flexibility is possible but is associated with disadvantages.

## 2.1 Hydroelectric Power Stations

Hydropower is one of the most important sources of energy for generating electricity. It is also ecologically sound (no CO<sub>2</sub> emissions) if the plant construction (river dams, reservoirs) respects nature and human settlements appropriately.

In 2016, hydropower installations accounted for 16.6% of global electricity production (for Europe see Table 2.1). This section provides an overview of the planning, engineering and modeling of hydraulic power stations.

**Table 2.1** Europe 2016, share of hydroelectric power in electricity production in %

Austria	62.8	Estonia	0.3	Iceland	72.6	Malta	0	Slovakia	17.0
Belgium	1.7	Finland	23.0	Ireland	3.2	Netherlands	0.1	Slovenia	29.0
Bulgaria	10.1	France	11.7	Italy	15.3	Norway	96.2	Spain	14.5
Croatia	55.1	Germany	4.0	Latvia	39.4	Poland	1.6	Sweden	39.8
Czech Republic	3.8	Greece	10.2	Lithuania	24.5	Portugal	28.1	Switzerland	58.1
Denmark	0.1	Hungary	0.8	Luxembourg	69.6	Romania	28.5	United Kingdom	2.5

**Fig. 2.3** Basic diagram of a hydropower plant: OW headwater, UW tailwater,  $H_b$  gross head,  $Q$  water flow, T turbine, G generator

The basic scheme shown in Fig. 2.3 can be used for any hydropower plant, whether it is a run-of-river or a storage power plant.

Due to the stagnation of the water, there is a fall height or gross head  $H_b$  (m) between the upper pool (the headwater) and the lower pool (the tailwater). The gross gradient varies somewhat depending on the amount of water present. The nominal gross head usually refers to the maximum quantity of usable water  $Q$  ( $\text{m}^3/\text{s}$ ) for which the system is dimensioned. The gross power  $P_b$  of the power plant is then

$$P_b = \rho Q g H_b \left( \frac{\text{kg}}{\text{m}^3} \frac{\text{m}^3}{\text{s}} \frac{\text{m}}{\text{s}^2} \text{m} = \frac{\text{J}}{\text{s}} = \text{W} \right). \quad (2.1)$$

Due to friction in the supply and discharge lines, the head is smaller at turbine level; this is known as the effective head  $H$  (m), and is obtained via

$$H = \eta_h H_b, \quad (2.2)$$

where  $\eta_h$  is the efficiency of the hydraulic system or the hydraulic efficiency (which also depends on the amount of water present).

The hydraulic power  $P_h$  that is actually available at the inlet of the turbine is

$$P_h = \rho Q g H. \quad (2.3)$$

The energy of the moving water is converted into mechanical power in the turbine, which is available as a turbine power  $P_t$  on the turbine shaft

$$P_t = \eta_t \rho Q g H, \quad (2.4)$$

where  $\eta_t$  is the turbine efficiency.

The mechanical power is finally converted into *electrical power* in the electrical generator. The net output of the power plant is

$$P = \eta_e P_t = \eta_e \eta_t \rho Q g H, \quad (2.5)$$

where  $\eta_e$  is the efficiency of the electrical device (generator, transformer, own requirements of the power plants).

### Example 2.1

A power plant with a net output of 100 MW and a gross head of 500 m has the following efficiencies:  $\eta_h = 0.92$ ;  $\eta_t = 0.85$ ;  $\eta_e = 0.96$ . Also,  $\rho = 1000 \text{ kg/m}^3$  and  $g = 9.81 \text{ m/s}^2$ . Determine:

- The turbine and hydraulic power
- The effective head and the nominal water flow
- The diameter of the circular feed gallery if the optimal water speed is 4 m/s
- A general expression for the specific energy  $w$  of a kg of water and the value of the specific energy  $gH$  at the turbine entrance.

### Solutions

$$(a) P_t = \frac{P}{\eta_e} = \frac{100}{0.96} = 104.2 \text{ MW}$$

$$P_h = \frac{P_t}{\eta_t} = \frac{104.2}{0.85} = 122.6 \text{ MW}$$

$$(b) H = H_b \eta_h = 500 \times 0.92 = 460 \text{ m}$$

$$Q = \frac{P_h}{\rho g H} = \frac{122.6 \times 10^6}{1000 \times 9.81 \times 460} = 27.2 \frac{\text{m}^3}{\text{s}}$$

$$(c) A = \frac{Q}{v} = \frac{27.2}{4} = 6.8 \text{ m}^2$$

$$D = \sqrt{\frac{4A}{\pi}} = \frac{4 \times 6.8}{\pi} = 2.94 \text{ m}$$

With increasing water speed, the loss costs due to friction increase approximately quadratically, while the investment costs of the tunnel decrease with smaller diameter. Optimizing the total cost results in the optimal speed.

- Since  $\rho Q$  represents the water flow in kg/s, the specific energy  $w$  of the water at the entrance to the turbine is  $gH$ , and can be calculated using (2.3). Therefore, the solution to (d) is:

$$w = \frac{P_h}{\rho Q} = gH, \quad (2.6)$$

$$gH = 9.81 \times 460 = 4.51 \text{ kJ/kg}.$$

## 2.2 Hydrological Planning Principles

Figure 2.4a shows the catchment area of the observation point P of a river.

Concerning the *annual water volume*, as a rule, long-term measurements are available that enable a statistical assessment of the above-ground discharge conditions. If no measured water quantities are available, but rainfall values are available, the mean annual runoff quantity can be used for preliminary studies.  $Q_{ma}$  can be estimated with the following formula

$$Q_{ma} = \beta h_m A \times 10^3 \quad (\text{m}^3/\text{h}),$$

where  $A$  is the catchment area of the observation point P ( $\text{km}^2$ ),  $h_m$  is the long-term average of the precipitation height ( $\text{mm}/\text{a}$ ), and  $\beta$  is the discharge coefficient ( $< 1$  because of evaporation and seepage, dependent on the type of ground and surface, e.g., vegetation).

In addition to the long-term mean values, the maximum values (wet years), as well as the minimum values (dry years) and their frequency, are also of interest.

Measurements at various observation points along the watercourse from the source to the estuary show the *discharge pattern* in Fig. 2.4b.

A part  $Q_a$  ( $\text{m}^3/\text{a}$ ) of the available water at  $P_1$  can be captured and used with the gross head (also gross drop height)  $H_b$ . The corresponding energy potential of the power station (gross energy/a) is

$$W_a = \rho Q_a g H_b \frac{1}{3.6 \times 10^6} \quad (\text{kWh}/\text{a}),$$

( $\rho \approx 1000 \text{ kg}/\text{m}^3$ ,  $Q_a$  ( $\text{m}^3/\text{a}$ ),  $g \approx 9.81 \text{ m}/\text{s}^2$ ,  $H_b$  (m)) and is thus proportional to the area  $Q_a H_b$ .

Several power stations along the watercourse, e.g., a low-pressure power station at  $P_2$ , provide for a more or less complete use of the water body, whose *potential* is shown by the area integral of the diagram in Fig. 2.4b. Figure 2.5 shows an example of an almost complete use of the gradient of a river section on the Rhine.

It is also important for the planning of the power station to take into account the *temporal fluctuations* of the water supply during the year. Figure 2.6a shows the typical behavior of alpine waters (snow melt) and Fig. 2.6b the long-term *duration line* (frequency curve) of the water supply, which serves as the most important planning basis.

Fig. 2.4 (a) Catchment area, (b) flow rate diagram of a river

Fig. 2.5 Power station chain on the Rhine between Lake Constance and Basel (adapted from [2.4])

**Fig. 2.6** (a) Typical annual water quantity curve of an alpine water body, (b) annual duration line of the water supply

The construction of a hydraulic power station constitutes an intervention in the natural, constantly renewing water outflow. *Water management planning* must therefore be given priority over the needs of the energy industry. Often other aspects such as irrigation, shipping and flood control [2.5] have to be taken into account. The requirements of *environmental protection* must be taken into account in the broadest sense (drinking and groundwater, fauna, flora, landscape protection). It should not be forgotten, however, that hydropower is a clean, ecologically valuable form of solar energy that can be used as a substi-

tute for more environmentally damaging primary energies.

Hydropower plants can be divided into three main categories from an energy-economy point of view, and are discussed below. They are:

- Run-of-river power stations, i.e., power stations without water storage
- Storage power stations with daily and weekly storage
- Storage power stations with annual and multiyear storage.

## 2.3 Run-of-River Power Stations

Run-of-river power stations have various *basic forms*:

- If the river has a sufficient gradient, the power station can be placed directly next to the weir (Fig. 2.7a). Full use of the water is then possible. The drop height is usually a few meters.
- A greater drop height is possible if the water is fed to a lower lying tailwater channel (Fig. 2.7b). However, a residual water amount in the river bed is prescribed, so that the full water amount cannot be used.
- The same applies to power stations at the end of an upstream channel (Fig. 2.7c).

**Fig. 2.7a-d** Types of run-of-river power stations: (a) Power station directly at the weir, (b) run-of-river power station with tailwater channel, (c) run-of-river power station with headwater channel, (d) run-of-river power station with upstream water supply through tunnels and pipelines (adapted from [2.4])

**Fig. 2.8** Run-of-river power station with Kaplan turbine (adapted from [2.6])

- With a larger river loop, the drop height can be considerably greater, and the water supply might even require a mountain cutting (Fig. 2.7d).

Due to the normally small drop height, run-of-river power stations are usually *low-pressure systems*. The turbines in question will then be either *Kaplan* (Fig. 2.8) or *bulb turbines* (Fig. 2.10) (see also Sect. 2.5). In special cases with greater drop heights (e.g., waterfalls, rapids and designs as in Fig. 2.7d), *Francis turbines* are also used.

### 2.3.1 Water Management

The natural water inflow is used, i.e., the management usually has no influence on the timing of water use. Sometimes short-term storage (in the hours range, e.g., in the case of hydropeaking [2.8]) is planned, and thus a small contribution to peak energy production is possible.

### 2.3.2 Execution

Figure 2.8 shows the section of a run-of-river power station with a *Kaplan turbine*. In order to dam the turbine chamber from headwater and tailwater, dam beams are provided that are inserted with special cranes into the grooves provided for this purpose. The screen prevents coarser items from reaching the turbine. A screen cleaning machine makes it possible to keep the screen free of alluvial material.

The version with a *bulb turbine* (Fig. 2.10a,b) makes practical a low construction method that is well compatible with landscape protection. The bulb turbine can

also be used on very small gradients. The inlet spiral is omitted and the generator is located in a watertight housing. Thanks to the favorable hydrodynamics, the efficiency is excellent.

### 2.3.3 Design

If the power plant is designed for the *design water flow rate*  $Q_a$  the hatched area in Fig. 2.9 is lost. The quantity  $Q_a$  is optimized with the following limit value consideration: comparison of fixed capital and operating costs for an additional  $\Delta Q_a$  with the revenue generated by the corresponding increase in energy. This consideration is also decisive in determining the new capacity for power-plant renewals. Note that, with the assumptions in Fig. 2.9, the surplus of energy occurs in summer, i.e., when there is more of an energy surplus in Central Europe and the market value of the energy is low (this is often not true for purely thermal production).

**Fig. 2.9** Selection of the design water quantity  $Q_a$ . Residual water is required if the version includes tailwater or headwater channels

**Fig. 2.10**

(a) Run-of-river power station with bulb turbine (adapted from [2.6]), (b) Low-pressure run-of-river power station: 1 weir system, 2 sluice gate, 3 stilling basin, 4 baffle pier, 5 machine hall, 6 assembly shaft, 7 generator housing, 8 access shafts, 9 turbine runner, 10 guide vanes, 11 guide apparatus, 12 generator, 13 cooler, 14 cable conduit, 15 screen, 16 screen cleaning machine, 17 dam beams, 18 turbine outlet, 19 control and switching building, 20 workshop and garage building, 21 fish ladder, 22 boat stairs, 23 open-air switchgear or energy transport (adapted from [2.7])

## 2.4 Storage Power Stations

### 2.4.1 Daily and Weekly Storage

As a rule, these are river power stations with a higher water level of several tens of meters. The headwater becomes a daily or even weekly storage basin. *Kaplan* or *Francis turbines* are used. A special type of daily storage basin are the *pure pumped-storage plants* (Sect. 2.4.3).

#### Application and Design

The design water quantity  $Q_a$  will be determined on the basis of considerations similar to those set out in Sect. 2.3.3 (Fig. 2.9). However, as more valuable peak energy is produced, it is usually worthwhile to use a larger  $Q_a$ . As long as  $Q_a$ , e.g., for a daily storage plant, exceeds  $Q_m$ , the amount of water available on the day under consideration (Fig. 2.11) energy production can be concentrated on the peak hours.

The quantity

$$k(t) = \frac{V_{\max}}{86\,400 [Q_a - Q_m(t)]} \quad (\text{h/d})$$

can be taken as the daily concentration factor, where  $V_{\max}$  is the daily storage capacity. This factor changes

Fig. 2.11 Use of a daily-storage facility

Fig. 2.12 Typical course of the useful content of a weekly storage unit

over the course of the year. The value of the energy increases with the concentration factor. If this dependency is known, the achievable annual revenue can be calculated and compared with the annual costs, and thus the storage capacity and design water quantity can be optimized.

For *weekly storage units*, similar considerations can be made. Figure 2.12 shows the typical course of the useful content of a weekly storage unit. The storage tank is refilled at night and on weekends, while emptying takes place during peak hours, especially on weekdays.

#### Example 2.2

The Schiffenen power plant on the Saane has an installed capacity of 73.2 MW and an average annual production of 136 GWh. The overall efficiency is 0.85. The lake has a useful volume of  $35 \times 10^6 \text{ m}^3$ , and the lake surface area is  $4.25 \text{ km}^2$ . The maximum drop height is 48.2 m. Calculate the following characteristic numbers:

- The storage capacity
- The theoretical draining time at full power
- The theoretical number of cycles per year
- The duration of use of the installed capacity.

What type of power plant and storage facility is it?

Fluctuation of the headwater level is

$$\Delta h = \frac{35 \times 10^6}{4.25 \times 10^6} = 8.2 \text{ m}.$$

The average head is thus approximately 44 m:

- Storage capacity =  $\eta \rho V_{\max} g H_m$  (Ws)  
 $= 0.85 \times 1000 \times 35 \times 10^6 \times 9.81 \times 44 \frac{1}{3600}$   
 $= 3570 \text{ MWh}$
- Theor. draining time =  $\frac{3570 \text{ MWh}}{73.2 \text{ MW}} = 48.8 \text{ h}$
- Theor. number of cycles =  $\frac{136\,000 \text{ MWh}}{3570 \text{ MWh/cycle}} = 38$
- Usage duration =  $\frac{136\,000 \text{ MWh/a}}{73.2 \text{ MW}} = 1857 \text{ h/a}.$

Evidently it is a weekly storage power plant for the production of peak energy.

### 2.4.2 Annual Storage (Seasonal Storage)

Alpine waters carry considerably more water in summer than in winter. It is an obvious strategy to collect these quantities of water (so-called seasonal water) with the help of annual reservoirs. Since in Switzerland in the winter usually *less running water* is available, a considerable part of the electricity will be generated from *seasonal water*. Accordingly, the water-processing curve in alpine annual storage power stations varies in the opposite direction to the supply curve (natural inflows), as Fig. 2.13 shows. The storage volume is determined by the size of the catchment area and the topographical conditions. Certain legally stipulated quantities of water must also be able to flow down the valley in summer.

The energy content of the stored water is higher when a greater drop height can be selected. Annual storage plants in the high mountains are economical because large amounts of energy can be produced with relatively little water.

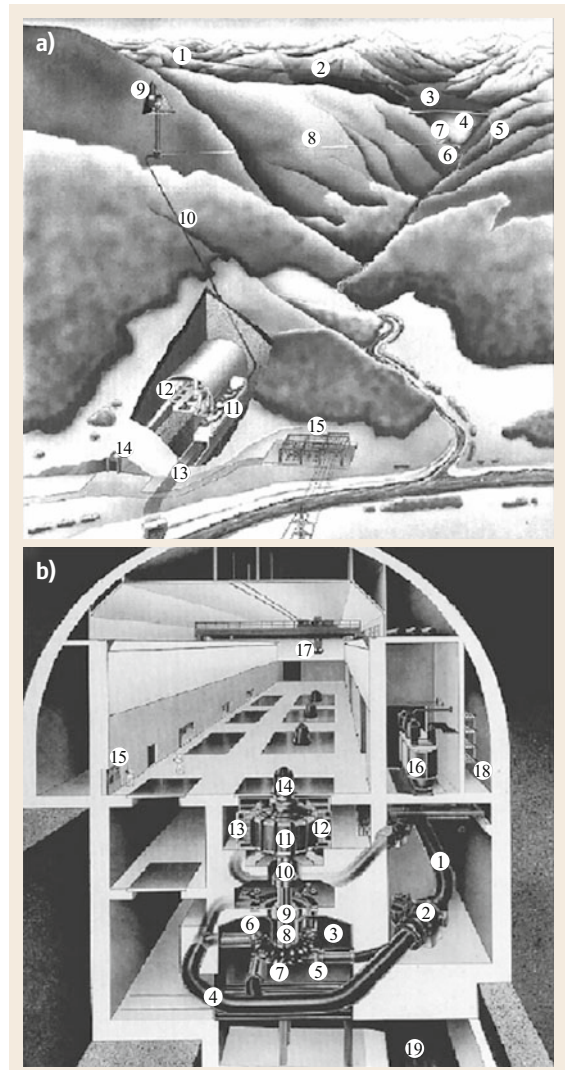

Larger storage volumes of rivers are not possible in Switzerland because of the high population density and for reasons of landscape protection. Worldwide, however, in various cases, rivers have been dammed to form large lakes with annual or even multiyear storage.

The main elements of an alpine annual storage power plant are shown in Fig. 2.14a. The *reservoir-stored water* is transported with an almost horizontal *pressure tunnel*, often over many kilometers to a suitable place, where it is led with a steep *pressure pipe* (or pressure shaft) to the power plant.

The head can be a few hundred to 2000 m. To provide for this, between the tunnel and the pen stock a *surge chamber* is required. This is an equalizing tank with the task of collecting the water flowing downstream when the turbine closes quickly and thus avoid-

**Fig. 2.13** Typical profile of water supply and water processing in annual storage power plants

**Fig. 2.14** (a) Main elements of an annual storage power plant (1 water catchments, 2 feed tunnel, 3 reservoir, 4 dam wall, 5 overflow, 6 bottom outlet, 7 inflow, 8 pressure tunnel, 9 surge chamber, 10 pressure shaft (or pressure line), 11 ball-valve chamber, 12 machine cavern (or center), 13 underwater tunnel, 14 access tunnel, 15 switching and possibly transformer station), (b) cavern power plant with Pelton turbines (1 distribution line, 2 ball valve, 3 turbine casing, 4 ring line, 5 inlet nozzle, 6 jet deflector, 7 Pelton turbine, 8 turbine shaft, 9 bearing, 10 generator shaft, 11 generator rotor, 12 generator stator, 13 cooler, 14 exciter machine, 15 control panel, 16 transformer, 17 crane, 18 cable gallery, 19 to the underwater tunnel) (adapted from [2.7])

**Fig. 2.15a–c** Types of dam: (a) gravity dam, (b) arch dam, (c) dam (adapted from [2.7])

ing impermissible pressure surges. The power plant is often located in a cavern (Fig. 2.14b).

The types of dams frequently encountered in Switzerland are shown schematically in Fig. 2.15. In a *gravity dam*, the weight of the dam is sufficient to retain the dammed water (example: Grande Dixence near Zion, 285 m high). Particularly elegant and material-saving is the *arch dam* that transmits water forces to the valley flanks through its curved shape (example: Mauvoisin

dam in Val de Bagnes, 237 m high). Another possibility is to use *dams* of soil, clay, gravel or sand (example: Mattmark dam in the Saas Valley, 120 m high).

For the drop heights mentioned, *Francis* and *Pelton turbines* are used (Sect. 2.4). The large drop height can often only be used with the aid of multistage systems. An example of a three-stage system is shown in Fig. 2.16: the total drop height is 1258 m; the individual stages are 524, 321, and 413 m high, with a total output

**Fig. 2.16** Multi-stage plant: Hinterrhein power plants (Switzerland, Canton of Grisons)

of 645 MW. The Ferrera top power station also allows the pumping up of the running water of a side valley (Sect. 2.4.3).

### 2.4.3 Pump Storage

With pumped storage, water is pumped up from a low-lying collecting basin to a higher reservoir. This fulfills two functions:

- Conversion of cheap night or summer energy into expensive peak and winter energy
- Collection of excess running water that would otherwise be lost.

A distinction is made between circulation systems and seasonal pump storage.

*Circulating systems* have a short-term storage, mostly day storage, for the conversion of night into day energy. Recently, they have the function not only of balancing load fluctuations, but also fluctuations of feed-in (wind and solar energy). They are often implemented as *pure pumped-storage plants* without natural inflows; then the turbinated water quantity is equal to the pumped water quantity. In this case, the upper basin is usually artificially excavated (Fig. 2.17a). In other plants, one finds pumped storage sets, combined with normal turbo sets with natural inflow.

The *seasonal pump storage* primarily serves to convert summer run-of-river energy into winter energy. The

**Fig. 2.17** (a) Pure pumped-storage plant with a head of usually 300–700 m: OW headwater (often artificially dredged), UW: tailwater (river or lake), DL: pressure line, Z: control center, (b) separate hydraulic machines (P: pump, T: turbine, MG: motor generator, K: clutch), (c) PT: pump turbine

running water is pumped into a seasonal reservoir at a higher altitude. Seasonal pump storage normally takes place in addition to the turbinating of natural inflows (Fig. 2.16).

There are two design options for the pump-storage units:

- Version with separate hydraulic machines. In turbine operation, the pump is disconnected, while the turbine idles (Fig. 2.17b) in pump operation.
- Version with pump turbine: is often cheaper in terms of investment, but has a lower efficiency. The pump turbine runs as a turbine when water is supplied and as a pump when the direction of rotation is reversed (Fig. 2.17c).

## 2.5 Water Turbines

According to Sect. 2.1, the turbine power is

$$P_t = \eta_t \rho Q g H \quad (\text{W}), \quad (2.7)$$

with  $H$  being the effective head.

The specific work performed by the turbine (per kg of water) is

$$w_t = \frac{P_t}{\rho Q} = \eta_t g H \quad \left( \frac{\text{J}}{\text{kg}} \right), \quad (2.8)$$

where  $gH$  represents the specific utility potential.

In any cross section of a water flow (Fig. 2.18), the specific energy can be expressed as [2.9, Annex A1]

$$e = \frac{p}{\rho} + \frac{1}{2} c^2 + gz \quad \left( \frac{\text{J}}{\text{kg}} \right). \quad (2.9)$$

The *flow energy* is composed of *pressure energy*, *kinetic energy* and *potential energy*.

With reference to Fig. 2.18, let  $e_1$  and  $e_2$  be the energies of cross sections 1 and 2. The flow performs work between points 1 and 2 in a turbine. The mechanical energy supplied by the turbine is in accordance with the principle of energy conservation

$$w_t = e_1 - e_2 - q_f, \quad (2.10)$$

where  $q_f$  are friction losses.

**Fig. 2.18** Water-flow energy ( $p$ : positive water pressure,  $c$ : mean water speed,  $z$ : height coordinates)

If (2.9) is inserted into (2.10), the following applies, namely the *Bernoulli equation* of fluid mechanics

$$w_t = \frac{p_1 - p_2}{\rho} + \frac{1}{2}(c_1^2 - c_2^2) + g(z_1 - z_2) - q_r \quad \left( \frac{\text{J}}{\text{kg}} \right). \quad (2.11)$$

The potential energy  $g(z_1 - z_2)$  plays a secondary role or can even be neglected. Depending on the significance of the two components of kinetic and pressure energy, a distinction is made between action and reaction turbines.

*Impulse turbines* (e.g., Pelton turbine). These are free-jet turbines, where the pressure is equal to atmospheric pressure, and  $p_1 = p_2 = 0$ . In these turbines, *kinetic energy* is converted into *mechanical energy*, and so

$$w_t \approx \frac{1}{2}(c_1^2 - c_2^2) - q_r.$$

*Reaction turbines* (e.g., Francis and Kaplan turbines). Within these turbines, there is a pressure difference ( $p_1 - p_2$ ), and both *pressure energy* and *kinetic energy* are transformed into *mechanical energy*. The *degree of reaction*  $r$  designates the proportion of the pressure energy converted in the impeller relative to the total available pressure energy ( $= gH$ ). The degree of reaction is between 0.3 and 0.8.

### 2.5.1 Pelton Turbine

Figure 2.19 schematically shows a plant with a Pelton turbine. A part of the gross head becomes friction loss  $H_v$  in the feeder lines. The height difference  $H_x$  between the jet level and tailwater level can also not be used. The hydraulic efficiency (Sect. 2.3.3) is thus

$$\eta_h = \frac{H}{H_b} = 1 - \frac{H_v + H_x}{H_b}.$$

The energy conversion of 1 kg of water on its way from the upstream water level to the turbine is illustrated in the energy diagram Fig. 2.20. When descending to the intake of the pressure line, part of the potential energy  $gH_b$  is converted into pressure energy and there partly also into kinetic energy. In the pressure line, the potential energy progressively becomes pressure energy as far as  $H_x$ . The pressure energy available before the nozzle, is converted in the nozzle (Fig. 2.21) into kinetic energy of the water jet.

Fig. 2.19 (a) Plant with Pelton turbine, (b) Pelton wheel

Figure 2.21 illustrates the energy conversion within a Pelton turbine (consisting of nozzle and wheel). The Pelton wheel has the diameter  $D$  and rotates at speed  $n$ . The circumferential speed of the wheel is  $u$ . The water jet hits cup-shaped blades and releases its energy. The nozzle needle regulates the jet diameter and thus the amount of water and the power of the turbine. The turbine can also have several nozzles. In the following, we calculate the specific energy in the cross sections 0, 1, and 2.

If the beam plane is selected as the reference plane, the potential energy in this plane is zero. The expression for the specific energy in front of the nozzle (cross section 0) is

$$e_0 = \frac{p_0}{\rho} + \frac{1}{2}c_0^2 = gH. \quad (2.12)$$

Fig. 2.20 Energy diagram (specific energy  $e$ ) of the Pelton plant

Fig. 2.21 Pelton turbine

The pressure energy in the jet is also zero. For the specific energy after the nozzle (cross section 1), it follows that

$$e_1 = \frac{1}{2}c_1^2 = \eta_D gH, \quad (2.13)$$

with  $\eta_D$  = nozzle efficiency (is a part of  $\eta_t$  and approximately 0.96).

From (2.13), the jet velocity is

$$c_1 = \sqrt{\eta_D 2gH}. \quad (2.14)$$

The jet velocity depends only on the effective head and is therefore independent of the set jet diameter  $d$ .

The specific energy immediately after the wheel (cross section 2) is calculated with the assumption of  $z_2 \approx 0$  to be

$$e_2 = \frac{1}{2}c_2^2,$$

where, for optimally shaped blades,  $c_2 \ll c_1$ .

The specific work and efficiency of the turbine are

$$\begin{aligned} w_t &= e_0 - e_2 - q_r = \eta_t gH, \\ (1 - \eta_t) gH &= \frac{1}{2}c_2^2 + q_r \rightarrow \eta_t = 1 - \frac{\frac{1}{2}c_2^2 + q_r}{gH}, \end{aligned}$$

with friction losses  $q_r$  in nozzle and wheel.

### Jet Diameter and Water Quantity

There is a relationship

$$Q = i \frac{\pi d^2}{4} c_1, \quad i = \text{number of nozzles}. \quad (2.15)$$

Therefore, the maximum jet diameter corresponding to the design volume of water  $Q_a$  is

$$d_0 = \sqrt{\frac{4Q_a}{i\pi c_1}}. \quad (2.16)$$

### Optimum Circumferential Speed

The relationship between turbine efficiency and wheel circumferential speed for a given amount of water is shown in Fig. 2.22. When the wheel is locked, no power is transmitted. If the wheel speed is equal to the jet speed, the power is also zero, since no power transmission is possible (momentum = 0). The efficiency of the wheel will be greatest at about half the jet velocity. The optimum circumferential speed is thus

$$u_{\text{opt}} = kc_1, \quad \text{with } k \text{ approximately } 0.5. \quad (2.17)$$

**Fig. 2.22** Power yield as a function of circumferential speed

From (2.17), the relationship between diameter and synchronous speed  $n$  (rpm) is

$$D = \frac{60}{\pi n} kc_1. \quad (2.18)$$

### Diameter, Specific Speed

To determine the diameter, a further correlation between diameter and speed is necessary. To find this, the ratio between the maximum jet diameter and the wheel diameter is calculated. From the relationships (2.16) and (2.18), one obtains

$$\frac{d_0}{D} = \frac{2Q_a^{0.5} \pi n}{i^{0.5} \pi^{0.5} c_1^{0.5} 60kc_1} = \frac{Q_a^{0.5} \pi^{0.5} n}{i^{0.5} (\eta_D 2gH)^{0.75} 30k}$$

and finally by introducing the *specific speed of rotation*

$$n_q = n \frac{Q_a^{0.5}}{H^{0.75}} \quad (2.19)$$

and the constant

$$a = \frac{\pi^{0.5}}{(2g)^{0.75} 30k\eta_D^{0.75}} = \frac{0.634 \times 10^{-2}}{k\eta_D^{0.75}} \quad (2.20)$$

we obtain

$$\frac{d_0}{D} = a \frac{n_q}{\sqrt{i}}. \quad (2.21)$$

The specific number  $n_q$  is defined as a *numerical value* with  $n$  in rpm,  $Q$  in  $\text{m}^3/\text{s}$  and  $H$  in m. It characterizes geometrically similar turbines. For the same number of jets and the same  $n_q$ , the ratio  $d_0/D$  that is proportional to the ratio of blade size to wheel diameter is constant. For a mechanically optimal Pelton wheel, this ratio varies only slightly; therefore, the ratio  $n_q/\sqrt{i}$  is for Pelton turbines practically a given. For large turbines and for large water heads (400–1000 m), the ratio  $n_q/\sqrt{i} = 5\text{--}6.5$  can be used. For heads  $> 1000$  m, these values must be corrected downwards (about 3–4 for 2000 m) and for small heads slightly upwards (for more details see [2.10]).

**Example 2.3**

Check the relationships using the Pelton facility depicted in Fig. 2.23. The nominal values are:  $P_t = 167$  MW,  $Q = 46.12$  m<sup>3</sup>/h,  $H = 413$  m,  $n = 180$  rpm.

The hydraulic power and turbine efficiency follow from the data

$$P_h = \rho Q g H = 1000 \times 46.12 \times 9.81 \times 413 = 187 \text{ MW},$$

$$\eta_t = \frac{P_t}{P_h} = \frac{167}{187} = 0.89.$$

From (2.19), one obtains

$$n_q = 180 \frac{46.12^{0.5}}{413^{0.75}} = 13.34,$$

$$\frac{n_q}{\sqrt{i}} = \frac{13.34}{\sqrt{6}} = 5.45.$$

Assuming that  $\eta_D = 0.96$  and  $k = 0.47$ , it also follows from (2.14) and (2.17) that

$$c_1 = \sqrt{0.96 \times 2 \times 9.81 \times 413} = 88.2 \text{ m/s},$$

$$u_{\text{opt}} = 0.47 \times 88.2 = 41.5 \text{ m/s}$$

and finally for the wheel diameter from (2.18)

$$D = \frac{60 \times 41.5}{\pi 180} = 4.40 \text{ m},$$

that corresponds well to the real wheel dimensions (4.35 m).

**Fig. 2.23** Six-jet free-jet turbine New Colgate on the Yuba River, California (Voith works drawing) (adapted from [2.4])

The maximum jet diameter determines the blade size. From (2.20) and (2.21), we can see that

$$a = 1.39 \times 10^{-2},$$

$$\frac{d_0}{D} = 1.39 \times 10^{-2} \times 5.45 = 7.58 \times 10^{-2}.$$

The maximum jet diameter is 7.6% of the wheel diameter or 33.4 cm. The guide values apply for the dimensions of blades and nozzle: blade spacing  $0.9d_0$ , blade length and width approximately  $3d_0$ , blade height  $0.3d_0$ , nozzle opening  $1.25d_0$  and nozzle tube diameter  $3d_0$ .

The specific energy at the turbine inlet is

$$gH = 9.81 \times 413 = 4.05 \frac{\text{kJ}}{\text{kg}}.$$

If the penstock diameter at the turbine inlet is estimated as  $d = 2$  m, it follows that

$$c_0 = \frac{4Q}{\pi d^2} = \frac{4 \times 46.12}{\pi 2^2} = 14.7 \frac{\text{m}}{\text{s}}, \quad \frac{1}{2} c_0^2 = 0.11 \frac{\text{kJ}}{\text{kg}}.$$

Using (2.12), the overpressure at the turbine inlet is

$$P_0 = \rho \left( gH - \frac{1}{2} c_0^2 \right) = 1000 \times (4.05 - 0.11)$$

$$= 39.4 \times 10^5 \frac{\text{N}}{\text{m}^2}.$$

**2.5.2 Reaction Turbines**

Figure 2.24 schematically shows the structure of a plant with a reaction turbine. The water moves from the pressure pipe (or penstock) to the *inlet spiral* and from there by mainly radial movement to the turbine. Thanks to the *diffuser* (or *suction tube*), the entire head to the tailwater level (UW) is used, minus friction losses in the supply lines. The hydraulic efficiency is

$$\eta_h = \frac{H}{H_b} = 1 - \frac{H_v}{H_b}.$$

**Fig. 2.24** Plant with reaction turbine. OW: headwater, UW: tailwater

**Fig. 2.25** (a) Sketch of the volute casing, (b) section through the turbine (adapted from [2.6])

Figure 2.25 shows a sketch of the volute casing and a section through the Francis turbine (adapted from [2.6]).

Francis and Kaplan turbines differ in the shape of the *impellers*. The *Francis turbine* (Figs. 2.26 and 2.31) has fixed rotor blades. The propeller-like *Kaplan turbine* (Figs. 2.27 and 2.32) has rotor blades whose angle of inclination is adjusted as a function of the amount of water in order to improve efficiency at partial load. A *propeller turbine* is the variant with fixed rotor blades and is only appropriate when operation can mainly be at full load.

To describe the energy conversion in the reaction turbine, the specific energy in cross sections 0, 1, 2, and 3 is considered, with the tailwater level being chosen as the reference plane for the potential energy. In cross section 0 in front of the inlet spiral (Fig. 2.24), the

following applies

$$e_0 = \frac{p_0}{\rho} + \frac{1}{2}c_0^2 + gz_0 = gH.$$

The specific energy in cross section 1, immediately after the guide wheel is

$$e_1 = \frac{p_1}{\rho} + \frac{1}{2}c_1^2 + gz_1 = \eta_{SL}gH. \quad (2.22)$$

$\eta_{SL}$  takes into account the losses in the inlet spiral and guide wheel.

The specific energy in cross section 3 (tailwater level) is

$$e_3 = 0, \quad (2.23)$$

because the water velocity and the overpressure are zero here, too.

Some energy is lost in the diffuser due to friction. For the specific energy in cross section 2, immediately after the impeller, the following applies

$$e_2 = \frac{p_2}{\rho} + \frac{1}{2}c_2^2 + gz_2 = q_D, \quad (2.24)$$

where  $q_D$  indicates the friction losses in the diffuser.

From (2.22) and (2.24), the specific energy available at the turbine shaft follows, in accordance with (2.10) and (2.11)

$$\begin{aligned} w_t &= e_1 - e_2 - q_f = \frac{p_1 - p_2}{\rho} + \frac{1}{2}(c_1^2 - c_2^2) \\ &\quad + g(z_1 - z_2) - q_f \\ &= \eta_{SL}gH - q_D - q_f = \eta_t gH, \end{aligned} \quad (2.25)$$

where  $q_f$  = friction losses in the impeller.

Also, from (2.24)

$$\frac{p_2}{\rho} = -\frac{1}{2}c_2^2 - gz_2 + q_D. \quad (2.26)$$

**Fig. 2.26** (a) Schematic representation of the Francis turbine, (b) Francis wheel

**Fig. 2.27** (a) Schematic diagram of the Kaplan turbine, (b) Kaplan wheel

**Fig. 2.28** Energy diagram (specific energy  $e$ ) of a reaction turbine plant

### Cavitation Effects

From (2.26), since  $q_D$  is small, a *negative pressure* results at the exit of the impeller. A too high negative pressure results in steam formation at the usual water temperatures and leads to the *cavitation effect*: implosion-like condensation of steam bubbles that causes noise, vibrations and, above all, corrosion of the blade surface over the course of time [2.11]. Efficiency and service life are reduced. The higher the water velocity  $c_2$ , the greater the negative pressure. Wheels with high rotational speeds are particularly at risk. The cavitation hazard is characterized by a cavitation number (or Thoma number), that is essentially proportional to

$$\frac{2(p_{2\text{abs}} - p_D)}{\rho c_2^2},$$

with  $p_{2\text{abs}}$  absolute pressure ( $= p_2 + \text{atmospheric pressure}$ ) and  $p_D$  vapor pressure (temperature-dependent, for details see [2.11]).

The geometry of the turbine is also determined for the reaction turbine by the specific rotational speed  $n_q$  (2.19) (see also (2.30)). To limit the water speed  $c_2$ , the specific speed may not exceed certain values as a function of the head  $H$ .

To limit the negative pressure, according to (2.26), not only can  $c_2$ , but also  $z_2$  be kept small or even made negative, so that the turbine lies lower than the tailwater level. This measure can be expensive if larger excavations in rocky ground are necessary.

### Energy Diagram

In summary, the energy conversion in a plant with reaction turbines can be illustrated by the energy diagram in Fig. 2.28. In contrast to the Pelton system (Fig. 2.20), the energy at the impeller inlet consists mainly of pres-

sure energy, that is directly converted into mechanical energy. The pressure energy at the impeller output is even negative. The diffusion allows recovering of the remaining kinetic energy (corresponding to  $c_2$ ), and if  $z_2$  is positive to also recover the potential energy, i.e., to convert it back into pressure energy.

### Flow Rate and Pressure Coefficient

In addition to the specific speed (2.19), further characteristic numbers are introduced for the reaction turbine, i.e., the *flow coefficient* and the *pressure coefficient*

$$\begin{aligned} \text{flow coefficient} \quad \varphi &= \frac{c_2}{u}, \\ \text{pressure coefficient} \quad \psi &= \frac{2gH}{u^2}. \end{aligned} \quad (2.27)$$

The flow coefficient is defined as the ratio of the water velocity at the outlet cross section 2 and the circumferential velocity  $u$  of the wheel in the same cross section. With reference to the outlet cross section 2, the following applies

$$Q = c_2 \frac{\pi D^2}{4} (1 - \alpha^2) = \varphi u \frac{\pi D^2}{4} (1 - \alpha^2), \quad (2.28)$$

with  $\alpha = D_t/D$ .

The factor  $\alpha$  takes account of the fact that in the Kaplan turbine (Fig. 2.27) the exit cross section is reduced by the propeller body (with diameter  $D_t$ ). With the Francis turbine, this effect can be neglected in a first approximation (Kaplan guide value:  $\alpha \approx 0.4$ , Francis:  $\alpha \approx 0$ ).

For a given turbine, the *flow coefficient* according to (2.28) is proportional to the instantaneous *amount of water*. In order to achieve optimum efficiency at full load (optimum peripheral speed), the flow rate has a certain nominal value  $\varphi_a$ . With increasing specific

**Fig. 2.29** Mussel diagram of a Francis turbine: O: Nominal point, A: opening degree,  $\eta$ : efficiency (adapted from [2.12])

**Fig. 2.30** Relationship between specific speed  $n_q$  and effective head  $H$ . Hatched area: optimum area from experience (adapted from [2.4])

speed, this value is 0.4–0.25 for Francis turbines and 0.2–0.35 for Kaplan turbines.

For a turbine with a given specific rotational speed, there is a so-called *mussel diagram* in the  $(\varphi, \psi)$ -plane (Fig. 2.29), with the curves for constant efficiency and constant guide wheel position (extent of opening).

Since the *pressure coefficient* depends only on the effective head, in stationary operation it has a practically constant value, independent of the output, that corresponds to the maximum efficiency. From the pressure coefficient, the *optimum peripheral speed* follows from (2.27).

**Relationship Between  $n_q$ ,  $\varphi_a$  and  $\psi$**

With (2.27), one can express  $H$  as dependent on  $\psi$ . Using  $H$  and  $Q_a$  (according to (2.28)) in the expression

(2.19) for specific speed, taking into account that

$$D = \frac{60u}{\pi n} \tag{2.29}$$

it follows that

$$n_q = n \frac{Q_a^{0.5}}{H^{0.75}} = \frac{60(2g)^{0.75}}{2\pi^{0.5}} \frac{\varphi_a^{0.5}}{\psi^{0.75}} \sqrt{1-\alpha^2}$$

$$\rightarrow n_q = 157.8 \frac{\varphi_a^{0.5}}{\psi^{0.75}} \sqrt{1-\alpha^2} \tag{2.30}$$

**Turbine Design**

When  $H$  and  $Q_a$  are given, the specific speed is first determined according to the effective head so that it lies within range of the diagram in Fig. 2.30 shown by experience to be economically optimal. Within this range,

**Fig. 2.31** Vertical machine set with Francis turbine, Paulo Alfonso at the Rio Sao Francisco, Brazil (Voith work drawing) (adapted from [2.4])

a compromise must be found between two opposing demands:

- A speed (and thus also a specific speed) as high as possible is indeed advantageous for both the turbine and generator for economic reasons.
- But the higher the speed selected, the greater the damage caused by cavitation may be.

Depending on  $n_q$ , the pressure coefficient follows from Fig. 2.30, from Fig. 2.24 the peripheral speed and from (2.29) the diameter of the impeller. Equation (2.30) gives the flow rate for rated operation.

#### Example 2.4

For the Francis turbine in Fig. 2.31, determine the most important parameters without knowing the mus-sel diagram and check the dimensions. The data values are  $H = 87.5$  m,  $Q = 284$  m<sup>3</sup>/s,  $n = 138.5$  rpm,  $P_t = 221$  MW, 60 Hz.

The hydraulic power and turbine efficiency are derived from the data

$$\begin{aligned}
 P_h &= \rho Q g H = 1000 \times 284 \times 9.81 \times 87.5 \\
 &= 243.8 \text{ MW} , \\
 \eta_t &= \frac{P_t}{P_h} = \frac{221}{243.8} = 0.907 .
 \end{aligned}$$

From (2.19), one obtains

$$n_q = 138.5 \frac{284^{0.5}}{87.5^{0.75}} = 81.47 .$$

This number is not far from the lower limit of the optimal range of Fig. 2.30. If the nominal flow rate is estimated at 0.3, the following relationship follows from (2.27), (2.29) and (2.30)

$$\psi^{0.75} = 157.8 \frac{0.3^{0.5}}{81.47} = 1.0609 \quad \rightarrow \quad \psi = 1.082 ,$$

$$u = \sqrt{\frac{2gH}{\psi}} = 39.8 \frac{\text{m}}{\text{s}} ,$$

$$D = \frac{60 \times 39.8}{\pi \times 138.5} = 5.49 \text{ m} ,$$

that is well in line with the real value (5.57 m). Conversely, since the flow coefficient is proportional to  $D^{-3}$ , the actual diameter results in

$$\begin{aligned}
 \varphi_a &= 0.287 , \quad \psi = 1.0505 \\
 \rightarrow u &= 40.4 \frac{\text{m}}{\text{s}} \\
 \rightarrow c_2 &= 11.6 \frac{\text{m}}{\text{s}} .
 \end{aligned}$$

**Fig. 2.32** Vertical Kaplan turbine Rosshaupten am Lech (Voith work drawing) (adapted from [2.4])

If the losses in the diffuser that have a favorable effect are neglected and assuming  $z_2 = 0$ , a negative pressure of 0.67 bar follows from (2.26). The turbine is positioned lower to reduce the negative pressure. For  $z_2 = -4$  m, follows, e.g., that  $p_2 = -0.28$  bar (for details regarding cavitation and permissible negative pressure see [2.11]).

#### Example 2.5

For the Kaplan turbine in Fig. 2.32, determine the most important parameters without knowing the mussel diagram and check the dimensions. The data is:  $H = 38$  m,  $Q = 75$  m<sup>3</sup>/s,  $n = 200$  rpm,  $P_t = 24.8$  MW, 50 Hz.

The hydraulic power and turbine efficiency are derived from the data.

$$\begin{aligned} P_h &= \rho Q g H = 1000 \times 75 \times 9.81 \times 38 \\ &= 27.96 \text{ MW} , \\ \eta_t &= \frac{P_t}{P_h} = \frac{24.8}{27.96} = 0.887 . \end{aligned}$$

Using (2.19) gives

$$n_q = 200 \frac{75^{0.5}}{38^{0.75}} = 113.17 .$$

This number is at the bottom of the hatched area of Fig. 2.30. If the nominal flow coefficient  $\varphi_a$  is estimated as 0.25 and  $\alpha$  as 0.4, (2.27), (2.29) and (2.30) give

$$\begin{aligned} \psi^{0.75} &= 157.8 \frac{0.25^{0.5}}{113.17} \sqrt{1 - 0.4^2} = 0.639 , \\ \rightarrow \psi &= 0.550 , \end{aligned}$$

$$u = \sqrt{\frac{2gH}{\psi}} = 36.8 \frac{\text{m}}{\text{s}} ,$$

$$D = \frac{60 \times 36.8}{\pi \times 200} = 3.51 \text{ m} .$$

The outlet velocity is  $c_2 = \varphi_a u = 9.2$  m/s. From this, the negative pressure can be estimated: for  $z_2 = 0$  and neglecting the diffuser losses, (2.26) gives,  $p_2 = -1.000(0.5 \times 9.2^2) = -0.42$  bar.

#### Types of Reaction Turbines and Rotary Pumps

A reaction turbine, by reversing the direction of rotation, becomes a *rotary pump*. As Table 2.2 shows, the characteristic speed and thus the geometry of reaction turbines and rotary pumps can vary greatly (for the turbines see also Fig. 2.28). A distinction is made be-

**Table 2.2** Specific speed of reaction turbines and rotary pumps

Turbine/pump	$n_q$
Francis slow	20–40
Francis medium	40–65
Francis fast	65–110
Kaplan (propeller)	90–300
Radial pump slow	10–30
Radial pump medium	30–60
Radial pump fast	60–150
Axial pump	110–500

tween *slow runners* (small  $n_q$  suitable for  $H$  large and  $Q$  small, with strongly curved blades), *medium-speed* and *fast runners* (large  $n_q$  suitable for  $H$  small and  $Q$  large, with slightly curved blades). It should be noted that the designations *slow* and *fast* refer to  $n_q$  and not to the effective speed.

The flow direction is radial-axial for Francis turbines and radial pumps and purely axial for Kaplan turbines and axial pumps. Pumps are often *multifluent* (splitting the water quantity into several wheels) and *multistage* (splitting of the pressure onto several wheels) (analogous to parallel and series electrical circuits). The *pump turbine* mentioned in Sect. 2.4.3 is a compromise machine, that has a lower efficiency, but results in lower plant costs.

### 2.5.3 Turbine Selection

The criteria that determine the choice of a turbine are briefly summarized and illustrated here by a few examples. As a rule,  $H$  and  $Q$  are given. The turbine type (specific speed), the speed (generator type) and the dimensions are to be determined. In principle, the speed of the turbine generator group should be chosen as high as possible, as this reduces dimensions and costs.

#### Pelton Turbine

The specific speed varies within narrow limits and can only be increased by the number of nozzles. This practically determines the speed and number of pole pairs of the generator, unless gearing is used. The head determines the jet velocity and thus the optimum circumferential speed. This essentially determines the diameter of the turbine and the blade size.

#### Reaction Turbine

The specific speed should be as high as possible. It has an upper limit because of cavitation (Fig. 2.28). For a specific head, it is therefore determined with narrow limits. From this the speed and number of pole pairs of the generator corresponding to the mains frequency can be found. If the mussel diagram is known, the optimum

value of  $\psi$ , and thus the circumferential speed  $u$  result. This also gives the diameter of the impeller.

#### Number of Groups

The *capacity of the hydropower plant* is determined by hydrological and topographical conditions and by economic considerations. For an optimal *choice of the number of groups* of the power plant, i.e., optimum distribution of the output, the following arguments are decisive:

- If the output is divided into several groups, the dimensions of the plant and thus the investments normally increase. It should be noted that the machines themselves do not necessarily become more expensive because they become faster when the amount of water is reduced.
- However, this disadvantage of higher investments is offset by the advantage that at partial load a better efficiency is achieved by switching off some groups and better utilizing the remaining ones. This is particularly the case for turbines with fixed blades, that exhibit poor efficiency at partial load (Francis and propeller turbines, Fig. 2.33). The loss calculation can be carried out by simulating the intended mode of operation of the power plant.
- The security of the grid feed-in increases with a larger number of groups. However, this argument is only significant in the case of larger outputs compared with the network output.

#### Example 2.6

Determine the turbine and generator types for 50 Hz, assuming a machine efficiency of  $\eta_t \eta_e 0.85$  for the following groups:

- $H = 100$  m,  $P = 30$  MW
- $H = 1000$  m,  $Q_a = 5$  m<sup>3</sup>/s.

According to Fig. 2.28, a Francis turbine with a characteristic rotation speed  $n_q$  of about 70 is chosen. Then,

$$\begin{aligned}
 Q_a &= \frac{P}{\eta_t \eta_e \rho g H} = \frac{30 \times 10^6}{0.85 \times 1000 \times 9.81 \times 100} \\
 &= 36.0 \frac{\text{m}^3}{\text{s}} \\
 n &= n_q \frac{H^{0.75}}{Q^{0.5}} = 70 \frac{100^{0.75}}{36^{0.5}} = 369 \text{ min}^{-1},
 \end{aligned}$$

choose  $p = 8$ ,

$$\begin{aligned}
 \rightarrow n &= 375 \text{ min}^{-1}, \\
 \rightarrow n_q &= 71.15.
 \end{aligned}$$

In order to roughly estimate the dimensions, assume, since no mussel diagram is available,  $\varphi_a = 0.32$ , from this and with (2.30),  $\psi = 1.35$ , with (2.27),  $u = 38.1$  m/s and finally with (2.29), the diameter  $D = 1.94$  m follows. A change in  $\varphi_a$  has a reciprocal effect with the cube root, i.e., relatively little; thus the choice would be  $\varphi_a = 0.25$  and diameter  $D = 2.11$  m.

Only the Pelton turbine is suitable for the 1000 m head. With the number of nozzles  $i = 4$ , and  $n_q = 5.5 \times \sqrt{4} = 11$ , it follows that

$$P = \eta_t \eta_c \rho Q_a g H = 0.85 \times 1000 \times 59.81 \times 1000 = 41.7 \text{ MW}$$

$$n = n_q \frac{H^{0.75}}{Q^{0.5}} = 11 \frac{1000^{0.75}}{50.5} = 875 \text{ min}^{-1},$$

possible solutions are

$$\begin{aligned} p = 4 &\longrightarrow n = 750 \text{ min}^{-1} &\longrightarrow n_q = 9.43, \\ p = 3 &\longrightarrow n = 1000 \text{ min}^{-1} &\longrightarrow n_q = 12.57. \end{aligned}$$

Further solutions are possible by changing the number of nozzles.

The jet velocity is  $c_1 = 137$  m/s (with  $\eta_D = 0.96$ ).

The solution with  $n = 1000$  rpm results in  $u \approx 68$  m/s and  $D \approx 1.3$  m.

### Exercise 2.1

A run-of-river power plant is equipped with bulb turbines with the following parameters:  $H = 13.57$  m,  $Q = 334.8$  m<sup>3</sup>/s,  $P_t = 41.22$  MW [2.8]. Determine the most important parameters and main dimensions of the turbine.

## 2.6 Dynamics

For the investigation of dynamic processes during normal or disrupted network operation, but also for planning studies concerning network stability or network reconstruction, models are necessary that correctly reflect the dynamics of the hydropower plant including the hydraulic part. For example, the speed behavior can be influenced by the characteristics of the hydraulic system. Dynamic calculations of the hydraulic system are also a prerequisite for the optimum design of the

Fig. 2.33 Typical turbine efficiency curve, a: Pelton, b: Francis, c: Kaplan, d: Propeller

### 2.5.4 Small Hydropower Plants

Full exploitation of the hydropower potential requires the construction of small-scale plants, where there are opportunities, often in conjunction with supplying drinking water (in Switzerland, usually < 300 kW). There are also programs to support this [2.13]. The calculations are mostly on the same basis as for a large plant. For the solution of the exercises see [2.9, annex F].

#### Exercise 2.2

1. A stream continuously supplies a usable water quantity of at least 200 L/s. Without any particular construction problems, an effective head of 10 m can be installed. Which turbine variants are possible and what are their characteristics and dimensions?
2. Which turbine is suitable if the usable water quantity is only 40 L/s, but the usable head can be increased to 50 m?

surge chamber and the pressure line (pressure surge processes, Sects. 2.6.3 and 2.6.5).

In the general case, the system consists, according to Fig. 2.34, of a storage tank, pressure tunnel, surge tank, pressure line and hydro group. The reservoir is usually very large, and the height of the headwater  $H_{OW}$  can be regarded as constant for dynamic processes. For processes that are not too slow, this also applies to the height  $H_{UW}$  of the tailwater. The gross head is  $H_b = H_{OW} - H_{UW}$ .

**Fig. 2.34** Hydropower plant: G: generator, T: turbine,  $Q$ : water flow,  $A$ : cross section,  $L$ : length; indexes: s: pressure tunnel, w: surge tank, c: penstock, D: pressure regulator

**Fig. 2.35** Pressure-tunnel model

### 2.6.1 Pressure Tunnel

The energy balance (specific energy) is

$$L_s \frac{dv_s}{dt} = gH_b - gH_a - gH_s \quad \left( \frac{J}{kg} \right), \quad (2.31)$$

with  $v_s$  = mean water speed,  $H_a$  = effective head at the end of the tunnel,  $H_s$  = loss of height in the tunnel.

The left-hand side shows the acceleration energy of the water masses ( $\int F dx = \int m (dv/dt) dx = m (dv/dt) L$ ). The following is a good approximation of the losses in the tunnel

$$gH_s = K_s Q_s |Q_s|, \quad \text{with } Q_s = v_s A_s. \quad (2.32)$$

Replacing  $v_s$  by  $Q_s$  in (2.31) gives

$$\frac{L_s}{A_s} \frac{dQ_s}{dt} = gH_b - gH_a - gH_s. \quad (2.33)$$

By introducing the *nominal head*  $H_r$  and the *nominal water quantity*  $Q_r$  and dividing (2.33) by  $gH_r$ , one ob-

tains

$$\begin{aligned} h_b &= \frac{H_b}{H_r}, \quad h_a = \frac{H_a}{H_r}, \quad h_s = \frac{H_s}{H_r}, \\ q_s &= \frac{Q_s}{Q_r}, \quad c_s = K_s \frac{Q_r^2}{gH_r}, \end{aligned} \quad (2.34)$$

the *per unit (pu) equations of the tunnel*

$$\begin{aligned} T_s \frac{dq_s}{dt} &= h_b - h_a - h_s \quad \text{with } T_s = \frac{L_s Q_r}{A_s g H_r} \\ h_s &= c_s q_s |q_s|, \end{aligned} \quad (2.35)$$

and the corresponding block diagram Fig. 2.35.

By linearizing the loss equation, the linear model follows as

$$\begin{aligned} T_s \frac{d\Delta q_s}{dt} &= \Delta h_b - \Delta h_a - \Delta h_s, \\ \Delta h_s &= 2c_s |q_0| \Delta q_s = c_{s0} \Delta q_s \end{aligned} \quad (2.36)$$

with the block diagram and transfer function of Fig. 2.36.

### 2.6.2 Surge Chamber

The exact representation of the surge chamber is quite complex [2.14], but with small oscillations of the water level the energy can be expressed with acceptable accuracy by: Energy  $gH_a$  at the end of the tunnel (or at the base of the surge chamber) is the sum of the potential energy corresponding to the water level  $H_w$  in the surge tank (Fig. 2.34) and the kinetic energy of the water at its base, the latter being assumed, as a good approximation, to be proportional to the square of the water flow in the tunnel [2.12, 14]. Kinetic energy and losses in the surge tank are neglected. Thus

$$gH_a = gH_w + K_w Q_s^2. \quad (2.37)$$

Furthermore

$$\begin{aligned} Q_w &= A_w \frac{dH_w}{dt}, \\ Q_s &= Q_c + Q_w. \end{aligned} \quad (2.38)$$

**Fig. 2.36** Linear tunnel model

Fig. 2.37 Model of the surge chamber

Fig. 2.38 Linearized model of the surge chamber

The introduction of the pu values, and the reference values  $Q_r$  and  $H_r$  analogous to (2.34), yields the pu equations

$$\begin{aligned} h_a &= h_w + K_w q_s^2, & \text{with } K_w &= K_w \frac{Q_r}{H_r}; \\ q_w &= T_w \frac{dh_w}{dt}, & \text{with } T_w &= A_w \frac{H_r}{Q_r}; \\ q_s &= q_c + q_w \end{aligned} \tag{2.39}$$

and the corresponding block diagram (Fig. 2.37). The coefficient  $k_w$  can be determined on the basis of theoretical considerations [2.14] or preferably by experimental identification.

Fig. 2.39 (a) Model of the rigid penstock, (b) transfer function

Linearizing the kinetic energy gives

$$\begin{aligned} \Delta h_a &= \Delta h_w + K_{w0} \Delta q_s, & \text{with } K_{w0} &= 2K_w q_0; \\ \Delta q_w &= T_w \frac{d\Delta h_w}{dt}; \\ \Delta q_s &= \Delta q_c + \Delta q_w, \end{aligned} \tag{2.40}$$

and the linear model in Fig. 2.38, where stationary  $q_{s0} = q_{c0} = q_0$ .

### 2.6.3 Rigid Penstock

With the assumption that water is incompressible and the penstock is *rigid*, the penstock model is identical to that of the pressure gallery (the elastic pressure shock is dealt with in Sect. 2.6.5). If the effective head is denoted by  $H$ , then, instead of (2.35), we have

$$\begin{aligned} T_c \frac{dq_c}{dt} &= h_a - h - h_c & \text{with } T_c &= \frac{L_c Q_r}{A_c g H_r}, \\ h_c &= c_c q_c |q_c|, \end{aligned} \tag{2.41}$$

or by linearizing the losses

$$\begin{aligned} T_c \frac{d\Delta q_c}{dt} &= \Delta h_a - \Delta h - \Delta h_c, \\ \Delta h_c &= 2c_c |q_0| \Delta q_c = c_{c0} \Delta q_c. \end{aligned} \tag{2.42}$$

The block diagram of the rigid pressure pipe (penstock) is shown in Fig. 2.39a, and the transfer function obtained by linearization is shown in Fig. 2.39b. The input variable is the water flow  $q_c$  dictated by the turbine.

### 2.6.4 Overall Model of the Hydraulic System

#### Nonlinear Block Diagram

By bringing together Figs. 2.35, 2.37 and 2.39, the nonlinear block diagram of the hydraulic system results (Fig. 2.40).

#### Transfer Function

From (2.36), (2.40) and (2.42), the linearized relation between the effective energy  $\Delta h$  and the amount of

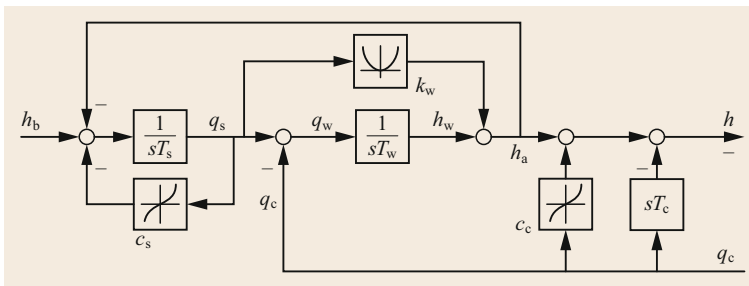

Fig. 2.40 Nonlinear model of the hydraulic system

**Fig. 2.41** Transfer function of the hydraulic system

water  $\Delta q_c$  or the change in the gross head  $\Delta h_b$  can be determined with

$$\begin{aligned}
 G(s) &= G_w(s) + G_c(s) \\
 &= \frac{c_{s0} + sT_s}{1 + s(k_{w0} + c_{s0})T_w + s^2T_wT_s} \\
 &\quad + (c_{c0} + sT_c) \\
 G_b(s) &= \frac{1 + sk_{w0}T_w}{1 + s(k_{w0} + c_{s0})T_w + s^2T_wT_s} \quad (2.43)
 \end{aligned}$$

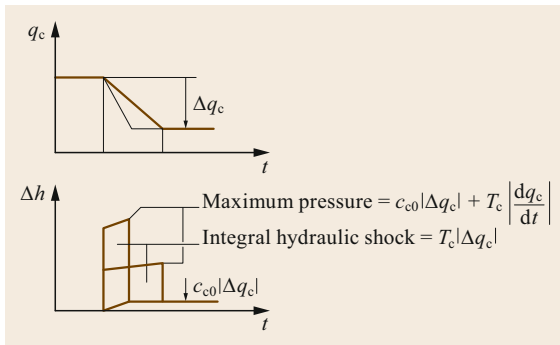

and is represented in Fig. 2.41.

The change of the gross head is usually zero or very slow, so the function  $G(s)$  is of little significance for dynamic processes.

The transfer function  $G_w(s)$  describes the *effect of pressure tunnel and surge tank*. A change of the water flow results in damped oscillations with the properties

$$\begin{aligned}
 \text{resonance frequency } \omega_0 &= \frac{1}{\sqrt{T_wT_s}}, \\
 \text{characteristic frequency } \omega_c &= \omega_0 \sqrt{1 - \zeta^2}, \\
 \text{damping factor } \zeta &= \frac{1}{2} (k_{w0} + c_{s0}) \sqrt{\frac{T_w}{T_s}}. \quad (2.44)
 \end{aligned}$$

For well-damped behavior, the time constant  $T_w$  and thus the cross section of the surge tank (2.39) must be sufficiently large. The period of oscillation is usually in the range of 100–300 s, while  $T_c$  is on the order of 1 s. For slow processes, the effect of the penstock can be neglected and  $G(s) = G_w(s)$  can be used.

**Fig. 2.42** Pressure surge

Conversely, for processes in the seconds range (primary speed control), the height  $h_a$  can be assumed to be constant and  $G(s) = G_c(s)$  can be used. By correctly dimensioning the surge tank, a decoupling between slow and fast processes is achieved.

The transfer function  $G_c(s)$  describes the *effect of the penstock* on the useful energy  $h$ . It is of a differential nature and is illustrated in Fig. 2.42. For large heads,  $h$  is practically the pressure at the lower end of the penstock. A linear decrease in the amount of water required by the turbines results in a pressure surge. If the water flow is restricted quickly, the pressure can assume very high values. An excessively rapid decrease in the water flow in the pressure line must therefore be avoided. To be able to reduce the turbine power quickly despite this (e.g., in the case of sudden load reduction), the Pelton turbine uses *jet deflectors* (Fig. 2.23), while the closing speed of the nozzle needle is limited. In reaction turbines, conversely, the guide wheel is quickly regulated according to the load and the pressure in the penstock is controlled by a *pressure valve* that diverts water upstream of the turbine inlet beyond an adjustable pressure limit (Fig. 2.34).

The preceding description of the penstock disregards the *compressibility of the water and the elasticity of the penstock wall* (together referred to concisely as elasticity). This causes the pressure conditions to be reproduced inaccurately. In Sect. 2.6.5, the elasticity is taken into account.

### 2.6.5 Elastic Pressure Surge

For systems with a large head, elasticity must also be taken into account because it makes it more difficult to stabilize the speed control. This generally applies to heads of approximately 100 m or more.

In any short section of the initially assumed *lossless penstock*, at a distance  $xL_c$  from the beginning of the line, the acceleration energy or acceleration force is

$$\begin{aligned}
 -gdH &= L_c dx \frac{dv}{dt} = \frac{L_c dx}{A_c} \frac{dQ_c}{dt} \left( \frac{\text{J}}{\text{kg}} \right), \\
 -\rho A_c g dH &= \rho L_c dx \frac{dQ_c}{dt} \quad (\text{N}). \quad (2.45)
 \end{aligned}$$

This force causes, in a time  $dt$ , as a result of the elasticity of water and the pipe, a change in the quantity of water per element  $L_c dx$

$$-\frac{dQ_c}{L_c dx} dt = \left( \frac{1}{\varepsilon} + \frac{D}{Ed} \right) \rho A_c g dH \quad (\text{m}^3), \quad (2.46)$$

where  $\varepsilon$  is the elastic constant of the water,  $E$  the modulus of elasticity of the conductor material, where  $D$

**Table 2.3** Analogy between electric cable and pressure line ( $Z_\tau$  = nominal impedance of the electric cable,  $Z_{w0}$  = wave impedance for  $\omega \rightarrow \infty$ ), see also [2.17, Chap. 5]

$U$	$h$
$I$	$q$
$Z_{w0}/Z_\tau$	$2\rho_A$
$\tau$	$\tau$
$CZ_\tau$	$\tau/(2\rho_A)$
$L/Z_\tau$	$T_c$
$R/Z_\tau$	$C_c q_c $ oder $c_{c0}^a$

<sup>a</sup> with linearization of losses

and  $d$  are the diameter and thickness of the pipe. From (2.45) and (2.46) it follows that

$$-\frac{\partial H}{\partial x} = \frac{L_c}{gA_c} \frac{\partial Q_c}{\partial t}$$

$$-\frac{\partial Q_c}{\partial x} = \left( \frac{1}{\varepsilon} + \frac{D}{Ed} \right) \rho_A c L_c g \frac{\partial H}{\partial t} \tag{2.47}$$

These equations are wave equations. Pressure waves (sound waves) propagate in the water with a speed  $a$  defined by

$$\frac{1}{a^2} = \rho \left( \frac{1}{\varepsilon} + \frac{D}{Ed} \right) \tag{2.48}$$

The order of magnitude of  $a$  is 1000 m/s. With the pu values, and the time constant  $T_c$  from (2.41) and the *penstock friction losses*, the following differential equations are finally obtained, where  $\rho_A$  is the *cable characteristic of Allievi*, and  $\tau = L_c/a$  is the *propagation time* of the pressure waves in the penstock [2.15, 16],

$$-\frac{\partial h}{\partial x} = T_c \frac{\partial q_c}{\partial t} + c_c |q_c| q_c,$$

$$-\frac{\partial q_c}{\partial x} = \frac{T_c}{(2\rho_A)^2} \frac{\partial h}{\partial x}, \quad \text{with } 2\rho_A = \frac{T_c}{\tau} \tag{2.49}$$

Equations (2.49) are analogous to Eq. 5.1 of the electric cable in [2.17], if the latter are brought into pu form. The analogous sizes are listed in Table 2.3.

**Penstock Models with Elasticity**  
**Pressure-Wave Model.** A model of the pressure-wave processes results, using the above-mentioned analogy, directly from Equations 5.86 [2.17, Chap. 5] of the distortion-free electric line, which, when rewritten analogously, are (with linearized losses)

$$h_a = h_{ae} + h_{ar},$$

$$h = h_{ae} e^{-(K+s\tau)} + h_{ar} e^{K+s\tau} = h_e + h_r,$$

$$q_c = \frac{h_{ae}}{2\rho_A} e^{-(K+s\tau)} - \frac{h_{ar}}{2\rho_A} e^{K+s\tau},$$

$$q_{ca} = \frac{h_{ae}}{2\rho_A} - \frac{h_{ar}}{2\rho_A} \tag{2.50}$$

The corresponding model is shown in Fig. 2.43;  $h_a$  and  $q_{ca}$  are energy and water flow at the intake, and  $h$  and  $q_c$  are those at the outlet of the penstock. The pressure wave attenuation is taken into account with a block  $e^{-K}$  that corresponds to the block  $e^{-\alpha l}$  of the electrical cable. For  $K$  values, using Table 2.3

$$\alpha l = \frac{R}{2Z_{w0}} \quad \longrightarrow \quad K = \frac{c_{c0}}{4\rho_A} \tag{2.51}$$

In order to include the stationary losses not correctly allowed for by (2.50), an appropriate correction and a non-linear block are introduced. The diagram is simplified if the formation of  $q_{ca}$  is not done and  $q_{ca} = q_c$  is used, i.e., the feedback effect of the fundamental and harmonic components on the sluggish plant on the mountain side is neglected.

For further analytical considerations, it is useful to write the first of the two-port Equations 5.12 [2.17] by the following analogy

$$h_a = h \cosh s\tau + q_c 2\rho_A \sinh s\tau + h_c, \tag{2.52}$$

or even

$$h = \frac{h_a - h_c}{\cosh s\tau} - q_c 2\rho_A \tanh s\tau, \tag{2.53}$$

where the equations for the lossless case are written and the losses are dealt with separately.

**Fig. 2.43** Model of the elastic penstock

**Fig. 2.44** Rational approximation to the elastic penstock corresponding to the electrically short line

**Rational Approximations.** Similar to the explanations in [2.17, Sect. 5.6.2] it can be advantageous to replace the transcendental relationships with rational approximations. With the approximation  $\cosh s\tau = 1 + s\tau^2/2$ ,  $\sinh s\tau = s\tau$ , it follows from (2.52) that

$$h_a = h \left( 1 + s \frac{\tau^2}{2} \right) + q_c s T_c + h_c, \quad (2.54)$$

that represents the analogue of the lossless electrically short line. According to this analogy (Table 2.3), by introducing attenuation, the characteristic polynomial  $(1 + s\tau^2/2)$  can be replaced by the characteristic polynomial

$$K(s) = 1 + s\tau \frac{c_{c0}}{4\rho_A} + s^2 \frac{\tau^2}{2}. \quad (2.55)$$

By transformation from (2.54), we have

$$h_a = h + sT_c \left( q_c + h \frac{s\tau}{4\rho_A} \right) + h \frac{s\tau}{4\rho_A} c_{c0} + h_c \quad (2.56)$$

and taking into account that  $2\rho_A = T_c/\tau$ , we have the corresponding block diagram in Fig. 2.44. In this representation,  $q_{ca} = q_c$  is used.

The fundamental oscillation is determined more exactly by the modal reduction analogous to [2.17, Eq. 5.95] with the characteristic polynomial

$$K(s) = 1 + s\tau \frac{2c_{c0}}{\pi^2 \rho_A} + s^2 \tau^2 \frac{4}{\pi^2}, \quad (2.57)$$

that can be used instead of (2.55). In Fig. 2.44, the propagation time  $\tau$  is then replaced by  $\tau^* = \tau \times 2\sqrt{2}/\pi$ .

A more convenient representation, essentially equivalent to Fig. 2.44, is obtained, if the second of [2.17, Eqs. 5.12] is also used with the somewhat coarser approximation  $\cosh s\tau = 1$ ,  $\sinh s\tau = s\tau$ . The analogy gives

$$q_{ca} = \frac{h}{2\rho_A} s\tau + q_c. \quad (2.58)$$

**Fig. 2.45** Efficient approximation of the elastic pressure line

**Fig. 2.46a,b** Response of  $h$  to a sudden change in  $q_c$ . (a) Model Fig. 2.43; (b) model Fig. 2.45,  $\Delta q_c = 0.2$  pu,  $h_0 = 1$  pu,  $T_c = 1.3$  s,  $\tau = 0.45$  s

By taking this relationship into account, it follows from (2.56) that

$$\begin{aligned} h_a &= h + sT_c q_{cm} + h_c, \\ \text{with } q_{cm} &= \frac{1}{2} (q_{ca} + q_c) = q_c + \frac{hs\tau^2}{2T_c}, \\ h_c &= c_c |q_{cm}| q_{cm}. \end{aligned} \quad (2.59)$$

Equations (2.58) and (2.59) give the model in Fig. 2.45 as a result. The formation of  $q_{ca}$ , that differs from  $q_c$  by only a fundamental oscillation component, and can be dispensed with, as this component has hardly any effect on the sluggish surge-tank-tunnel system. A similar representation can be found in [2.18].

Also in this model, the frequency of the fundamental oscillation is represented more accurately if  $\tau$  is replaced by  $\tau^* = \tau \times 2\sqrt{2}/\pi$ .

Figure 2.46 shows the change in the effective head  $h$  if there is a sudden change in the water flow for the models in Figs. 2.43 and 2.45.

### Transfer Function of the Elastic Penstock

Through linearization of (2.58) and (2.59) and with  $\tau^*$  instead of  $\tau$ , it follows that

$$\begin{aligned}\Delta q_{ca} &= \frac{s\tau^{*2}}{T_c} \Delta h + \Delta q_c, \\ \Delta h_a &= \Delta h + sT_c \Delta q_{cm} + c_{c0} \Delta q_{cm}, \\ \Delta q_{cm} &= \frac{1}{2} (\Delta q_{ca} + \Delta q_c).\end{aligned}\quad (2.60)$$

If  $\Delta q_{cm}$  and  $\Delta q_{ca}$  are eliminated and taking into account the elasticity, the transfer function of the penstock becomes

$$\begin{aligned}\Delta h &= \frac{\Delta h_a - (c_{c0} + sT_c) \Delta q_c}{1 + \frac{c_{c0}\tau^{*2}}{2T_c}s + \frac{\tau^{*2}}{2}s^2} \\ &= \frac{\Delta h_a - (c_{c0} + sT_c) \Delta q_c}{K(s)}.\end{aligned}\quad (2.61)$$

### 2.6.6 Overall Model of the Hydraulic System with Elasticity

#### Transfer Function

The block diagram in Fig. 2.41 is still valid, where for  $G_c(s)$  the following expression is used

$$G_c(s) = \frac{c_{c0} + sT_c}{K(s)}.\quad (2.62)$$

The effect of  $K(s)$  on  $h_a$  (and thus on  $G_w(s)$  and  $G_b(s)$ ) can be neglected because of the inertia of the surge tank.

#### Nonlinear Block Diagram

If in Fig. 2.40 the rigid penstock is replaced by the model of the elastic penstock given in Fig. 2.45, the block diagram Fig. 2.47 is as follows.

### 2.6.7 Turbine and Hydroelectric Plant Model

The behavior of the turbine is statically determined if the mussel diagram in the  $(\varphi, \psi)$ -plane and the two sets

of

$$\begin{aligned}\psi &= f(\varphi, A), \\ \psi &= g(\varphi, \eta_t)\end{aligned}\quad (2.63)$$

are known (2.32). The curves are largely independent of the rotation speed. Let  $A$  be the degree of opening of the control element of the turbine. For analytical treatment, it is advantageous to solve these two equations for  $\varphi$  and  $\eta_t$ . From (2.27) and (2.28), it follows that

$$\begin{aligned}Q &= K_0 \omega \varphi(\psi, A), \\ \eta_t &= \eta(\psi, A), \\ \psi &= \frac{4}{D^2} \frac{2gH}{\omega^2},\end{aligned}\quad (2.64)$$

where  $K_0$  can be determined from (2.28) or experimentally from the mussel diagram for the nominal speed  $\omega_t$  in the  $(Q, H)$ -plane.

For the Pelton turbine ((2.14) and (2.15)), the first line of (2.64) simplifies to

$$Q = K\omega \frac{D}{2} A \sqrt{\psi} = KA \sqrt{2gH}.\quad (2.65)$$

#### Power Equations

The turbine power according to (2.7) is

$$P_h = \rho Q g H, \quad P_t = \eta_t P_h,\quad (2.66)$$

and for the drive torque  $M_t$

$$P_t = M_t \omega.\quad (2.67)$$

The rotation rate is determined by the mechanical equation, which in the simplest case assumes the form

$$M_t - M = J \frac{d\omega}{dt}.\quad (2.68)$$

Here,  $M$  is the load torque and  $J$  is the moment of inertia of the generator group. With the assumption that the

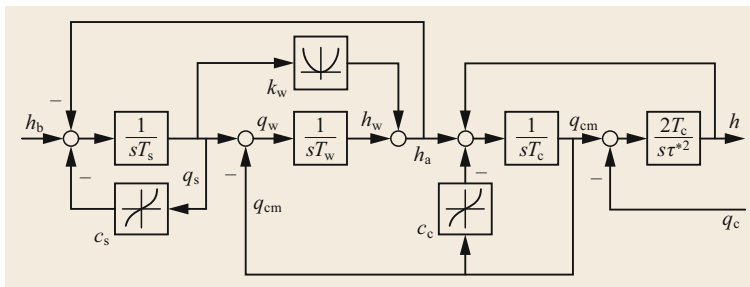

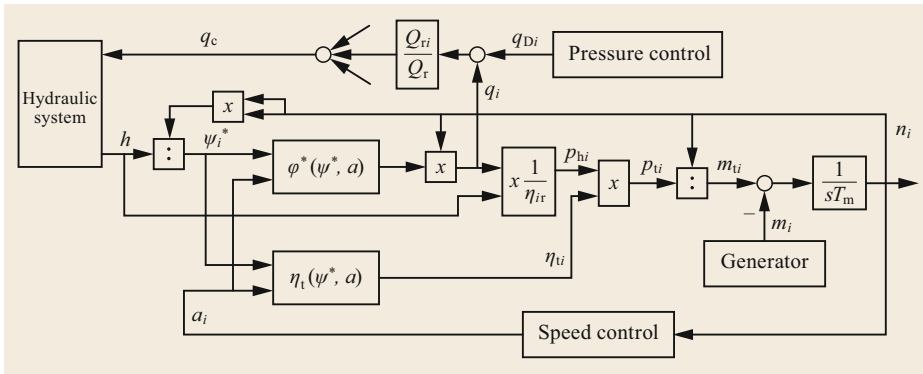

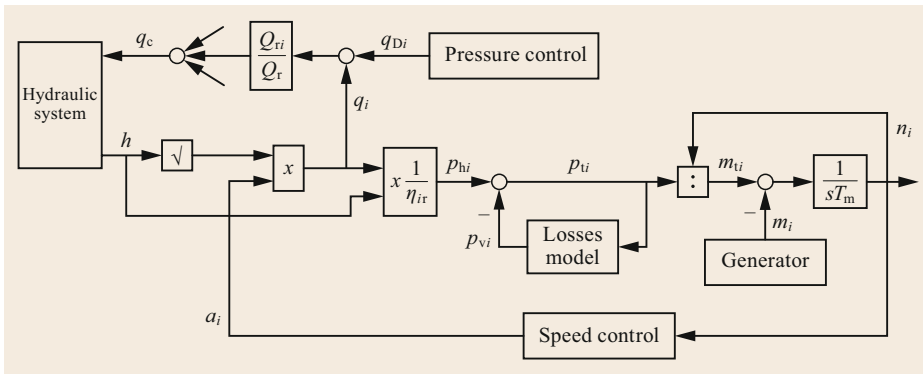

Fig. 2.47 Nonlinear overall model of the hydraulic part

**Fig. 2.48**  
Nonlinear block diagram of the hydropower plant

**Fig. 2.49**  
Simplified block diagram of the hydropower plant

penstock feeds  $m$  turbines and introducing the following reference or nominal values

the following pu system of equations is obtained from (2.64) and (2.66)–(2.68)

$$\begin{aligned}
 \text{Penstock:} \quad & H_r, Q_r = \sum_{i=1}^m Q_{ir}; & q_i &= n_i \varphi_i^*(\psi_i^*) \text{ with } \psi_i^* = \frac{h}{n_i^2}, \\
 \text{Turbine:} \quad & Q_{ir}, \text{ rated speed } \omega_{ir}, & \eta_{vi} &= \eta_i(\psi_i^*, a_i), \\
 & \text{rated efficiency } \eta_{ir}, & p_{hi} &= \frac{1}{\eta_{ir}} q_i h, \\
 & P_{ir} = \eta_{ir} \rho Q_{ir} g H_r = M_{ir} \omega_{ir}^3, & p_{ui} &= \eta_{vi} p_{hi} = m_{vi} n_i, \\
 \text{Pelton turbine:} \quad & Q_{ir} = K_i A_{ir} \sqrt{2gH_r}, & m_{vi} - m_i &= T_{mi} \frac{dn_i}{dt} \text{ with } T_{mi} = J_i \frac{\omega_{ir}}{M_{ir}}, \\
 \text{Reaction turbine:} \quad & Q_{ir} = K_{0i} \omega_{ir} \varphi(\psi_{ir}, a_{ir}), & & \\
 & \text{with } \psi_{ir} = \frac{8gH_r}{D_{ir}^2 \omega_{ir}^2} & & 
 \end{aligned} \tag{2.69}$$

and the corresponding block diagram in Fig. 2.48. For the Pelton turbine, the first equation simplifies to

and as well as the following pu values

$$q_i = a_i \sqrt{h}. \tag{2.72}$$

$$\begin{aligned}
 h &= \frac{H}{H_r}, \quad q_i = \frac{Q_i}{Q_r}, \quad a_i = \frac{A_i}{A_{ir}}, \\
 \phi_i^* &= \frac{\phi_i}{\phi_{ir}}, \quad \psi_i^* = \frac{\psi_i}{\psi_{ir}}, \quad p_{hi} = \frac{P_{hi}}{P_{ir}}, \\
 p_{ui} &= \frac{P_{ui}}{P_{ir}}, \quad n_i = \frac{\omega_i}{\omega_{ir}}, \quad m_{vi} = \frac{M_{vi}}{M_{ir}}, & & 
 \end{aligned} \tag{2.70}$$

A simpler representation results from the assumption that the efficiency depends only on  $a$  or if the losses are modeled instead of the efficiency, where these are usually expressed as a function of the output power. A loss model can be obtained from the efficiency curve for a nominal head and nominal speed. For the Pelton turbine, Fig. 2.49 (without pressure regulator) is appli-

cable. This model is also often used for the reaction turbine, but it should be noted that (2.72) is a rather rough approximation for this turbine [2.12].

### Linearization of Turbine Equations

If we omit the index  $i$  for the sake of clarity, the linearization of (2.71) at the operating point (index 0) yields

$$\begin{aligned}\frac{\Delta q}{q_0} &= K_1 \frac{\Delta h}{h_0} + (1 - 2K_1) \frac{\Delta n}{n_0} + K_2 \frac{\Delta a}{a_0} \\ &\text{with } K_1 = \frac{\partial \varphi}{\partial \psi} \frac{\psi_0}{\varphi_0}, \quad K_2 = \frac{\partial \varphi}{\partial a} \frac{a_0}{\varphi_0}, \\ \frac{\Delta \eta_t}{\eta_0} &= K_3 \frac{\Delta h}{h_0} - 2K_3 \frac{\Delta n}{n_0} + K_4 \frac{\Delta a}{a_0} \\ &\text{with } K_3 = \frac{\partial \eta}{\partial \psi} \frac{\psi_0}{\eta_0}, \quad K_4 = \frac{\partial \eta}{\partial a} \frac{a_0}{\eta_0}, \\ \frac{\Delta p_h}{P_{h0}} &= (1 + K_1) \frac{\Delta h}{h_0} + (1 - 2K_1) \frac{\Delta n}{n_0} + K_2 \frac{\Delta a}{a_0}, \\ \frac{\Delta p_t}{P_{t0}} &= (1 + K_1 + K_3) \frac{\Delta h}{h_0} \\ &\quad + (1 - 2K_1 - 2K_3) \frac{\Delta n}{n_0} \\ &\quad + (K_2 + K_4) \frac{\Delta a}{a_0}, \\ \frac{\Delta m_t}{m_0} &= \frac{\Delta p_t}{P_{t0}} - \frac{\Delta n}{n_0}, \\ \Delta m_t - \Delta m &= T_m \frac{d\Delta n}{dt}.\end{aligned}\quad (2.73)$$

The coefficients  $K_1 - K_4$  can be taken from the musel diagram. In the case of the Pelton turbine, (2.72) is applicable and therefore  $K_1 = 1/2$ ,  $K_2 = 1$ . If the efficiency is only expressed as a function of  $a$ , then  $K_3 = 0$ . If the efficiency is assumed to be constant,  $K_4 = 0$  also.

If, on the other hand, a loss model is used, as shown in Fig. 2.49 with

$$\begin{aligned}p_t &= p_h - p_v(p_t) \\ \rightarrow \Delta p_t &= \Delta p_h - \frac{dp_v}{dp_t} \Delta p_t,\end{aligned}\quad (2.74)$$

the equation for turbine power should be replaced by

$$\begin{aligned}\frac{\Delta p_t}{P_{t0}} &= K_5 (1 + K_1) \frac{\Delta h}{h_0} + K_5 (1 - 2K_1) \frac{\Delta n}{n_0} \\ &\quad + K_5 K_2 \frac{\Delta a}{a_0} \\ \text{with } K_5 &= \frac{1}{\frac{P_{t0}}{P_{h0}} \left(1 + \frac{dp_v}{dp_t}\right)}.\end{aligned}\quad (2.75)$$

Regardless of which assumptions are made, the following generally applies

$$\frac{\Delta p_t}{P_{t0}} = K_h \frac{\Delta h}{h_0} - K_n \frac{\Delta n}{n_0} + K_a \frac{\Delta a}{a_0}, \quad (2.76)$$

where the three coefficients can be obtained from (2.73) or (2.75), depending on the model. Finally, if the electrical power is introduced instead of the torque, then

$$\begin{aligned}\Delta p &= \Delta m n_0 + \Delta n m_0, \\ \text{where } p_0 &= p_0, \quad m_0 = m_0,\end{aligned}\quad (2.77)$$

and the linearized block diagram of the hydro group in Fig. 2.50 results.

The hydraulic system can be described by the following equation, corresponding to Fig. 2.48

$$\begin{aligned}\Delta h &= -G(s) \sum_{i=1}^m \alpha_i (\Delta q_i + \Delta q_{Di}) \\ &= -G(s) \alpha \Delta q + \Delta h_z, \\ \text{with } \alpha_i &= \frac{Q_{ir}}{Q_r};\end{aligned}\quad (2.78)$$

$\Delta h_z$  represents the disturbance caused by the pressure regulator and the change in the water flows of the other turbines fed from the same penstock. For fast processes in the seconds range, as they occur in the primary speed control, we have  $G(s) = G_c(s)$  that is given by (2.62).

### Transfer Function of the Turbine

If the first equations of (2.73) are inserted into (2.78), and (2.78) (or  $\Delta h$ ) into (2.76), one obtains

$$\begin{aligned}\Delta p_t &= G_t(s) \Delta a + G_z(s) \Delta h_z - S_t(s) \Delta n \\ \text{with } G_t(s) &= \frac{P_{t0}}{a_0} K_a \frac{1 - C_2 G(s)}{1 + C_1 G(s)}, \\ G_z(s) &= \frac{P_{t0}}{h_0} K_h \frac{1}{1 + C_1 G(s)}, \\ S_t(s) &= \frac{P_{t0}}{n_0} K_n \frac{1 + C_3 G(s)}{1 + C_1 G(s)}, \\ C_1 &= \frac{\alpha q_0}{h_0} K_1, \quad C_2 = \frac{\alpha q_0}{h_0} \left( K_2 \frac{K_h}{K_a} - K_1 \right), \\ C_3 &= \frac{\alpha q_0}{h_0} \left[ K_1 - (1 - 2K_1) \frac{K_h}{K_n} \right],\end{aligned}\quad (2.79)$$

and the linear block diagram of the hydropower plant as shown in Fig. 2.51, which is suitable for control engineering investigations.

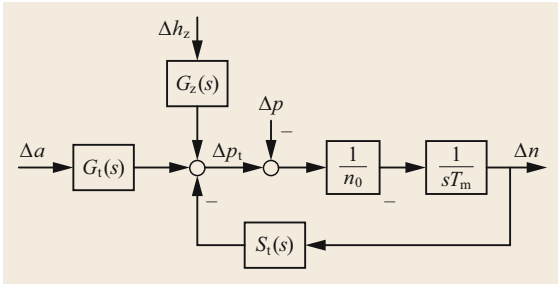

Fig. 2.50 Linearized block diagram of the hydro group

**Fig. 2.51** Linearized block diagram of the hydropower plant

In  $G_t(s)$  is the transfer function of the turbine; it describes the dependence of the turbine power on the degree of opening;  $G_z(s)$  describes the influence of groups fed from the same penstock on the turbine power;  $S_t(s)$  is the *self-regulating function* of the turbine. If it is positive, an increase in speed leads to a reduction in power and thus to a self-regulating effect.

With the *loss model*, the following applies exactly

$$c_2 = \frac{\alpha q_0}{h_0} . \tag{2.80}$$

An approximation of (2.72) is often used, with the exact equation for Pelton turbines, but for reaction turbines this is mostly inadequate, and the following applies

$$K_1 = \frac{1}{2} , K_2 = 1$$

$$\rightarrow C_3 = C_1 = \frac{1}{2} \frac{\alpha q_0}{h_0} . \tag{2.81}$$

The self-regulating function is then reduced to the coefficient  $K_n$ . In the case of the loss model, or if the efficiency depends only on the degree of opening,  $K_n = 0$  and the self-regulation effect is absent, otherwise  $K_n = 2K_3$ .

If even the change in efficiency is neglected, that is exactly correct at the point of maximum efficiency, the following applies

$$K_h = 1.5 , K_n = 0 , K_a = 1$$

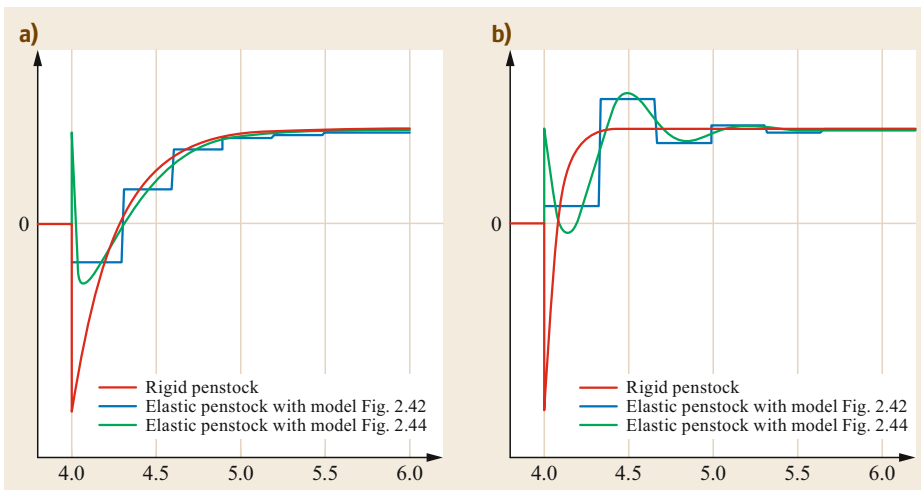

$$\rightarrow G_t(s) = \frac{p_{t0}}{a_0} \frac{1 - \frac{\alpha q_0}{h_0} G(s)}{1 + \frac{1}{2} \frac{\alpha q_0}{h_0} G(s)} , \quad s_t(s) = 0 . \tag{2.82}$$

If  $G(s) = G_c(s)$  is used, corresponding to (2.62), while the elasticity and losses of the penstock are neglected, and the load-dependent effective time constant  $T_{cx}$  introduced, the result is

$$T_{cx} = \frac{\alpha q_0}{h_0} T_c$$

$$\rightarrow G_t(s) = \frac{p_{t0}}{a_0} \frac{1 - sT_{cx}}{4(1 + s\frac{T_{cx}}{2})} . \tag{2.83}$$

Figure 2.52 shows the typical course of turbine power with an abrupt change in the degree of opening. When the elasticity of the penstock is taken into account, damped vibrations are superimposed (if  $\rho_A < 1$ ) with a frequency corresponding to (2.44)  $f_0 = 1/(4\tau) \approx 250/L_c$  Hz ( $L_c$  in m). With a weakly loaded turbine,  $T_{cx}$  and correspondingly, also  $\rho_A = T_{cx}/(2\tau)$ , are small.

**Fig. 2.52a,b** Time course of turbine output  $\Delta p_t/p_{t0}$  in the event of a sudden increase in the degree of opening  $\Delta a/a_0$ :  
**(a)**  $\rho_A = 1.73$ ,  
**(b)**  $\rho_A = 0.433$

## 2.7 Thermal Power Stations

The efficiency of power generation from fossil fuels in thermal power plants has risen considerably over time and today reaches almost 60% in natural gas-powered, combined cycle power plants. Nevertheless over 40% of the energy is still lost as waste heat.

### 2.7.1 Combined Heat and Power Generation

In combined heat and power (CHP), useful heat is produced in addition to electrical energy, thus further increasing overall energy efficiency. In the case of *steam turbines*, this can be done in two ways:

- 1) Through *steam extraction* (as with feed water pre-heating)
- 2) By increasing the condensation pressure (*counter pressure system*).

Variants and combinations of these two basic configurations are possible.

In the case of *gas turbine* with or without a recuperator or downstream steam turbine, the useful heat is recovered from the exhaust gases, with double compression also from the cooler [2.9, Sect. 5.2, Fig. 5.8].

Finally, for small capacities, *diesel systems* are also used, such as so-called *Block unit power plants* or *TOTEM* (total energy modules), whereby heat is extracted from the exhaust gases or the cooling circuit of the engine.

#### Extraction Condensation Circuit

The part  $m'_e$  of the steam mass  $m'$  is extracted at the extraction point G (Fig. 2.53). The corresponding heat is used for a heating system. The *extraction ratio* is defined as

$$\alpha = \frac{m'_e}{m'} \quad (2.84)$$

With reference to the cycle of Fig. 2.53, turbine power  $P_t$ , extracted heat output  $Q_H$  and supplied heat

$Q_1$  are

$$\begin{aligned} P_t &= m' [(h_E - h_G) + (1 - \alpha)(h_G - h_F)], \\ Q_H &= m' \alpha (h_G - h_A), \\ Q_1 &= m' (h_E - h_A). \end{aligned} \quad (2.85)$$

For the *performance figure*  $\varepsilon$  of the extraction condensation circuit, the ratio between the decoupled heat and the reduction of the turbine output is used

$$\varepsilon = \frac{Q_H}{\Delta P_t} = \frac{h_G - h_A}{h_G - h_F}. \quad (2.86)$$

The performance figure is independent of the extraction ratio. If the performance figure is specified (usually  $\varepsilon = 7-10$ ), the enthalpy of extraction  $h_G$  can be calculated from (2.86) and thus the extraction pressure. With the stated values of  $\varepsilon$ , the electrical power is reduced by less than 10% when maximum heat is extracted.

The *power-heat ratio* that indicates the ratio between electrical power and extracted thermal power is

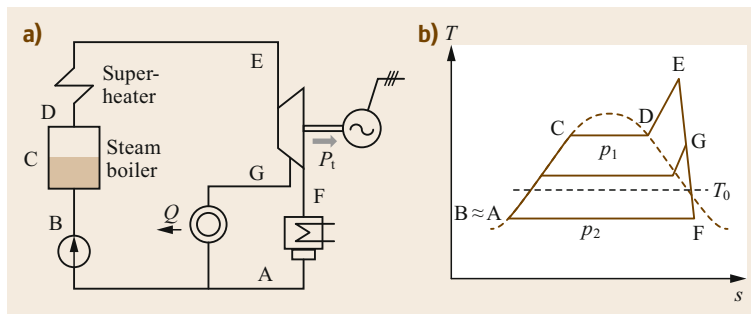

$$\begin{aligned} \sigma &= \frac{\eta_e P_t}{Q_H} = \eta_e \frac{(h_E - h_F) - \alpha (h_G - h_F)}{\alpha (h_G - h_A)} \\ &= \eta_e \frac{(\varepsilon - 1)(h_E - h_F) - \alpha (h_F - h_A)}{\alpha \varepsilon (h_F - h_A)}. \end{aligned} \quad (2.87)$$

The extraction condensation circuit enables a *flexible* adaptation of the heat extraction to the requirements. At full steam extraction ( $\alpha = 1$ ), one obtains the minimum electricity/heat ratio

$$\sigma_{\min} = \eta_e \frac{h_E - h_G}{h_G - h_A} = \eta_e \frac{\varepsilon (h_E - h_F) - (h_E - h_A)}{\varepsilon (h_F - h_A)}. \quad (2.88)$$

The *overall energy efficiency* is

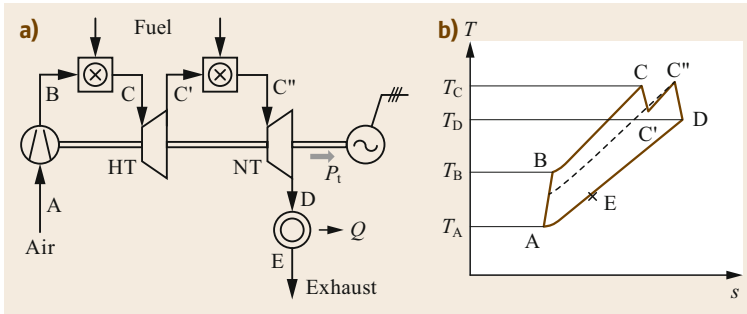

$$\begin{aligned} \eta_{\text{nutz}} &= \frac{\eta_e P_t + Q}{Q_b} = \left( \frac{\eta_e P_t}{Q_H} + \frac{Q}{Q_H} \right) \frac{Q_H}{Q_b} \frac{\eta_e P_t}{Q_b} \\ &= \frac{\sigma + \eta_H}{\sigma} \eta, \end{aligned} \quad (2.89)$$

**Fig. 2.53a,b** Heat-power generation by steam extraction. **(a)** Basic circuit diagram,  $P_t$  = turbine power,  $Q = \eta_H \times Q_H$  = useful heat output. **(b)** Temperature-entropy diagram,  $T_0$  = flow temperature of the heating system

**Fig. 2.54a,b** Combined heat and power with back-pressure system. **(a)** Basic circuit diagram,  $P_t$  = turbine power,  $Q = \eta_H \times Q_H$  = useful heat output. **(b)** Temperature–entropy diagram,  $T_0$  = flow temperature of the heating system

**Fig. 2.55a,b** Gas turbine with sequential combustion and combined heat and power generation. **(a)** Basic circuit diagram,  $P_t$  = turbine power,  $Q = \eta_H \times Q_H$  = useful heat output. **(b)** Temperature–entropy diagram,  $T_0$  = flow temperature of the heating system

where  $Q = \eta_H Q_H$  is the useful heat output,  $Q_b$  the heat content of the fuel and  $\eta$  the efficiency of the power plant without steam extraction. The overall efficiency increases with increasing heat extraction, from  $\eta$  for the process without heat extraction ( $\alpha = 0, \sigma = \infty$ ) up to the maximum value ( $\alpha = 1, \sigma = \sigma_{\min}$ ) according to (2.89).

### Back-Pressure System

In the back-pressure circuit, the turbine outlet temperature  $T_F$  is higher than the inlet temperature of the heating system (Fig. 2.54). This reduces the thermal efficiency of the process, but the full condensation heat is used. The main relationships result from (2.85) that illustrates the extraction condensation circuit for  $h_G = h_F$  and  $\alpha = 1$

$$\begin{aligned} P_t &= m' (h_E - h_F), \\ Q_H &= m' (h_F - h_A), \\ Q_1 &= m' (h_E - h_A). \end{aligned} \quad (2.90)$$

The formula for the *power-heat ratio* is always

$$\sigma = \frac{\eta_e P_t}{Q_H} = \eta_e \frac{h_E - h_F}{h_F - h_A}. \quad (2.91)$$

For the *overall energy efficiency*, it follows that

$$\begin{aligned} \eta_{\text{nutz}} &= \frac{\eta_e P_t + Q}{Q_b} = \eta + \frac{Q}{Q_b} = \eta \frac{\sigma + \eta_H}{\sigma} \\ &= \frac{Q}{Q_b} \frac{\sigma + \eta_H}{\eta_H}, \end{aligned} \quad (2.92)$$

where  $Q$  represents the heat effectively used and  $\eta$  represents the efficiency of electricity generation. The back-pressure circuit does not allow efficient adaptation of the heat extraction for reduced requirements, without a proportional reduction of the electricity production. If electricity production remains constant, the overall energy efficiency decreases in line with the reduction in useful heat efficiency  $\eta_H = Q/Q_H$ .

### Gas Turbines

Gas turbine plants are ideally suited for combined heat and power generation because the waste heat is generated at a high temperature. This also applies to the gas-turbine plant with a recuperator or downstream steam turbine.

With reference to the sequential combustion process of Fig. 2.55, the main relationships ( $m' \approx \text{const.}$  due to the large excess of air in the combustion process) are applicable according to [2.9, Sect. 5.2].

$$\begin{aligned} P_t &= m' c_p [(T_C T_{C'}) + (T_{C''} - T_D) (T_B - T_A)], \\ Q_H &= m' c_p (T_D T_A) \\ Q_1 &= m' c_p [(T_C T_B) + (T_{C''} T_{C'})]. \end{aligned} \quad (2.93)$$

For the power-heat ratio, we have

$$\sigma = \eta_e \frac{(T_C - T'_C) + (T''_C - T_D) - (T_B - T_A)}{T_D - T_E} \quad (2.94)$$

and for the overall energy efficiency

$$\eta_{\text{nutz}} = \frac{\eta_e P_t + Q}{Q_b} = \eta \frac{\sigma + \eta_H}{\sigma}, \quad (2.95)$$

**Fig. 2.56** Energy balance of a combined heat and power plant (gas turbine with sequential combustion and downstream steam turbine) as a function of steam extraction [2.19]

where  $Q = \eta_H Q_H$  is the heat effectively used and  $\eta$  represent the efficiency of electricity generation.

By combining it with a downstream steam turbine and using the heat from the exhaust gases and steam extraction, it is possible to achieve particularly high levels of overall energy efficiency paired with flexible heat extraction. As an example, Fig. 2.56 shows the energy balance of a combined cycle plant in the 100 MW range [2.9, Sect. 5.3, Fig. 5.13], with an overall energy efficiency of up to 85%.

### Block-Type Thermal Power Stations

In a similar way, heat can also be recovered from the exhaust gases and the cooling circuit in diesel- or gas-engine power plants. The basic circuit for this is shown in Fig. 2.57. Units in the power range 50 kW–15 MW are offered, with overall energy efficiencies from 85 to 90%.

### Combined Heat and Power and CO<sub>2</sub> Balance

In countries in which the production of electrical energy is predominantly from fossil fuels (such as Germany),

**Fig. 2.57** Combined heat and power unit

combined heat and power (CHP) enables a much more rational use of fossil fuels and thus contributes to the mitigation of the CO<sub>2</sub> problem (increased greenhouse effect).

In Switzerland, where electrical energy is generated almost exclusively with hydroelectric and nuclear power, the question arises as to whether the widespread use of combined heat and power leads to increased consumption of fossil fuels and thus to the opposite effect, unless biomass is used. The CO<sub>2</sub> balance looks much better when CHP is combined with heat pump technology [2.9, Chap. 6].

## 2.7.2 Fossil-Fired Steam Power Plants

A distinction is made between three main circuits, as illustrated in Fig. 2.58, in which the last two also occur in nuclear power plants:

- Air–fuel–flue gas/ash circuit
- Water–steam cycle
- Cooling water circuit.

### Air–Fuel–Flue Gas/Ash Cycle

The fuel and the air preheated by the flue gases are fed into the combustion chamber. Flue gas cleaning (flue gas treatment) includes, among other things, denitrification, desulfurization and dust removal. An ash extractor is required for coal fired systems. For more information on the combustion process, flue gas treatment and technology of fossil-fired steam generators see [2.20–22].

### Water–Steam Cycle, Losses

The thermodynamics of the water–steam cycle is described in [2.9, Sect. 5.1]. The main elements are the boiler, including a superheater and intermediate superheater, the turbine, the condenser and a feed-water preheater.

The dimensioning of the *steam generator (cauldron)* is based on the vapor pressure ( $p_1$ ) and the amount of steam required. For the latter, the rough guide value is approximately 3 t/(h, MWe); the exact values can be calculated from the process data (Mollier diagram) and efficiency  $\eta_e$ .

The *steam turbine* is a flow machine that converts the enthalpy difference between inflow and outflow into mechanical energy.

The rotation rate is 3000 or 1500 rpm at 50 Hz (3600 or 1800 rpm at 60 Hz), see also [2.17, Sect. 6.1]. Sometimes higher speeds are also chosen, and then the coupling to the generator is via a gear.

In the *condenser* the condensation heat is extracted from the humid or saturated steam leaving the turbine. Condensation pressure ( $p_2$ ) and temperature are related

**Fig. 2.58** (a) Main circuits in a fossil-fired steam power plant (principle), (b) steam turbine (1 live steam line, 2 stop and control valve, 3 high pressure turbine, 4 water separator/reheater, 5 steam line, 6 low pressure turbine, 7 guide vanes, 8 rotor blades, 9 condenser, 10 support plate, 11 vibration dampers) (adapted from [2.7])

via the vapor-pressure curve. In modern power plants, condensation pressures of 0.04–0.1 bar are usually selected (corresponding to temperatures of 29–46 °C). The choice of condensation pressure strongly influences the efficiency of the cycle, but also the cost of the condenser.

For more information on the technology and design of steam generators, steam turbines and condensers, see [2.22].

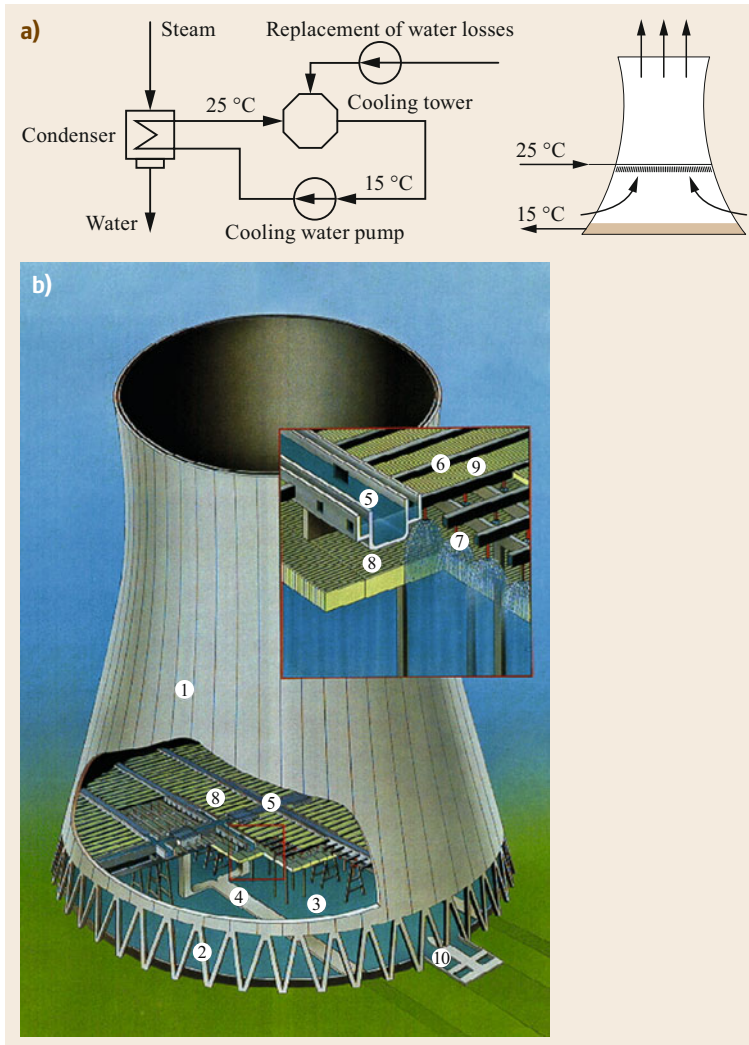

The *losses*, see also [2.9, Sects. 3.2 and 5.1], are the losses of the boilers and the circulation –  $\eta_K$  (guideline value 0.88), the losses of the idealized cycle  $\eta_{\text{threv}}$  (guide value 0.45–0.6 depending on the implementation), turbine losses (guide value 0.85) and generator losses and on-site power  $\eta_e$  (guide value 0.94). The indicated guide give, for example, a power plant efficiency of 31–42%. A small part of the heat loss is released into the environment with the flue gas and at various points in the plant. Most of the *waste heat* is transferred to the cooling water of the *condenser* that emits this heat to the environment via the cooling-water circuit.

### Cooling-Water Circuit

A distinction is made between freshwater cooling and tower cooling. The principle of *freshwater cooling* is shown in Fig. 2.59. The cooling water is taken from a river or lake and the heated water is returned to the source. The necessary cooling water quantity is about 50–70 times the steam weight, if cooling water heating of approximately 10 °C is permitted. For example, for a 300 MW power plant with approximately

**Fig. 2.59** Principle of freshwater cooling, possible values for 900 t/h steam

**Fig. 2.60** (a) Principle of the wet cooling tower, (b) cooling tower (1 shell, 2 supports, 3 basin, 4 water supply lines (from condenser), 5 distribution channels, 6 distribution troughs, 7 spray nozzles with baffle plate, 8 trickle plates, 9 drip catcher, 10 cooling water outlet (to condenser)) (adapted from [2.7])

900 t/h steam, 54 000 m<sup>3</sup>/h or 15 m<sup>3</sup> of cooling water is required. As the river temperature should only rise slightly for ecological reasons (the oxygen content decreases with increasing temperature), large rivers are needed even for these relatively small quantities of water (e.g., the River Rhine near Schaffhausen has a flow rate of around 180 m<sup>3</sup>/s). For this reason, tower cooling is usually used, especially when several power plants are operated on one river. The standard solution used today is wet tower cooling. The principle of *wet tower cooling* is shown in Fig. 2.60. The heated water trickles in a counterflow to the air rising in the cooling tower and partly evaporates. This removes heat, and the cooled water can be recycled. The water losses amount to only 2–3% of the required cooling-water quantity. The air flow results from the natural draught and can be amplified by fans.

The steam vapors above the tower are disruptive, especially for nearby human settlements. Alternatives that do not have this disadvantage are dry or hybrid cooling towers, that however, have a lower cooling capacity for the same dimensions. For more information on the cooling system and the calculation and performance of wet and dry cooling towers, please refer to the section on the cooling system [2.20–22].

#### Unit Control

The power fed into the interconnected electrical grid by the power-plant units must correspond to the power drawn by consumers.

The grid frequency drops if the consumers draw more electrical power than the power plants feeds in, and increases if more power is fed in than is taken out. By controlling the mains frequency, a balance be-

**Fig. 2.61** (a) Energy conversion in a steam power plant. (b) Sliding pressure diagram

tween supply and consumption is established. This is achieved on the one hand by means of fast primary frequency control, in which the power plants involved increase or decrease the output in proportion to the deviation from the target frequency in order to support the grid frequency. On the other hand, the load distributor also specifies power setpoints for the individual power plants so that the grid frequency can be brought back to the desired setpoint (secondary frequency control).

Unit control of a power plant regulates the power setpoint, that is varied with a given load change rate (MW/min) according to the expected power requirements for the grid. Short-term changes in the power drawn from the electrical network are regulated by the primary frequency control. In accordance with the set values (MW/Hz), each power station involved in maintaining the frequency increases or decreases the supplied electrical power proportionally to the deviation of the mains frequency from the set frequency. Further details on primary and secondary frequency control can be found in [2.17, Sect. 6.5.2] and [2.3, Chap. 2].

Figure 2.61 shows the principle of the *energy conversion* in a steam power plant. The thermal energy in the water vapor obtained from the primary energy must be in equilibrium with the electrical energy, taking into account the energy conversion losses. The steam pressure in the boiler falls when more electrical power is consumed than can be generated with the fuel supplied in.

**Fig. 2.62** Unit control principle: *boiler follows*

Unit control is the higher-level load control, that regulates the unit power capacity according to the network requirements and coordinates the interaction between the steam generator and the turbo-generator set of a power-plant unit, taking into account the dynamic behavior of the power-plant unit and the permissible load on the power-plant components.

The electrical output can be changed quickly with the control valves of the steam turbine, whereas firing control and steam generation act slowly. Furthermore, the storage behavior of the boiler can be used to handle short-term load changes of the turbine.

Depending on the plant design, the boiler pressure is set to a fixed set point (fixed pressure control) or to a variable load-dependent set point (sliding pressure). In a condensing turbine, the pressure upstream of the turbine valves and the turbine output are approximately proportional to the steam mass flow. If the steam turbine is operated with fully opened valves (*natural* sliding pressure), the pressure value before the turbine will correspond to the steam mass flow generated by the boiler.

In natural sliding-pressure operation, the turbine output cannot be increased by opening the control valves. Turbine power control is made possible by regulating the boiler pressure slightly above the sliding-pressure characteristic curve determined by the turbine design by means of firing control. This mode of operation is called modified sliding pressure.

In principle, two *types of unit control* can be distinguished [2.23].

In the first case, the steam turbine regulates the electrical power by means of the control valves, and the boiler regulates the steam pressure by means of the firing in order to establish the balance between the electrical power and the corresponding steam production. The steam pressure can be specified as a fixed setpoint or as a variable setpoint for modified sliding-pressure operation. The boiler *follows* the turbine power, as shown schematically in Fig. 2.62.

This procedure allows the boiler storage tank to be used for rapid load changes. If, however, the boiler cannot follow the desired load increase, the steam pressure drops. In order to avoid an inadmissible pressure reduction due, for example, to malfunctions in the steam

**Fig. 2.63** Unit control principle: *turbine follows* or sliding-pressure control

generator, an additional limitation control is applied to the control valves of the steam turbine if the steam pressure falls below the minimum value.

To improve the dynamics of the boiler pressure control, load changes are connected to the fuel control as feed forward control. When operating with modified sliding pressure, it must be taken into account that the boiler pressure must also be increased if the load is increased or reduced if the load is reduced. This type of control enables fast and precise control of the electrical power and requires extra outlay to achieve fuel control that is both sufficiently fast and smooth.

In the second case, the boiler regulates the electrical output, and the steam pressure is regulated by the steam turbine. In this approach, the turbine follows the load changes of the boiler, as schematically shown in Fig. 2.63.

The advantage of this circuit is that the control is stable on its own and also automatically copes with malfunctions in the boiler area. To be able to meet fast performance requirements, the control valves can be operated with some throttling (modified sliding pressure). This increases the steam pressure in the boiler and the stored energy can then be called up for a short-term increase in output before the steam production is adjusted to suit the changed requirements.

A short-term increase in performance can also be achieved by the *condensate-accumulation process*. In

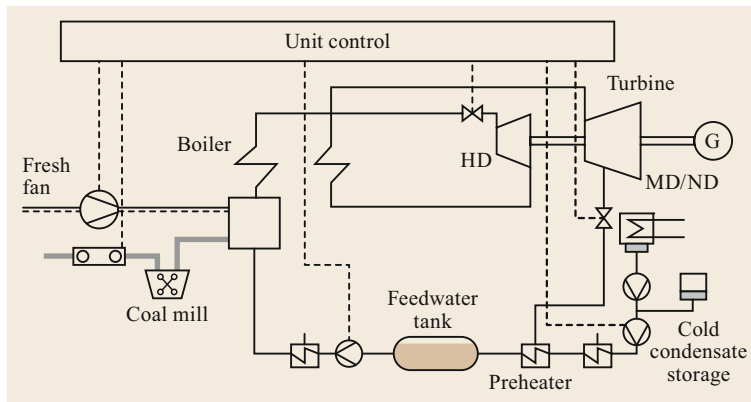

this process, the steam supply to the low-pressure preheaters is temporarily reduced, resulting in an increase in the electrical output of the steam turbine. The condensate supply is reduced accordingly to avoid a drop in the feed-water tank temperature. Depending on the capacity of the feed-water tank and of the cold condensate storage tank, it is thus possible to vary the output for a limited period with almost no reaction before the steam production is adjusted to meet the changed requirements.

Figure 2.64 schematically shows the main intervention points of a unit control with an integrated condensate-accumulation process. The required fuel flow is determined from the required power. Depending on the fuel flow, the combustion air must be adjusted for complete combustion and the feed-water flow set to meet steam production. Fast dynamic-load changes are achieved by the turbine control valves, that are slightly throttled in straight operation, and the extraction flaps for the low-pressure preheaters until the fuel flows again, corresponds to the electrical output.

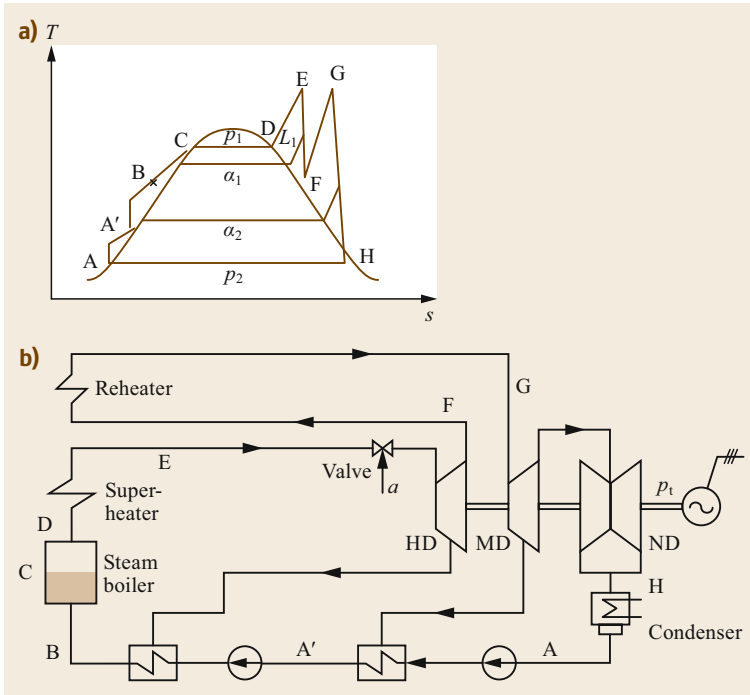

In addition to unit power plants, which serve exclusively to generate electrical energy, there are also power plants that provide process heat in addition to electrical energy (Sect. 2.7.1). Depending on the system configuration, the process steam or process heat extraction can be considered as a disturbance variable in the unit control for the electrical output, so that these power plants can participate in the primary and secondary control of the electrical grid. In many industrial power plants, however, the case occurs where the extracted process heat is the actual main control task, and the electrical output is adjusted according to the required process heat.

### Dynamics

In view of the rich variety and complexity of the steam power plants, only the basic behavior with regards to the reference scheme is described in Fig. 2.65. Although several coordinated valves can be active in a steam turbine, a single equivalent control valve between the

**Fig. 2.64** Unit control with integrated condensate accumulation

**Fig. 2.65** (a) Temperature–entropy diagram. (b) Schematic diagram of a steam power plant with a three-stage turbine, reheating and regenerative preheating

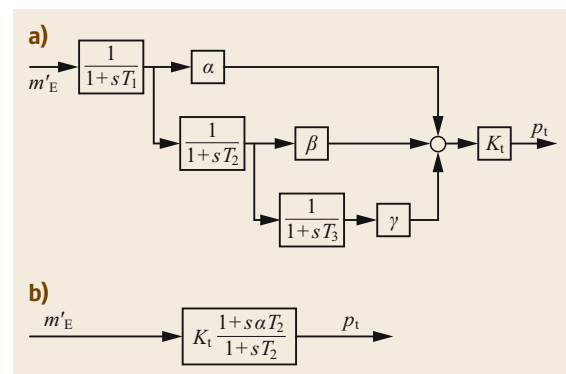

superheater and high-pressure (HP) turbine is assumed for the sake of simplicity. The thermal power available for the conversion at the superheater output E is given by  $P_E = m'_E \times \Delta h$ , where  $m'_E$  is the mass flow and  $\Delta h$  the available enthalpy change. If it is assumed that the subordinate control loops are capable of maintaining the temperature  $T_E$ , the enthalpy change is also constant and thus the power is proportional to the mass flow. This in turn is proportional to the degree of opening of the valve, that is controlled by the primary speed governor [2.3, Chap. 2].

Delays of the mass flow occur due to the volumes of the steam power plant. If we consider the volume  $V$  between two cross sections 1 and 2, then

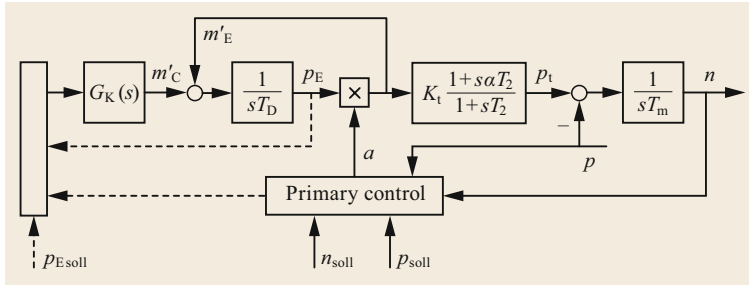

$$\begin{aligned}
 m'_1 - m'_2 &= V \frac{d\rho}{dt} = V \frac{\partial \rho}{\partial p} \frac{dp}{dt} \\
 &= V \frac{\partial \rho}{\partial p} \frac{1}{K} \frac{dm'_2}{dt} = T \frac{dm'_2}{dt}, \quad (2.96)
 \end{aligned}$$

where  $\rho$  represents the mass density. If it is also assumed that the output mass flow is proportional to the pressure, the mass flow  $m'_2$  follows the mass flow  $m'_1$  with the time constant  $T$ , that characterizes the inertia of the steam mass. In the plant under consideration, the largest delay is caused by the *reheater* whose time constant  $T_2$  is of the order of 10 s. Further first-order delays are between the valve and the HP turbine (guide value  $T_1 = 0.3$  s) and between medium-pressure (MP) and low-pressure (LP) turbine (guide value  $T_3 = 0.5$  s).

The relationship between the mechanical pu power  $p_t$  and the pu mass flow  $m'_E$  can be described by the block diagram of Fig. 2.66a. The coefficients  $\alpha, \beta, \gamma$  take into account the shares of the three turbine stages in the total output (with  $\alpha + \beta + \gamma = 1$ ). Stationary power losses can be accounted for with the constant  $K_t$ . Figure 2.66a leads to a third-order transfer function. It can be seen from the above-mentioned reference values that the output of the MP and LP turbines react much slower than that of the HP turbine because of the reheating. In view of the magnitude difference between the three time constants, a first approximation can set  $T_1 \approx 0$

**Fig. 2.66a,b** Transfer function of the steam turbine plant. (a) General third-order schema, (b) first-order approximation

**Fig. 2.67** Dynamic block diagram of the steam power plant ( $p_E$ : live steam pressure,  $p_t$ : turbine power,  $p$ : electrical power)

or  $T_1 \approx T_3 \approx 0$ , with the turbine plant represented approximately by a second- or even first-order transfer function, as in Fig. 2.66b.

Between mass flow in the HP turbine, live steam pressure  $p_E$  and the degree of opening  $a$  of the valve, there is the following pu relationship

$$m'_E = p_E a. \quad (2.97)$$

An increase in valve cross section  $\Delta a$  leads directly to an increase in mass flow and thus to a delayed increase in turbine output as shown in Fig. 2.66. On the other hand, the change in the mass flow causes a drop in pressure and thus, also in the density in the steam generator, that must be compensated by the boiler control. This decrease in pressure can be described by the pu equation

$$T_D \frac{dp_E}{dt} = m'_C - m'_E, \quad (2.98)$$

where  $m'_C$  represents the mass flow generated in the steam boiler. The time constant  $T_D$  can range between several tens of seconds and several hundred of seconds, depending on the type of boiler. The *boiler control* that controls the mass flow  $m'_C$  comprises several control loops that monitor the fuel, fresh air and feed-water supply. For example, it can have the task of maintaining the live steam pressure at the desired setpoint; in this case it is called *fixed pressure control*. In the case of *sliding pressure control*, it is controlled directly by speed or power (Sect. 2.7.2, *Unit Control*).

Figure 2.67 provides a dynamics diagram of the steam power plant, where the turbine is represented by a first-order system (Fig. 2.66b) and the boiler by the transfer function  $G_K(s)$ . The latter includes both the delays caused by heat release and the transfer function of the boiler controller (often a proportional integral (PI) controller).

### 2.7.3 Nuclear Power Plants

Nuclear power plants are essentially (as they are at present) steam-turbine power plants that are operated with nuclear instead of fossil fuel. The furnace is re-

placed by the *reactor*. An additional cooling circuit can be connected between the reactor and turbine ([2.9, Sect. 3.4], Fig. 2.71a).

A distinction is made between the:

- *Primary system*: reactor + in some cases additional cooling circuit and
- *Secondary system*: the other conventional elements of the steam circuit (for which the explanations in Sect. 2.7.2 essentially apply).

#### Energy Generation by Nuclear Fission

Nuclear energy can be released in two ways [2.9, Annex B]:

- By fusion of light atomic nuclei, i.e., from the hydrogen isotopes deuterium and tritium to helium. Industrial application is still a long way off (more details in [2.9, Chap. 11]).
- By splitting heavy atomic nuclei such as uranium, thorium and plutonium into medium-weight nuclei. The current industrial production of nuclear energy is based on the *uranium-fission reaction*. Thorium can be used in high temperature reactors. Plutonium is a by-product of uranium fission. For use in fast breeder reactors, the breeding is required be purified (Sect. 2.7.3).

**Uranium Fission.** Of uranium, 99.3% is the isotope  $^{238}\text{U}$  (238 nucleons, of which 92 are protons and 146 neutrons) and approximately 0.7% is  $^{235}\text{U}$  (with only 143 neutrons), and there are further small amounts of  $^{234}\text{U}$ . Only  $^{235}\text{U}$  can be split, and that is by slow (*thermal*) neutrons. The corresponding reaction is described in a somewhat simplified form in Fig. 2.68: the fission produces two nuclei of medium-weight (e.g.,  $^{137}\text{Ba}$  and  $^{97}\text{Kr}$ ), that have a higher binding energy and are therefore stable, releasing around 200 MeV. The fission of one kg of  $^{235}\text{U}$  results in the amount of energy

$$20 \frac{\text{Tcal}}{\text{kg}} \approx 24 \frac{\text{GWh}}{\text{kg}} = 1000 \frac{\text{MWd}}{\text{kg}}. \quad (2.99)$$

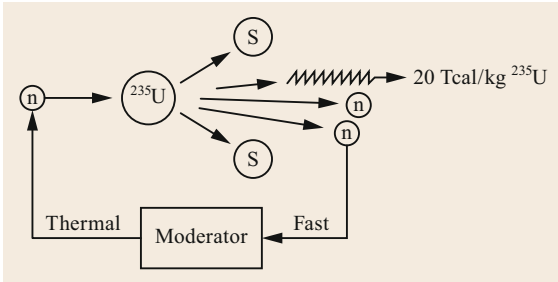

Fig. 2.68 Uranium fission: n: neutrons, S: fission products

Fig. 2.69 Basic design of the thermal reactor

The fission of  $^{235}\text{U}$  atoms, releases an average of 2–3 neutrons, that have a high kinetic energy (*fast* neutrons). These neutrons are partly absorbed and partly available for further fissions as so-called *fission neutrons*. If on average more than one fission neutron remains, the number of fissions increases like an avalanche, i.e., there is a *chain reaction* with exponentially increasing heat output. With less than one fission neutron on average, the reaction fades out. In a *controlled reaction* it is ensured that just one fission neutron maintains the reaction (Fig. 2.68). The reactor is then *critical*, and the power output is constant.

For the fission neutron to be able to maintain the reaction, however, further conditions must be met. Fast

neutrons with kinetic energies in the range 1 eV to MeV lead much less often to fission of  $^{235}\text{U}$  than thermal neutrons with energies below 0.1 eV. In addition, fast neutrons are more easily captured by  $^{238}\text{U}$  atoms. This has the consequence that, for example, in natural uranium that contains a lot of  $^{238}\text{U}$  and not much  $^{235}\text{U}$ , the reaction ends immediately. The reaction can only be maintained if, with the help of a *moderator*, the speed of the neutrons is reduced to thermal values. Substances that strongly slow down neutrons without capturing them are  $\text{H}_2\text{O}$ , the best  $\text{D}_2\text{O}$  (heavy water) and graphite. Further information on uranium fission can be found in [2.9, Annex B.6].

These physical conditions lead to the basic structure of the *thermal reactor* as in Fig. 2.69. The *fuel rods* containing an uranium compound ( $\text{UO}_2$ ) are surrounded by the moderator. The *control rods* consist of a neutron-absorbing material (e.g., boron), and can be lowered into the reactor to the desired depth, so that the critical state of the reaction can be assured, i.e., the power of the reactor can be regulated. Liquids or gases are used as *coolants* to transport the resulting heat away ( $\text{H}_2\text{O}$ ,  $\text{D}_2\text{O}$ ,  $\text{CO}_2$ , He).

**Conversion Processes.** For each fission reaction of  $^{235}\text{U}$  nuclei, on average, slightly more than two neutrons are generated. One of these is needed to maintain the reaction. The remaining neutrons are absorbed by the moderator, control rods and fuel (without fission) or escape from the reactor core. The neutrons absorbed by  $^{238}\text{U}$  lead in a few cases to the rapid fission of  $^{238}\text{U}$  (that also contributes, to a small extent, to energy and neutron production), but they are mainly absorbed. The resulting  $^{239}\text{U}$  is transformed by electron emission into neptunium  $^{239}\text{Np}$  (atomic number 93) with a half-life of 23 min, as shown in Fig. 2.70. With a half-life

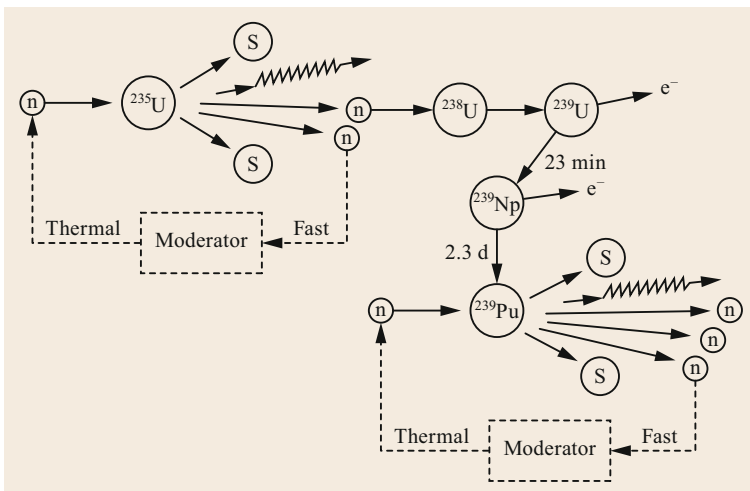

Fig. 2.70 Conversion reaction

of 2.3 days, this unstable element decays into a long-lived isotope *plutonium*  $^{239}\text{Pu}$ , that is fissile and has properties similar to those of  $^{235}\text{U}$  and contributes to energy production (see [2.9, Annex B.5]). Both reactions correspond to the following scheme  $n \rightarrow p^+ + e^-$  ( $\beta$ -radiation).

The conversion factor is the ratio of newly formed  $^{239}\text{Pu}$  nuclei to consumed  $^{238}\text{U}$  nuclei. Depending on the reactor type, it can assume different values, but is always small in *thermal reactors* (reactors in which fission is done by thermal neutrons). The conversion processes only slightly improve the utilization of natural uranium.

The conversion of  $^{238}\text{U}$  can also be triggered by  $^{239}\text{Pu}$  instead of  $^{235}\text{U}$ . Then, starting from  $^{239}\text{Pu}$ , new *Pu* is formed from  $^{238}\text{U}$ . If conversion factors  $> 1$  are reached, this is no longer called conversion, but breeding and breeding factors.

### Reactor Types

The reactors built to date are classed according to the *moderator used*:

- Light water reactors
- Heavy water reactors
- Graphite moderated reactors
- Fast breeder reactors (without moderator).

By far the largest proportion of the reactors used worldwide are *light water reactors* that have gained great importance in the energy sector. The individual reactor types are described briefly in the following, for further details see the relevant extensive technical literature.

**Light Water Reactors (PWR, BWR, EPR).** Normal (light) water is a good moderator, but not an excellent one. The critical state of the reaction therefore cannot be reached with natural uranium as the fuel (contains only 0.7%  $^{235}\text{U}$ ). For this purpose *enriched uranium* is required with a *degree of enrichment* (content of  $^{235}\text{U}$ ) ranging usually from 3–3.5%. For the enrichment natural uranium, available as  $\text{UO}_2$ , is first transformed into the gaseous uranium hexafluoride  $\text{UF}_6$ . This is then centrifuged, using the difference in weight between  $^{235}\text{U}$  and  $^{238}\text{U}$  to separate the enriched and depleted components.

A great advantage of the light water reactors is that the moderator and coolant are identical, namely  $\text{H}_2\text{O}$ . This makes the design very simple and the problem of heat transport can be solved relatively easily.

The achievable steam-inlet temperature of the turbines is significantly lower for all light water reactors than for fossil-fuel fired plants. Correspondingly, the achievable power plant efficiency is generally lower, at approximately 33%.

Light water reactors are built as pressurized water reactors (PWR) and boiling water reactors (BWR). In the pressurized water reactor, the heat is taken to a *separate* steam generator by the pressurized *primary cooling water*. The basic, somewhat simplified structure of the power plant with typical steam data is shown in Fig. 2.71a. The detailed structure of a pressurized water reactor power plant is shown in Fig. 2.71b.

The pressurized water reactor is currently experiencing an upswing as the EPR (European pressurized reactor, French–German financed). A first reactor of this type is under construction in Finland (capacity 1600 MW) and a second one in France (Fig. 2.71). These reactors of the so-called 3rd *generation* have significantly better safety properties. Also the efficiency is said to be better (at 36%).

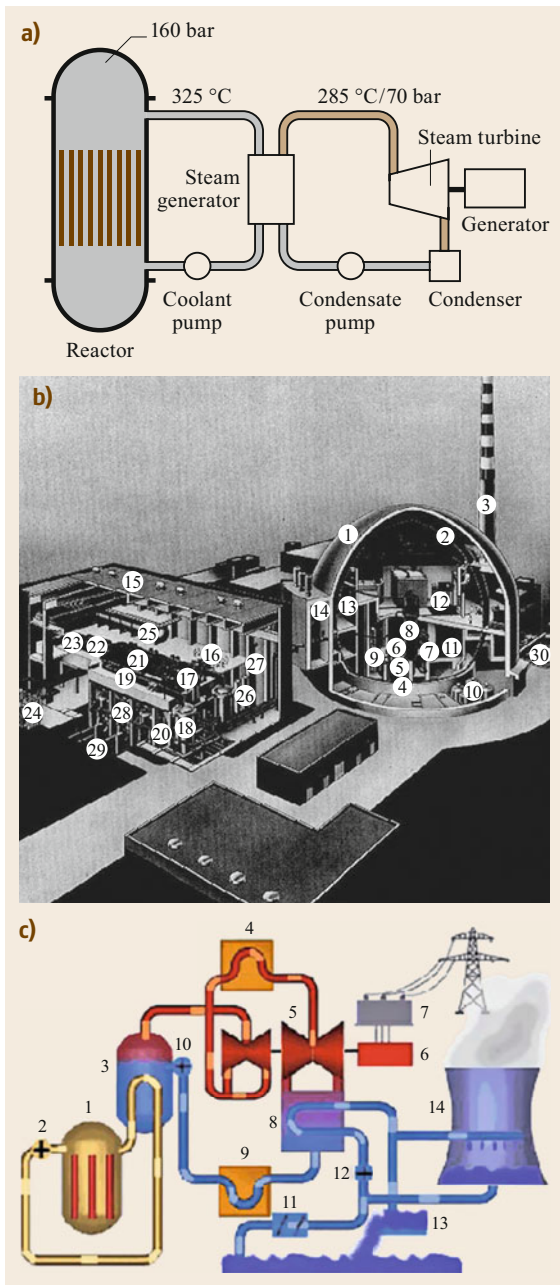

In a *boiling-water reactor*, steam production takes place in the reactor itself. The structure of the power plant and typical steam data are shown in Fig. 2.72.

**Heavy Water Reactor (HWR).** In the heavy water reactor,  $\text{D}_2\text{O}$  (heavy water) is used instead of normal water as the moderator and coolant. The fuel elements are located in pressure tubes that are cooled individually. The heated heavy water transports the heat to the steam generator (as in the pressurized water reactor Fig. 2.71). Since heavy water is an excellent moderator, *natural uranium* can be used as fuel, which is the main advantage of this type of reactor (no enrichment necessary). HWR were developed to industrial maturity in Canada and are used there and in India. The achievable power plant-efficiency is around 32%.

**Graphite-Moderated Reactors.** Various types of graphite-moderated reactors have been developed and used over time.

In the *RBMK (reaktor bolshoy moshchnosti kanalnyy) reactor*, that was developed in the former USSR and is still in operation in the successor countries, the fuel elements are also located in pressure tubes in which  $\text{H}_2\text{O}$  flows (coolant). The pressure tubes are housed in a graphite block. The moderator is  $\text{H}_2\text{O}$  and above all *graphite*. The achievable steam temperatures are comparable to those of light and heavy water reactors. After the accident in *Chernobyl*, the development of this reactor line has been halted.

In the *AGR reactor* (advanced gas cooled reactor), that is being developed and used in Great Britain, the fuel elements in steel tubes are located directly in the graphite. Cooling is done with  $\text{CO}_2$ . The materials used make it possible to reach temperatures of  $550^\circ\text{C}$  and thus implement steam processes with superheating. This increases the power plant efficiency to around 40%.

**Fig. 2.71** (a) Principle of the pressurized water reactor and typical steam and pressurized water data (1 reactor, 2 steam turbine, 3 generator, 4 condenser, 5 condensate pump, 6 steam generator, 7 coolant pump), (b) pressurized water reactor power plant (1 reactor building, 2 safety container (steel shell), 3 exhaust chimney, 4 reactor pressure vessel, 5 fuel elements, 6 control rods, 7 primary coolant pump, 8 steam generator, 9 pressurizer, 10 flood tank, 11 fuel element storage pool, 12 fuel element loading machine, 13 live steam line, 14 safety valves, 15 machine hall, 16 fast-closing and control valves, 17 high pressure turbine, 18 water separator reheater, 19 steam line, 20 steam bypass system, 21 low pressure turbine, 22 generator, 23 exciter, 24 transformer, 25 feed water tank, 26 pre-heater, 27 feed water pipe, 28 capacitor, 29 cooling C pipe (cooling circuit), 30 interim storage facility for radioactive waste (underground)) (adapted from [2.24]), (c) diagram of the EPR power plant under construction in Finland (Areva) (1 reactor, 2 reactor cooling pumps, 3 steam boiler, 4 re-heater, 5 turbine, 6 generator, 7 switchgear, 8 condenser, 9 water preheater, 10 condensate pump, 11 cooling water circuit, 12 cooling water pumps, 13 cooling water system, 14 cooling tower) ◀

**Fig. 2.72** Principle of the boiling water reactor and typical steam data

Since graphite is a better moderator than light water, both reactor types (RBMK and AGR) use fuel elements with a slightly lower enrichment of approximately 2%.

In a *high-temperature reactor* (HTR), graphite and silicon are used as fuel cladding materials and helium as the coolant (nuclear research facility Jülich, Germany, 1970s). This allows coolant temperatures of 700–950 °C to be achieved, enabling the operation of

both superheated steam circuits and gas turbines or combined cycle plants. Accordingly, the power plant efficiencies can reach 40–48% [2.25]. The fuel must have a relatively high enrichment level > 8%. Despite the great advantages of this reactor line, and also the inherent *passive safety* (inherent operational safety), the development towards industrial maturity in Germany is currently blocked. The development of this reactor line, that was to become the *reactors of the so-called 4th generation* is mainly being pursued in China, Japan and South Africa. It also allows thorium (about three times abundant as uranium) to be used as fuel.

**Fast Breeder Reactors.** The fast breeder reactor focuses on the conversion process described in Fig. 2.70 with a conversion factor  $> 1$  (breeder factor). It is not, however, driven by thermal neutrons, but by *fast neutrons* which is why a moderator is not necessary. However, since fast neutrons produce fewer fission neutrons than thermal neutrons, a relatively high enrichment level is necessary. In this respect, plutonium behaves much better than uranium, which is why the reactor core typically consists of an inner *fission zone* with 80% natural uranium and 20% plutonium and an outer *breeding zone* with  $^{238}\text{U}$ . Liquid sodium is used as a coolant because of its non-moderating properties.

Interest in the breeder reactors lies in the far better utilization of uranium, that in thermal reactors is about 1%, while in breeder reactors can be increased 30–50 times. It could therefore solve the problem of limited uranium reserves. This development is stagnating as a result of the risks associated with this reactor line and the resulting lack of acceptance (see also Sect. 2.7.3).

### Steam Cycle and Control

The only difference between a nuclear power plant and a normal fossil steam-power plant is that the reactor replaces the furnace or boiler. The steam cycle of light water reactors is characterized by weak superheating and reheating to temperatures only slightly over the evaporation temperature. Accordingly, as already mentioned, the efficiency is lower than that of fossil-fired plants. Reheating is primarily intended to prevent steam condensation in the turbines.

Nuclear power plants are used as base-load power plants, i.e., they operate at constant power and do not participate in the frequency power control of the grid [2.3, Chap. 2]. In principle, the block diagram in Fig. 2.67 applies to the dynamics of the nuclear power plant, with the reactor control replacing the boiler control. For more information about reactor dynamics and reactor control see, for example, [2.23, 26].

### Reactor Safety and Fuel Cycle

The radiation generated by nuclear fission and the radioactive fission products must be isolated from the environment, for which appropriate safety and disposal measures must be set up. This concerns the nuclear power plant itself and all plants involved in the fuel cycle. [2.27]

**Reactor Safety.** For safety reasons, the primary plant, that comprises the reactor and the primary cooling circuit, is housed in a separate, often spherical building. The fission products produced in the reactor are separated by a graduated *barrier system* isolated from

the environment. The pressure-resistant and gas-tight casings of the fuel elements form the first barrier. A second barrier is the equally pressure-resistant steel shell of the reactor or primary system. Finally, the reactor plants are located in the aforementioned reactor protection building made of steel and concrete, that forms the third barrier. This triple barrier system is intended to provide protection against internal and external influences. Aircraft crashes and earthquakes should be mentioned as external influences. In addition to the radioactive radiation generated during operation, which must be absorbed, the internal influences also includes the increase in pressure or heat build-up occurring in the event of accidents, that in the worst case can lead to core meltdown if the multiple control and shutdown devices fail. During normal operation or in the event of malfunctions, the discharge of contaminated air or water is prevented by suitable *filter systems*.

**Fuel Cycle and Disposal.** The steps involved in the supply and disposal of fuel are shown schematically in Fig. 2.73a.

The *supply* comprises the mining of uranium ore, the extraction of natural uranium and finally the uranium enrichment with subsequent fuel production required for the operation of light water reactors.

After use in the NPP, the spent fuel elements are initially *stored temporarily* in water in the reactor building for about one year and cooled until the residual heat has decayed. Then they are taken into reprocessing or prepared for final storage.

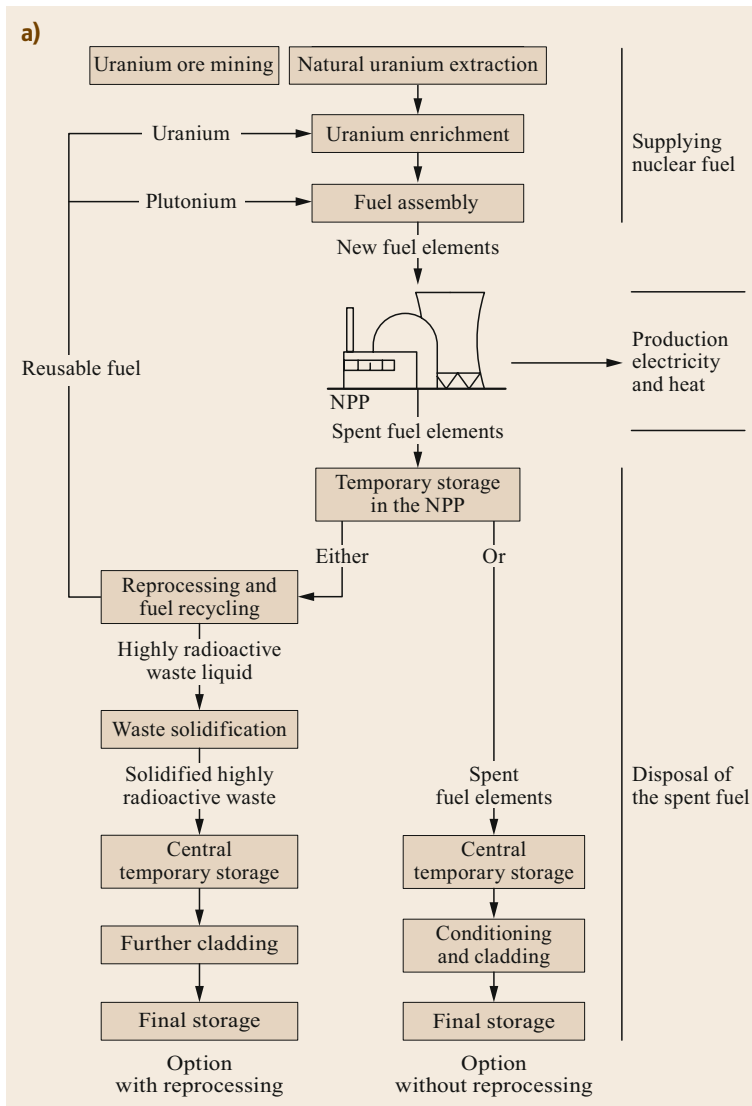

If no reprocessing is planned, the spent fuel elements are temporarily stored centrally for a long time and finally *conditioned*. Conditioning includes vitrification and containment of waste in steel containers. The final storage sites are sealed caverns impermeable to gases and liquids (e.g., salt mines).

During reprocessing, reusable materials such as uranium and plutonium are separated and taken for enrichment or fuel production. Non-usable waste is conditioned and put into permanent storage.

Low and intermediate level waste from power plants is conditioned together with waste from medicine, research and industry (using other processes) and finally disposed of in suitable repositories.

Reprocessing has the advantage that less natural uranium is required and allows the use of plutonium, that reduces the amount of high-level radioactive waste (by a factor of about five). On the other hand, however, the amount of low- and intermediate-level waste increases considerably as a result of the reprocessing process.

**Fig. 2.73 (a)** Fuel cycle of nuclear power plants with light water reactors and associated work steps. The disposal routes for low- and intermediate-level waste are not marked [2.27]. **(b)** Disposal and storage of nuclear waste of high, medium and low activity (adapted from [2.27])

Since civilization with technology produces radioactive waste (not only in nuclear power plants), it is imperative to dispose of it safely. Practical problems arise in democratic, federally organized countries due to the initial lack of regional acceptance of the repositories, which must be achieved through laborious educational work or the centralization of competencies by political means.

Another controversial issue and the subject of technical and political discussion is whether the final disposal of waste should be sustainable, safe and definitively monitored over the long term, and whether the monitoring and maintenance of the repositories should

then be ensured over a long period of time and adapted to the latest technology.

### Hazards of Nuclear Power

Like other processes in our technical civilization, nuclear power has associated hazards. These depend on the state of development of technology that will ultimately decide whether or not nuclear power will continue to play an important role in energy supply in the future. If breeder reactor technology does not prevail, nuclear energy from fissile material will only remain an (albeit important) temporary energy source because of limited uranium and thorium reserves and

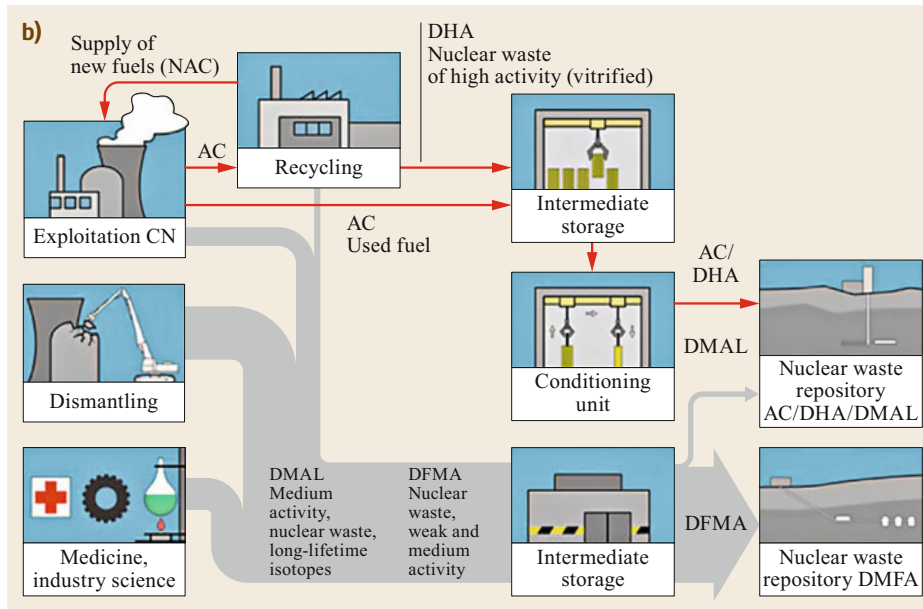

Fig. 2.73  
(continued)

will very probably play a major role only in the 21st century.

Four factors need considering in the hazard discussion:

- 1) Safety during the operation of nuclear power plants
- 2) The possible environmental contamination caused by the fuel cycle
- 3) The safe storage of radioactive waste
- 4) The question of the possible use of fissile material, in particular plutonium, in the manufacture of weapons.

**Safety of the Power Plant.** The *safety measures* taken during planning and construction are described in Sect. 2.7.3 [2.28]. Modern nuclear power plants designed to Western standards offer maximum safety, as demonstrated by the many years of operation of the more than 430 power plants installed and producing energy worldwide, amounting to an experience of more than 10000 man-years. The additional radioactivity level during normal operation in the vicinity of a nuclear power plant is far below that of natural radioactivity.

In the case of a MCA (maximum credible accident), the consequences for man and the environment are not noticeable if the protective devices function correctly, as they are designed to avoid the external effects of such an accident. For a reactor built to Western standards, this also includes the meltdown of the reactor core (the only accident of this kind is Harrisburg 1979, with no consequences for the environment).

If a contamination of the environment occurs (as in Chernobyl 1986), it is referred to as a super-GAU. The

accident at Chernobyl was specifically due to the type of construction used and is not possible in light water reactors. It was also caused by inadequate safety precautions.

In the case of a super-GAU, as in Chernobyl, there is considerable harm to the environment and to people, which must be avoided under all circumstances. In high-standard reactors, such an accident is extremely unlikely, but its probability cannot be reduced to zero. Whether such a loss or risk is acceptable (and insurable) or not is the subject of socio-political debate (a question of assessing a very small probability of a residual risk occurring with major consequences). The ecological benefits of nuclear energy in view of the climate problem must be taken into account and the possible damage must be assessed in relation to that caused each year by other technical facilities (e.g., road and air traffic, chemicals) but tolerated. Section 2.7.3, *Effect of Radioactivity*, considers the hazards of radioactive contamination.

Nuclear technology is also making progress, with (international) efforts moving towards light-water reactors with even greater safety margins (EPRs), with the aim of further reducing the probability of GAUs or super-GAUs [2.25], but also towards an intrinsically safe HTR reactor (China, Japan, South Africa) in terms of both nuclear reaction and heat removal.

**Fuel Cycle.** Concerning the fuel cycle (Sect. 2.7.3), sins have been committed in the past especially in uranium mines and reprocessing. Radioactive contamination can be avoided through high technical and also

ethical standards, which respect the imperatives of social and ecological sustainability, through careful and responsible protective measures during processing and transport as well as through international cooperation. The problem is no more serious than that of other industries (e.g., chemical), where dangerous substances are also used.

**Waste Disposal.** It should be added to the explanations in Sect. 2.7.3 that a distinction must be made between the disposal of low- and intermediate-level waste and that of high-level radioactive waste. The first problem does not only concern nuclear reactors and must therefore be dealt with regardless of whether or not electricity is produced by nuclear power. The technical solutions are in place and the policy is to solve the implementation issues (see Fig. 2.73b).

Concerning the *high-level radioactive waste* that is specific to the nuclear power industry, there are also technical solutions that need to be tested. The problem is the subject of technical and political argument and has not yet been resolved. However, the quantities of high-level radioactive waste to be disposed of are relatively small (see the examples in [2.9, Sect. 3.4]) and not comparable with the enormous amount of climate-damaging CO<sub>2</sub> that results from the combustion of fossil fuels. The latter problem could be much more difficult to solve (see Chap. 1).

**Nuclear Weapons Production.** Highly enriched uranium is required for the manufacture of nuclear weapons. It is feared that the plutonium present in small quantities in spent fuel rods from nuclear power plants could be misused for this purpose. This cannot be completely ruled out, although disposal is subject to strict controls, and recovery is not a simple technical problem. On the other hand, the production of nuclear weapons has been possible in the past independently of the peaceful use of nuclear energy, and will continue to be possible in principle for all those who have gained access to highly enriched uranium or plutonium from nuclear arsenals (USA, former USSR and other countries with nuclear weapons) or are able to operate an enrichment facility. The dangers that this poses are real and are prevented by political measures and appropriate monitoring (non-proliferation agreements). The risks posed by the peaceful use of nuclear energy plants with low-enriched uranium are comparatively low (fast breeders would be somewhat more worrying in this respect).

### Effect of Radioactivity

We will limit ourselves here to a few summary statements. For more details, see [2.28, 29]. Radioactivity

is caused by the decay of *unstable isotopes* [2.9, Annex B.3]. These mainly emit  $\alpha$ -,  $\beta$ - and  $\gamma$ -radiation. The half-life of the isotopes can vary widely. Examples are

$$\begin{aligned} {}^{131}\text{J} &\longrightarrow 8 \text{ d} , \\ {}^{238}\text{Pu} &\longrightarrow 88 \text{ a} , \\ {}^{226}\text{Ra} &\longrightarrow 1620 \text{ a} , \\ {}^{239}\text{Pu} &\longrightarrow 24\,000 \text{ a} , \\ {}^{238}\text{U} &\longrightarrow 4.5 \times 10^9 \text{ a} . \end{aligned} \quad (2.100)$$

The rays have different penetration power.

**$\alpha$ -Radiation.** They do not penetrate deeply; a few cm of air, clothing or a sheet of paper is enough to stop them. If they encounter unclothed body parts, only the skin is affected. However, with their relatively high energy, their biological effectiveness is about 20 times stronger than that of the  $\beta$ -rays. Their energy is usually around 5 MeV.

**$\beta$ -Radiation.** The energy of electrons is most frequently 0.5 MeV, but can also reach a maximum of 1.7 MeV. To reduce their intensity to 37% (defines the range or depth of penetration, exponential characteristic), a few cm of water or a few mm of aluminum are required. In body tissue the radiation penetrates about 2–10 mm deep in the energy range mentioned [2.28].

**$\gamma$ -Radiation.** This high-energy electromagnetic radiation (frequency range  $3 \times 10^{18}$ – $6 \times 10^{21}$  Hz) has an energy of 0.01–20 MeV. Their range in cm (reduction to 37%) is described in Table 2.4. It shows the danger of  $\gamma$ -radiation, that cannot be completely shielded even by layers of lead several cm thick.

**Activity.** The activity of a radioactive substance is defined as the number of decay processes per second. Units are the becquerel (Bq) and the curie (Ci) (formerly)

$$\begin{aligned} 1 \text{ Bq} &= 1 \text{ decay/s} \\ 1 \text{ Ci} &= 37 \times 10^9 \text{ Bq} \longrightarrow 1 \text{ nCi} = 37 \text{ Bq} \end{aligned} \quad (2.101)$$

1 Ci corresponds to the activity of 1 g of radium.

Radioactivity is present everywhere in nature because of radioactive isotopes in the *earth's crust*, but also as a result of the radioactivity arriving from the

**Table 2.4** Penetration of  $\gamma$ -radiation (cm)

	Water	Aluminum	Concrete	Lead
0.1 MeV	6.3	2.3	2.6	0.018
1 MeV	14.3	6.2	6.8	1.36
10 MeV	45.5	15.5	18.6	1.77

*cosmos*. This is called *natural radioactivity*. All living beings are radioactive; human beings have an average radioactivity of 130 Bq/kg through food intake, drinking water and breathing air [2.28]. Building materials, such as concrete, bricks and granite can have several 100 Bq/kg. Wood, on the other hand, normally has a very low level. The radioactive noble gas radon escaping from the earth's interior gives air an activity of approximately 14 Bq/m<sup>3</sup>; in dwellings this value increases on average to 50 Bq/m<sup>3</sup> because of radioactive masonry.

**Radiation Dose.** The energy of terrestrial and cosmic radiation can be measured. The radiation energy absorbed per unit of mass is called the *absorbed dose D*. The unit is the gray (Gy) or (formerly) the rad (rad)

$$1 \text{ Gy} = 1 \frac{\text{J}}{\text{kg}} \quad (1 \text{ Gy} = 100 \text{ rad}) . \quad (2.102)$$

**Equivalent Dose.** The *biologically effective radiation dose* is called *equivalent dose*. It is the product of absorbed dose *D* and quality factor *Q*. The quality factor *Q* indicates the biological effectiveness of the type of radiation. It is  $Q = 1$  for  $\beta$ - and  $\gamma$ -radiation,  $Q = 10$  for neutron radiation and  $Q = 20$  for  $\alpha$ -radiation. Neutron and  $\alpha$ -radiation have much more damaging effects on cell tissue.

The equivalent dose unit is the sievert (Sv) or (formerly) röntgen equivalent man (rem)

$$D \text{ (Gy)} \longrightarrow DQ \text{ (Sv)} \quad (1 \text{ Sv} = 100 \text{ rem}) . \quad (2.103)$$

The biological effect consists of damage to molecules, the fragments of which react chemically and biochemically differently and can impair the functionality of the affected cell. Although living beings possess effective repair mechanisms (since life originated in a radioactive environment), these are not always sufficient, and they can lead to genetic or somatic damage, the latter immediately (early damage) or only after a long time (long-term damage). Many insights have been gained in this respect from the experience with the atomic bomb.

With *single exposure*, the threshold dose above which immediate damage is to be expected in humans is indicated as 200–300 mSv. Embryonic damage can already occur after a single irradiation of 100–200 mSv. A dose of 3–5 Sv is lethal, with a 50% probability.

There is no threshold value for long-term damage, but only the probability of contracting the disease increases with the amount of radiation (e.g., risk of cancer or genetic damage). It is important to note the *cumulative burden* in mSv/a, that can be compared with the natural background radiation. However, as explained

below, there is a large range of fluctuation in background (or natural) radiation.

**Natural Radioactivity.** This consists of cosmic radiation and earth radiation. Cosmic radiation is constant over time (except for large solar flares) and depends strongly on altitude. The annual burden is

$$\begin{aligned} 0 \text{ m a.s.l.: } & 0.30 \text{ mSv/a} \\ 400 \text{ m a.s.l.: } & 0.36 \text{ mSv/a} \\ 800 \text{ m a.s.l.: } & 0.45 \text{ mSv/a} \\ 2000 \text{ m a.s.l.: } & 0.80 \text{ mSv/a} \\ 4000\text{--}5000 \text{ m a.s.l.: } & 2 \text{ mSv/a} \\ & (\text{Mont Blanc} \rightarrow 0.00023 \text{ mSv/h}) , \\ 8000\text{--}9000 \text{ m a.s.l.: } & 15 \text{ mSv/a} \\ & (\text{Mount Everest} \rightarrow 0.0017 \text{ mSv/h}) , \\ 12\,000 \text{ m a.s.l.: } & 40 \text{ mSv/a} \\ & (\text{Aircraft} \rightarrow 0.0045 \text{ mSv/h}) . \end{aligned} \quad (2.104)$$

The Earth's radiation varies from region to region depending on geology and soil conditions. It is relatively strong in granite rocks (the Alps of Europe) and weak in sedimentary rocks (Jura, Swiss central plateau). In Switzerland, it varies between 0.4 and 1.5 mSv/a, on average about 1.2 mSv/a. There are regions in China, Brazil and the Indian subcontinent where 20 mSv/a and much higher are common, with no significant variations observed yet in cancer, malformations, fertility, etc., indicating the effectiveness of biological repair mechanisms. Examples of natural exposure in Switzerland can be found in Table 2.5.

The exposure from food and housing must be added to the natural one. In Germany, it is estimated to be about twice as large as the natural one, that is about 0.8 mSv/a, resulting in a total exposure of 2.4 mSv/a. In addition, there is the radiation exposure due to medical care, that is given as approximately 1.6 mSv/a [2.28, 29]. The accident at Chernobyl in 1986 led to an additional exposure of 0.04 mSv/a in Germany in 1992.

For persons with occupational radiation risk, in Switzerland an exposure limit of 10–50 mSv/a is set, or an accumulated level of 350 mSv over one's entire occupational career.

**Table 2.5** Examples of natural radioactive exposure in Switzerland

City	Cosmic (mSv/a)	Terrestrial (mSv/a)	Total (mSv/a)
Biel	0.37	0.39	0.76
Zurich	0.36	0.83	1.19
Geneva	0.35	0.89	1.24
St. Moritz	0.74	1.1	1.84

## 2.8 Wind Power

The potential of wind energy and the prerequisites for its economic use have already been briefly discussed in Sect. 1.2.3. This section deals in more detail with the technical and economic aspects of wind-energy use.

### 2.8.1 The Kinetic Energy of Wind

An air mass  $m$  moving with speed  $v_0$  has the kinetic energy

$$E_{\text{kin}} = \frac{1}{2} m v_0^2 \quad \left( \text{kg} \left( \frac{\text{m}}{\text{s}} \right)^2 = \text{J} \right). \quad (2.105)$$

For a cross-section  $A$  through which there is an air mass flow with density  $\rho$  and speed  $v_0$ , the air mass  $m'$  per second is

$$m' = A \rho v_0 \quad \left( \text{m}^2 \frac{\text{kg}}{\text{m}^3} \frac{\text{m}}{\text{s}} = \frac{\text{kg}}{\text{s}} \right), \quad (2.106)$$

and the *theoretical wind power* is

$$P_0 = \frac{1}{2} m' v_0^2 = \frac{1}{2} A \rho v_0^3 \quad (\text{W}). \quad (2.107)$$

#### Theoretical Wind Power

The theoretical wind power increases with the third power of the *wind speed* and thus has a strong influence on the economic efficiency.

Another important parameter is the air density. For dry air at normal pressure (1013 mbar) and 0 °C this is  $\rho = 1.292 \text{ kg/m}^3$ . Pressure and temperature influence can be determined from the relationship

$$\frac{P}{\rho} = RT \quad \longrightarrow \quad \rho = \frac{P}{RT} \quad \text{with } R = 287.1 \frac{\text{J}}{\text{kg K}}. \quad (2.108)$$

It should also be noted that the pressure changes with altitude according to the barometric formula ( $P_0$  at 20 °C)

$$P = P_0 e^{-\frac{h-h_0}{a}} \quad \text{with } a = 29.27 \frac{\text{m}}{\text{K}}. \quad (2.109)$$

#### Wind Speed

The relationship between wind force and wind speed is shown in Table 2.6.

Annual mean wind speeds above 5 m/s usually occur only in coastal regions or on free-standing mountain peaks. It should be noted, however, that the mean value, because of  $v_0^3$  (2.107) does not allow a direct statement about the energy content. The wind speed also changes with height, due to ground friction according to the formula

$$\frac{v}{v_0} = \left( \frac{h}{h_0} \right)^\alpha, \quad (2.110)$$

$$\text{where } \begin{cases} \alpha = 0.16 & (\text{sea}), \\ \alpha = 0.17-0.2 & (\text{plain without obstacles}). \end{cases}$$

With obstacles,  $\alpha$  can assume much higher values. An uneven topography can also cause large local differences and alter the altitude profile of the wind. The location of a wind turbine is therefore of great importance.

#### Example 2.7

Calculate the theoretical power per  $\text{m}^2$  of area for  $v_0 = 4 \text{ m/s}$  and  $7 \text{ m/s}$  and the corresponding theoretical power with constant wind conditions:

- For 0 m a.s.l. at standard pressure and 20 °C
- At 2000 m a.s.l. at the corresponding pressure and 10 °C (in % of a))

**Table 2.6** Wind force and wind speed [2.30]

Wind force on Beaufort scale	Wind velocity		Effect of the wind
	(m/s)	(kn)	
0 Calm	0.0–0.2	0–1	Smoke rises vertically
1 Light air	0.3–1.5	1–3	Smoke rises obliquely
2 Light breeze	1.6–3.3	4–7	Draught slightly perceptible
3 Gentle breeze	3.4–5.4	8–11	Leaf movement on trees
4 Moderate breeze	5.5–7.9	12–15	Small tree branches move
5 Fresh breeze	8.0–10.7	16–21	Tree branches move
6 Strong breeze	10.8–13.8	22–27	Large tree branches move; telegraph wires whistle
7 Near gale	13.9–17.1	28–33	Tree movement, wind resistance when walking
8 Gale	17.2–20.7	34–40	Tree twigs break; difficulty in walking

c) Assuming that the above speed values apply to a height of 10 m above the ground, how does the power change in % if the wind turbine is installed 20 m above the ground (ground without obstacles)?

$$\begin{aligned} \text{a) } \rho &= 1.292 \frac{273}{293} \\ &= 1.205 \frac{\text{kg}}{\text{m}^3} \begin{cases} 4 \frac{\text{m}}{\text{s}}: P_0 = \frac{1}{2} 1.205 \times 4^3 = 38.6 \frac{\text{W}}{\text{m}^2} \\ 7 \frac{\text{m}}{\text{s}}: P_0 = \frac{1}{2} 1.205 \times 7^3 = 207 \frac{\text{W}}{\text{m}^2} \end{cases} \end{aligned}$$

$$\begin{aligned} \text{b) } p &= p_0 e^{-\frac{2000}{29.27283}} = p_0 0.7855 \\ \rightarrow \rho &= 1.205 \frac{293}{283} \times 0.7855 = 1.205 \times 0.8133, \end{aligned}$$

The power is reduced by almost 19%.

$$\text{c) } \left(\frac{v}{v_0}\right)^3 = \left(\frac{20}{10}\right)^{3(0.17 \dots 0.2)} = 1.424 \dots 1.516$$

The power increases by 42–52%!

### Energy Supply

In order to be able to evaluate the potential wind-energy supply of a site, long-term measurements must be available or measurements using anemometers must be carried out over a lengthy period. The measurement results can be displayed in the form of a duration curve (Fig. 2.74). The duration curve indicates during how many hours  $h_i$  in the period under consideration a certain wind speed  $v_i$  is reached or exceeded. From the duration curve of the wind, the duration curve of the theoretical power can be calculated with (2.105), and from this, taking into account the operating limits and the efficiency of the wind turbine, the effective available energy can be determined.

Experience shows that working with 10 min mean values is a good basis for the design of the wind turbine. To learn about the influence of the superimposed wind turbulence see [2.31].

### The Weibull Distribution

Analysis of wind statistics has shown that in very many cases the wind distribution can be described with ade-

**Fig. 2.74** Wind duration curve (mean values of 10 min)

quate approximation by the Weibull distribution. This is defined by the following cumulative frequency (duration curve)

$$\frac{h}{h_{\max}} = S(v) = e^{-\left(\frac{v}{c}\right)^k} \quad (2.111)$$

The distribution is thus given by the two parameters  $c$  (position parameter, proportional to the mean speed) and  $k$  (scattering parameter).

The wind frequency is obtained by differentiation of the cumulative frequency

$$f(v) = -\frac{dS(v)}{dv} = \frac{k}{c} \left(\frac{v}{c}\right)^{k-1} e^{-\left(\frac{v}{c}\right)^k} \quad (2.112)$$

and is generally represented by Fig. 2.75.

The following quantities can be determined from position and scattering parameters

$$\begin{aligned} \text{mean wind speed } v_m &= c \Gamma\left(1 + \frac{1}{k}\right), \\ \text{and energy factor } K_E &= \frac{\Gamma\left(1 + \frac{3}{k}\right)}{\Gamma\left(1 + \frac{1}{k}\right)}, \end{aligned} \quad (2.113)$$

where

$$\Gamma(x) = \int_0^{\infty} e^{-t} t^{x-1} dt \quad (2.114)$$

represents the gamma function evaluated in [2.1, Annex E].

The energy factor  $K_E$  is the ratio between the supply of wind energy at variable wind speed and the supply at

**Fig. 2.75** Weibull wind frequency

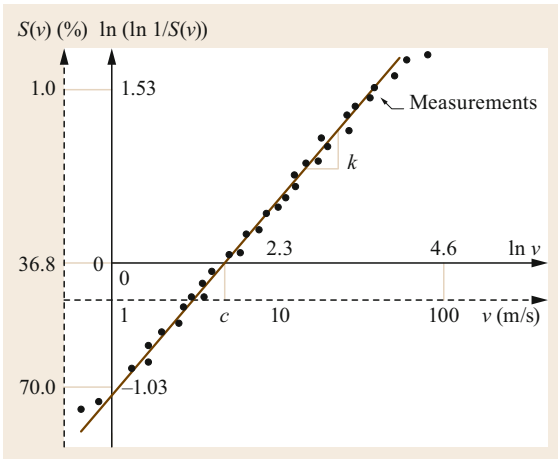

Fig. 2.76 Wind measurements and their evaluation

constant mean wind speed. The theoretical wind energy potential of a site is then

$$W_0 = 8.76 \frac{1}{2} \rho v_m^3 K_E \left( \frac{\text{kWh}}{\text{m}^2 \text{a}} \right). \tag{2.115}$$

To calculate this potential, the parameters  $c$  and  $k$  are first determined from the measured values. For this pur-

pose, (2.111) is written with double logarithms as

$$\ln \left( \ln \frac{h_{\max}}{h} \right) = \ln \left( \ln \frac{1}{S(v)} \right) = k(\ln v - \ln c) \tag{2.116}$$

and the measured values  $\ln[\ln(1/S(v))]$  are plotted as a function of  $\ln v$  (Fig. 2.76). If the measured values in the range  $S(v) = 1-70\%$  lie on a straight line, the assumption of a Weibull distribution is justified. The slope of the straight line is  $k$  and  $c$  is the intersection with the abscissa.

From  $c$  and  $k$ , with the help of the gamma function with (2.113), the mean wind speed and the energy factor are obtained. The two values are listed in [2.1, Annex E] as a function of  $k$ . The air density is derived from pressure and temperature ((2.108) and (2.109)) and the wind-energy potential is finally derived from (2.115).

### 2.8.2 Wind-Turbine Types and Their Performance

Figure 2.77 shows the most important wind turbine types. A distinction is made between wind turbines that

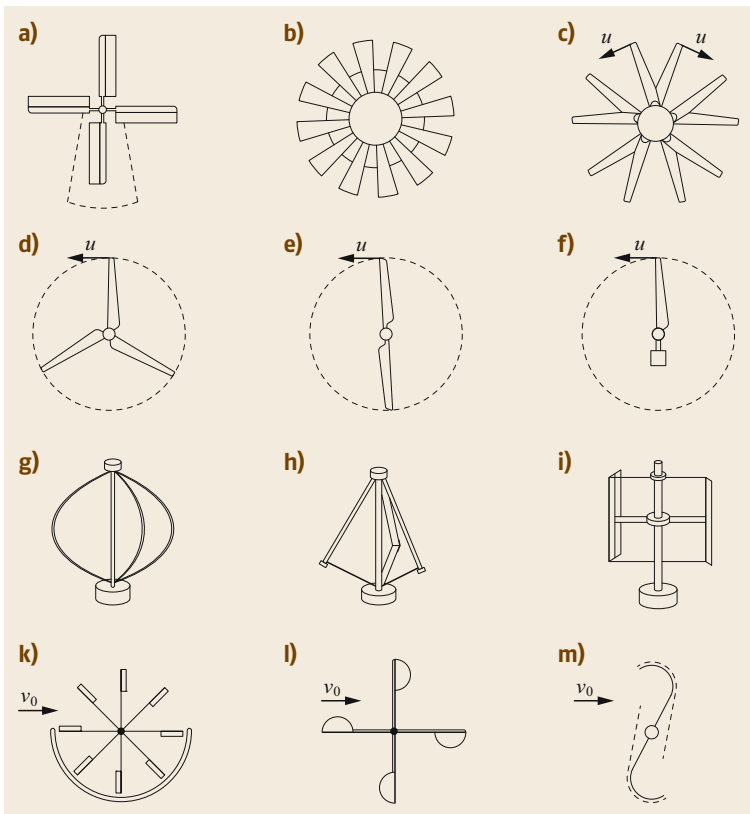

Fig. 2.77a-m Wind turbine types: (a) La Cour wind turbine, (b) American wind turbine, (c) 2 x 5-blade rotor, (d) three-blade rotor, (e) two-blade rotor, (f) one-blade rotor, (g) three-blade Darrieus, (h) Δ-Darrieus, (i) H-Darrieus, (k) semi-shielded drag rotor, (l) cup cross, (m) Savonius rotor (dotted line: divided rotor); (a-f) horizontal axis, using lift; (g-i) vertical axis, using lift; (k-m) using drag

**Fig. 2.78** Drag and lift force

operate predominantly on the *principle of resistance* (drag-type) and those based on the *lift principle* (lift-type).

Every surface of area  $A$  exposed to the wind, experiences a force  $F_w$  in the wind direction (Fig. 2.78) and a force  $F_a$  perpendicular to it.

$$\begin{aligned} F_w &= c_w \times 0.5\rho Av^2, \\ F_a &= c_a \times 0.5\rho Av^2. \end{aligned} \tag{2.117}$$

The drag and lift coefficients  $c_w$  and  $c_a$  depend on the shape (profile) and position of the surface (angle  $\alpha$ ) relative to the wind direction. They can be calculated numerically or determined by tests, e.g., in a wind tunnel [2.31].

The resulting force on the surface is  $F_r$ .

If the surface moves with speed  $v_e$  (Fig. 2.79), the relative wind speed in (2.117) is  $w$  instead of the absolute  $v$

$$w = v - v_e. \tag{2.118}$$

If the resulting force  $F_r$  gives a positive component  $F_t$  (driving force) in the direction of motion, the motion is increased (Fig. 2.79); in the opposite case it is retarded.

This most important wind turbine types are discussed in the following sections. For more details see [2.31, 32] and for the construction of wind turbines

**Fig. 2.79** Forces on moving wind turbine

see [2.33].

Theoretical power of the wind turbine:  $P_{th} = c_p P_0$ ,

$$\text{Effective power: } P = \eta_t P_{th} = \eta_t c_p P_0 = c_p' P_0. \tag{2.119}$$

$P_0$  is the theoretical wind power according to (2.107). Added terms are:

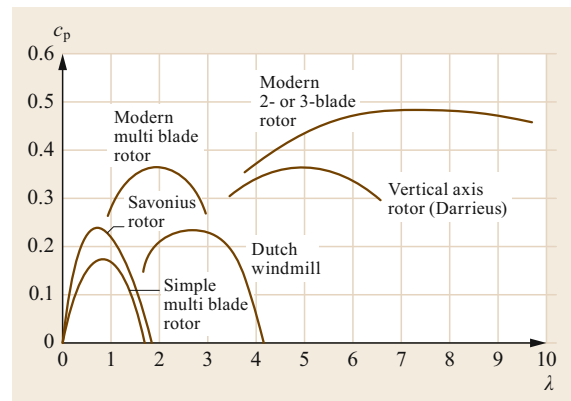

- $c_p$  ideal power coefficient of the turbine (always  $< 1$ )
- $\eta_t$  efficiency of the turbine (relative to loss-free operation)
- $c_p' = \eta_t c_p$  effective coefficient of power.

$c_p$  determines the upper power limit, that cannot be exceeded for physical reasons (even without friction losses). It can be shown that  $c_p$  (and therefore also  $c_p'$ ) are dependent on the *tip speed ratio*  $\lambda$  of the wind turbine (Sect. 2.8.3)

$$\lambda = \frac{u}{v_0}, \tag{2.120}$$

where  $u$  represents the *peripheral speed* of the turbine blade and  $v_0$  the *absolute wind speed* before the turbine. Figure 2.80 shows the ideal power coefficients of some wind turbines. For all wind turbines,  $c_p$  has a maximum for a certain (optimal) tip speed ratio  $\lambda_{opt}$ . For optimal operation, the speed of the wind turbine would have to be adapted to the wind speed. For reasons of cost, this is often dispensed with, but in modern systems it is increasingly done, thanks to cheaper power electronics (see Sect. 2.8.3, *Airfoil Theory*).

Wind turbines are classified as slow-speed or high-speed turbines according to the optimum tip speed ratio. The last category includes Darrieus rotors and 1–3-blade horizontal-axis rotors. In practice, horizontal-axis

**Fig. 2.80** Ideal power coefficient  $c_p$  of various rotors as a function of the tip speed ratio  $\lambda$

rotors have become established and account for by far the largest share of all wind turbines worldwide.

### 2.8.3 Horizontal-Axis Wind Turbines

#### Betz's Law

With reference to Fig. 2.81, consider the wind mass  $m$  passing through the wind-turbine section  $A$ . The wind speed before the turbine is  $v_0$ . The wind is slowed down by the turbine, so that the wind speed after the turbine is  $v_1 < v_0$ . In the turbine itself, the wind speed is  $v$ .

If ideal lossless conditions are assumed, the difference between the kinetic energies ( $W_0 - W_1$ ) is fully converted into mechanical energy and appears as the theoretical power  $P_{th}$  on the turbine shaft

$$W_0 - W_1 = \frac{1}{2}mv_0^2 - \frac{1}{2}mv_1^2 = \frac{1}{2}m(v_0^2 - v_1^2).$$

The mass flow per time unit through the turbine is  $m' = \rho Av$ . The theoretical power is therefore

$$P_{th} = \frac{1}{2}\rho Av(v_0^2 - v_1^2). \quad (2.121)$$

On the other hand, using the momentum equation, the force follows as momentum change per s

$$F = m'(v_0 - v_1) = \rho Av(v_0 - v_1).$$

The power from the wind is therefore

$$P_{th} = Fv = \rho Av^2(v_0 - v_1). \quad (2.122)$$

Comparison of (2.121) and (2.122) provides

$$v = \frac{v_0 + v_1}{2}. \quad (2.123)$$

From (2.122), the power is

$$P_{th} = \frac{1}{4}\rho A(v_0 + v_1)(v_0^2 - v_1^2), \quad (2.124)$$

and for the ideal power coefficient

$$\begin{aligned} c_p &= \frac{P_{th}}{P_0} = \frac{\frac{1}{4}\rho A(v_0 + v_1)(v_0^2 - v_1^2)}{\frac{1}{2}\rho Av_0^3} \\ &= \frac{1}{2} \left(1 + \frac{v_1}{v_0}\right) \left(1 - \frac{v_1^2}{v_0^2}\right). \end{aligned} \quad (2.125)$$

Fig. 2.81 Horizontal axis wind turbine, Betz's law

Replacing  $v_1$  by  $v$  (see (2.123)), then (Fig. 2.82)

$$c_p = 4 \left(\frac{v}{v_0}\right)^2 \left(1 - \frac{v}{v_0}\right). \quad (2.126)$$

The maximum value is  $c_{p,max} = 16/27 = 0.593$  and is achieved for  $v/v_0 = 2/3$  or  $v_1/v_0 = 1/3$ . There is a fixed relationship between the speed  $v$  and the rotational speed of the turbine or the tip-speed ratio, that depends on the *blade solidity* (completeness) and the *profile shape* of the blade (see airfoil theory). The completeness increases with the number and width of the blades. A distinction is made between two extreme versions:

1. Low speed rotors  
(Example: American wind turbine, Fig. 2.77). Due to the high blade solidity, the optimum speed  $v$  is reached at low speeds ( $\lambda_{opt}$  small).
2. High speed rotors  
(Example: two-blade rotor, Fig. 2.77). The blade solidity is small, the optimum speed  $v$  requires high rotational speed and precise design of the blades ( $\lambda_{opt}$  large).

The power supplied by the turbine is calculated according to (2.119)

$$P = \eta_t c_p P_0 = c'_p P_0. \quad (2.127)$$

The overall efficiency can reach for  $\lambda_{opt}$  a value  $c'_p = 0.45$  (Fig. 2.84), that corresponds to a turbine efficiency  $\eta_t = 0.76$ .

#### Airfoil Theory

Consider the blade element  $dr$  (Fig. 2.83a), that is moving at the speed  $u_r$ . With the wind speed  $v$  in the axial

Fig. 2.82 Curve of the ideal power coefficient of horizontal-axis wind turbines

**Fig. 2.83a,b** Speeds (a) and forces (b) of a wing element

direction, the relative wind speed is  $w_r$  (Fig. 2.83b).

$$\begin{aligned} w_r &= v - u_r, \quad \text{with } u_r = \omega r, \\ w_r &= \sqrt{v^2 + u_r^2} = v \sqrt{1 + \left(\frac{u_r}{v}\right)^2}, \\ \cos \beta &= \frac{v}{w_r} = \frac{1}{\sqrt{1 + \left(\frac{u_r}{v}\right)^2}}. \end{aligned} \quad (2.128)$$

The blade profile has an adjustable angle  $\theta$  relative to the normal to the wind direction. This angle is often a function of  $r$ . The angle of attack  $\alpha$  is the angle between the profile and the relative wind speed (Fig. 2.83b). Thus

$$\alpha = 90^\circ - (\theta + \beta). \quad (2.129)$$

The forces acting on the wing element (Fig. 2.83b) are:

- $F_a$  Lift, perpendicular to  $w_r$
- $F_w$  Drag, direction  $w_r$
- $F_r$  Resultant force  $F_a + F_w$
- $F_t$  Driving force, direction  $u_r$
- $F_n$  Normal force, perpendicular to  $u_r$

For the area  $dA = s_r dr$  of the blade element, the following apply, according to (2.117)

$$\begin{aligned} dF_w &= c_w \times 0.5 \rho s_r dr w_r^2 \\ dF_a &= c_a \times 0.5 \rho s_r dr w_r^2, \end{aligned} \quad (2.130)$$

where  $c_a$  and  $c_w$  are profile-dependent, wind-tunnel measurable and thus known functions of the angle of attack  $\alpha$ .

For tractive force and normal force, Fig. 2.83b shows

$$\begin{aligned} dF_t &= dF_a \cos \beta - dF_w \sin \beta \\ dF_n &= dF_a \sin \beta + dF_w \cos \beta \\ \longrightarrow dF_t &= \frac{1}{2} \rho s_r dr w_r^2 (c_a \cos \beta - c_w \sin \beta). \end{aligned} \quad (2.131)$$

The torque generated by the blade element  $dr$  is thus

$$dM = dF_t r = \frac{1}{2} \rho s_r r dr w_r^2 (c_a \cos \beta - c_w \sin \beta). \quad (2.132)$$

If  $z$  is the number of blades, the total torque is then

$$\begin{aligned} M &= z \int_{R_{\min}}^R dM \\ &= \frac{1}{2} \rho z \int_{R_{\min}}^R s_r r w_r^2 (c_a \cos \beta - c_w \sin \beta) dr. \end{aligned} \quad (2.133)$$

Finally, the theoretical power is  $P_{th} = M\omega$ , from which the ideal power coefficient can be calculated as a function of tip speed ratio and orientation angle. In particular, the optimum tip speed ratio  $\lambda_{opt}$  follows from this. Figure 2.84 shows the typical curve for a high-speed machine.

### Exercise 2.1

- a) A horizontal three-blade rotor ( $\lambda_{opt} \approx 8$ ) should deliver an effective output of 15 kW at an optimal wind speed of 6 m/s. The efficiency of the turbine  $\eta_{opt}$  is 0.72. Estimate:
  - The radius of the blades (assumption  $\rho = 1.2 \text{ kg/m}^3$ )
  - The optimum rotation speed of the rotor
  - The specific power in relation to the wind turbine area.
- b) Repeat the calculation with  $v_{0, opt} = 8 \text{ m/s}$ .
- c) Same calculations for an American wind turbine of the same power, if  $\eta_{opt} = 0.5$  and  $\lambda_{opt} \approx 1$ .

The solution can be found in [2.9, Annex F].

**Fig. 2.84** Power coefficient  $c_p$  of a high-speed turbine as a function of tip speed ratio  $\lambda$  and pitch angle  $\theta$

### 2.8.4 Modern Horizontal-Axis Wind Turbines

The vast majority of modern wind-power plants use horizontal-axis, high-speed turbines with three rotor blades. An even number of rotor blades have disadvantages in terms of dynamic stability, and the (cheaper) solution with a single rotor blade is also mechanically unfavorable for reasons of dynamic balance.

The investment costs of large plants (output in the MW class up to 5 MW) today are about 860 €/kW. At an average wind speed of 6 m/s and a rated speed of 15 m/s (corresponding to  $P_{\max}$  = rated power), the annual usage time is 1767 h/a from (2.107) and (2.115) assuming an energy factor of 0.7 [2.9, Annex E] and an average power coefficient of 0.45. With an 8% annual return the energy costs are 3.9 ct/kWh. These costs do not take into account the expenses for operating and transporting the energy. Wind energy is a base-load energy like that of hydraulic run-of-river power plants, but much more irregular; it must therefore be compensated by other rapidly controllable energy supplied by hydroelectric or gas turbine-power plants, or used or stored locally.

A greater tower height allows a better energy yield thanks to stronger wind, but increases the costs. The optimum height is usually about 1–1.5× the diameter of the rotor.

Large wind farms, consisting of a large number of wind turbines, are most common near the sea. The distances between the turbines in the wind direction must be approximately 5–9 rotor diameters; 3–5 rotor diameters across the wind direction are sufficient. For details, see Wind Power [2.34] (<http://www.windpower.dk/en>).

In the mountains, the requirements for measurements and modeling in the planning phase are particularly high [2.35].

For the future, large *offshore installations* (installations anchored in the sea) are planned. This avoids the often serious aesthetic problems associated with coastal locations; in addition, the energy potential increases considerably. The problems associated with anchoring (floating systems) are currently being investigated. A coupling with *tidal-power plants* is quite conceivable ([https://en.wikipedia.org/wiki/Marine\\_current\\_power](https://en.wikipedia.org/wiki/Marine_current_power); [https://en.wikipedia.org/wiki/Wind\\_power](https://en.wikipedia.org/wiki/Wind_power)).

### 2.8.5 Other Types of Wind Turbines

We shall consider two types of vertical-axis wind turbine. The first type, the Darrieus rotor, belongs to the high-speed category and works on the lift principle; the second, the Savonius rotor, is a low-speed rotor and works on the drag principle (Figs. 2.77 and 2.80).

#### The Darrieus Rotor

This rotor was invented in the 1920s by the Frenchman Georges Darrieus, but it was not used in practice until around 1970. Since then, rotors up to approximately one MW have been built. The rotor usually consists of two or three blades attached at their ends to a co-rotating vertical axis (Fig. 2.77g). If we rotate a rope instead of the wings, it would take the shape of a troposkein (skipping-rope curve). If the blade is given such a shape, only tensile forces occur, which is mechanically ideal. In practice, the troposkein is approximated by an arc and a straight line. The airfoil profiles are generally symmetrical. Compared to the horizontal-axis

rotor, the Darrieus rotor has the following advantages and disadvantages:

- **Advantages**
  - The Darrieus Rotor is independent of wind direction. This means that no mechanism for wind tracking is necessary, no alignment units, such as wind vanes, auxiliary rotors or servomotors, are required.
  - The power plant with gearbox, generator and control unit is located on the ground. Therefore, no complex tower constructions are necessary, and maintenance is easier.
- **Disadvantages**
  - The torque pulsates because of the variable angle of attack (resulting in mechanical problems).
  - The lower height above the ground leads to weaker wind in the lower parts of the rotor blades, that has a negative effect on the power coefficient.
  - A starting aid is necessary (motor, Savonius) as the angle of attack is not adjustable.

**Rotor Geometry.** The troposkein is approximated by circle and straight line, with the data values  $R$ ,  $R_0$  and  $H$  (Fig. 2.85). From this the auxiliary variables are as follows

$$\begin{aligned} x_0 &= R - R_0, \\ \gamma_0 &= \pi - \gamma_1 - \gamma_2, \\ r_0 &= x_0 + R_0 \cos \gamma_0, \\ z_0 &= R_0 \sin \gamma_0, \end{aligned} \quad (2.134)$$

where

$$\begin{aligned} \gamma_1 &= \arctan \left( \frac{H}{2(R - R_0)} \right), \\ \gamma_2 &= \arctan \sqrt{\left( \frac{H}{2} \right)^2 + R^2 - 2RR_0}. \end{aligned}$$

If  $(r, z, \vartheta)$  denote the general coordinates of a blade element; this results in the following equations for the circle and the straight line (with  $z$  as a parameter):

Circle equations for  $-z_0 < z < z_0$

$$\begin{aligned} \gamma &= \arctan \left( \frac{z}{\sqrt{R_0^2 - z^2}} \right), \\ r &= x_0 + R_0 \cos \gamma, \\ \sin \delta &= \frac{r - x_0}{R_0} = \cos \gamma. \end{aligned} \quad (2.135)$$

**Fig. 2.85** Geometry of the Darrieus rotor

Straight line equations for  $z > z_0$  and  $z < -z_0$

$$\begin{aligned} m &= \frac{H/2 - R_0 \sin \gamma_0}{x_0 + R_0 \cos \gamma_0}, \\ r &= \frac{H/2 - |z|}{m}, \\ \sin \delta &= \frac{m}{\sqrt{1 + m^2}} \end{aligned} \quad (2.136)$$

( $m$  being the slope).

**Forces on the Wing Elements.** For the elementary wind tube (Fig. 2.86), the following applies

$$dA = r d\vartheta \sin \vartheta dz. \quad (2.137)$$

The wind meets the blade profiles at 1 and 2. The mean force at 1 results from the momentum equation (analogous to Sect. 2.8.3)

$$d^2 F_{1m} = dm' (v_0 - v_1) \quad (2.138)$$

Set according to (2.123),  $v_1 = 2v_{e1} - v_0$ , gives

$$\begin{aligned} d^2 F_{1m} &= dm' 2 (v_0 - v_{e1}), \\ \text{with } dm' &= 2\rho r d\vartheta \sin \vartheta dz v_{e1}. \end{aligned} \quad (2.139)$$

This force acts on the rotating blade element only for a short time (during the angle  $d\vartheta$ ). Using  $dF_1$  as the

**Fig. 2.86** Forces on the Darrieus blade

element  $dz$  has the inclination  $\delta$  to the horizontal and has the surface area

$$dA_p = \frac{sdz}{\sin \delta} \tag{2.143}$$

The forces acting on the blade element (2.117) are

$$\begin{aligned} dF_a &= \frac{1}{2}c_a\rho dA_p w_1^2 \text{ (lift) ,} \\ dF_w &= \frac{1}{2}c_w\rho dA_p w_1^2 \text{ (drag) ,} \end{aligned} \tag{2.144}$$

where  $w_1$  represents the relative wind speed, the components of which are against the direction of motion  $u$  and normal to the blade and given by (Fig. 2.87)

$$\begin{aligned} w_1 \cos \alpha &= u + v_{e1} \cos \vartheta , \\ w_1 \sin \alpha &= v_{e1} \sin \vartheta \sin \delta , \end{aligned} \tag{2.145}$$

force actually acting on the profile element, the relationship is

$$d^2F_{1m} = dF_1 \frac{Nd\vartheta}{2\pi} , \tag{2.140}$$

where  $N$  is the number of blades.

From (2.139) and (2.140),

$$dF_1 = \frac{1}{N}4\pi\rho r \sin \vartheta dz v_{e1} (v_0 - v_{e1}) . \tag{2.141}$$

The same consideration for position 2 leads to

$$dF_2 = \frac{1}{N}4\pi\rho r |\sin \vartheta| dz v_{e2} (v_0 - v_{e2}) , \tag{2.142}$$

where  $v_2 = 2v_{e2} - v_1$ .

**Airfoil Theory.** The blade element in position 1 (Fig. 2.86) should be examined more closely with regard to resistance and lift force (Fig. 2.87). The vertical

where  $\alpha$  is the angle that  $w_1$  makes with the direction of motion.

**The Savonius Rotor**

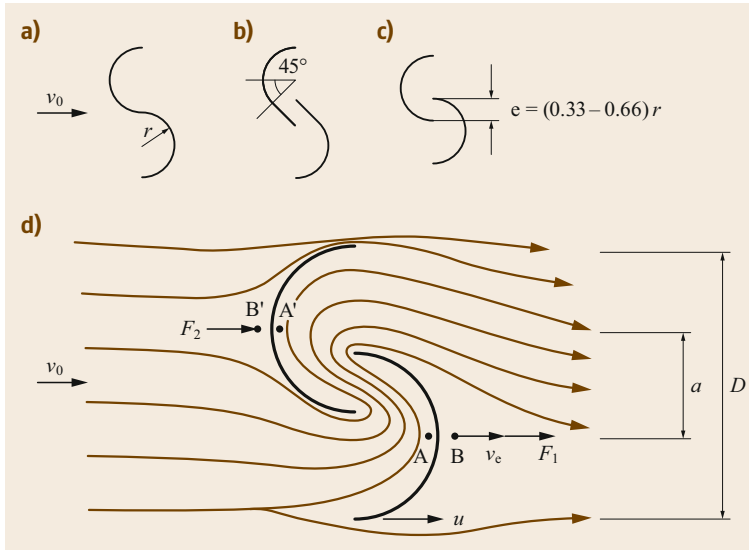

The Savonius rotor will be considered more closely as an example of a low-speed rotor that works predominantly according to the principle of drag. As Fig. 2.80 shows, power coefficients of 0.2–0.25 are achieved, i.e., at best 25% of the maximum theoretical wind power.

**Structure.** The vertical-axis Savonius rotor originally consists of two semi-circular cylinders as shown in Fig. 2.88a and is then a pure drag-type rotor. The split Savonius rotor (Fig. 2.88b,c) achieves a better power coefficient due to the contribution of the lift forces, that are also effective.

Fig. 2.88d shows the airflow in the split rotor. Due to the different resistance coefficients,  $F_2 < F_1$  and setting  $F = F_1 - F_2$ , the torque is  $M = F - a/2$ . Splitting the rotor gives a higher value  $F$  than in the case of the undivided rotor.

**Fig. 2.87a,b** Depiction of the airfoil theory of the Darrieus rotor. (a) Airfoil of the Darrieus rotor. (b) Cut  $\overline{AB}$

**Fig. 2.88a–d** Savonius rotor (a) pure drag turbine, (b) and (c) improved variants with drag and lift (split Savonius), (d) airflow path for rotor (c)

**Power Output.** The power can be expressed by

$$P = M\omega = M \frac{2u}{D} = M \frac{2v_c}{a} = Fv_c. \quad (2.146)$$

Using (2.117) and (2.118), the force is

$$F_{th} = c \frac{1}{2} \rho A (v_0 - v_c)^2, \quad (2.147)$$

where  $A = DH$ , with  $H$  = effective height of the rotor. In the case of the drag-type rotor (Fig. 2.88a),  $c = c_w$ , with  $c_w = 2.3$  for the concave and  $c_w = 1.2$  for the convex side [2.30, 35], that results in a total of  $c_w = 1.1$ .

For the theoretical power,

$$P_{th} = F_{th}v_c = c \frac{1}{2} \rho \frac{1}{2} \rho A v_c (v_0 - v_c)^2, \quad (2.148)$$

and, for the *ideal coefficient of power*

$$\begin{aligned} c_p &= \frac{P_{th}}{P_0} = \frac{c \frac{1}{2} \rho A (v_0 - v_c)^2}{\frac{1}{2} \rho A v_0} \\ &= c \frac{v_c}{v_0} \left( 1 - \frac{v_c}{v_0} \right)^2. \end{aligned} \quad (2.149)$$

The speed ratio  $v_c/v_0$  can be expressed as a function of the tip speed ratio using the geometry factor  $\beta$

$$\beta = \frac{D}{a} = \frac{u}{v_c}, \quad \rightarrow \quad \frac{v_c}{v_0} = \frac{u}{v_0} \frac{v_c}{u} = \frac{\lambda}{\beta}. \quad (2.150)$$

Thus it follows that (Fig. 2.89)

$$c_p = \frac{\lambda}{\beta} \left( 1 - \frac{\lambda}{\beta} \right)^2. \quad (2.151)$$

The optimal value is  $\lambda = \beta/3$  with  $c_p/c = 4/27 = 0.148$ . For the rotor in Fig. 2.88a,  $\beta = 2$  and therefore  $\lambda_{opt} = 0.67$ . In rotors like that in Fig. 2.88c, it is more likely that  $\beta \approx 2.5 \rightarrow \lambda_{opt} \approx 0.83$ . The Savonius rotor clearly belongs to the slow-speed category.

The effective power is

$$P = \frac{c_p}{c} c \eta_t P_0 \quad \rightarrow \quad P_{max} \approx 0.15 c \eta_t P_0. \quad (2.152)$$

With good design and build,  $c \eta_t$  is approximately 1.5.

**Fig. 2.89** Ideal power coefficient of the Savonius rotor

**Torque.** From the power,

$$M = \frac{P}{\omega} = P \frac{D}{2u} = P \frac{D}{2\lambda v_0} = \frac{c_p}{c} c \eta_t \frac{D}{\lambda 2 v_0} P_0$$

$$\rightarrow M = \left(1 - \frac{\lambda}{\beta}\right)^2 M_A, \text{ with } M_A = c \eta_t \frac{D}{\beta 2 v_0} P_0, \quad (2.153)$$

where  $M_A$  is the starting torque ( $\lambda = 0$ ).

An advantage of drag-type rotors is that they have a high starting torque and are therefore able to start up and produce electricity even in weak winds.

### Exercise 2.2

Configure a Savonius rotor for an output of 300 W at the optimum wind speed of 6 m/s. Choose  $\beta = 2.5$ ,  $\rho = 1.2 \text{ kg/m}^3$ ,  $c \eta_t = 1.5$ .

- Find the following:
  - The specific power per  $\text{m}^2$  at 6 m/s
  - The diameter and height of the rotor
  - The rated rotation speed of the system.
- From what wind speed  $v_{0\min}$  is power supplied? What is the starting torque at  $v_{0\min}$ ? Draw the power as a function of wind speed  $v_0$  at rated rotation speed.

A solution can be found in [2.9, Annex F].

## 2.8.6 Operation and Control, Design

### Performance and Operating Modes

Fig. 2.90 shows the power actually produced by a given wind turbine with area  $A$  as a function of wind speed:

*Curve a:* Theoretical wind power

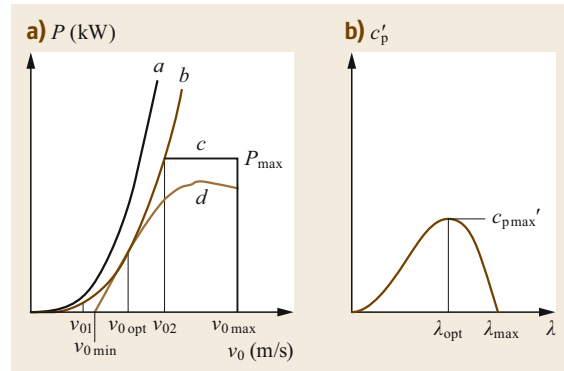

$$P_0 = \frac{1}{2} \rho A v_0^3. \quad (2.154)$$

*Curve b:* Wind-turbine power at maximum efficiency

$$P = c_{p\max}' P_0. \quad (2.155)$$

*Curve c:* Effective wind-turbine power when operating at optimized rotation speed. At the minimum wind speed  $v_{01}$ , the power plant begins to supply energy. Between  $v_{01}$  and  $v_{02}$ , rotation speed control ensures optimum adaptation to the wind speed

$$\omega_{\text{opt}} = \frac{\lambda_{\text{opt}}}{R} v_0, \quad (2.156)$$

**Fig. 2.90** (a) Power of the wind power plant: *a* theoretical wind power, *b* wind-turbine power at maximum efficiency, *c* effective power at optimized speed, *d* effective power at constant speed. (b) Effective power coefficient as a function of the tip speed ratio

that complies with (2.155). For  $v > v_{02}$  the maximum allowable power  $P_{\max}$  is reached and power control is implemented, so that  $P = P_{\max}$ . The speed  $v_{02}$  is usually approximately 15 m/s in modern plants. If the maximum permissible wind speed  $v_{0\max}$  is exceeded, the power plant is switched off (mechanical safety).

*Curve d:* effective wind turbine power at constant rotation speed operation. At the freely selected optimum wind speed  $v_{0\text{opt}}$ , the maximum efficiency is achieved. The corresponding rotation speed is ( $R =$  radius of the wind turbine)

$$\omega = \frac{v_{0\text{opt}} \lambda_{\text{opt}}}{R}$$

$$\rightarrow n = 30 \frac{\omega}{\pi} = 30 \frac{v_{0\text{opt}} \lambda_{\text{opt}}}{\pi R}. \quad (2.157)$$

For other wind speeds, the power decreases according to  $c'_p(\lambda)$ . The wind turbine delivers energy from  $v_{0\min}$  according to the tip speed ratio  $\lambda_{\max}$ .

For a given location with a given wind frequency distribution, the annual energy produced reaches a value

**Fig. 2.91** Optimum wind speed or rotation speed

that depends on the choice of the optimal wind speed, as illustrated in Fig. 2.91. For a certain value of  $v_{0opt}$ , this energy becomes maximum. Whether this value also represents an economic optimum depends on the cost figure as a function of the selected rotation speed (gearbox investment and losses, rotor blade strength, etc.).

### Power Regulation

A distinction is made between systems with *stall control* and systems with *pitch control* (blade angle control) [2.35, 36]. In horizontal-axis rotors, the power factor at a given rotation speed depends not only on the wind speed but also on the angle of attack of the profile (blade angle), as illustrated in Fig. 2.84.

In stall-controlled systems, the blade angle is fixed over the entire speed range up to  $v_{0max}$ . The power limiting is effected by the geometry of the rotor blade, that is aerodynamically designed in such a way that, on reaching the speed  $v_{02}$ , turbulences arise, leading to a stall. Thus a power curve is achieved approximately similar to curve *d* in Fig. 2.90. Stall control avoids the relatively complicated blade-angle control mechanism. Approximately two-thirds of the installed systems have stall control [2.35] (<http://www.windpower.dk/en>). The stall control is called active if the rotor blades have several fixed positions that are selected according to the wind speed.

The blade angle control automatically searches for the optimum angle of attack at a given wind speed, as shown in Fig. 2.84. This enables the power coefficient at the given speed to be maximized with the appropriate outlay. When the maximum permissible power  $P_{max}$  is reached, the power is kept constant. The maximum possible power coefficient corresponding to curve *c* in Fig. 2.90 can only be obtained with variable rotation speed.

### Grid Operation

The electricity produced is fed into the power grid. The simplest and cheapest scheme is shown in Fig. 2.92. The wind turbine drives an asynchronous generator via a gearbox. The power supplied to the grid is

$$P_c = \eta_c \eta_m P = \eta_c \eta_m c'_p P_0. \tag{2.158}$$

Fig. 2.92 Simplest wind energy system (Gt: gearbox, G: generator)

Fig. 2.93 Wind energy system with optimized speed (Gt: Gearbox, G: Generator, U: Converter, R: speed governor)

Asynchronous generators are inexpensive and robust, but they cannot deliver reactive power without the use of capacitors. For higher powers, therefore, a synchronous generator is preferred. In both cases

$$\begin{aligned} \text{Generator speed } n_i &= 60 \frac{f}{p} \\ (p &= \text{number of pole pairs}), \\ \text{Gear ratio } \ddot{u} &= \frac{n_1}{n} = \frac{2\pi f R}{p v_{0opt} \lambda_{opt}} \end{aligned} \tag{2.159}$$

and the delivered power corresponds essentially to curve *d* in Fig. 2.90, the rotation speed being constant (dictated by the grid frequency).

Power according to curve *c* in Fig. 2.90 is possible, but requires the use of a frequency converter, e.g., as shown in Fig. 2.93. By controlling the frequency conversion, the rotation speed is kept optimal. The higher energy yield must be earned through higher investments. It should also be noted that the energy gain from the higher average efficiency of the wind turbine is somewhat reduced by the losses in the converter (lower electrical efficiency).

In addition to the solution shown in Fig. 2.93, solutions with wound-rotor asynchronous machines are also available, in which the converter changes the frequency of the rotor current. The converter power required for this is considerably smaller [2.35, 37].

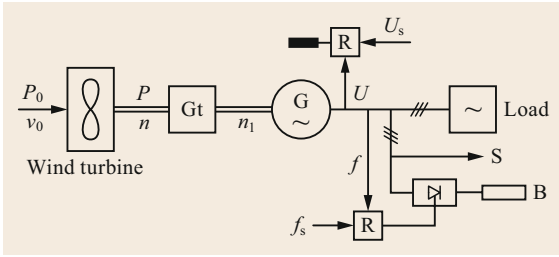

### Island Operation

Normally, the consumer requires a constant frequency and a constant voltage (exception: heating resistors). The most suitable generator is then a synchronous generator, that allows voltage regulation via the excitation [2.3, Sect. 1.1]. An asynchronous generator with regulated capacitor battery is also possible.

Since wind energy supply is very variable, storage facilities and/or ballast resistors must be provided for frequency control (Fig. 2.94). The rotation speed changes according to

$$M - M_b = J \frac{d\omega}{dt}. \tag{2.160}$$

**Fig. 2.94** Wind energy system in island operation: Gt: Gearbox, G: Generator, R: Regulator, S: Storage (flywheel, pump storage, accumulator), B: Ballast resistor (sewage treatment plant, storage heating)

The graph of the drive torque  $M$  as a function of rotation speed and wind speed is shown in Fig. 2.95 ( $n_s =$  synchronous rotation speed).

The load torque  $M_b$  must be adjusted accordingly. Its value depends on the nature of the load and on

**Fig. 2.95** Torque characteristic of a wind turbine  $M = f(n, v_0)$

the voltage–frequency characteristic. Operation with optimized rotation speed is also possible with a converter.

## 2.9 Photovoltaics

In this section, the basics of photovoltaics (photoelectric effect) and solar cells (structure, types, characteristics, efficiencies) are given. To use them optimally requires knowledge of the radiation intensity and thus the calculation of the apparent movement of the Sun relative to the Earth.

### 2.9.1 Physical Basics, Photoelectric Effect

The behavior of semiconductors and insulators can be well explained by the *energy-band model* [2.38, 39]. For the photoelectric effects, only the *valence band* with upper energy level  $W_V$  and the *conduction band* with lower energy level  $W_L$  play a role (Fig. 2.96a). The two bands are separated by a band gap  $\Delta W = W_L - W_V$  that is, e.g., 1.12 eV for silicon. The density of states  $Z(W)$  of the electron energy  $W$  within the bands is described by a parabola. According to Pauli’s exclusion principle, the probability of occurrence of an energy state results from multiplication with Fermi–Dirac statistics (Fig. 2.96b)

$$F(W) = \frac{1}{1 + \exp\left(\frac{W - W_F}{kT}\right)}, \quad (2.161)$$

where  $W_F$  is the Fermi energy and  $k$  is the Boltzmann constant

$$k = 8.62 \times 10^{-5} \frac{\text{eV}}{\text{K}} = 1.30805 \times 10^{-23} \frac{\text{J}}{\text{K}}. \quad (2.162)$$

Integrating over the conduction band gives the electron density [2.38, 40]

$$n = \int_{W_L}^{\infty} F(W)Z(W)dW \approx N_L \exp\left(-\frac{W_L - W_F}{kT}\right)$$

$$\text{with } N_L = 2 \left(\frac{2\pi m_n kT}{h^2}\right)^{\frac{3}{2}} \quad (2.163)$$

and

$$h = \text{Planck’s constant} = 6.6256 \times 10^{-34} \text{ J s}$$

$$m = \text{electron mass} = 0.9109 \times 10^{-27} \text{ g}. \quad (2.164)$$

**Fig. 2.96a,b** Band model of the semiconductor. (a) Density of possible energy states within the valence and conduction band,  $\Delta W =$  band gap (forbidden zone), (b) Fermi–Dirac statistics for the probability of occurrence of an energy state

**Fig. 2.97** Influence of temperature on the Fermi–Dirac distribution

The effective mass  $m_n$  of the electron differs somewhat from the rest mass due to the effect of the potential of the solid-state lattice  $m$  [2.39]. While the band gap  $\Delta W$  is of the order of 1 eV for semiconductors, it is significantly larger for insulators. The Fermi level is located in the middle of the forbidden zone.

For  $T = 0$  K,  $n = 0$  according to (2.163), that is, there are no electrons in the conduction band (sharp Fermi level). The higher the temperature, the more the Fermi level becomes blurred (Fig. 2.97). At room temperature, a few electrons get into the conduction band. At 20 °C, for example,  $4kT \approx 0.1$  eV, and for silicon with  $\Delta W = 1.12$  eV, (2.163) gives  $n = 5.7 \times 10^9$  electrons/cm<sup>3</sup>. At first sight this may seem a lot, but silicon has a density of 2.33 g/cm<sup>3</sup> and an atomic weight of 28. Thus, the number of atoms per cm<sup>3</sup> is (Avogadro)

$$6 \times 10^{23} \frac{2.33}{28} = 5 \times 10^{22} \frac{\text{atoms}}{\text{cm}^3} \left( \frac{\text{atoms g/cm}^3}{\text{mol g/mol}} \right).$$

Thus, only about one electron in  $10^{13}$  silicon atoms is in the conduction band. Accordingly, the *intrinsic conductivity* of silicon at 20 °C is very low.

### Photoconductivity

When light falls on a thin semiconductor wafer of surface area  $A$  and thickness  $d$ , the energy level of electrons is raised by the absorption of photons (light quanta) and, as long as the photons have an energy of  $hf > \Delta W$ , electrons from the valence band are lifted into the conduction band. In *direct* semiconductors [2.40], such as GaAs, layers of only a few  $\mu\text{m}$  are needed to completely absorb the radiation. In *indirect* semiconductors, such as crystalline silicon, on the other hand, several hundred  $\mu\text{m}$  (200  $\mu\text{m}$  for 90% absorption) are required.

The electrons of the conduction band move freely in the crystal and form the negatively charged electron

**Fig. 2.98** Spectral intensity  $S_\lambda$  of solar radiation

flow. This makes it possible to convert radiant energy into electrical energy (photoelectric effect). Gaps (holes) remaining in the valence-band can also move by the movement of neighboring electrons that forms the positive current. The *recombination* of electrons with holes, counteracts the proliferation of conduction band electrons, so that an equilibrium state is established. The number of electrons in the conduction band increases according to the law

$$\frac{dn}{dt} = \eta \varphi_q \frac{1}{Ad} - \frac{n}{\tau}, \quad (2.165)$$

where:

$\varphi_q$  photon flux (photons/s)

$\eta$  quantum efficiency

$\tau$  recombination time of electron–hole pairs.

The stationary solution of this differential equation is

$$n = \eta \varphi_q \frac{\tau}{Ad} \left( \frac{\text{electrons}}{\text{m}^3} \right). \quad (2.166)$$

From the spectral intensity  $S_\lambda$  of the radiation falling perpendicular to the surface (Fig. 2.98), the photon flux can be calculated

$$S_\lambda d\lambda \left( \frac{\text{W}}{\text{m}^2} \right) = \frac{d\varphi_q}{A} hf \left( \frac{\text{photons}}{\text{m}^2 \text{ s}} \frac{\text{W s}}{\text{photons}} \right). \quad (2.167)$$

Since  $f = c/\lambda$  ( $c$  = speed of light),

$$d\varphi_q = \frac{A}{hc} S_\lambda \lambda d\lambda. \quad (2.168)$$

If photons of wavelength  $\lambda$  have an efficiency  $\eta_\lambda$ , then

$$\eta \varphi_q = \frac{A}{hc} \int_0^\infty \eta_\lambda S_\lambda \lambda d\lambda. \quad (2.169)$$

Inserting this into (2.166), leads to the *intrinsic conductivity* of the irradiated semiconductor.

### The p-n Junction

By implanting foreign atoms (*doping*), the conductivity of the semiconductor can be influenced. This is known as *impurity conduction*.

If the valence electron number of the foreign atoms is greater than that of the semiconductor material (e.g., pentavalent P in tetravalent Si), the excess electrons in the crystal can detach themselves from the impurity and increase the conductivity of the semiconductor. The foreign atoms in this case are called *donors*. The semiconductor doped in this way has *n-conductivity*, i.e., the electrons are majority carriers, the holes minority carriers.

Conversely, if the foreign atoms have fewer valence electrons (e.g., trivalent boron), then we speak of *acceptors* and of *p-conductivity*, the number of holes being increased. The holes are majority carriers and the electrons minority carriers.

If a p-n junction is formed according to Fig. 2.99a, then, as consequence of the different concentrations of the charge carriers, there is a *diffusion of the majority carriers*, i.e., of the electrons from n to p and of the holes from p to n. In the boundary layer, the now ionized donors and acceptors remain behind, forming a potential barrier that stops the diffusion current. This produces the diffusion voltage  $U_D$  (Fig. 2.99c), with the

value (for further details see [2.30, 39, 40])

$$U_D = \frac{kT}{e} \ln \frac{n_n}{n_p}, \quad (2.170)$$

where:

$n_n$  density of the n-majority carriers  
 $n_p$  density of the p-minority carriers  
 $e$  electron charge ( $1.6021 \times 10^{-19}$  A s).

In terms of energy, the bands on the n-side are lowered by  $eU_D$ , as shown in (Fig. 2.99b), with

$$eU_D = \Delta W - \delta_n - \delta_p, \quad (2.171)$$

where  $\delta_n$  and  $\delta_p$  are the distances between the conduction and valence bands and the Fermi level. With increased doping, these distances become smaller and smaller, and in the case of high doping, we get

$$U_D \approx \frac{\Delta W}{e}. \quad (2.172)$$

The thickness of the space charge zone is [2.40]

$$x = \sqrt{\frac{2\varepsilon U_D (n_D + n_A)}{en_D n_A}}, \quad (2.173)$$

where  $n_D$  and  $n_A$  are the densities of donors and acceptors.

### 2.9.2 Photovoltaic Effect, Photocurrent

When an external voltage  $U$  is applied, a p-n junction acts as a diode (Fig. 2.100a). The result is the characteristic curve in Fig. 2.100b. For  $U < 0$ , the potential barrier is increased and the diffusion is reversed. The diode blocks the flow of current. The thermally generated electrons are sucked off and generate the saturation current  $I_s$  in the reverse direction [2.38]

$$I_s \propto T^3 \exp\left(-\frac{U_D}{U_T}\right). \quad (2.174)$$

For  $U > 0$ , the potential barrier is reduced, diffusion is favored and the current flows, where

$$I_d = I_s \left[ \exp\left(\frac{U}{U_T}\right) - 1 \right]$$

$$U_T = \frac{kT}{e} = \text{thermodynamic voltage}$$

$$= 25.7 \text{ mV at } 25^\circ \text{C}. \quad (2.175)$$

**Fig. 2.99** (a) p-n junction, (b) energy-band scheme, (c) potential curve

**Fig. 2.100** (a) p-n junction as diode, (b) characteristic current–voltage curve

If the p-n junction is irradiated with photons with  $hf > \Delta W$  (Fig. 2.101), electrons jump from the valence band into the conduction band. Since there is a potential gradient in the space charge zone, the electrons migrate via the external electrical connection to the positive pole (n-region) and the holes to the negative pole (p-region). This results in an opposite flow to the diffusion flow, the *photocurrent*. However, only the electron–hole pairs directly formed in the boundary layer contribute to the photocurrent, since the others recombine before they can be separated by the potential gradient. The radiation must therefore be brought as close as possible to the boundary layer (Fig. 2.101). For details on the structure of the solar cell, see [2.39, 40].

The resulting photocurrent  $I_{ph}$  is *proportional to the irradiance*. From (2.175), the total current in the conducting direction of the diode is

$$I^* = I_s \left[ \exp\left(\frac{U}{U_T}\right) - 1 \right] - I_{ph} .$$

The diode characteristic decreases by  $I_{ph}$  as illustrated in Fig. 2.102. In the 4th quadrant, the arrangement works as a *generator* (solar cell). The current generated by the *solar cell* is  $I = -I^*$

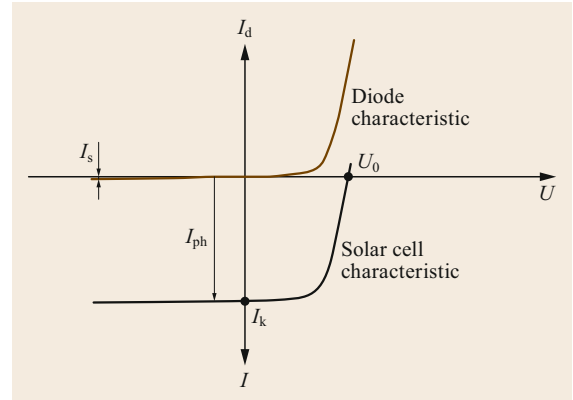

$$I = I_{ph} - I_s \left[ \exp\left(\frac{U}{U_T}\right) - 1 \right] . \tag{2.176}$$

*Short-circuiting* the solar cell ( $U = 0$ ), gives, in the ideal case

$$I = I_k = I_{ph} . \tag{2.177}$$

**Fig. 2.101** Irradiated solar cell

**Fig. 2.102** Formation of the solar-cell characteristic curve by irradiation of the p-n junction

With *no load* ( $I = 0$ ), (2.176) yields

$$U = U_0 = U_T \ln \left( 1 + \frac{I_{ph}}{I_s} \right) . \tag{2.178}$$

The short-circuit current is equal to the photocurrent and thus proportional to the irradiance, while the open-circuit voltage has a logarithmic curve as a function of the irradiation (Fig. 2.103). Through  $U_T$  (2.175) and  $I_s$  (2.174) the temperature has a big influence on the open-circuit voltage in such a way that it decreases with increasing temperature. Rising temperature thus reduces the performance of the solar cell. The short-circuit current, on the other hand, is only slightly influenced by the temperature (Fig. 2.110).

**Fig. 2.103** Dependence of short-circuit current and open-circuit voltage of the solar cell on irradiation intensity

### Calculation of the Photocurrent

For spectral intensity  $S_\lambda$  as in Fig. 2.98 and according to (2.168), the photon flux for wavelengths between  $\lambda$  and  $\lambda + d\lambda$  is

$$d\varphi_q = \frac{A}{hc} S_\lambda \lambda d\lambda \left( \frac{\text{photons}}{\text{s}} \right). \quad (2.179)$$

The number of electrons contributing to the photocurrent is smaller, because of the losses.

$$dn = \eta_\lambda d\varphi_q = \frac{A}{hc} n_\lambda S_\lambda \lambda d\lambda \left( \frac{\text{electrons}}{\text{s}} \right). \quad (2.180)$$

The efficiency  $\eta_\lambda$  takes into account that:

- *Photons are lost* through reflection, transmission and thermalization.
- Some of the generated electron–hole pairs *recombine* before they are separated by the potential gradient.

The photocurrent is then

$$dI_{\text{ph}} = edn = en_\lambda d\varphi_q = \frac{e}{hc} A \eta_\lambda S_\lambda \lambda d\lambda \quad (\text{A}),$$

and the photocurrent density

$$dJ_{\text{ph}} = \frac{e}{hc} n_\lambda S_\lambda \lambda d\lambda \quad \left( \frac{\text{A}}{\text{m}^2} \right).$$

Integrating over the whole spectrum, the photocurrent density is obtained as

$$J_{\text{ph}} = \frac{e}{hc} \int_0^\infty \eta_\lambda S_\lambda \lambda d\lambda \quad \left( \frac{\text{A}}{\text{m}^2} \right). \quad (2.181)$$

The power density of the radiation is, on the other hand,

$$P_s = \int_0^\infty S_\lambda d\lambda \quad \left( \frac{\text{W}}{\text{m}^2} \right). \quad (2.182)$$

The spectral response of the solar cell is defined as

$$\varepsilon = \frac{J_{\text{ph}}}{P_s} = \frac{\int_0^\infty n_\lambda S_\lambda \lambda d\lambda}{\int_0^\infty S_\lambda d\lambda} \quad \left( \frac{\text{A}}{\text{W}} \right). \quad (2.183)$$

Overcoming the band gap  $\Delta W$  is only possible for radiation with

$$hf = h \frac{c}{\lambda} > \Delta W.$$

The radiation is therefore only effective if

$$h < \frac{hc}{\Delta W} = \lambda_{\text{max}}, \quad (2.184)$$

$\lambda_{\text{max}}$  depends on the semiconductor material. For example, for silicon, it is, e.g.,  $\Delta W = 1.12$  eV, from which  $\lambda_{\text{max}} = 1.11 \mu\text{m}$ . For  $\lambda > \lambda_{\text{max}}$ ,  $\eta_\lambda = 0$  because the photons do not provide enough energy to overcome the band gap. The corresponding energy is thermalized. Therefore

$$\int_0^\infty \eta_\lambda S_\lambda \lambda d\lambda = \int_0^{\lambda_{\text{max}}} \eta_\lambda S_\lambda \lambda d\lambda,$$

and the spectral response can also be expressed as follows

$$\varepsilon = \frac{e}{hc} \frac{\int_0^{\lambda_{\text{max}}} S_\lambda d\lambda}{\int_0^\infty S_\lambda d\lambda} \frac{\int_0^{\lambda_{\text{max}}} \lambda S_\lambda d\lambda}{\int_0^{\lambda_{\text{max}}} S_\lambda d\lambda} \frac{\int_0^{\lambda_{\text{max}}} \eta_\lambda S_\lambda \lambda d\lambda}{\int_0^{\lambda_{\text{max}}} \lambda S_\lambda d\lambda}, \quad (2.185)$$

or written in shorter form as

$$\varepsilon = \frac{e}{hc} \eta_1 \lambda_0 \eta_3. \quad (2.186)$$

Discussion of the individual factors: The first factor is a constant

$$\frac{e}{hc} = 0.807 \frac{\text{A}}{\text{W} \mu\text{m}}. \quad (2.187)$$

The efficiency parameter  $\eta_1$  takes into account losses for  $\lambda > \lambda_{\text{max}}$  (*thermalization* of the corresponding photon energy). It is a function of the solar spectrum and the band gap of the semiconductor material. It increases with decreasing band gap. The guideline value for silicon is  $\eta_1 \approx 0.75$ , i.e., around 25% of the solar energy lies in the wavelength range above  $\lambda_{\text{max}}$ . With monochromatic light of wavelength  $\lambda_{\text{max}}$ , it would be  $\eta_1 \approx 1$ .

The wavelength  $\lambda_0$  is proportional to the ratio between the number of photons in the range  $0 - \lambda_{\text{max}}$  and the corresponding radiation energy ((2.181) and (2.182)). For  $\lambda = \lambda_{\text{max}}$ , the photon energy is just enough to overcome the band gap and is fully transferred to the electrons. For  $\lambda < \lambda_{\text{max}}$ , it is too large, and the excess energy is *thermalized*. The corresponding losses can be represented by the efficiency factor  $\eta_2$

$$\lambda_0 = \eta_2 \lambda_{\text{max}},$$

$$\longrightarrow \int_0^{\lambda_{\text{max}}} \lambda S_\lambda d\lambda = \eta_2 \lambda_{\text{max}} \int_0^{\lambda_{\text{max}}} S_\lambda d\lambda,$$

$$\text{thus, } \varepsilon = \frac{e}{hc} \lambda_{\text{max}} \eta_1 \eta_2 \eta_3. \quad (2.188)$$

**Fig. 2.104** Spectral radiation distribution of sunlight. AM0: Radiation characteristic outside the Earth's atmosphere; AM2: Radiation characteristic with atmosphere ( $2\times$  atmosphere thickness at the equator, with the sun at zenith and 0 m altitude); the calculations mostly refer to AM1.5 ( $1.5\times$  atmosphere thickness) (adapted from [2.39])

If the solar cell were irradiated with monochromatic light of wavelength  $\lambda_{\max}$ , this would give  $\eta_2 = 1$ . With the solar spectrum AM1.5 (Fig. 2.104), the guide value for monocrystalline silicon is  $\eta_2 \approx 0.66$ . This means that for silicon  $\eta_1\eta_2 \approx 0.49$  so 51% of the solar energy cannot be used because of the spectral composition of sunlight. The product  $\eta_s = \eta_1\eta_2$  is therefore also called the spectral efficiency of the solar cell.

The efficiency  $\eta_3$  is proportional to the ratio between useful electrons and photons in the range  $0-\lambda_{\max}$  according to (2.179) and (2.180). It therefore takes into account *photon losses* and *recombination losses*. This efficiency depends on the state of solar cell technology. For silicon solar cells with an overall efficiency of 15%, it is likely to be  $\eta_3 \approx 0.75$ . Theoretically, the limit is one, so that a further increase can be expected if the technology is improved.

With monochromatic light of wavelength  $\lambda_{\max}$  and  $\eta_3 = 1$ , the theoretically maximum attainable spectral response would be

$$\varepsilon_{\max} = \frac{e}{hc}\lambda_{\max} = \frac{e}{hf_{\min}} = \frac{e}{\Delta W} \quad (2.189)$$

It is therefore inversely proportional to the band gap energy  $\Delta W$ . For silicon, one obtains  $\varepsilon_{\max} = 0.89 \text{ A/W}$ . The equation can finally be written as

$$\varepsilon = \varepsilon_{\max}\eta_1\eta_2\eta_3 \left( \frac{\text{A}}{\text{W}} \right) \quad (2.190)$$

With the reference numbers mentioned, e.g., for crystalline silicon

$$\varepsilon \approx 0.89 \times 0.75 \times 0.66 \times 0.75 = 0.33 \frac{\text{A}}{\text{W}} \quad (2.191)$$

From the spectral response, the photocurrent density and photocurrent of the solar cell are

$$\begin{aligned} J_{\text{ph}} &= \varepsilon P_s \left( \frac{\text{A}}{\text{m}^2} \right) \\ I_{\text{ph}} &= \varepsilon P_s A \quad (\text{A}), \end{aligned} \quad (2.192)$$

where  $P_s$  is the radiation power ( $\text{W/m}^2$ ) and  $A$  is the active semiconductor area ( $\text{m}^2$ ).

Since  $\eta_3$  can theoretically be increased to one, the upper limit of the spectral response for silicon when irradiated with the AM1.5 solar spectrum is  $\varepsilon_{\text{th}} \approx 0.44 \text{ A/W}$ .

Figure 2.105 shows the maximum possible current density ( $\eta_3 = 1$ ) with an AM0 and AM1.5 spectrum and  $P_s = 1000 \text{ W/m}^2$  as a function of the band-gap energy of the semiconductors

$$J_{\max} = \varepsilon_{\text{th}} P_s = \varepsilon_{\max} \eta_s P_s \quad (2.193)$$

The spectral efficiency is derived from (2.193) as

$$\eta_s = \frac{J_{\max}}{\varepsilon_{\max} P_s} = \frac{J_{\max} \Delta W}{P_s e} \quad (2.194)$$

It is shown in Fig. 2.106 as a function of band gap energy for irradiation of semiconductors with AM0 and AM1.5 and  $1000 \text{ W/m}^2$ .

### 2.9.3 Solar Cell, Overall Efficiency

#### Characteristic Curve and Equivalent Circuit

The characteristic curve of the solar cell and how it arises are shown in Fig. 2.102. Figure 2.107 shows a typical *real* (measured) characteristic curve for a cer-

**Fig. 2.105** Maximum current density as a function of the band gap ( $\eta_3 = 1$ ) [2.41]

**Fig. 2.106** Spectral efficiency as a function of band gap (adapted from [2.41])

tain radiation intensity with the most important characteristic values. The maximum power is reached at point P. The solar cell should therefore be operated as close as possible to this point (MPP) by adjusting the load resistance.

The characteristic curve can be well described qualitatively with the equivalent circuit of Fig. 2.108, which is analyzed in the following. More accurate models are discussed in [2.9, Sect. 8.5.5].

The photocurrent is proportional to the irradiation intensity, and is simulated by a current source. According to (2.176), the difference between the photocurrent and diode current is theoretically the useful current of the solar cell. The equivalent circuit also takes into account that leakage currents cannot be avoided (parallel

resistance  $R_p$ ) and that ohmic losses occur at transition points and in the contacts (series resistance  $R_s$ ).

The size and effect of the two resistors on the characteristic curve of the solar cell can be determined by idealizing the diode characteristic curve with  $U_{d0}$  and  $R_d$  as in Fig. 2.109. It has proved useful to define the diode resistance as the differential resistance at half the photocurrent.

From (2.175), for  $I_d \gg I_s$  and with  $A =$  ideality factor (2.198)

$$U_d = AU_T \ln \left( \frac{I_d}{I_s} \right)$$

$$R_d(I_{ph}) = \left( \frac{dU_d}{dI_d} \right)_{I_{ph}/2} = \frac{2AU_T}{I_{ph}}. \quad (2.195)$$

**Fig. 2.107** Real characteristic curve of a solar cell ( $U_0$ : open-circuit voltage,  $I_k$ : short-circuit current, P: point of maximum power (MPP maximum power point),  $R_p$ : parallel resistance,  $R_s$ : series resistance,  $R_d$ : diode resistance)

**Fig. 2.108** Equivalent circuit diagram of the solar cell (single-diode model)

The *no-load range* of the solar cell (diode conducting) can then be approximated by the straight line

$$U = U_0 - \left( R_s + \frac{R_p R_d}{R_p + R_d} \right) I$$

with  $U_0 = \frac{R_p}{R_p + R_d} (U_{d0} + R_d I_{ph})$ . (2.196)

The corresponding resistance line is shown in Fig. 2.107.

For the *short-circuit range* of the solar cell (diode blocking), the idealized characteristic curve follows, since  $U_d \leq U_{d0}$  and  $I_d = 0$ , giving

$$U = (R_p + R_s) (I_k - I)$$

with  $I_k = \frac{R_p}{R_p + R_s} I_{ph} \approx I_{ph}$ . (2.197)

The corresponding resistance line is also shown in Fig. 2.107. The two resistance lines intersect at P'. The values  $R_s$  and  $R_p$  can be calculated from the experimentally determined characteristic curve.

Figure 2.110 shows the typical characteristic curves of a silicon cell as functions of radiation intensity and

**Fig. 2.109** Diode characteristic curve and its idealization

temperature. Noteworthy for the control of the solar cell is that the optimum voltage (MPP) weakly depends on the irradiation and the optimal current weakly depends on the temperature.

From the equivalent circuit in Fig. 2.108 it follows, by also adding a parallel capacitance, a dynamically satisfactory simulation circuit for the solar cell, that is described by (2.198). The values  $I_{ph}$ ,  $I_s$  and  $U_T$  are temperature-dependent, and also the temperature dependency of  $R_s$  and  $R_p$  can be taken into account. The diode characteristic curve is described more accurately by introducing the ideality factor  $A$  (usually  $A = 1-1.5$ )

$$I_{ph} = I_d + I_c + I_p + I,$$

$$I_d = I_s \left( \exp \left( \frac{U_d}{A U_T} \right) - 1 \right),$$

$$I_c = C \frac{dU_d}{dt},$$

$$U_d = R_p I_p,$$

$$U = U_d + R_s I. \quad (2.198)$$

### Open-Circuit Voltage

From (2.174), (2.116) and (2.122), for  $I_{ph} \gg I_s$

$$U_0 = U_T \ln \left( 1 + \frac{I_{ph}}{I_s} \right) \approx U_T \ln \left( \frac{I_{ph}}{I_s} \right)$$

$$I_s = K_s(T) \exp \left( -\frac{U_D}{U_T} \right) \quad \text{with } U_D = \frac{\Delta W}{e}$$

$$\rightarrow U_0 = \left[ 1 - \frac{U_T e}{\Delta W} \ln \left( \frac{K_s(T)}{I_{ph}} \right) \right] \frac{\Delta W}{e}$$

$$= \eta_4 \frac{\Delta W}{e} = \frac{\eta_4}{\varepsilon_{\max}}. \quad (2.199)$$

Fig. 2.111 shows the open-circuit voltage  $U_0$  and the efficiency  $\eta_4$  (also called the voltage factor) as a function of the band gap for 25 °C and for an ideal solar cell.

**Fig. 2.110** Typical current–voltage characteristics of a silicon solar cell as a function of irradiation and temperature (adapted from [2.36])

**Fig. 2.111** Open-circuit voltage  $U_0$  and efficiency  $\eta_4$  (voltage factor) of an ideal solar cell as a function of the band gap for 25 °C (adapted from [2.41])

The open-circuit voltage  $U_0$  can theoretically reach at most the value of the diffusion voltage, that corresponds to the band gap at a high doping level according to (2.172). In reality, for a real cell or module, the open-circuit voltage is slightly lower. The efficiency  $\eta_4$  is strongly dependent on irradiation intensity and temperature. With the assumptions (2.174) and (2.178) for silicon (with  $\epsilon_{\max} \approx 0.89$  A/W), the dependency is shown in Fig. 2.112. With an irradiation of 1000 W/m<sup>2</sup> and a temperature of 25 °C, an efficiency of  $\eta_4 = 0.54$  was assumed ( $U_0 = 0.6$  V, according to Fig. 2.110).

Concentrating the radiation by a factor of 100 (concentrator cells [2.40]) would increase the efficiency by about 20% (relative), provided the cell temperature

remains the same. A temperature increase causes, as already mentioned, the open-circuit voltage to drop and accordingly reduces the efficiency by approximately 0.3% (relative) per °C.

#### Fill Factor

The *fill factor*  $F$  is the ratio between the product of voltage and current at the optimum point (MPP) and the product of open circuit voltage and short-circuit current

$$F = \frac{U_{\text{opt}} I_{\text{opt}}}{U_0 I_k} \quad (2.200)$$

If  $P$  is replaced by  $P'$  (Fig. 2.107), from the theoretical characteristic curve and with the following generally

**Fig. 2.112** Dependence of  $\eta_4$  (voltage factor) on radiation intensity  $P_s$  and temperature (crystalline silicon) for a solar module

**Fig. 2.113** Idealized fill factor  $F$  of various semiconductors (adapted from [2.41])

good approximation for high irradiation levels,

$$R_s, R_d \ll R_p, \quad R_0 = \frac{U_0}{I_k}, \quad (2.201)$$

the following can be written

$$F < F_{\text{th}} \approx 1 - \frac{R_s + R_d}{R_0} - \frac{R_0 - 2(R_s + R_d)}{R_p}. \quad (2.202)$$

Finally, we introduce the partial efficiency

$$\eta_5 = \frac{R_p}{R_p + R_s} F, \quad (2.203)$$

that takes into account *leakage currents* and *ohmic losses* of the diode and contacts. For good silicon modules, the standard value of  $\eta_5 = 0.75$  can be expected. It is theoretically possible to approach 1. Figure 2.113 shows the idealized fill factor  $F$  (with  $F < F_i$ ) as a function of the bandgap of the semiconductor.

### Overall Efficiency

The efficiency is defined as the ratio of power at the optimal point P (MPP) and radiation power

$$\eta = \frac{U_{\text{opt}} I_{\text{opt}}}{A \int_0^\infty S_\lambda d\lambda} = \frac{U_{\text{opt}} I_{\text{opt}}}{A P_s}. \quad (2.204)$$

**Fig. 2.114** Theoretical maximum efficiency of solar cells (adapted from [2.41])

Introducing the fill factor (2.200) and considering (2.197), as well as the photocurrent (2.192), gives

$$\eta = \frac{R_p}{R_p + R_s} F U_0 \varepsilon . \quad (2.205)$$

According to Sect. 2.9.2 and, in particular, (2.190), the spectral response is

$$\varepsilon = \varepsilon_{\max} \eta_1 \eta_2 \eta_3 .$$

If, in addition, the open-circuit voltage according to (2.199) and the fill factor according to (2.203) are used, the five-factor formula is obtained

$$\eta = \eta_1 \eta_2 \eta_3 \eta_4 \eta_5 . \quad (2.206)$$

With the indicated guide values for silicon modules at  $1000 \text{ W/m}^2$  and  $25^\circ\text{C}$ ,  $\eta \approx 0.75 \times 0.66 \times 0.75 \times 0.55 \times 0.75 = 0.15$ , that corresponds approximately to the efficiency of today's good commercial solar cells. With the assumptions  $\eta_3 = \eta_5 = 1$  the theoretical maximum efficiency is

$$\eta_{\text{th}} = \eta_1 \eta_2 \eta_4 . \quad (2.207)$$

Figure 2.114 shows this efficiency as a function of the bandgap for different semiconductors for AM0 and AM1.5 solar spectrum. For crystalline silicon, the theoretical maximum value is  $\eta_{\text{th}} = 0.28$ . In the laboratory, efficiencies up to approximately 21% or even 23–24% [2.40] have been achieved.

### Possibilities for Improving Efficiency

An increase in efficiency is of great importance from an economic point of view, as it reduces the required area and thus considerably lowers the costs of the photovoltaic system. It can also be allowed to incur a further cost (but not too much). The previously defined theoretical maximum efficiency

$$\eta_{\text{th}} = \eta_1 \eta_2 \eta_4$$

cannot be exceeded and is scarcely achievable with affordable costs. For crystalline silicon at  $1000 \text{ W/m}^2$  and  $25^\circ\text{C}$ , it is approximately 0.28 as mentioned before. To approach this value, the efficiencies  $\eta_3$  and  $\eta_5$  whose product today for commercial modules is approximately 0.56, must be further improved. For this, primarily the *electrical losses* from *recombination* and *ohmic resistance* (there is a good analysis of this in [2.40]) have to be reduced as well as the *leakage losses*. The efficiency  $\eta_3$  is also reduced by *optical losses* (photon losses) in the range  $\lambda = 0 - \lambda_{\max}$ . Antireflection coatings and texturing of the surface (pyramidalization of the silicon surface) reduce reflection and light scattering as much as possible (on the textured surface), reflection on the rear of the solar cell also improves absorption [2.40, 41].

There is the further question of the possibility of increasing the low theoretical efficiency  $\eta_{\text{th}} = \eta_1 \eta_2 \eta_4$  of approximately 28%.

**Radiation Concentration.** The efficiency  $\eta_4$  can be improved by *concentration* of the radiation (Fig. 2.112).

Theoretically, this efficiency increases logarithmically with the radiant power, only to flatten out to one at a very high concentration. With a hundredfold concentration, e.g., at 25 °C,  $\eta_4$  increases from 0.54 to approximately 0.65, but only the *direct radiation* can be used (Sect. 1.2.3, Solar Radiation); this technology therefore only makes sense for sites with a low diffuse-light component. With lens and mirror concentrators, concentration factors up to over 1000 can be achieved.

However, the improvement in the overall efficiency of the solar cell is usually less than expected for the following reason: as can also be seen from Fig. 2.112, the improvement only occurs if the temperature remains constant. Since the concentration of the energy causes more heating, cooling would have to be provided, incurring more costs. In this context, it should be noted that the temperature increase negatively affects not only the efficiency  $\eta_4$ , but also  $\eta_5$  (the temperature dependency of  $R_p$ ).

This difficulty, as well as the additional costs associated with tracking and concentration, despite the reduction of the active area, have led to the fact that the coupling of focusing mirror devices with conventional silicon cells has not yet been successful. One solution could be special *concentrator cells* implemented as point contact cells [2.39, 42].

**Improving the Use of the Solar Spectrum.** The product  $\eta_1\eta_2$  is determined by the spectral distribution of the effective radiation and the semiconductor material. With AM1.5 (1.5 atmosphere lengths, see Fig. 2.104) it is approximately  $0.75 \times 0.66 = 0.49$  for crystalline silicon. Other semiconductors are also no better (Fig. 2.106). A significant improvement can only be achieved with *tandem* or *multiple cells*. This means the combination of various semiconductors, whereby each semiconductor absorbs as far as possible that part of the spectrum whose wavelengths are directly below its own  $\lambda_{\max}$  (for  $\lambda = \lambda_{\max}$ ,  $\eta_1\eta_2 = 1$ ). In practice, there are difficulties with the choice of the circuit. The simple series circuit is commonly used, but it has the disadvantage that the worst solar cell determines the current. With parallel connection, problems arise with the contacts and the necessary transparent intermediate layers. Either way, tandem cells require a more complex technology, which implies a considerable additional cost [2.40]. Accordingly, this technology, although promising, has not yet been commercially successful, except for aerospace cells, where it has achieved efficiencies over 30% which are quite common. Tandem cells are also used for thin-film cells (Sect. 2.9.3). More information about tandem and triple cells can be found in [2.41].

### Solar-Cell Types

The most successful solar cell for power applications to date is clearly the *monocrystalline* or *polycrystalline* silicon cell. Virtually all photovoltaic systems today are based on this technology, that is accordingly well-developed, even if it is too expensive by a factor of five for grid applications. The efficiencies of the commercially available modules today are in the range of 12–18% (the laboratory record for a single solar cell is 24.7%). A major handicap of this technology is that more than 50% of the costs are accounted for by the solar cell itself, not least because of the large amount of material required (cell thickness of 200  $\mu\text{m}$  for 90% absorption).

**Thin-film Solar Cells.** For this reason, on the one hand, efforts are being made to reduce the cell thickness of silicon cells to approximately 100  $\mu\text{m}$  (or less) to minimize the cost of materials. On the other hand, attempts are being made to bring actual thin-film solar cells to commercial maturity. An initial area of research is:

- *Thin-film cells made of crystalline silicon* whose thickness is up to about 5  $\mu\text{m}$  (e.g., on glass) and therefore they have considerable advantages in terms of material use (and costs). To achieve the necessary absorption of the radiation, the light is reflected several times (optical confinement). For details, see [2.40, 43].  
It was mentioned in Sect. 2.9.1 that there are semiconductors with much greater absorptive power than crystalline silicon. Research efforts have led to the development of various types of solar cells. The most important are:
- *Amorphous silicon solar cells* With layers of < 1  $\mu\text{m}$ , it is possible to build solar cells that have become widely used in the low-power range (pocket calculators, watches, etc.). For higher powers, the stabilized efficiency achieved is approximately 6% for modules and max. 13% in the laboratory. Although the initial efficiencies are higher, they are reduced to the stated values due to light-induced degradation.
- *Gallium arsenide (GaAs) solar cells.* This crystalline material enables 90% absorption at 2  $\mu\text{m}$ . The band gap of 1.42 eV is also very favorable. With AM1.5, efficiencies of up to 24.5% are achieved in the laboratory. The price (at present) and above all environmental aspects (toxicity of Ga and As) stand in the way of the spread of these cells. Cells of GaAs are being developed for space applications and as concentrator cells. With these cells, higher

efficiencies can be achieved, particularly in the configuration of tandem and multiple cells (see above). However, such cells are very expensive.

- **Solar cells made of cadmium telluride CdTe.** These thin-film cells are very much under discussion today (the laboratory record is 16.5%, modules probably at 6% approximately). Problems are that cadmium is toxic, and tellurium is not sufficiently available. Minimal production costs.
- **Solar cells made of copper indium diselenide CuInSe<sub>2</sub>.** For this arrangement of polycrystalline material, also known as *CIS solar cells*, a layer of approximately 2 μm is sufficient to absorb the radiation. The slightly less favorable band gap of 1 eV can be increased to the optimum of 1.4 eV by adding Ga to the In. In this way, efficiencies of 18.8% have been achieved in the laboratory. However, commercial modules have an efficiency of approximately 9%. The development potential is assessed as good. A disadvantage could be the limited availability of indium.
- **Dye-sensitized cells (Grätzel cell).** This is a cell that uses organic dyes to convert light energy into electrical energy. Among the organic cells, it provides one of the best efficiencies, up to 12%. Significantly higher efficiencies can be achieved according to more recent research. Significant progress has also been made in terms of service life, and mass production is now within reach. Its flexibility makes it particularly suitable for building integration.

Thin-film solar cells are particularly suitable for *tandem structures*. In particular *micromorph solar cells*, that combine microcrystalline and amorphous solar cells, open up new perspectives here [2.44, 45]. Many production facilities for micromorph modules are currently being planned; commercial module efficiencies are slightly above 8% (with hopes for achieving 10% soon). The manufacturing costs and the cost of materials are significantly lower than for classic crystalline silicon cells.

### 2.9.4 The Sun as a Source of Energy

About five billion years ago, at a certain point of the Milky Way, the fusion reactor called the Sun was formed by local compression of the original gas mass of the universe (consisting of about 75% H and 25% He), that led to the critical temperature of about  $12 \times 10^6$  K. Possibly a supernova explosion was the cause of the compression. Over the past five billion years, radiation intensity has probably increased by about 25%. The Sun will continue to burn hydrogen to helium in the same way for another five billion years, and its radiation in-

tensity will continue to increase slightly. Then it will enter into a kind of energy crisis and inflate into a *red giant*, collapse later and continue to shine as a *white dwarf*, finally burning out slowly and ending its star career as an invisible sphere.

Today the Sun is a gas ball with the following dimensions

$$\begin{aligned} \text{Radius: } & 696\,000 \text{ km } (109 \times \text{Earth}) \\ \text{Volume: } & 1.412 \times 10^{27} \text{ m}^3 \\ \rightarrow \text{Surface: } & 6.087 \times 10^{18} \text{ m}^2 \\ \text{Density: } & \frac{1.41 \text{ t}}{\text{m}^3} \left( \frac{1}{4} \text{ of Earth} \right) \\ \text{Mass: } & 2 \times 10^{27} \text{ t } (\text{Earth: } 6 \times 10^{21} \text{ t}). \end{aligned} \quad (2.208)$$

The total radiation is  $380 \times 10^{12}$  TW; referred to the surface, that has a temperature of 5900 K; this is about 62 TW/m<sup>2</sup>.

The radiated energy is  $12 \times 10^{33}$  J/a and the corresponding mass loss according to the relation  $E = mc^2$  is  $\Delta m = 133 \times 10^{12}$  t/a. Approx.  $20 \times 10^{15}$  t/a of hydrogen is burned. In five billion years, it will be about  $10^{26}$  t, that is about 10–15% of the original amount.

#### Extraterrestrial Radiation Intensity

The Earth's orbit around the sun is slightly elliptical. The distance between the Earth and the Sun is

$$\begin{aligned} d_{\max} &= 152 \times 10^6 \text{ km: at the beginning of July,} \\ d_{\min} &= 147 \times 10^6 \text{ km: at the beginning of January,} \\ d_m &= 149.5 \times 10^6 \text{ km: at the beginning of} \\ &\quad \text{April/October.} \end{aligned} \quad (2.209)$$

This can be used to calculate the average *extraterrestrial radiation intensity* (outside the atmosphere, but near the Earth)

$$D_0 = \frac{380 \times 10^{14}}{4\pi d_m^2} = 1353 \frac{\text{W}}{\text{m}^2} = \text{solar constant}; \quad (2.210)$$

The minimal value at the beginning of July is 1310 W/m<sup>2</sup>, while the maximal value at the beginning of January is 1400 W/m<sup>2</sup>.

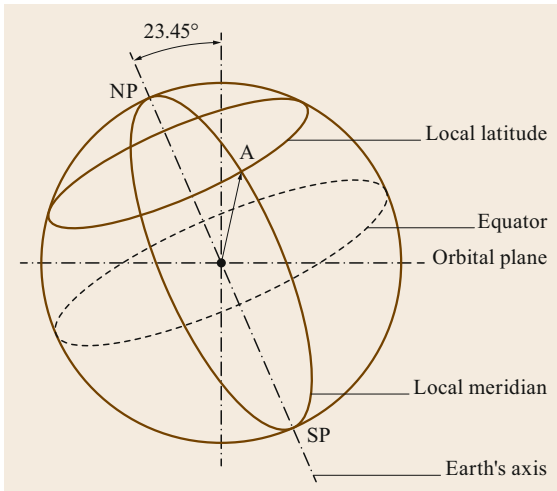

The total radiant power on Earth can be calculated from this, taking into account the Earth's radius of approximately  $6.38 \times 10^6$  m (incl. the atmosphere). The average radiant power is

$$1353\pi(6.38 \times 10^6)^2 = 173 \times 10^{15} \text{ W} = 173\,000 \text{ TW}. \quad (2.211)$$

Between July and January, it changes from 167 000 to 179 000 TW.

**Apparent Solar Motion Relative to the Earth**

Figure 2.115 shows the Earth's coordinate system (longitude and latitude) and the inclination of the Earth's axis of rotation at  $23.45^\circ$  from the perpendicular to the orbital plane. Projection onto the celestial sphere, gives the so-called celestial-equator system for the location under consideration (Fig. 2.116). Because of the small size of the Earth's radius, location A is practically at the center of the system. The direction of the celestial axis is determined by the latitude of the location. At the equator, the celestial axis is horizontal; at the poles it corresponds to the nadir–zenith axis.

**Fig. 2.115** Coordinates of location A on the Earth (longitude, latitude)

**Fig. 2.116** Apparent motion of the Sun, for the latitude  $\phi$  obtained by projecting the coordinates of the location onto the celestial sphere. Position of the Sun is given by declination  $\delta$  and hour angle  $\omega$  (adapted from [2.46])

The Sun appears to describe a circular orbit around the celestial axis. This orbit is shifted by the declination  $\delta$  (given as an angle) relative to the celestial equator. The shift depends on the time of year because of the inclination of the rotation axis of the Earth in the orbital plane. It varies between  $-23.45^\circ$  and  $+23.45^\circ$  and is zero at the spring and autumn equinoxes (Fig. 2.117). The declination can be calculated using the following formula ( $n_d$  = daily index, starting on January 1)

$$\delta = \arcsin \left[ 0.398 \sin \left( 360^\circ \frac{n_d - (79 - 79.75)}{365.25} \right) \right] + 0.026 \sin \left( 360^\circ \frac{n_d - 173}{365.25} \right). \quad (2.212)$$

The second term is a consequence of the elliptical orbit of the earth and differs from zero only for  $173 < n_d \leq 366$ . In the first term

$$\left. \begin{array}{l} n_d - 79 \quad \text{for leap years,} \\ n_d - 79.25 \\ n_d - 79.50 \\ n_d - 79.75 \end{array} \right\} \text{for the next three years.} \quad (2.213)$$

The exact position of the Sun during the day is given by the hour angle, measured from the celestial meridian (relative to the South Pole). When the Sun is due south, the true local time (solar time)  $TS = 12.00$  h. The hour angle (angle deviation from true south) is then

$$\omega = (TS - 12) \times 15. \quad (2.214)$$

**Fig. 2.117** Path of the Sun at: 1 summer solstice, 2 spring and autumn equinoxes, 3 winter solstice; SA: sunrise, SU: sunset (adapted from [2.46])

It should also be kept in mind that the effective local time (*zone time* TL) is not the same as TS. The world is divided into 15 zone times. In the general case

$$TS = TL + \frac{L - L_0}{15} + ET \quad (2.215)$$

where:

$L$  longitude of the location ( $L > 0 \rightarrow$  longitude east)

$L_0$  longitude of the normal-time location (where  $TS = TL - ET$ )

ET correction term, (2.217).

For Western European or Greenwich Time (England, Portugal),  $L_0 = 0^\circ$  (Greenwich or zero meridian, London).

For central European time (CET, valid for most European countries)  $L_0 = 15^\circ$ ; for Eastern European Time or Moscow Time  $L_0 = 30^\circ$  etc. For Switzerland and most European countries the following therefore applies

$$\begin{aligned} \text{Winter: } TS &= CET + \frac{L - 15}{15} + ET, \\ \text{Summer: } TS &= SUT - 1 + \frac{L - 15}{15} + ET, \end{aligned} \quad (2.216)$$

where summer time  $SUT = CET - 1$ .

The term ET is a consequence of the elliptical orbit of the Earth, whose solar orbital velocity is not constant according to Kepler's laws. With sufficient accuracy for solar applications (but not for nautical applications), one can write

$$ET(h) = \sum_{k=1}^3 a_k \cos(kN) + b_k \sin(kN), \quad (2.217)$$

with  $N = \frac{360}{365.25} n_d$  ( $n_d$  = current day number),

$$\begin{aligned} a_1 &= 0.072, & a_2 &= -0.0528, & a_3 &= -0.0012, \\ b_1 &= -0.1229, & b_2 &= -0.1565, & b_3 &= -0.0041. \end{aligned}$$

The behavior of the correction term ET in minutes over the year is shown in Fig. 2.118.

### Calculation of the Position of the Sun

The position of the Sun is defined by the *elevation angle*  $h$  (above the horizon) or the *zenith angle*  $z = 90^\circ - h$  and the *azimuth*  $a$  (deviation from south).

With the help of theorems of spherical trigonometry (sine and cosine theorem), for the spherical triangle

Fig. 2.118 Correction term ET

north-pole-zenith-solar position ( $\varphi > 0$  for the northern hemisphere)

$$\begin{aligned} \sin h &= \cos z \\ &= \sin \varphi \sin \delta + \cos \varphi \cos \delta \cos \omega, \end{aligned} \quad (2.218)$$

$$\begin{aligned} \sin a &= \frac{\cos \delta \sin \omega}{\cosh}, \\ \cos a &= \frac{\sin \varphi \sin h - \sin \delta}{\cos h \cos \varphi}. \end{aligned} \quad (2.219)$$

Both equations (2.219) must be obeyed because of the ambiguity. For the *theoretical sunrise* or sunset (with a flat horizon)

$$\begin{aligned} h = 0 &\rightarrow \sin \varphi \sin \delta = -\cos \varphi \cos \delta \cos \omega, \\ \cos \omega_0 &= -\tan \varphi \tan \delta, \\ \cos a_0 &= -\frac{\sin \delta}{\cos \varphi}. \end{aligned} \quad (2.220)$$

### Calculation of Radiation Intensity

The extraterrestrial radiation intensity  $D_0$  varies according to (2.210) by a good 3% around the mean value and can be expressed as a function of the declination. If  $D_1$  is the effective incoming radiation, the radiation intensity on a *horizontal surface* is

$$D = D_1 \sin h \quad (2.221)$$

as shown in Fig. 2.119.

For an *inclined surface*, with inclination relative to the horizontal given by the angle  $\psi$  and with orientation given by the azimuth  $a$  (Fig. 2.120), the plan view in Fig. 2.121a is considered with the vertical sections in

Fig. 2.119 Radiation on a horizontal surface

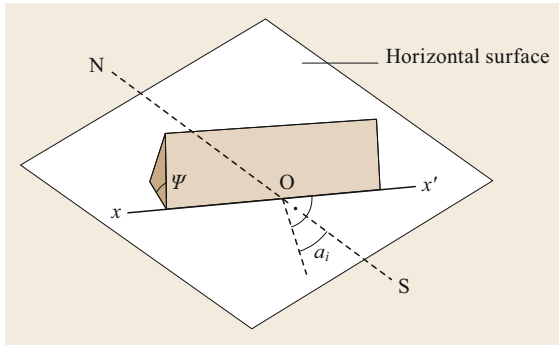

Fig. 2.120 Inclined surface in any direction

Fig. 2.121b,c. The vertical radiation component  $D$  acting on the surface results in then

$$\begin{aligned}
 D &= x_1 + x_2 \\
 \text{with } y_1 &= D_1 \sin h \tan \psi, \\
 y_2 &= D_1 \cos h \cos (a - a_i) - y_1, \\
 x_1 &= \frac{D_1 \sin h}{\cos \psi}, \quad x_2 = y_2 \sin \psi. \quad (2.222)
 \end{aligned}$$

From (2.222), with substitutions and rearrangements

$$D = D_1 [\sin h \cos \psi + \cos h \sin \psi \cos (a - a_i)]. \quad (2.223)$$

The special case of (2.221) follows for  $\psi = 0$ . If the surface is traced around a vertical axis of the Sun, so that  $a = a_i$ , this gives  $D = D_1 \sin(h + \psi)$ . Finally, if the surface is also rotated about a horizontal axis corresponding to the position of the Sun, so that  $\psi = 90^\circ - h$ ,  $D = D_1$  results.

### Radiant Energy per Day

The radiation density  $D_1$  is not constant during the day because of the effect of the atmosphere and the weather, and the effective daily radiation energy is therefore not readily accessible for calculation and can only be obtained empirically and statistically. As the highest guide value, with  $D_1 = D_0$ , the extraterrestrial daily sum (irradiation without atmosphere) can be given as:

#### Horizontal Surface.

$$W_d = \int_{SA}^{SU} D dt = D_0 \int_{SA}^{SU} \sin h dt. \quad (2.224)$$

If the time is replaced by the hour angle according to (2.214),

$$dt = d\omega \frac{24}{2\pi}, \quad (2.225)$$

where the integration limits for a flat horizon can be replaced by  $\pm\omega_0$  according to (2.220), and using (2.218),

$$W_d = D_0 \int_{-\omega_0}^{\omega_0} (\sin \varphi \sin \delta + \cos \varphi \cos \delta \cos \omega) \frac{24}{2\pi} d\omega.$$

For the location and day in question,  $\varphi$  and  $\delta$  are constant, and finally

$$W_d = \frac{24}{\pi} D_0 (\sin \varphi \sin \delta \omega_0 + \cos \varphi \cos \delta \sin \omega_0) \left( \frac{\text{kWh}}{\text{m}^2 \text{d}} \right). \quad (2.226)$$

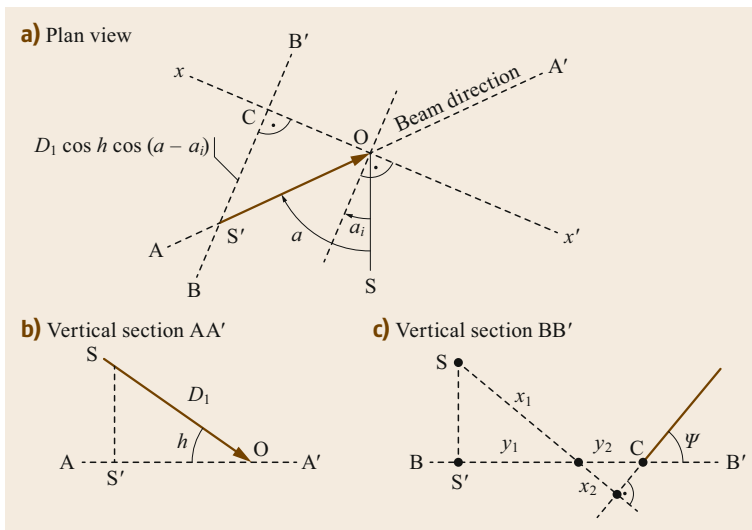

Fig. 2.121a–c Plan view (a) and vertical sections (b,c) for Fig. 2.120; calculation of the vertical component of  $D_1$

**Fig. 2.122** Annual variation of the daily energy on a horizontal surface for different latitudes (extraterrestrial irradiation  $D_0(\delta) = 1.353 \text{ kW/m}^2$ )

**Fig. 2.123** Annual energy on a horizontal surface without atmosphere as a function of the latitude of the site

Figure 2.122 shows the annual variation of the daily energy for various latitudes and assuming  $D_0(\delta) = \text{const} = 1.353 \text{ kW/m}^2$ . The integral over the year as a function of latitude gives Fig. 2.123.

**Inclined Surface.** If the surface is oriented to the south (northern hemisphere) with slope  $\psi$  (Fig. 2.120), then  $a_i = 0$ , and it is sufficient in (2.226) to replace  $\varphi$  by  $(\varphi - \psi)$ . As a rule, an orientation other than to the south supplies less daily energy. However, there are also cases where this does not apply and another orientation makes sense: the effect of mountain profiles ( $\omega_0$  then does not result from (2.218) for  $h = 0$ , but from  $h_{\min}$ , depending on the mountain profile), regular morning mist, clouds in the afternoon, reflection effects (snow, glaciers, water), diffuse light, etc.

**Fig. 2.124** Optimal slope  $\psi_{\text{opt}}$  as a function of the latitude of the location, without atmosphere (during the year, summer or winter with unchanged slope)

Integration of (2.226) gives the general result

$$W_d = \frac{24}{\pi} D_0 [(\cos \psi \sin \varphi - \sin \psi \cos \varphi) \sin \delta \omega_0 + (\cos \psi \cos \varphi + \sin \psi \sin \varphi) \cos \delta \sin \omega_0]. \tag{2.227}$$

If the slope and orientation of the surface are not changed over a certain period of time (month, season, year), the summation

$$W = \sum_{n_d} W_d(\delta(n_d)), \tag{2.228}$$

gives an expression of the form

$$W = A \cos \psi + B \sin \psi, \tag{2.229}$$

$$\text{with } \begin{cases} A = \frac{24}{\pi} D_0 \times (\sin \varphi \sum_{n_d} \sin \delta \omega_0 + \cos \varphi \sum_{n_d} \cos \delta \sin \omega_0) \\ B = \frac{24}{\pi} D_0 \times (-\cos \varphi \sum_{n_d} \sin \delta \omega_0 + \sin \varphi \sum_{n_d} \cos \delta \sin \omega_0) \\ \times \cos a_i. \end{cases}$$

The energy of the period is maximized for  $dW/d\psi = 0$ , from which the optimal inclination is

$$\tan \psi_{\text{opt}} = \frac{B}{A} \tag{2.230}$$

that is shown in Fig. 2.124 as a function of the latitude of the location with orientation to the south (northern hemisphere). It increases up to the Arctic Circle,

**Fig. 2.125** Separation of incident solar radiation by reflection, scattering and absorption, and also heat radiation (numbers correspond to the world average)

then decreases again. With an atmosphere, the optimum slope is somewhat smaller because the horizontal position gives the best result for the diffuse-light component.

### Effect of the Atmosphere

If the previous calculations are applied to geostationary satellites, they deliver exact results (the elevation angle at SA and SU is not zero, but slightly negative and depends on the satellite altitude).

For installations on Earth, the effect of the atmosphere must be taken into account, that can only be determined empirically. The atmosphere causes reflection, scattering and absorption of solar radiation. Above all, absorption at 20–30 km altitude by ozone and in the lower layers by H<sub>2</sub>O and CO<sub>2</sub> causes not only a decrease of the radiation intensity, but also a change of the spectrum (see also Fig. 2.104). The distribution of solar radiation in the atmosphere can be explained in more detail using the diagram in Fig. 2.125.

The incoming short-wave radiation  $S_0$  is partly absorbed by the atmosphere and converted into long-wave heat radiation. A further part is reflected or scattered directly into space by air and clouds. What remains meets the earth as *direct radiation*  $S$ . The scattered radiation also reaches the earth as *sky radiation*  $H$ . The *diffuse radiation* measured on the ground can also contain some of the reflective radiation from the environment, in addition to the sky radiation. The sum of direct radiation and

**Fig. 2.126** Daily and seasonal distribution of direct solar radiation on normal surface for the Swiss Midlands at 400 m above sea level, with a clear sky,  $1 \text{ kcal}/(\text{h m}^2) = 1.163 \text{ W}/\text{m}^2$  (Meteo Schweiz, Zurich)

**Fig. 2.127** Seasonal variation of direct radiation for various hours of the day at 2000 m.a.s.l., with clear sky,  $1 \text{ kcal}/(\text{h m}^2) = 1.163 \text{ W}/\text{m}^2$  (courtesy Battelle Institute)

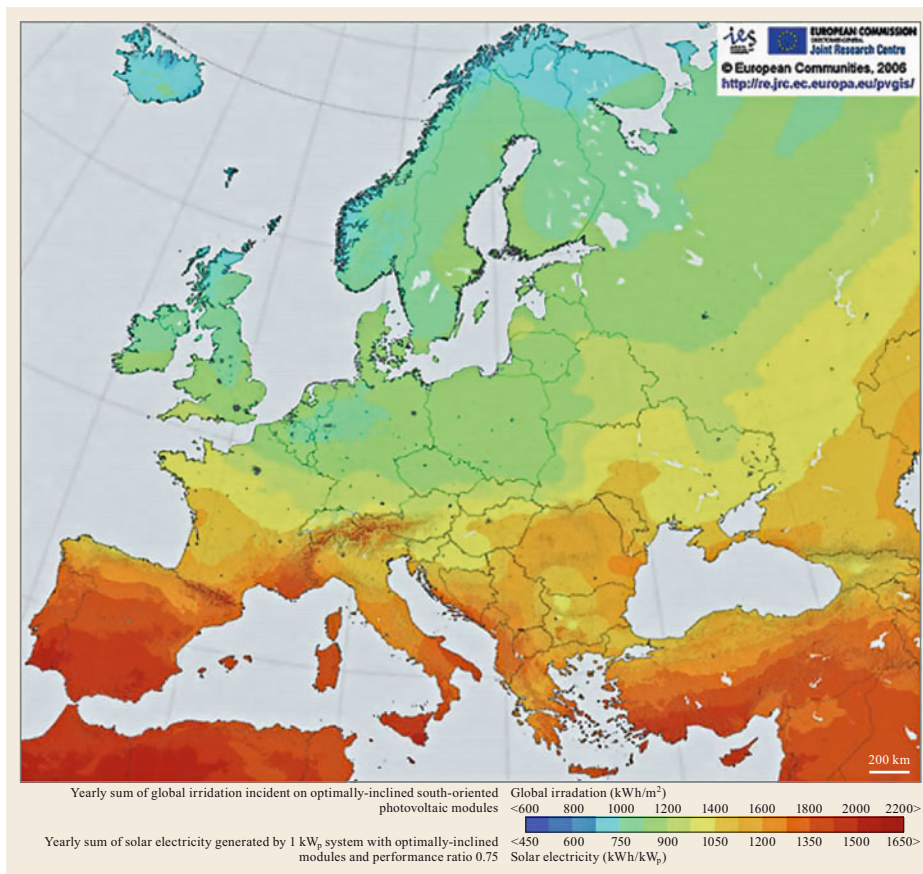

sky radiation (or diffuse radiation) is called the *global radiation*  $G$ .

After subtracting the radiation  $R$  reflected from the Earth, the rest is the radiation absorbed by the Earth, which is converted into heat. Since the Earth is in thermal equilibrium, this heat must be emitted again, about  $2/3$  by convection and evaporation and  $1/3$  by thermal radiation ( $E - A$ ) into the atmosphere. The atmosphere as a whole radiates approximately  $71\%$  of the solar radiation as heat into space.

#### Radiation Intensity with the Atmosphere

The radiation intensity can be measured by measuring global radiation and direct radiation [2.30]. For Switzerland, measurements of direct radiation are available for a clear sky and different altitudes (Figs. 2.126 and 2.127) and of global radiation for individual stations.

At maximum radiation intensity (TS = 12:00, Sect. 2.9.4), the indicative values in Table 2.7 (on a surface area normal to the radiation) apply to direct radiation.

**Fig. 2.128** Annual energy yield in kWh/kW<sub>p</sub> with optimum alignment of the PV system. (Photovoltaic geographical information system (PVGIS) European Communities)

The maximum global radiation in the Swiss Midlands has a typical value of  $1000 \text{ W/m}^2$  under a cloudless sky, of which about 10% is diffuse under a clear blue sky. On a hazy summer afternoon, the diffuse component is up to 50%. On a cloudy winter day, the global radiation can only be  $50\text{--}100 \text{ W/m}^2$  (100% diffuse).

Figure 2.128 gives an estimate of the possible energy yield in  $\text{kWh/kW}_p$  in Europe with photovoltaic (PV) systems, with optimal orientation of the solar generators.

**Table 2.7** Direct radiation in Switzerland (around 12:00 LT, in  $\text{W/m}^2$ ) as a function of altitude (in m) for different times of year

Altitude	End of March/ start of April	June	December
Extraterrestrial	1350	1320	1390

## 2.10 Fuel Cells

Fuel cells can be used to directly convert hydrogen as well as natural gas or biogas, and other hydrocarbons (e.g., petrol, methanol) electrochemically into electrical energy. Compared to thermal machines, which make a detour via mechanical energy, this results in higher efficiencies and this is without rotating parts and the associated noise emissions. Efficiencies of 50–60% can be achieved, even for small outputs, that is only possible with conventional technology with combined systems in the 10–100 MW range. The environmental impact of using natural gas is lower than with conventional thermal power plants due to the higher efficiency and different combustion methods (no soot, no nitrogen oxides, no unburned hydrocarbons).  $\text{CO}_2$  emissions can be further reduced by increasing the hydrogen content.

The technology is evolving but it has not yet reached the economic viability threshold except in special applications, such as spaceships or submarines. However, it is predictable that in the course of the next decades it will open up a wide range of applications for *mobile* and *stationary* applications.

### 2.10.1 Structure and Fuel Cell Types

Figure 2.129 shows the basic structure of a fuel cell. It consists of an *anode*, *cathode*, and *electrolyte*, like

**Fig. 2.129** Structure of a fuel cell

a battery. Fuel gas ( $\text{H}_2$ ,  $\text{CO}$ ,  $\text{CH}_4$ ) flows through or around the anode and air through or around the cathode. The electrolyte is *gas-tight* and therefore does not allow a direct contact between fuel and oxygen. Ions transport the electrons from cathode K to anode A, the type of ion being dependent on the electrolyte used.

Five fuel cell families are known and under development. They differ primarily in the *electrolyte* used. Sorted in descending order of cell temperature, these are the following:

1. **SOFC: solid oxide fuel cell**,  $\approx 800^\circ\text{C}$ : A ceramic layer of zirconium oxide is used as the electrolyte. The atmospheric oxygen is ionized on the cathode side to  $\text{O}^{2-}$  by taking up two electrons. It can thus penetrate the electrolyte as an ion, is neutralized again on the anode side by electron release and initiates the oxidation reaction. The cell can also be operated directly with natural gas, propane or biogas.
2. **MCFC: molten carbonate fuel cell**,  $650^\circ\text{C}$ : A molten carbonate (mostly lithium and potassium carbonate) is used as the electrolyte. The carbonate ion serves as the ion. The air is enriched with  $\text{CO}_2$  to form new carbonate ions. On the anode side it dissociates into  $\text{CO}_2$  and oxygen, that oxidizes the fuel. Hydrogen and CO can be used as fuels.
3. **PAFC: phosphoric acid fuel cell**,  $200^\circ\text{C}$ : Diluted phosphoric acid is used as the electrolyte. The fuel is hydrogen, that gives off its electron on the anode side and crosses the electrolyte as a hydrogen ion  $\text{H}^+$ . It takes up an electron again on the cathode side and is oxidized by atmospheric oxygen. The air must contain little or no CO.
4. **PEFC: polymer electrolyte fuel cell**,  $80^\circ\text{C}$ : The electrolyte is a plastic film that behaves like an acid.

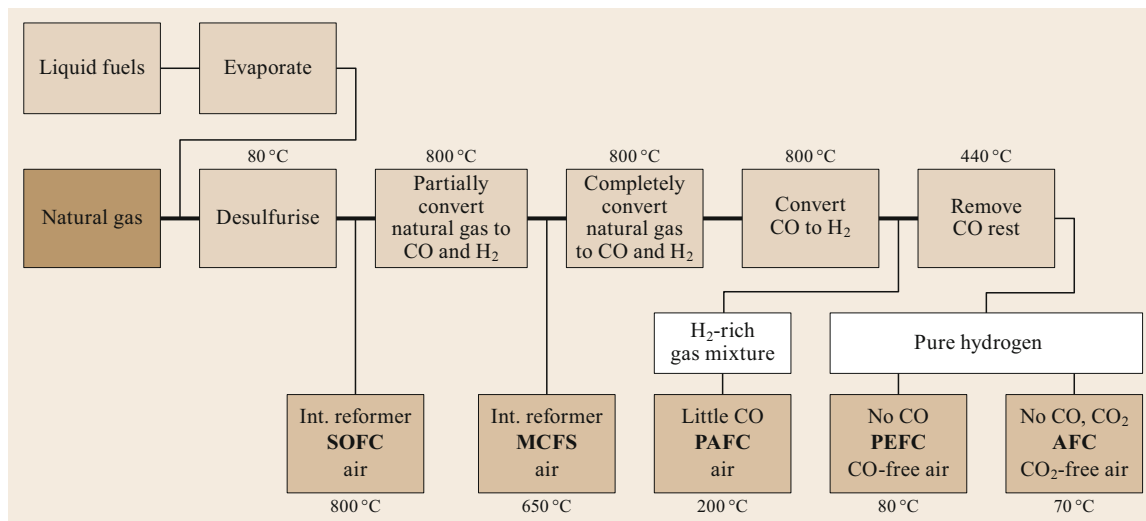

Fig. 2.130 Processing of natural gas for the five fuel cell types (adapted from [2.47])

Also in PEFCs, the hydrogen ion  $H^+$  (processes as in PAFC) serves as the ion.

5. *AFC: alkaline fuel cell, 70°C*: Diluted potassium hydroxide solution is used as the electrolyte. The hydroxyl ions  $OH^-$  formed from the reaction  $H_2O + O = 2OH^-$  take over the electron transport. The oxidation reaction takes place on the anode side with pure hydrogen. The air must not contain  $CO_2$ .

All five types of fuel cell can operate with natural gas, and all fuel cell types except SOFC and MCFC must first convert natural gas into hydrogen or hydrogen + CO. This conversion is very costly (also in terms of space requirements, up to 60% of the construction volume). Figure 2.130 provides an overview.

Today, the AFC families are expected to have only limited future prospects [2.47]. The PEFC is of interest for mobile applications and is being further developed primarily by the automotive industry. In addition to the five families mentioned, the direct methanol fuel cell DMFC should also be mentioned. It can be operated directly (without reformer) with methanol (working temperature similar to PEFC). Its prospects are still not clear.

PAFC, MCFC and SOFC are predestined for stationary energy applications. The phosphoric acid fuel cell is the most highly developed and already commercially available. It is economically viable for certain applications. The ceramic fuel cell is still under development, but has great potential. Section 2.10.3 shows these two fuel cells in more detail.

## 2.10.2 Principles and Modeling

### Electrochemical Fundamentals

The most important chemical reactions for energy conversion are the following

The associated specific enthalpy change  $\Delta h$  is 120 MJ/kg at normal pressure for  $H_2$ , 10 MJ/kg for CO and 50 MJ/kg for  $CH_4$ . The temperature has only a minor effect on these values (slight increase for  $H_2$ , for more details see [2.48]), standard enthalpy change). At a mass flow of  $m$  (kg/s), the available chemical power is

$$P_{ch} = m\Delta h \quad \left( \frac{\text{kg}}{\text{s}} \frac{\text{J}}{\text{kg}} = \text{W} \right). \quad (2.232)$$

From the enthalpy  $\Delta h$  only the *free enthalpy*  $\Delta h_f$  (Gibbs potential) can be converted into electrical energy [2.49, 50]. This is defined by

$$\Delta h_f = \Delta h - T\Delta s \quad (\text{Ws/kg}), \quad (2.233)$$

where  $\Delta s$  denotes the specific entropy change [2.9, Annex A.1]. The corresponding maximum electrical energy is  $w_{e0} = \eta_e \Delta h_f$ , where

$$\begin{aligned} w_{e0} &= QE = n \frac{F}{M} E \quad \left( \frac{\text{As}}{\text{kg}} \text{V} \right), \\ P_{e0} &= mw_{e0} = nm \frac{F}{M} E = IE \quad (\text{W}), \end{aligned} \quad (2.234)$$

Fig. 2.131 Free enthalpy  $\Delta h_f$  as a function of temperature

where:

- $F$  Faraday's constant ( $9.6485 \times 10^4$  A s/mol)
- $M$  molar mass (kg/kmol)
- $n$  number of exchanged electrons (valence)
- $E$  EMF (open circuit voltage, V)
- $m$  mass flow (kg/s).

The efficiency  $\eta_e$  takes into account that, especially at low temperatures, the reaction induced by the catalytic converter proceeds through several steps, of which only the first contributes to voltage formation. The open-circuit voltage therefore does not correspond to the Gibbs potential (at low temperatures, e.g., PEFC cell,  $\eta_e \approx 0.8$ ).

$P_{e0} = EI$  represents the *internal electrical power* of the cell. The free enthalpy for the three most important reactions (2.231) is shown in Fig. 2.131 (calculated from [2.48]). The EMF  $E$  can be determined from (2.234)

$$E = \frac{w_{e0} M}{n F} \quad (2.235)$$

with  $n = 2$  for  $H_2$  and  $CO$  and  $n = 8$  for  $CH_4$ . Then, for the methane reaction, for example, at  $25^\circ C$ ,  $E = 1.06\eta_e$  (V), for the  $H_2$  reaction  $E = 1.23\eta_e$  (V). By connecting fuel cells in series to form a *fuel cell stack*, the open-circuit voltage required for practical applications can be achieved.

The voltage  $U$  effectively available at the electrodes is lower than the EMF when the cell is loaded due to the internal voltage drop. As a result, the effectively obtained electrical power is further reduced

$$\begin{aligned} P_e &= P_{e0} \frac{U}{E} = P_{ch}, \\ \eta_e \frac{\Delta h_f}{\Delta h} \frac{U}{E} &= P_{ch} \eta_e \eta_0 \eta_u, \end{aligned} \quad (2.236)$$

Fig. 2.132 Theoretical efficiency  $\eta_0$  as a function of temperature

where  $\eta_0$  denotes the theoretical no-load efficiency, and  $\eta_u$  is the voltage efficiency. Figure 2.132 shows the theoretical no-load efficiency as a function of the cell temperature for the three reactions of (2.231) [2.48]. The good efficiency of the methane reaction is striking, if we take into account that the fuel is not used 100%, i.e., that the effectively converted chemical power  $P_{ch} = u_f P_b$  is smaller than the delivered chemical gross power  $P_b$ , where  $u_f$  is the fuel utilization factor  $< 1$ , we have

$$P_e = \eta_e \eta_0 \eta_u u_f P_b = \eta P_b. \quad (2.237)$$

#### Linear Model

If we assume as a first approximation that the internal resistance of the cell is independent of the current, the following applies

$$\eta_u = \frac{E - RI}{E} = 1 - \frac{RI}{E}. \quad (2.238)$$

If the current is replaced by the power, the voltage efficiency follows from (2.234), (2.235), and (2.236) and,

$$\begin{aligned} \eta_u &= 1 - \frac{R \eta_e \eta_0 u_f P_b}{E^2} = 1 - \frac{P_{e0}}{P_k} = 1 - p_0 \\ \text{with } P_{e0} &= \eta_e \eta_0 u_f P_b, \quad P_k = \frac{E^2}{R} = EI_k, \end{aligned} \quad (2.239)$$

where  $p_0$  is the internal electrical power related to the short-circuit power. The *short-circuit power*  $P_k$  was defined as the product of the short-circuit current and open-circuit voltage, as is usual in power supply technology. If all powers are related to the short-circuit power, the overall efficiency  $\eta$  of the fuel cell stack and the electrical output power  $p$  then

$$\begin{aligned} \eta &= \eta_e \eta_0 u_f (1 - p_0), \\ p &= \frac{P_e}{P_k} = P_0 (1 - p_0). \end{aligned} \quad (2.240)$$

**Fig. 2.133** Typical graph of power and efficiency of fuel cells:  $p_0 = P_{e0}/P_k$  = internal power,  $p_b = P_b/P_k$  = gross power (chemical),  $p = P_e/P_k$  = electrical output power,  $\eta$  = efficiency of the fuel cell stack,  $\eta_a$  = plant efficiency, A = design point (example:  $\eta \approx 50\%$ ,  $\eta_a \approx 45\%$ )

Figure 2.133 shows these two quantities as a function of the internal electrical power  $p_0$ . The maximum output power is obtained when  $P_{e0} = 0.5P_k$  and  $P_e = 0.5P_{e0} = 0.25P_k$ . At this maximum power, however, the efficiency of the fuel cell stack is only  $\eta = 0.5\eta_e\eta_0\eta_f$ . The economic optimization of the system usually leads to a design point corresponding to a power  $P_{e0} < 0.5P_k$ , and the stack efficiency will be 50% or more.

For smaller loads, the efficiency of the fuel cell theoretically increases, i.e., the fuel cell has a generally good part-load behavior. If the load becomes too

small, however, the energy requirement of the auxiliary equipment, such as pumps, fans, controls, etc., which is practically independent of the load, has an unfavorable effect, as shown by the expected plant efficiency  $\eta_a$ , indicated in Fig. 2.133.

### 2.10.3 Fuel Cells for Stationary Applications (German Original by Prof. Michael Höckel, see [2.9])

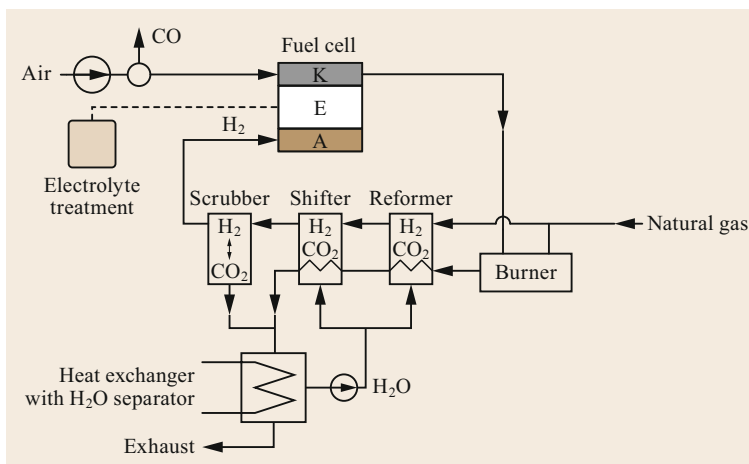

#### Phosphoric Acid Fuel Cell (PAFC)

Figure 2.134 shows the basic structure of a PAFC plant. Since this cell requires a gas mixture rich in  $H_2$  (without CO), it must be extracted from natural gas in the reformer using steam. The reform reaction produces  $H_2$  and CO. In two subsequent stages, the CO is oxidized to  $CO_2$  and the  $CO_2$  is partially rejected. The hydrogen is ionized at the anode and passes through the electrolyte as an  $H^+$  ion before being oxidized to water at the cathode. The exhaust gas is water vapor and  $CO_2$ .

The cell temperature is  $200^\circ C$ . The power density achievable today is  $1.3 \text{ kW/m}^2$  and should be able to be increased to about  $2 \text{ kW/m}^2$ . The PAFC fuel cell technology is the most advanced and tested. Plants from 1 kW and greater are commercially available. The largest plant built to date has an output of 11 MW (Japan). Hydrogen is used as the fuel for small plants, as the complex conversion of natural gas becomes economical only for outputs above 100 kW. The investment for a 200 kW plant is around 3300 €/kW, but the business calculation looks favorable thanks to the long service life of more than 8000 h/a.

#### Molten Carbonate Fuel Cell (MCFC)

The MCFC uses the alkaline carbonates lithium, potassium and sodium as electrolytes. For sufficient ionic

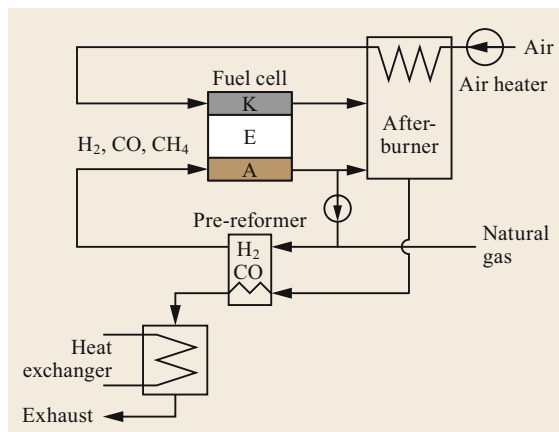

**Fig. 2.134** Basic system of a PAFC plant (adapted from [2.47])

conduction, the mixture must be in molten form, that requires an optimum operating temperature of 600 °C. The mixed melt is retained in a matrix. Special catalysts are not necessary and nickel can be used as electrode material. The MCFC is therefore relatively inexpensive from the point of view of the materials, but the achievable power densities are relatively low and for a long service life it is necessary to operate as consistently as possible and to regenerate the electrolyte. Consequently, the MCFC is suitable for stationary applications with waste heat recovery.

MTU Friedrichshafen developed its *HotModule* over a longer period of time until it was ready for series production. The MCFC is operated directly with natural gas, that is internally reformed using part of the waste heat and achieves an electrical efficiency of almost 50%. The *HotModule* was offered in plant sizes of 250 kW<sub>el</sub> and 345 kW<sub>el</sub> and a total of 10 plants were produced. Due to the poor sales forecasts, the planned series production was not started by the Tognum fuel cell division, which emerged from the former MTU, and the activities were discontinued in 2010.

### Solid Oxide Fuel Cell (SOFC)

The SOFC is the simplest concept in terms of structure (Fig. 2.135). Thanks to the high operating temperature of 800 °C, the natural gas (or other hydrocarbons) can be converted directly at the anode into hydrogen and carbon monoxide. Since carbon precipitation at the anode leads to problems, the natural gas is partially processed in the pre-reformer after desalination in order to accelerate the reactions. The proportion of carbon in the fuel gas is reduced and a hydrogen-rich gas is produced. The oxygen O<sup>2-</sup> ionized on the cathode side penetrates the electrolyte consisting of

**Fig. 2.135** Basic system of a SOFC plant (adapted from [2.47])

zirconium oxide and oxidizes the fuels on the anode side.

The operating temperature of the SOFC can be easily controlled by the excess air, and the high temperature of the exhaust gases allows heat to be extracted for a wide variety of applications or for the plant to be operated as a block-type thermal power station. The SOFC fuel cell is still under development, and only prototypes up to 100 kW are currently in operation. Although many technological problems still have to be solved and the economic threshold has not yet been reached, it should have a promising future due to its simplicity and high power density (today approximately 6 kW/m<sup>2</sup>, proven in the laboratory up to 19 kW/m<sup>2</sup>) as well as its high efficiency (plant efficiency over 50%).

Sulzer AG started the development of a fuel cell heater based on SOFC technology under the project name *Hexis* in 1991. In 2006 the development team of the product founded a company of the same name with the aim of continuing the development. In 2011, the third generation of the fuel cell heater *Galileo 1000 N* was presented. The system is designed for an output of 1 kW<sub>el</sub> and 1.8 kW<sub>th</sub>. With additional burners, the thermal output can be increased up to 20 kW. The device can be connected directly to the natural gas grid and can also be operated with biogas. In the meantime, more than 200 devices have already been manufactured, that provide practical operating experience within the framework of funding programs.

### System Technology

Fuel cell systems generate a direct current similar to photovoltaic systems, that is used directly for small applications and converted into alternating current by means of inverters for larger applications in stand-alone operation or grid connection (Fig. 2.136). The inverter, having problems similar to those of photovoltaics (Sect. 2.8.5), has the possibility of regulating the reactive power output or consumption within certain limits.

In addition to the application of the SOFC cell as a block-type thermal power station, as already mentioned, which can have fuel efficiency rates of 80%, the combination with microturbine technology is also of interest. The hot exhaust gases of the fuel cell are used at pressures of 3–4 bar for the operation of a downstream gas turbine (Fig. 2.137). Pilot plants up to 1 MW are planned.

Dr-Ing Valentin Crastan is professor emeritus. After practical and managerial work in energy technology companies (Brown Boveri/ABB, Baden, Swiss electricity and transport company (Suisselectra), Basel), he has been appointed professor of energy systems and control engineering at the Bern University of Applied Sciences, Engineering and Computer Science, Biel. He also served as the Dean of the Department of Electrical Engineering/Communications for nine years.

# High Voltage

## 3. High Voltage Engineering

Ernst Gockenbach

High-voltage engineering is knowledge about power transmission at high voltages and about stress on equipment used in high-voltage transmission systems. The basis for the design of high-voltage equipment is stress on the insulation by the electric field, whereby the stress magnitude depends on the voltage type. The electric field distribution is given by relative permittivity for alternating current (AC) and by conductivity for direct current (DC) and homogeneity of the electrode arrangement. Evaluation of the electric strength requires statistical and adjusted test methods. Basic knowledge about the breakdown behavior in gases is the basis for understanding the breakdown in fluids and solids. The breakdown of fluids is influenced by moisture, impurities, and stressed volume. Solids suffer from the same parameters, but thermal and erosion breakdowns and residual life time are of interest. Different kinds of insulation gases, fluids and solids, inorganic and organic, as well as impregnated solids are used in high-voltage insulation, and each of them has its own characteristics, which requires a careful selection depending on the equipment and the expected electric stress. Generation of test voltages requires specialized voltage and current generators for AC, DC, and impulse voltages. The measurement of different voltage types also requires specialized measuring circuits, including partial discharge and dielectric characteristics measurement.

### 3.1 Why High-Voltage Engineering?

Someone may ask why high voltage and high-voltage engineering? With the invention of the dynamo-electric principle by Werner von Siemens in 1866, the use of electric power started its worldwide triumph due to the fact that power transmission with electricity was much easier than mechanical transmission by belts or gears. The transmission of electric power can be easily car-

ried out with overhead lines, cables, or gas-insulated lines. The fundamental requirements on the transmission systems are the cross section of the conductor, depending on the required current and the material of the conductor, copper or aluminum, and the strength of the insulation between the conductor and ground, because a potential difference between the conductor

and ground, generally expressed as voltage, is necessary to drive a current through the conductor. There are some further requirements on electric power transmission, like the thermal behavior of cable insulation or the allowed sag of an overhead line, but they very often depend on the local situation and, therefore, will not be described here in detail.

An actual electric system consists of generation stations with conventional energy sources like coal, gas, or oil, or with nuclear or regenerative sources like water, wind, sun, biomass, or geothermal ones. Transmission systems are necessary to bring electric power to the consumer, and these days these systems are usually divided into transmission systems for large distances and distribution systems for local distribution of the electric power.

Electric power is given by the voltage multiplied with the current

$$P = UI. \quad (3.1)$$

The values for  $U$  and  $I$  are peak values for DC voltage of the root mean square (rms) value for AC voltages, where the phase angle between voltage and current should also be taken into account. The simple equation (3.1) will be used to explain the reason why different voltage levels are used in the entire transmission system and, therefore, no details concerning active or reactive power are considered. There are two parameters in (3.1), and for a given power  $P$ , the optimum of the combination of the two parameters is important for an economic transmission system of electric power. Electric power transmission will have some losses, and these losses  $P_{\text{los}}$  are mainly given by the resistance of the conductor and the square of the current

$$P_{\text{los}} = RI^2. \quad (3.2)$$

This means that the losses increase with the square of the current, and the reduction of the losses requires a larger cross section of the conductor. On the other hand, the increase of the voltage  $U$  requires a higher insulation performance, and this can be reached depending on the insulation material, for example, with thicker insulation for cables or larger distances for air insulation of overhead lines. For a given transmission length and power, the total costs, investment, and losses have a minimum at a certain voltage level, because the investment costs increase with the voltage level, and the losses decrease with the voltage level. Figure 3.1 schematically shows the total costs for an electric power transmission system.

Following this general rule according to Fig. 3.1 would lead to a large number of voltage levels depending on the length and power of the transmission system.

Fig. 3.1 Typical total costs for an electric power transmission system as function of the system voltage

This is economically not reasonable and, therefore, the International Electrotechnical Commission (IEC) and its relevant Technical Committees in cooperation with the scientific organization Conseil International des Grands Réseaux Électriques (CIGRE) have fixed a number of voltage levels, as given in [3.1]. The tables in [3.1] divide the voltage levels into two ranges, range I from 3.6 kV as the highest voltage for equipment  $U_m$  up to 245 kV, and range II from 300 kV as the highest voltage for equipment  $U_m$  up to 1200 kV. These voltage ranges for high-voltage equipment are related to different test procedures, with AC voltage at a power frequency between 48 and 62 Hz and to withstand tests with switching- and lightning-impulse voltages. The main reason for the coordination of the kind and value of the different test voltages is that the selected withstanding voltages should be associated with the highest voltage for equipment  $U_m$  for insulation coordination purposes only. Further advantages of fixed voltage levels are standardization of the equipment and simplified requirements for the equipment manufacturer.

The number of voltage levels has led to some expressions in the high-voltage range that are not fixed as well-defined voltage levels. Up to 1 kV, the voltage level is named low voltage, above 1 kV there exist expressions like medium voltage in the range up to about 60 kV, very often termed the distribution system voltage level, high voltage up to 400 kV, extra high voltage up to 800 kV, and ultra-high voltage (UHV) above 800 kV. These terms are not standardized and may be used differently in various countries.

For reliable insulation coordination, standardized test voltages in frequency, amplitude, and shape are defined by the IEC recommendation IEC 60060-1 [3.2]. An AC test voltage should be in the frequency range from 48 to 62 Hz with a small deviation from the sinusoid shape, which is defined as that the ratio of peak to rms values equals  $\sqrt{2}$  within  $\pm 5\%$ . The tests

**Fig. 3.2** Standard lightning-impulse voltage according IEC 60060-1 (adapted from [3.2])

with impulse voltages should represent the voltage stress caused by switching operations by a standardized switching-impulse voltage and the stress caused by atmospheric overvoltage by a standardized lightning-impulse voltage. Both impulse voltages can generally be described as a sum of two exponential functions, like

$$u(t) = KU_0[\exp(-t/\tau_1) - \exp(-t/\tau_2)], \quad (3.3)$$

where  $K$  is a constant depending on the parameters of the impulse voltage generator,  $U_0$  is the DC charging voltage of the impulse generator, and  $\tau_1$  and  $\tau_2$  are time constants that also depend on the impulse generator.

A standard lightning impulse according IEC [3.2] is shown in Fig. 3.2.

The time  $T_1$  is the front time, defined as 1.67 times the time  $T_{AB}$ , which is the measured time between

points A (30%) and B (90%) of the maximum value of test voltage  $\hat{u}$ . The front time of a standard lightning impulse is  $1.2 \mu\text{s} \pm 30\%$ . The time  $T_2$  is the time to half value, which means the difference between the two 50% points of the voltage curve. The time to the half value of a standard lightning impulse is  $50 \mu\text{s} \pm 20\%$ . The virtual origin  $O_1$  is the intersection with the time axis of a straight line drawn through the reference points A and B on the front assuming a linear time scale, which is usually the case for lightning impulse measurements.

There are two other standard impulse voltages in [3.2], where the impulse is chopped in the front of the impulse or in the tail of the impulse. Figure 3.3 shows the two chopped impulses.

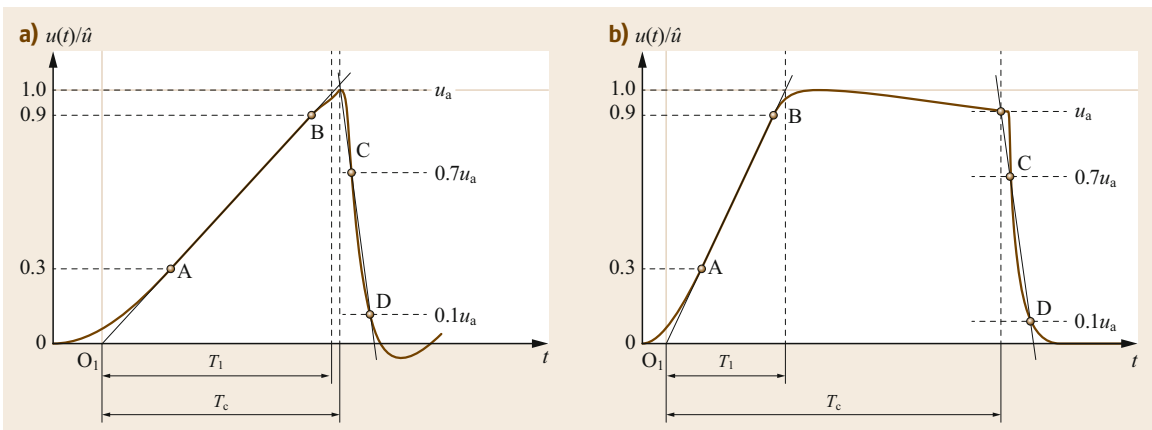

Additional parameters like chopping time  $T_c$  and the chopping steepness, based on the time interval between points C and D in Fig. 3.3 are introduced, whereby the values are defined by the relevant technical committees and also depend on the chopping device used.

The stress of the equipment during switching operations is simulated by the standard switching impulse shown in Fig. 3.4.

The time  $T_{AB}$  is the measured time between point A (30%) and B (90%) of the maximum value of test voltage  $\hat{u}$ . The time to peak  $T_p$  is then calculated according to

$$T_p = KT_{AB} \quad \text{with } K = 2.42 - 3.08 \times 10^{-3} T_{AB} + 1.51 \times 10^{-4} T_2, \quad (3.4)$$

which is valid for the standard switching impulse with a time to peak of  $250 \mu\text{s} \pm 20\%$  and a time to the half value of  $2500 \mu\text{s} \pm 60\%$  and where  $T_{AB}$  and  $T_2$

**Fig. 3.3a,b** Chopped lightning-impulse voltages (a) front-chopped (b) tail-chopped according to IEC 60060-1 (adapted from [3.2])

**Fig. 3.4** Switching impulse according to IEC 60060-1 (adapted from [3.2])

are given in microseconds. A simpler definition of  $T_p$  is given in IEC 60060-3 for on-site tests with

$$T_p = 2.4T_{AB} \quad (3.5)$$

Some further voltage shapes representing overvoltage with different frequencies and voltage amplitudes are also described in IEC 60071-1 [3.1]. In the low-frequency range, temporary overvoltage exists within a frequency range from 10 to 500 Hz, which may be caused by changes in the electric power system. The duration of the temporary overvoltage ranges between ms and up to 1 h. The transient overvoltage can be divided into three parts: slow-front transient overvoltage with a time to peak  $T_p$  in the range from 20 to

5000  $\mu$ s and a duration up to 20 ms, fast-front transient overvoltage with a front time between 0.1 and 20  $\mu$ s with a duration of less than 300  $\mu$ s, and very-fast-front transient overvoltage with a raise time of less than 100 ns and superimposed high-frequency oscillations in the range of 300 kHz up to 100 MHz on lower frequencies in the range of 30 up to 300 kHz.

Besides the standardized impulse voltages, current impulses are also defined and described in IEC 62475 [3.3]. An example of an impulse current is shown in Fig. 3.5.

The definition of the front time  $T_1$  is different to that of the impulse voltage, and it is 1.25 times the measured time  $T$  between 10 and 90% of the maximum value of the test current  $\hat{i}$ . The time to half value  $T_2$  is defined analogously to the lightning-impulse voltage as the time difference between the two 50% values. Depending on the test objects, the front time  $T_1$  varies between 1 and 10  $\mu$ s, and the time to half value  $T_2$  between 20 and 350  $\mu$ s, whereby the tolerances for the front time are in the range from 10 to 30% and for the time to half value 20%.

In recent years, the DC voltage for transmission systems has become increasingly important. The DC voltage is usually generated by rectification of an AC voltage, supported by a capacitor, and, therefore, the amplitude of the DC voltage is not smooth. The deviation from the mean value is named ripple, and the allowed value for a standard DC voltage is  $\pm 3\%$  of the mean value, whereby the ripple is defined as half of the difference between the maximum and minimum values of the applied voltage.

**Fig. 3.5** Typical shape of an impulse current according to IEC 62475 (adapted from [3.3])

The task of high-voltage engineering is to design high-voltage equipment that is safe and economical with respect to operation and insulation systems. Transmission systems are necessary because generation and consumption of electric power usually do not occur at the same place, even if recently a decentralization of electric power generation has been demanded. Due to the losses of electric power transmission and also to an increase in

insulation costs with increasing voltage level, a compromise is required to obtain the optimum parameters of an electric power transmission system. As a general rule, it can be stated that the voltage level in kV should be similar to the distance in km, whereby also exceptions exist. Finally, high-voltage applications also exist, e.g., in the medical sector, electromagnetic interference tests, x-ray technology, and lightning protection.

## 3.2 Lightning

Lightning is the effect of thunderstorms. Most lightning occurs between clouds, and these are not of interest for high-voltage engineering, except the possible magnetic field that may be caused by lightning discharge. Some lightning strokes touch the ground or objects on the ground, and the most favored objects are those that tower above their surroundings, like high buildings, church towers, or overhead line towers. Therefore, lightning protection is one parameter regarding insulation coordination, and the risk of lightning can be defined by the frequency of lightning strokes and the ground flash density, which is given as the average number of strokes per unit area and per unit time at a particular location. Another parameter is the keraunic level, which gives the average number of thunderstorm days for a given locality. For most regions, maps are available for ground flash density and keraunic level. For high-voltage engineering, the possible voltages that may occur on overhead lines or outdoor substations belong to the group of external overvoltage, and it should be noted that the voltage level of a lightning stroke in an electric power system is independent of the system voltage.

### 3.2.1 Generation of a Lightning Stroke

The basis for a lightning stroke is a thunderstorm cloud. This requires strong up winds and wet air. Within the thunderstorm cloud a separation of positive and negative charges occurs due to upwards-moving condensed water droplets and downwards-moving ice crystals, and freezing rain. The typical distribution of charges within a thunderstorm cloud is positive ice crystals in a high area of about 8–10 km, a main area below with negative charges at a level of about 5 km, and, sometimes, a limited area with positive charge below the main negative charge area. The discharge then occurs between the cloud and the ground, and in most cases, a negative charge will be transferred from the cloud to the ground. The direction of the discharge is downwards in most

cases, and in a few cases of discharge upwards if tall structures like a tower exist. Figure 3.6 shows the final situation with a still image of downwards lightning (left part) and upwards lightning (right part) starting from a high tower.

The development of lightning can be divided into several parts: the leader discharge, starting from the cloud, the downwards and upwards leader, the main discharge channel, and a number of possible subsequent strokes. Figure 3.7 shows schematically the development of a negative cloud into ground lightning.

A leader starts from the cloud (1 in Fig. 3.7) but due to missing charges, the leader stops and only continues if enough charges flow in the channel again. Then, the

**Fig. 3.6** Downwards (*left*) and upwards (*right*) lightning (adapted from [3.4])

**Fig. 3.7** Chronological development of a negative lightning stroke (adapted from [3.4])

leader grows further in steps of about 50 m (2 and 3 in Fig. 3.7), but the direction depends on the conditions in the neighborhood. The leader now jumps in the direction towards the ground (4 and 5 in Fig. 3.7), and it may happen that a higher building will be bypassed, because the leader path is not influenced by the structure on the ground. If the leader approaches the ground, discharge channels start from the tip of the leader (negative, downwards leader) and at the same time from the protection device or air (6 in Fig. 3.7) (positive, upwards leader) due to the high electric field. Then, the main discharge occurs (7 in Fig. 3.7) with possible subsequent so called return strokes (8 in Fig. 3.7). Limited downwards and upwards leader lengths (6 in Fig. 3.7) are the cause of lightning strokes being possible alongside higher structures like buildings or towers. Therefore, air terminations have a limited protection area. The individual shapes of lightning strokes may differ significantly, but a standardized lightning impulse test voltage is defined with  $1.2 \mu\text{s}$  front time and  $50 \mu\text{s}$  time to half value in order to simulate the reproducible effect of a lightning stroke.

The effect of a lightning stroke can be divided into direct and indirect effects. Direct effects are overvoltage, traveling waves on overhead lines, and mechanical forces between conductors. Furthermore, heat generation can damage conductors in the path of the lightning current. Indirect effects can cause voltage drops across impedances with transient potential differences

between grounded parts and can cause so-called *back flashovers* from grounded conductors into active lines of electric systems. The strong and varying magnetic field of a lightning stroke current may induce high voltages in loops.

Lightning can be characterized by its current parameter. The peak value is responsible for the voltage drop over earthing resistances for overvoltage and traveling waves. The rate of current rise  $di/dt$  allows the calculation of voltage drops at inductances and induced voltages in nearby conductor loops. The charge of the lightning stroke is the integral of the current over the time and is responsible for the heat energy, which may cause fusing of the conductors. The integral of the squared current over time is related to the ohmic losses in the conductors and the mechanical impulse.

The range of the current of a lightning stroke is a few kA up to 200 kA, according to Fig. 3.8.

The dots in Fig. 3.8 are values that are used for the evaluation of lightning protection level I. Lightning protection levels are divided into four levels; level I has the strongest requirements. The maximum value for a positive lightning is 200 kA at a probability of about 7%. At a glance this seems to be a relatively high value, but it should be taken into account that the number of positive lightning strokes is about 10% of the total number of lightning strokes, which results in a probability of 0.7% for a positive lightning stroke. The probability of a first negative lightning with an amplitude of 200 kA

**Fig. 3.8** Probability of lightning stroke current (1 – first negative lightning, 2 – subsequent negative lightning, 3 – positive lightning) (adapted from [3.5])

is, according Fig. 3.8, so low that the probability of all lightning strokes reaching 200 kA is in the range of 1%, and this was the reason to fix 200 kA as the basis for lightning protection level I.

### 3.2.2 Lightning Protection

A general concept of lightning protection is given in IEC 62305-1:2010 [3.6]. There are several methods to evaluate the necessary protection devices, and the most common methods are classical empirical curve design using a fixed protection angle, electrogeometric model known as the rolling sphere method and the collection volume method. The first method is not recommended for high-voltage substations, particularly for substations at higher system voltages. The second method contains an imaginary sphere of a fixed radius, representing the lightning stroke distance and the stroke current; the sphere is rolled over the structure, and no part of the equipment intersects with the sphere. However, the

method assumes a fixed striking distance, regardless of the height of a structure. The third method is based on Eriksson's Attractive Radius Model and takes into account the physical features of the structure. Based on this and the intensification of the electric field created by different points of the structure, the method provides recommendations for the optimum placement of lightning rods or air terminals. General statements for high-voltage engineering regarding lightning protection are the following. Lightning strokes cannot be prevented because they are natural events. Lightning protection devices should attract the lightning stroke so that the discharge takes place at a defined point. The protection of high-voltage apparatus should then be ensured by proper insulation coordination with the help of surge arresters or with a controlled discharge by an adapted conductive lead between the lightning protection device and the ground. In most cases, the interception unit is a metallic rod, which is reasonably higher than the environment and is well known as the Franklin rod.

## 3.3 Electric Field

### 3.3.1 Basics

In most cases, the high-voltage engineer is dealing with an electric field and mostly with an electrostatic electric field. Due to the low power frequency of 50 or 60 Hz,

the coupling between the electric and magnetic fields is very small and can be neglected. In consequence, the Maxwell equations can be simplified, because all the terms with a time derivative become zero. If the conductivity  $\kappa$  is negligible or theoretically zero, the electric

and magnetic fields are totally decoupled. The electric field  $\mathbf{E}$  can be expressed as

$$\oint_s \mathbf{E} ds = 0, \quad (3.6)$$

which means that the integral of the electric field for a closed loop is zero. Another equation describes the displacement density  $\mathbf{D}$ , which is related to the electric field  $\mathbf{E}$  and the product of the permittivity of vacuum  $\varepsilon_0$  and relative permittivity of the relevant material  $\varepsilon_r$ ,

$$\mathbf{D} = \varepsilon_0 \varepsilon_r \mathbf{E}. \quad (3.7)$$

With (3.7) the charge  $Q$ , which is enclosed by a closed area  $A$ , can be calculated

$$\oint_A \mathbf{D} d\mathbf{A} = Q. \quad (3.8)$$

These equations are the result of the simplified Maxwell equations, and (3.8) is often named the basic law of the electric field.

The electric field can also be described by a scalar potential, which is sometimes clearer. The electric field is then given by gradient of the potential

$$\mathbf{E} = -\text{grad } \varphi. \quad (3.9)$$

The minus sign comes from the definition of the direction of the electric field; the electric field vector is positively directed in the direction of the decreasing potential, which gives a negative gradient, and with the minus sign a positive direction of the electric field [3.4, 7].

### 3.3.2 Homogenous Electric Field

The typical electrode arrangement for a homogenous electric field is a capacitor under disregard of the edges of the electrodes, as shown in Fig. 3.9.

The potential of the upper electrode is  $U$ , and the potential of the lower electrode is 0. The equipotential lines are linearly distributed, and only the lines for  $3/4 U$ ,  $1/2 U$  and  $1/4 U$  are plotted. The electric field lines go from potential  $U$  to potential 0, and this also gives the orientation of the field vector of the electric field, as well as the vector of the displacement density. The vectors  $\mathbf{D}$  and  $d\mathbf{A}$  are parallel oriented and, therefore, the vectors can be replaced by the magnitudes. The electric field stress can be calculated as

$$E(x) = \frac{Q}{\varepsilon_0 \varepsilon_r A} = E_0 = \text{const.} \quad (3.10)$$

Fig. 3.9 Capacitor with a homogeneous dielectric

The parameter charge  $Q$ , permittivity of the vacuum  $\varepsilon_0$ , and relative permittivity of the related material  $\varepsilon_r$  (homogeneous material), and the area  $A$  are all independent of the variable  $x$  or on the location within the capacitor and, therefore, the electric field is constant in the entire volume of the capacitor. The electric field is the main parameter of the performance of a dielectric; however, in high-voltage engineering the main parameter is the applied voltage during service or during tests. Therefore, the relation between the electric field stress and applied voltage is important. From (3.9), the voltage can be calculated by the following steps

$$\begin{aligned} E &= -\text{grad } \varphi \Rightarrow E = -\frac{d\varphi}{dx} \\ \Rightarrow \int_0^d E dx &= - \int_{\varphi=U}^{\varphi=0} d\varphi \Rightarrow Ed = U. \end{aligned} \quad (3.11)$$

The charge  $Q$  and the capacitance of the capacitor can then be expressed by

$$Q = \varepsilon_0 \varepsilon_r A \frac{U}{d} \quad \text{and with} \quad C = \frac{Q}{U} \Rightarrow C = \varepsilon_0 \varepsilon_r \frac{A}{d}. \quad (3.12)$$

### 3.3.3 Layered Dielectrics

In high-voltage components, layered dielectrics very often exist, and, therefore, the distribution of the electric field within the complete insulation system and in the individual sections is important. This situation can be described by three simplified models with only two different materials. The first example is the arrangement where the boundary is transverse to the vector of the electric field; the second example is the arrangement where the boundary is parallel to the vector of the electric field, and the third example is the arrangement where the boundary has a random angle to the vector of the electric field.

Fig. 3.10 Electric field with transverse boundary

#### Arrangement with Transverse Boundary

Figure 3.10 shows a schematic sketch of the first example.

The permittivity of materials is given by  $\varepsilon_1$  and  $\varepsilon_2$ , which is the abbreviation for the product of the permittivity of the vacuum  $\varepsilon_0$  and the relative permittivity for the material  $\varepsilon_r$ .

The applied voltage is  $U$  and the electric field stress  $E_1$  and  $E_2$  should be evaluated. According to (3.7), the vector of the electric field  $\mathbf{E}$  has the same direction as the vector of the displacement density  $\mathbf{D}$ . These vectors can generally be separated in a component rectangular to the boundary, named with index n, and a component parallel to the boundary, named with index t. For the displacement density it applies that the normal component  $D_n$  is equal in both materials, and this leads to

$$D_{1n} = D_{2n} . \quad (3.13)$$

This results in the different electric fields in the two materials according to

$$\varepsilon_1 E_{1n} = \varepsilon_2 E_{2n} \Rightarrow \frac{E_{1n}}{E_{2n}} = \frac{\varepsilon_2}{\varepsilon_1} \Rightarrow E_{1n} = E_{2n} \frac{\varepsilon_2}{\varepsilon_1} . \quad (3.14)$$

The material with the lower relative permittivity will be more stressed due to the higher electric field, and the increase is reversed proportional to the relative permittivity; this consequence is very important for the evaluation of the electric stress in insulation systems with different materials and different permittivities.

#### Arrangement with Parallel Boundary

Figure 3.11 shows a schematic sketch of the second example with the same nomination as for Fig. 3.10.

In this case, the tangential components of the electric field vectors are the same in both materials, and no normal components exist. This can be expressed as

$$E_{1t} = E_{2t} . \quad (3.15)$$

Fig. 3.11 Electric field with parallel boundary

This results in the displacement density in the two materials according to

$$\frac{D_{1t}}{\varepsilon_1} = \frac{D_{2t}}{\varepsilon_2} \Rightarrow \frac{D_{1t}}{D_{2t}} = \frac{\varepsilon_1}{\varepsilon_2} \Rightarrow D_{1t} = D_{2t} \frac{\varepsilon_1}{\varepsilon_2} . \quad (3.16)$$

The displacement density is proportional to the relative permittivity.

The equations (3.13)–(3.16) are only valid for AC and impulse voltage, where the conduction current is negligible. However, for DC voltage, the same fundamental equations can be used if the permittivity  $\varepsilon$  is replaced by the related conductivity  $\kappa$  under the assumption that the displacement current can be neglected.

#### Arrangement with Random Boundary

Figure 3.12 shows an example of the situation where the electric field or the displacement density vector have a certain angle to the boundary.

For the evaluation of the different displacement densities in the two insulation materials, the following equations can be used, and then it is clear that only the two special cases, shown in Figs. 3.10 and 3.11, and their relevant equations (3.14) and (3.16) are required,

$$\frac{D_{1t}}{D_{2t}} = \frac{\varepsilon_1}{\varepsilon_2} \quad \text{and} \quad \frac{E_{1n}}{E_{2n}} = \frac{\varepsilon_2}{\varepsilon_1} \quad \varepsilon_2 > \varepsilon_1 . \quad (3.17)$$

Due to these conditions, the angle  $\alpha$  will be changed from the insulation material to the other one. The same applies for the electric field vector.

Fig. 3.12 Displacement density with random boundary

### 3.3.4 Inhomogeneous Electric Field

The magnitude of the electric field is one of the main parameters for insulation materials with respect to its strength and breakdown behavior. A homogeneous electric field in a plate–plate capacitor can be reached for material investigations in a laboratory, but in real electrode arrangements in high-voltage equipment, the electric field is not completely homogenous. The arrangements with inhomogeneous electric fields can be divided into weak inhomogeneous or strong inhomogeneous fields, but there is no clear definition for the differentiation. Very often, the maximum value of the electric field in an insulation system is the source for the beginning of a breakdown process and, therefore, to know this value is very important. The degree of inhomogeneity was already evaluated a long time ago, and the calculation of the electric field was very difficult and time consuming. In [3.8], a method is described that gives a relation between the actual electric field configuration and the electric field in an arrangement with the same electrode distance but a homogeneous electric field, and this relation is named after the inventor the *Schwaiger utilization factor*  $\eta$ . Depending on the value of this factor, also a separation of the inhomogeneous electric fields can be made. Nowadays, this factor is still very convenient for estimating the maximum electric field in an arrangement, even if the field calculation with the different methods uses the charge simulation method, the finite differences methods, and the finite element method, as numerical field calculation methods deliver more precise values. The factor is defined as

$$\eta = \frac{E_0}{E_{\max}} \quad \text{with} \quad E_0 = \frac{U}{d}, \quad (3.18)$$

with the maximum electric field  $E_{\max}$  and the average field  $E_0$  given by the applied voltage  $U$  divided by the electrode distance  $d$  of the electrode arrangement, simulating a homogeneous electric field. A further method for calculation of the electric field is the conformal map based on the theory of complex variables; however, nowadays it is only available in textbooks on high-voltage engineering.

A typical electrode arrangement in high-voltage equipment is the coaxial electrode arrangement shown in Fig. 3.13, which can be found in a high-voltage cable, a high-voltage gas insulated system, or in gas-insulated switchgears (GIS) or gas-insulated transmission lines (GIL).

The inner electrode is a cylinder with the radius  $r_1$ , and the outer electrode a cylinder with the radius  $r_0$ . The electric field vector  $\mathbf{E}$ , as well as the displacement

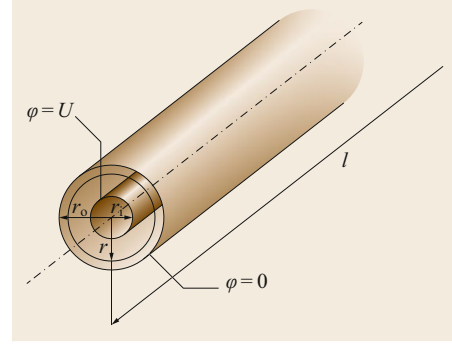

Fig. 3.13 Coaxial electrode arrangement

density vector  $\mathbf{D}$ , are perpendicular to the surface of the inner and outer electrodes. With (3.8), the charge  $Q$  can be applied to calculate the electric field. The area  $A$  of the inner electrode is given by the surface of the inner electrode (conductor), neglecting the area of the surface of the two ends of the conductor, because the length  $l$  is much larger than  $\pi r_1^2$ . The electric field at the position  $r$  is given by (3.19), whereby  $r_1 \leq r \leq r_0$ ,

$$\oint_A \mathbf{D} dA = Q \Rightarrow Q = DA = \varepsilon_0 \varepsilon_r E_r 2\pi r l$$

$$\Rightarrow E_r = \frac{Q}{\varepsilon_0 \varepsilon_r 2\pi r l}. \quad (3.19)$$

The electric field is only dependent on the radius  $r$ , and with (3.11) the electric field can be expressed as a function of the derivative of the potential  $\varphi$ ,

$$E_r = \frac{Q}{\varepsilon_0 \varepsilon_r 2\pi r l} = -\frac{d\varphi}{dr}. \quad (3.20)$$

An integration of (3.20) from  $r_1$  to  $r_0$  is equivalent to the integration of the potential  $\varphi$  from  $U$  to zero or ground

$$\int_{\varphi=0}^{\varphi=U} d\varphi = -\frac{Q}{\varepsilon_0 \varepsilon_r 2\pi l} \int_{r_0}^{r_1} \frac{1}{r} dr$$

$$\Rightarrow U = -\frac{Q}{\varepsilon_0 \varepsilon_r 2\pi l} (\ln r_1 - \ln r_0), \quad (3.21)$$

and this leads to the final equation concerning the dependence of the electric field on the radius  $r$

$$E_r = \frac{U}{r \left( \ln \frac{r_0}{r_1} \right)}. \quad (3.22)$$

The electric field of a simple electrode arrangement can be manually calculated, and from (3.22) it can be de-

**Fig. 3.14** Schwaiger utilization factor as function of electrode geometry (adapted from [3.4])

pictured that the electric field has its maximum at  $r = r_i$ , which means on the surface of the inner electrode.

For such an electrode arrangement, but also for other configurations, the Schwaiger utilization factor can be found in the literature [3.4] and [3.9]. The coaxial cylinder and the coaxial spheres are listed as the same electrode configuration due to the same cross section defined with the variable  $p$ , depending on the electrode distance and the radius of the inner electrode

$$p = \frac{r_i + (r_o - r_i)}{r_i} . \quad (3.23)$$

For the value of the Schwaiger utilization factor, it should be differentiated between the plane electric field, coaxial cylinder, and the rotational symmetry electric field and coaxial spheres, as shown in Fig. 3.14.

As an example, the electric field in a gas-insulated line (GIL) should be calculated using (3.22) and the Schwaiger utilization factor according Fig. 3.14.

The dimensions of the GIL should be  $r_o = 250$  mm and  $r_i = 75$  mm. According to (3.22), the electric field

at the inner electrode is

$$E_r = \frac{318 \text{ kV}}{75 \text{ mm} \left( \ln \frac{250 \text{ mm}}{75 \text{ mm}} \right)} = 3.52 \frac{\text{kV}}{\text{mm}} . \quad (3.24)$$

With these data, the parameter  $p$  is given as

$$\begin{aligned} p &= \frac{r_i(r_o - r_i)}{r_i} \\ &= \frac{75 \text{ mm} + (250 \text{ mm} - 75 \text{ mm})}{75 \text{ mm}} = 3.33 , \end{aligned} \quad (3.25)$$

and according to Fig. 3.14,  $\eta$  is 0.52 for a coaxial cylinder. With (3.18), the maximum electric field can be calculated or estimated to

$$\begin{aligned} E_{\max} &= \frac{E_0}{\eta} = \frac{1.82 \frac{\text{kV}}{\text{mm}}}{0.52} = 3.5 \frac{\text{kV}}{\text{mm}} \\ \text{with } E_0 &= \frac{U}{d} = \frac{318 \text{ kV}}{175 \text{ mm}} = 1.82 \frac{\text{kV}}{\text{mm}} . \end{aligned} \quad (3.26)$$

The difference between both values for the maximum electric field is very small, only about 0.6%, and this confirms the helpful use of the Schwaiger utilization factor for the estimation of the maximum electric field in an inhomogeneous electric field arrangement.

As a general statement concerning electrode arrangements for homogeneous and inhomogeneous electric field it can be stated that the best configuration is a plane-plane electrode with a homogeneous electric field, assuming a perfectly smooth electrode surface. The coaxial cylinder arrangements usually have a weak inhomogeneous electric field, which is shown in Fig. 3.14 by the higher values of  $\eta$  at the same value of  $p$ . The stronger inhomogeneous electric field has coaxial sphere arrangements, but these usually do not exist in high-voltage equipment.

### High-Voltage Cables as an Example of the Inhomogeneous Electric Field

Figure 3.13 shows a cross section of a typical coaxial cylinder. The insulation is a polymeric material, e.g., crosslinked polyethylene (XLPE) with inner and outer conductive layers as electrodes with a smooth surface. The task of a high-voltage engineer could be to optimize the design of the cable, so that the maximum electric field at the conductor reaches a minimum at a given radius of the outer electrode. The solution can be found by the partial derivative of (3.22) with respect to the radius of the inner electrode  $r_i$

$$\frac{\partial E_r}{\partial r_i} = U \frac{\partial}{\partial r_i} \frac{1}{r_i \ln \left( \frac{r_o}{r_i} \right)} \Rightarrow \frac{r_o}{r_i} = e , \quad (3.27)$$

**Fig. 3.15** Electric field distribution in a DC cable depending on temperature ( $E$  – field strength,  $\Delta\vartheta(r_i - r_o)$  – temperature difference) (adapted from [3.10])

### 3.4 Electric Strength

The performance of high-voltage equipment is mainly based on the performance of the insulation system and its electric strength, which means the ability to withstand an electrical breakdown. The evaluation of the performance is based on an empirically determined withstand voltage, where different types of voltages are applied, such as the system voltage AC with 50 or 60 Hz, the system voltage DC, and the relevant impulse voltages. In [3.1], the amplitudes for the voltages for withstand tests are listed as depending on the system voltage and sometimes depending on the local insulation coordination. These test voltages are related to high-voltage equipment like transformers, switchgears, insulators, surge arresters, etc. For insulation materials, the manufacturer usually describes the electric performance in addition to some other important parameters, depending on the type of material – gaseous, fluid, or solid, with the breakdown voltage. For an insulating fluid based on mineral oil, the breakdown voltage  $V_b$  at power frequency is given in kV, based on an IEC recommendation IEC 60156 [3.11] in which the determination of the breakdown voltage is defined with a special

without a detailed derivation of the mathematical steps. The interpretation of (3.27) means that  $\ln(r_o/r_i)$  is equal to 1 to minimize the maximum electric field on the inner electrode. However, for a real high-voltage cable maybe other parameters, like the manufacturing process, limitation of the insulation thickness, etc., will determine the final cable design, which will then lead to a slightly inhomogeneous electric field. A special case are high-voltage DC cables with polymeric insulation, which are coming increasingly into operation also at voltage levels above 500 kV. The electric field distribution is related to the conductivity  $\kappa$  and not to the relative permittivity  $\epsilon$ . Figure 3.15 shows the change of the electric field with an increasing temperature difference between the inner conductor ( $r_i$ ) and the outer conductor ( $r_o$ ).

The reason that the electric field can be higher at the outer electrode than on the inner electrode is the strong dependency of the conductivity on the temperature. The conductivity  $\kappa$  changes in the temperature range from 25 to 80 °C depending on the material, by about two orders of magnitude. The change of the permittivity  $\epsilon$  is, in contrast, in the range of some 10% [3.10].

electrode arrangement. The two partially spherical electrodes have a distance of 2.5 mm and a radius of 25 mm. The ratio between the average electric field and the maximum electric field on the surface of the electrodes is 0.97 [3.7], and this means that the electric field is nearly homogeneous. The breakdown voltage is given as a rms value in kV as the average value of six consecutive breakdowns. Furthermore, the voltage is increased continuously with  $2 \text{ kV/s} \pm 0.2 \text{ kV/s}$ , and the temperature is  $20 \text{ }^\circ\text{C} \pm 5 \text{ K}$ .

The determination of the electric strength of an insulating material requires breakdown tests and an evaluation of the results, because the breakdown voltages differ. In [3.11], the procedure and test parameters are described, and in the case of mineral oil, the average breakdown voltage is the mean value of six breakdown tests; furthermore, the standard deviation and the coefficient of variation, which is the ratio between the standard deviation and the mean breakdown voltage, should be calculated. It is also mentioned that the reproducibility in measuring individual dielectric breakdowns has shown a range of  $\pm 30\%$ . Such tests are different from

the withstand voltage tests for high-voltage equipment, where the performance should be checked with different types of voltages, power frequency AC or DC, and impulse voltages, with voltage levels according to the table of the insulation coordination given in [3.1].

### 3.4.1 Basics of Statistical Analysis

A fundamental requirement in high-voltage technology is to ensure that the electric stress is lower than the electric strength of the insulation under all expected conditions. This requires knowledge of the electric stress as well as of the electric strength of the insulation. The electric strength, however, has a random behavior and, therefore, statistical evaluation procedures are necessary to determine the electric strength. The failure of an insulation system is generally a breakdown, and this can happen due to high electric stress, for example at a voltage test. Furthermore, the decrease of the electric performance may be caused by partial discharges (PD), an electric discharge that only partially bridges the insulation between conductors, which later lead to a breakdown of the insulation, or by ageing of the insulation system caused by several effects like electrical, mechanical, thermal, or chemical stress. In conclusion, the electric strength depends on many parameters, which require a statistical evaluation, because a breakdown is a random event. Depending on the insulation material, the test procedure can be different, for example the breakdown voltage of gas insulation can be determined by several voltage tests with a breakdown, assuming that the performance of the gas is not be changed by previous breakdowns. However, the breakdown voltage of solid insulation can be determined using a new test sample for each breakdown test, and

Fig. 3.16 Gaussian or normal probability function (adapted from [3.12])

besides the normal scattering of the breakdown voltage, this contributes additionally to the scattering. A very large number (infinitely large) of tests would allow us to determine the withstand voltage with a probability of breakdown of 0%, a probability of breakdown of 50%, and a breakdown probability of 100%, but in reality, the number of tests is limited for several reasons, like costs, time, the number of test samples, etc. Therefore, the parameter for the discharge or breakdown must be estimated from a limited number of test results, and the estimation is more precise the more results that are available. With the same procedure, further parameters, like time to breakdown or breakdown as a function of the stress time, can be determined.

### 3.4.2 Distribution Functions

The breakdown voltage of the sphere gap in air can be determined by a progressive stress test. The evaluation follows the typical treatment for random variables, where all independent variables, randomly distributed, contribute to an insignificant amount to the sum. Figure 3.16 shows the distribution function, where the parameter  $x$  can be the breakdown voltage of a progressive stress test [3.12].

The type of distribution is very often used to determine the 50% value, because the distribution is characterized by its 50% value (arithmetic value) and the standard deviation  $\sigma$  estimated by the difference of the values of  $x$  at the probabilities 84 and 50 or 50 and 16%, according to

$$\sigma = (x_{84} - x_{50}) = (x_{50} - x_{16}) . \quad (3.28)$$

This Gaussian distribution is useful for random events and, therefore, also for breakdown tests. In addition to some other probability functions, the Weibull function is very often used to describe extreme values, but it should be used with care due to the possible adaption of the structure. The definition is given in (3.29) and is characterized by three parameters: its 63% value ( $x_{63}$ ), the Weibull exponent  $\delta$  as a measure of the dispersion, and the initial value  $x_0$

$$F(x; \eta; \delta; x_0) = 1 - \exp \left[ - \left( \frac{x - x_0}{\eta} \right)^\delta \right] \\ \text{with } x > x_0 . \quad (3.29)$$

The value of  $F$  is zero for  $x \leq x_0$  and  $\delta = 1.2898 / \log(x_{63}/x_{05})$  [3.12].

For the investigations of time to breakdown, the Weibull function is ideal, setting  $x_0 = 0$ . However, for breakdown voltage investigations, the function should be handled carefully due to the fact that for  $x = x_0$ ,

**Fig. 3.17** Cumulative breakdown frequency  $h_\Sigma$  function in a Gaussian distribution scale (adapted from [3.12])

the value of  $F$  is 0, and this means a breakdown probability of  $p = 0$ , which represents the ideal withstand voltage. For the estimation of the withstand voltage, the proper selection of a theoretical distribution function is very important, and confidence estimation should be performed, where different methods for the estimation of the mean value and the standard deviation are used [3.13].

In high-voltage tests, the empirical distribution function is usually determined from a limited number of experimental test results. The results are ordered according to an increasing magnitude between the lowest and highest value and the cumulative breakdown frequency  $h_\Sigma$ , which is equivalent to the probability, as is shown in Fig. 3.17.

The interpretation of Fig. 3.17 is the following. Impulse voltage tests at a voltage level of 940 kV leads to breakdown probability of 25%, at a voltage level of 960 kV to breakdown probability of 70%. It is clear the evaluation of the breakdown percentage is more precise as more impulses at the same voltage and more different voltage levels are applied. If the approximation of the test results gives a straight line the used distribution function is acceptable and the 50% value can be determined as 953 kV. With the so called maximum likelihood method which is an efficient estimation of parameters including confidence levels the estimated

value can be judged. In Fig. 3.17 the standard deviation  $\sigma$  can also be evaluated according to (3.28) and is 18 kV which is about 2%.

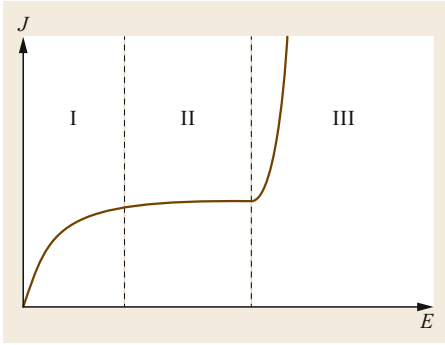

### Test Methods

The simplest method to determine the breakdown voltage is the voltage rise test, which can be applied with self-restoring insulation material. The voltage is increased with a given speed until breakdown happens, and this value is then recorded. The test is repeated several times, and then the average value will be the breakdown voltage. With impulse voltage, two methods can be used. The first one is the up and down method. The test starts with a voltage value at which it is certain that no breakdown occurs. Then the voltage value is increased by fixed steps until the first breakdown occurs. Then the voltage value is reduced by the same step until no breakdown occurs. The voltage value is again increased by the same step until, again, a breakdown occurs. Then the reduction of the voltage value is repeated. After a certain number of impulses, the voltage varies around the 50% value, which has to be estimated. The second method is the application of a given number of impulses at a voltage value where at least one breakdown is expected. For example, with ten impulses and one breakdown, the estimation of the breakdown probability is 10%. If lower values are required, the number of applied impulses should be increased, which increases the test time and the costs. Then the applied voltage value is increased, and the percentage of breakdowns is again calculated. The tests are stopped if a probability of 90% is reached, because no information is available if all impulse tests at the chosen value lead to a breakdown. At the end, probabilities between 10 and 90% are available, and if these values fit in a straight line in a distribution function grid, the 50% value can be estimated. Depending on the kind of insulation, further test methods for the characterization of the material performance should be used, but these methods are described in sections on the breakdown of insulating materials (Sect. 3.4.4 and 3.4.5).

### 3.4.3 Breakdown in Gases

Breakdown in gases depends on the electric field stress and, therefore, the applied voltage, which for a given distance and the arrangement of the electrodes is responsible for the electric field, is less meaningful. A simple example should confirm this. In a homogeneous electrode arrangement, with a plate–plate arrangement of 1 cm distance, the breakdown in air under reference conditions such as air pressure 1013 mbar and temperature 20 °C, occurs at 30 kV, which is an electric field of 3 kV/mm. In an integrated circuit, the distance

**Fig. 3.18** Current density  $J$  as function of the electric field  $E$

between conductors is in the range of some nm or some 10 nm, which at a voltage of 3 V leads to an electric field of  $3\text{ V}/10\text{ nm} = 300\text{ kV}/\text{mm}$ , which is much higher than the electric field in air.

Air is a fundamental gaseous insulation material because it is available everywhere but not always under the same conditions, because pressure, temperature, and humidity can be different, and these parameters influence the general breakdown behavior. At low electric fields gases are very good insulation material due to their low conductivity  $\kappa$  and nearly frequency-independent constant relative permittivity  $\varepsilon \approx 1$ . The current through an air gap is proportional to the applied voltage at low electric fields, and the free charge carriers, like electrons and positive or negative ions, move to the relevant electrodes, the negative charge carrier to the anode and the positive one to the cathode. This behavior is shown in Fig. 3.18, area I, where the current density increases and then passes to a stable value. With increasing electric field, the current density remains constant, where all free charge carriers, generated by different sources like photo-ionization or thermal ionization, are adsorbed by the electrodes before any recombination happens, as is shown in Fig. 3.18 area II. A further increase of the electric field leads to possible impact ionization if the free charge carrier gets enough energy by the acceleration due to the force of the electric field. At this voltage, free-charge carriers are generated by the applied voltage itself, and this process is called the self-sustaining discharge, as is shown in Fig. 3.18, area III. Depending on the character of the electric field and the impedance of the test circuit, this voltage is called the breakdown voltage for a homogeneous electric field and a low impedance test circuit or inception voltage for partial discharges, or glow or corona discharge for an inhomogeneous electric field and high impedance test circuit.

### Homogeneous Electric Field

The breakdown behavior of gases in a homogeneous electric field can be described by the generation of avalanches, also known as generation or the Townsend mechanism or the streamer mechanism. The basis for ionization and generation of an avalanche is the mobility of the free-charge carrier, the electric field, and the ambient gas condition, like gas pressure and temperature, and less gas humidity. The mobility of the electrons and ions is very different. The mobility values  $b$  for the different types of free-charge carriers are given in [3.7] with some simplifications:

- Mobility  $b$  for electrons  $\approx 500\text{ cm}^2/(\text{Vs})$
- Mobility  $b$  for ions (positive or negative)  $\approx 1\text{--}2\text{ cm}^2/(\text{Vs})$ .

This leads to a drift velocity of electrons of  $150\text{ mm}/\mu\text{s}$  and for ions of  $0.3\text{--}0.6\text{ mm}/\mu\text{s}$  for an electric field in air of  $30\text{ kV}/\text{cm}$  and, therefore, only the electrons are taken into account for the breakdown development in gases. The ionization of neutral molecules requires certain energy, and this energy should be equal to or higher than the ionization energy of the used gas, for example the ionization energy  $W_1$  for  $\text{N}_2$  is  $15.6\text{ eV}$  and for  $\text{O}_2$   $12.1\text{ eV}$  [3.7]. Assuming a mean free path  $\lambda$  of an electron in a gas, depending on the gas pressure and the gas temperature, the energy  $W$  is given by the charge of the electron  $q$  and the integral of the electric field  $E$  over the mean free path length

$$W = q \int_0^{\lambda} E(x) dx. \quad (3.30)$$

In a homogeneous electric field, the electric field stress is independent of the position  $x$ , and, therefore, (3.30) can be simplified to become

$$W = qE\lambda \quad (3.31)$$

and can be used to calculate the required ionization voltage  $U_1 = E\lambda$  or the required electric field  $E$ .

In a plate–plate arrangement in air, the breakdown will occur according to the generation or Townsend mechanism [3.14]. Figure 3.19 shows the idealized process.

The electric field is homogeneous, and, therefore, the electrons will get the same energy independently of their location. The number of electrons at the beginning of the discharge process is  $n_0$ , and this already demonstrates one of the conditions of a breakdown: that at least one electron should be available. The best condition for a breakdown is the start of the first electron

Fig. 3.19 Townsend breakdown mechanism

from the cathode. On its way to the anode, the electron may ionize some neutral molecules, and the number of ionization processes is given by the so-called Townsend ionization coefficient  $\alpha$ . This coefficient is defined as the number of ionization processes of one electron per path length, usually in cm, in the direction of the electric field. The last condition is necessary, because the path of an electron after a collision is not always parallel to the electric field direction. The increase of the number of electrons on the way from the cathode to the anode is given by

$$dn = \alpha(x)n(x)dx, \quad (3.32)$$

where  $\alpha$  is independent of  $x$ , and, therefore, the solution of the differential equation is

$$n = n_0 \exp(\alpha x) \quad (3.33)$$

for the distance between the plate  $s$  and the number of electrons  $n_0$  in the position  $x = 0$  in air. In some gases, the atomic structure allows to catch an electron, and this behavior will be characterized by the attachment coefficient  $\eta$ . For example, the gas sulfur hexafluoride ( $\text{SF}_6$ ), which is actually often used in high-voltage equipment but will in future be replaced by more environmentally friendly alternative gases, has a strong affinity to catch an electron due to the fact that the six fluor atoms endeavor to catch an electron to get the so-called inert gas configuration. For gases with an electron affinity, the ionization coefficient  $\alpha$  is reduced by the attachment coefficient  $\eta$ , and this leads to an effective ionization coefficient of  $(\alpha - \eta)$ . The number of electrons reaching the anode is given by (3.33), and it can be clearly seen that the increase follows an exponential function with  $\alpha$  or  $(\alpha - \eta)$  in the exponent. The number of positive ions reaching the cathode is

$$n = n_0 \{ \exp[(\alpha - \eta)s] - 1 \}. \quad (3.34)$$

These positive ions generate electrons at the impact on the cathode, depending on the cathode material, the gas and the gas pressure, and the number of electrons is given by the so-called second Townsend ionization coefficient  $\gamma$ . These electrons are the starting electrons for the next generation of ionization processes and are named in Fig. 3.19,  $n_{0s}$ . The electrons again move to the anode and generate further electrons and positive ions. Then two conditions exist, first, the number of the electrons in the second generation is smaller than the number of the starting electrons, and then the discharge process stops due to the lack of starting electrons. Second, the number of the electrons in the second generation is higher than the number of starting electrons, and then the total number of electrons increases with the number of generations, which leads to a breakdown. The theoretical condition for a breakdown in air ( $\eta \approx 0$ ) is given if the number of electrons of the second generation  $n_{0s}$  is equal to the number of starting electrons  $n_0$ , as is shown in (3.35)

$$\begin{aligned} n_{0s} &= \gamma n_0 [\exp(\alpha s) - 1] = n_0 \\ &\Rightarrow \gamma [\exp(\alpha s) - 1] = 1 \\ &\Rightarrow \exp(\alpha s) = \frac{1}{\gamma} + 1, \end{aligned} \quad (3.35)$$

$$\alpha s = \ln \left( \frac{1}{\gamma} + 1 \right) = k. \quad (3.36)$$

In [3.7], a value of  $\gamma = 10^{-5}$  is given that leads to a value of  $k = 9.2$ , but there are also values between 11 and 3 [3.4]. For air, a value of  $k = \alpha s = 20$  is also possible, which leads to a number of electrons in the range of  $10^8$ . The validity of the theory of this breakdown mechanism is limited to small gap distances and low pressure, with a low value of the Townsend ionization coefficient  $\alpha$ .

With an increase in the gap distance, the gas pressure, and the applied voltage, the theory of the generation mechanism could not explain the experimental results. An initial electron generates an avalanche, where the electrons are concentrated at the head of the avalanche, and the larger and less mobile ions are distributed within the tail of the avalanche. Figure 3.20 shows schematically the development of such a discharge process, which is named streamer breakdown.

The electric field of the avalanche is superimposed on the electric field generated by the applied voltage, and the increase of the electric field at the head and the tail of the avalanche generates radiation emission and photons. The photons are responsible for the generation of further avalanches, and they move with the speed of light. The numerous avalanches will finally bridge the whole gap in a time that is much shorter than the time

Fig. 3.20 Streamer breakdown

necessary for a breakdown after the generation mechanism. The criterion for a streamer breakdown is that the electric field around the avalanche be more or less equal to the electric field generated by the applied voltage. Assuming that all charges of the electrons in an avalanche are concentrated in the center of the head of the avalanche and with constant electron mobility, the critical number of electrons in the avalanche head is about  $10^8$ . This leads to (3.37), if at least one starting electron  $n_0 = 1$  is available

$$\begin{aligned} n &= n_0 \exp(\alpha - \eta)s = 10^8 \\ \Rightarrow (\alpha - \eta)s &= \ln(10^8) = 20.7. \end{aligned} \quad (3.37)$$

The criteria of the generation mechanism and the streamer mechanism are very similar, and, therefore, the main parameter for the breakdown in gases is the difference between the ionization and attachment coefficient called the effective ionization coefficient  $(\alpha - \eta)$ .

Paschen showed with his experiments that the breakdown voltage in a homogeneous electric field with a gap distance  $s$  and pressure  $p$  depends on the product of  $ps$  [3.15]. Figure 3.21 shows the Paschen curves for air and  $\text{SF}_6$ .

The breakdown criterion according to (3.36) and (3.37) is reached if the product of the effective ionization coefficient  $(\alpha - \eta)$  and the gap distance  $s$  is about 20, which represents  $10^8$  electrons generated by either the generation or the streamer mechanism. The strong increase of the current density, shown in Fig. 3.18, as a function of the electric field occurs at different electric field values depending on the kind of gas. The values for air and  $\text{SF}_6$  are  $24.4 \text{ kV}/(\text{cm bar})$  and  $87.7 \text{ kV}/(\text{cm bar})$  [3.7], and are called the limit electric field stress with respect to the breakdown behavior of the gas. For the calculation of the effective ionization coefficient, the following equations can be used

$$(\alpha - \eta)s = k \Rightarrow \frac{(\alpha - \eta)}{p} = \frac{k}{ps} = f\left(\frac{E}{p}\right). \quad (3.38)$$

The dependence of the effective ionization coefficient from the electric field can be described with a linear equation for  $\text{SF}_6$  or with a quadratic equation for air,

$$\begin{aligned} \frac{(\alpha - \eta)}{p} &= K \left( \frac{E}{p} - 87.7 \frac{\text{kV}}{\text{cm bar}} \right) \\ \text{with } K &= 28 \frac{1}{\text{kV}}, \end{aligned} \quad (3.39)$$

for the electric field in  $\text{SF}_6$  between  $60 \text{ kV}/(\text{cm bar})$  and  $120 \text{ kV}/(\text{cm bar})$  and

$$\begin{aligned} \frac{(\alpha - \eta)}{p} &= K \left( \frac{E}{p} - 24.4 \frac{\text{kV}}{\text{cm bar}} \right)^2 \\ \text{with } K &= 0.22 \frac{\text{cm bar}}{(\text{kV})^2}, \end{aligned} \quad (3.40)$$

for the electric field in air between  $24.4 \text{ kV}/(\text{cm bar})$  and  $60 \text{ kV}/(\text{cm bar})$ .

From (3.39), it can be seen that in a homogeneous electric field, the breakdown of  $\text{SF}_6$  happens if the actual electric field at a pressure of 1 bar is slightly above the limit of the electric field strength of  $87.8 \text{ kV}/(\text{cm bar})$ . If the applied electric field is  $88.4 \text{ kV}/(\text{cm bar})$  at 1 bar and a 1 cm gap distance  $s$ , the value of  $(\alpha - \eta)$  is about 20, which, according to (3.37), is the criterion for breakdown. The difference between the applied electric field and the limit electric field is only 0.8%, which is within the uncertainty of the voltage measurement from which the electric field is calculated by the applied voltage divided by distance of the electrode. Furthermore, it should be taken into account that the difference in the electric field becomes much smaller for higher pressure, for example, only  $0.24 \text{ kV}/(\text{cm bar})$  at a pressure of 5 bar and a 1 cm gap distance.

For air the breakdown criterion of  $(\alpha - \eta)s \approx 10$  is fulfilled if the applied electric field is in the range of  $31 \text{ kV}/(\text{cm bar})$ , which is about 27% above the limit electric field. The reason for this behavior is the low increase of the effective ionization coefficient with increasing electric field, represented by the low value of factor  $K$  compared to  $\text{SF}_6$ .

### Inhomogeneous Electric Field

The breakdown criteria for an homogeneous electric field can also be used for an inhomogeneous electric field, but then the dependence of the effective ionization coefficient on the electric field, and, thereby, on the location within the gap should be taken into account. Furthermore, the criteria only describe the start of stable pre-discharges, and the following development of a complete breakdown takes place with streamer and leader discharges. Also space charges influence the breakdown

**Fig. 3.21a,b** Paschen curves for air (a) and SF<sub>6</sub> (b) (air temperatures: 20 °C) (adapted from [3.15], where all details of the measurements are given)

**Fig. 3.22** Space charges in rod–plane electrode arrangements

behavior, and a typical electrode arrangement is the rod–plane. Here, the polarity of the rod is important for the electric field distribution and the breakdown value. Figure 3.22 shows the space charge distribution of rod–plane air gaps with different polarity of the rod.

The electric field is high near the rod in both arrangements, and, therefore, discharge processes start at the rod. In the case of negative polarity of the rod, the provision of electrons is supported by the electrode material, whereas with positive polarity of the rod, the electrons are only provided by the free electrons in the gas. Therefore, predischarges occur at a lower voltage if the rod has negative polarity. Further development of the discharges is shown in Fig. 3.22. For a positive rod, the ionization takes place in front of the rod, and the slow ions are placed around the rod and reduce the electric field there but enhance the electric field in the rest of the gap. For a negative rod, the slow ions are also placed around the rod, but there they increase the electric field and reduce it in the rest of the gap. Therefore, the breakdown voltage of a positive rod is lower than that of a negative rod.

For an inhomogeneous electric field in  $\text{SF}_6$ , (3.37) and (3.39) should be modified, because the effective ionization coefficient depends on the location, and the integral over the path from the electrode with the highest electric field to the other electrode in the direction of the electric field should be calculated there,

$$\int_0^{x_{\text{cr}}} (\alpha - \eta) dx = \int_0^{x_{\text{cr}}} p \frac{28}{\text{kV}} \left( \frac{E}{p} - 87.7 \frac{\text{kV}}{\text{cm bar}} \right) dx \approx 20. \quad (3.41)$$

The interpretation of (3.41) is that from the electrode with the highest electric field up to the point  $x_{\text{cr}}$ , the value of the integral should be around 20, because no ionization takes place between  $x_{\text{cr}}$  and the electrode with a lower electric field due to the fact that the value of the attachment coefficient  $\eta$  is higher than that of the ionization coefficient  $\alpha$ .

### Breakdown Parameters

In the previous sections on breakdown in gases, the conditions were more or less ideal. In reality, the breakdown is influenced by some more parameters. One influencing factor is the roughness of the electrode surface. As was already mentioned, the pressure is also important; the breakdown electric field strength, therefore, depends on the product of the surface roughness and the pressure, and this should be taken into account with increasing pressure.

For impulse voltage, the breakdown depends on the availability of a starting electron, the time to develop a first avalanche and the time to the final breakdown. The surge characteristic of a gas insulation is given by the so-called voltage–time area, which means that for higher voltage amplitudes, a shorter time is necessary, and for lower voltages, a longer time, but the product voltage times time is always constant [3.16].

As air is the most used insulation gas, the breakdown behavior will be described here in more detail. The breakdown depends on air pressure, air temperature, and air humidity. In [3.2], the relevant details concerning the influencing factors are given. The influence of humidity on the breakdown of air has been under discussion for a long time, and, actually, a revision of [3.2] will probably deliver more information. The influence of air pressure and air temperature is handled in [3.1], where it is called the altitude correction factor, and in [3.2], where it is called the atmospheric correction factor. The altitude correction factor is a kind of average value of the atmospheric correction factor used for the design of high-voltage equipment and takes the air density depending on the height above sea level into account. The atmospheric correction factor is for the correction of test voltage depending on the actual situation during the withstand test. In [3.2], the air density correction factor is

$$k_1 = \delta^m, \quad (3.42)$$

where the exponent  $m$  depends on the type of pre-discharge, but very often  $m$  is 1. Then, the air density

correction factor  $k_1$  can be calculated

$$\delta = \frac{p}{p_0} \frac{273 + t_0}{273 + t} = k_1, \quad (3.43)$$

where the temperatures  $t$  and  $t_0$  are expressed in  $^{\circ}\text{C}$ , and the atmospheric pressures  $p$  and  $p_0$  are expressed in the same units. Usually, the reference temperature  $t_0$  is  $20^{\circ}\text{C}$ , and the reference pressure  $p_0$  1013 mbar. The test voltage should then be corrected according to (3.43), and the applied voltage should be increased, if the air pressure is above the reference value or decreased, if the temperature is above the reference temperature. Another use of (3.43) is the evaluation of the test voltage, if a withstand voltage test should be done at, for example, a high-voltage laboratory at sea level, but the equipment under test should be installed at 2000 m above sea level. Assuming a withstand voltage of 1050 kV, according to the insulation coordination [3.1] and a place of operation at 2000 m above sea level, the test voltage in a high-voltage laboratory at sea level and an ambient temperature of  $25^{\circ}\text{C}$  should be

$$\begin{aligned} U_{\text{test}} &= \frac{1050 \text{ kV}}{\delta} \quad \text{with } \delta = \frac{794}{1013} \times \frac{273 + 20}{273 + 25} \\ &= \frac{1050 \text{ kV}}{0.77} = 1362 \text{ kV}. \end{aligned} \quad (3.44)$$

### 3.4.4 Breakdown in Fluids

Discharges in fluid cannot be described by a comprehensive theory like it was possible for gases. Fluids include a number of substances with different physical and chemical behavior, and these characteristics may change due to manufacturing conditions, impurities, or ageing processes, which lead to a large spread and deviation in the electrical performance. Therefore, the difference in electric strength under ideal conditions and service conditions can be within one order of magnitude. Generally the discharge processes in fluids are hindered by an increased density of the fluids compared to gases and the shorter free-path length, and, therefore, ionization processes are rarer, which leads to a higher electric strength.

The advantages of fluids are the high electric strength, the high thermal conductivity, and the impregnation properties. Typical application areas of fluid insulating materials are transformers, capacitors, bushings, and in the past, cables. However, the use of fluids requires a tight container. Due to the high density of fluids, the formation of electron avalanches by ionization is nearly impossible, and, therefore, a theory was developed, called masked gas discharge, assuming that micro bubbles exist in the fluid, and the breakdown happens in these micro bubbles, similarly to breakdown in

gas. Another theory is that the breakdown is caused by percolation, whereby the structure of the molecules of the fluid generates channels with a higher current density. Local heating produces evaporation of the fluid and a lower density, which allows the generation of streamer. The breakdown behavior in an inhomogeneous electric field shows a clear polarity effect. In a rod–plane gap there exists a higher breakdown voltage for a rod with positive polarity compared with a rod with negative polarity. Such breakdown behavior occurs at short-time voltage stress.

For longer stress times, another theory may explain the breakdown behavior of fluids. If fluids are used in combination with paper as an insulating material fibrous impurities exist, and they are adjusted according to the applied electric field due to electrostatic forces. These impurities may contain humidity due to the largely hygroscopic behavior of paper, and their conductivity is much higher than the ambient fluid. Then a conductive path will be created, which becomes overheated and finally leads to a breakdown. This type of breakdown is called a fiber bridge breakdown.

The breakdown of fluids depends on humidity, temperature, volume, and electrode coating. With an increase of the electrode distance, the probability of generating a fiber bridge increases, and an empiric function for the breakdown field strength at AC voltage  $E_d$  for transformer design was developed in [3.17],

$$E_d = E_0 \left( \frac{d}{\text{mm}} \right)^{-a}, \quad (3.45)$$

where  $E_0$  is a reference for different kinds of fluids, ranging for coated electrodes from 21 kV/mm for dry and degassed mineral oil up to 17.8 kV/mm for gas saturated mineral oil, and for blank electrodes from 17.8 kV/mm for dry and degassed mineral oil up to 13.5 kV/mm for gas saturated mineral oil [3.4];  $d$  is the distance of the electrode in mm, and the parameter  $a$  depends on the type of electrode and the quality of the fluid and ranges between 0.364 and 0.375.

Besides the ageing of fluids and the generation of impurities and gases, the humidity has the most influence on the breakdown of fluids and, particularly, on mineral oil, which is still the most used fluid in high-voltage equipment. Figure 3.23 shows the breakdown behavior of two kinds of fluids, mineral oil and ester, as a function of the relative water content  $w_{\text{rel}}$ .

The breakdown voltage was determined with a standard sphere–sphere electrode arrangement with a curvature radius of 25 mm and a gap distance of 2.5 mm, following the procedure given in [3.11]. The dependency of the breakdown voltage on the temperature is not directly visible in Fig. 3.23, but the relative water

**Fig. 3.23** Breakdown voltages  $V_b$  of oil and ester as a function of the relative water content  $w_{rel}$  (adapted from [3.7])

content is defined as the percentage of the actual water content  $w_{act}$  in relation to the water saturation content  $w_{sol}$  at the relevant temperature,

$$w_{rel} = \frac{w_{act}}{w_{sol}(\vartheta)} 100\% . \quad (3.46)$$

Figure 3.23 also shows that for mineral oil, a defined function exists between the breakdown voltage and the relative water content, but for ester only a certain range exists. The large difference between these two fluids regarding the influence of humidity or water content is the difference in the performance of the water solution. For an absolute water content of 20 ppm at 20 °C, the relative water content is 40% at a water saturation content of 50 ppm at 20 °C for mineral oil, but only 1% for a water saturation content of 2000 ppm at 20 °C for ester fluid.

The stressed fluid volume also has an effect on the electric strength. Figure 3.24 shows the influence of the gap distance and stressed volume on the electric breakdown field  $E_d$  for two different temperatures [3.7].

It can be seen that the electric field strength decreases with increasing stressed volume.

In a real electrode arrangement, the field configuration is not ideally homogeneous but slightly or strongly inhomogeneous. In this case, the estimation of the breakdown voltage for a homogeneous electrode arrangement can be used to evaluate the inception voltage for partial discharges. Partial discharges are discharges in a limited area and will not lead directly to a complete breakdown of the arrangement. It may happen that

**Fig. 3.24** Breakdown electric field strength  $E_d$  for mineral oil as function of gap distance  $s$  for a fluid temperature of 20 °C (light brown curve), and 100 °C (dark brown curve) (adapted from [3.7])

a limited number of partial discharges takes place for a long time, sometimes longer than the service time of the equipment. However, partial discharge measurements are a very good tool to detect a weak point within an insulation system, and, therefore, many recommendations for high-voltage equipment require a limit of

**Fig. 3.25a–c** Definition of the loss factor (also named dissipation factor). (a) Symbol of a solid test sample, (b) pointer diagram, (c) equivalent circuit diagram

partial discharges at a certain voltage. In addition, the measurement of the partial discharge inception voltage at a defined point–plane electrode arrangement with a fixed radius of the point electrode and a fixed electrode distance can be used to qualify the insulating fluid under test for use in high-voltage equipment [3.18]. The partial discharge inception voltage (PDIV) is defined as the lowest peak value of the test voltage at which the charge becomes greater than the specified discharge magnitude when the test voltage is increased above a low value for which no discharge occurs [3.19].

### 3.4.5 Breakdown in Solids

The breakdown mechanisms in solid insulation systems are, in general, similar to the mechanism in gas and fluids. A specific feature for solids is the reduced heat transfer, which may lead to an overheating of the insulation and damage. Therefore, the loss factor of a solid is important, and this factor usually has three components: the losses due to conduction processes, polarization, and ionization.

The conduction processes are temperature and electric field-dependent, similarly to the processes in gas shown in Fig. 3.18. This means that the losses are constant up to a critical electric field and then increase exponentially. The sources for the conduction process are impurities in the solid insulation or in the solid insulation itself by dissociation of ions. In principle, the polarization losses are based on deformation of the molecule, on orientation of the dipoles in the solid, and on boundary polarization. For power frequencies of 50 or 60 Hz, only the boundary surface polarization is important for the loss factor. Boundaries can be grain boundaries within the solid or boundaries between two different materials, like in solid–fluid insulation systems. The ionization losses are partial discharges in voids in the solid, and they occur if the voltage across the void is higher than the partial discharge inception voltage. This means that partial discharges start at a discrete voltage level, but it should be taken into account

that voids in a solid may have different geometric dimensions and, therefore, different inception voltages. The ionization losses are fixed, which means that the discharges always take place at the same location, and this may finally lead to a breakdown of the complete solid insulation system.

A general characterization of a solid is the loss factor, which is very often denoted as  $\tan \delta$ , which represents the ratio of the reactive current to the active current. Figure 3.25 shows a simplified schematic diagram of a solid and the related voltage and currents.

Figure 3.25a shows a solid insulation system with applied voltage  $U$  and current  $I$ . Voltage and current are complex variables, and in Fig. 3.25b these variables are shown as pointers. An ideal solid is an ideal capacitor without any losses. A real solid can be characterized by a resistor and capacitor in parallel, as shown in Fig. 3.25c. The electric loss factor of a solid can be described by the  $\tan$  of the loss angle  $\delta$ , which represents the deviation of the solid from an ideal capacitor. The complex phasor of the current  $I$  can be divided into a pointer of the active current  $I_a$  parallel to the pointer of the applied voltage  $U$  and a pointer of the reactive current  $I_r$  rectangular to the pointer of the applied voltage  $U$ . Then the following equations can be derived

$$\tan \delta = \frac{I_a}{I_r} = \frac{U/R}{U\omega C} = \frac{1}{\omega RC}. \quad (3.47)$$

Measurements of the loss factor showed that the losses depend on the temperature and the frequency, but this means that the equivalent circuit diagram in Fig. 3.25c cannot describe all effects in a solid. The losses are represented by the resistor  $R$ , which is not frequency dependent, and the impedance of the capacitive path is certainly frequency dependent but without losses. The use of a complex relative permittivity  $\epsilon_r$  can improve the equivalent circuit diagram in Fig. 3.25c by replacing the capacitor  $C$  by a complex capacitor  $C_c$ . The complex capacitor  $C_c$  is given by the complex relative permittivity  $\epsilon_r$  and the related capacitor with vacuum

**Fig. 3.26** Breakdown field strength  $E_b$  as function of stress time  $t_s$

$C_0$ . For a parallel plate capacitor as reference, the following equations will be used to describe the loss factor more correctly

$$C_0 = \varepsilon_0 \frac{A}{d}, \quad (3.48)$$

where  $\varepsilon_0$  is the permittivity of the vacuum,  $A$  the area of the parallel plate capacitor, and  $d$  the distance between the two plates. Then the complex capacitor  $C_c$  is

$$C_c = \varepsilon_r C_0 = (\varepsilon'_r - j\varepsilon''_r) C_0. \quad (3.49)$$

The current  $I$  can then be described by

$$I = \frac{U}{R} + j\omega C_c U = \frac{U}{R} + j\omega(\varepsilon'_r - j\varepsilon''_r) C_0 U, \quad (3.50)$$

and separated into the active and reactive parts

$$I_a = \frac{U}{R} + j\omega\varepsilon''_r C_0 U = \left( \frac{1}{R} + \omega\varepsilon''_r C_0 \right) U \quad \text{and} \\ I_r = \omega\varepsilon'_r C_0 U. \quad (3.51)$$

The dielectric loss factor is then

$$\tan \delta = \frac{I_a}{I_r} = \frac{\left( \frac{1}{R} + \omega\varepsilon''_r C_0 \right)}{\omega\varepsilon'_r C_0} = \frac{1}{R\omega\varepsilon'_r C_0} + \frac{\varepsilon''_r}{\varepsilon'_r}, \quad (3.52)$$

where the first part represents the conduction processes and the second part the polarization effects.

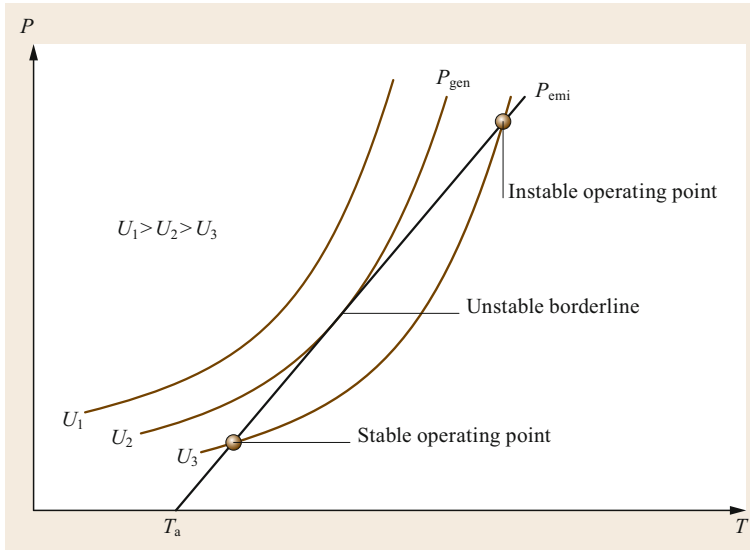

The breakdown in solids has two further characteristics: the dependency on the duration of the voltage stress or relevant electric field stress and on the stressed volume. Figure 3.26 shows the electric field strength as a function of the stress duration. The longer the

stress duration, the lower the electric breakdown field strength. In the range of the impulse voltage stress, the electric strength of solids is high, but with increasing stress time, the thermal behavior becomes more important, and the electric strength decreases, which is a typical disadvantage of solid insulation systems. For longer stress times, the effect of the erosion usually triggered by partial discharge in small voids within the solid determines the electric strength. The behavior in this area depends on several factors, like the quality of the solid, temperature, electric field stress, and the duration of the electric field stress.

The behavior shown in Fig. 3.26 is typical for a solid with a high loss factor. Two parameters are of importance here: the duration of the stress and the thermal conditions. For a plate–plate electrode arrangement with a constant electrode distance and location-independent temperature, the generated power in the solid  $P_{\text{gen}}$  due to losses depends on the applied voltage and the difference of the temperatures between the electrodes and the inside of the solid,

$$P_{\text{gen}} \approx U^2 \exp[\beta(T - T_a)], \quad (3.53)$$

where  $\beta$  is a parameter depending on the geometry of the test sample,  $T$  the inside temperature,  $T_a$  the ambient temperature, and  $U$  the applied voltage. The losses for DC applications depend on  $U^2/R$  and for AC applications on  $U^2\omega C \tan \delta$ , but for both cases, the losses follow an exponential function as shown in (3.53), and the generated power  $P_{\text{gen}}$  increases exponentially with the increase of the inside temperature. Figure 3.27 shows the generated and emitted power assuming that the heat can be emitted only via electrode surfaces. The emitted power  $P_{\text{emi}}$  increases linearly with the temperature difference  $T - T_a$ .

**Fig. 3.27** Generated power  $P_{gen}$  and emitted power  $P_{emt}$  as functions of temperature  $T$

**Fig. 3.28** Breakdown field strength  $E_b$  as a function of stress time  $t_s$  for XLPE

A safe and reliable service can only be achieved if the emitted power is equal to the generated power. For the voltage level,  $U_1$  this condition does not exist. For the lower voltage level  $U_2$ , the condition is fulfilled, but the straight line of  $P_{emt}$  is only a tangent on the curve  $P_{gen}$  for the voltage level  $U_2$ , and the relevant point is called an unstable borderline. A simple check shows that if the temperature  $T$  changes, the generated power is higher than the emitted power. A further reduction of the voltage level with  $U_3$  delivers two points where the generated power and the emitted power are equal. However, only one point is called a stable operating point, because an additional requirement should be fulfilled,

$$\frac{dP_{gen}}{dT} < \frac{dP_{emt}}{dT}, \tag{3.54}$$

which is not true for an instable operating point.

With increasing AC-system voltages, the importance of the loss factor increases due to the fact that the losses increase with the square of the system voltage, frequency is fixed, and capacitance can be only influenced within narrow limits. Therefore, solids with low or very low loss factor are preferred for the application in high-voltage equipment, because no thermal breakdown occurs. A typical material is crosslinked polyethylene (XLPE) for high-voltage cables, because cables are apparatus where the performance depends strongly on the thermal behavior. Figure 3.28 shows the electric field strength of XLPE as a function of the stress time.

The area of thermal breakdown has disappeared, and there is a transition from the electric breakdown to the erosion breakdown. Due to the logarithmic scale of the y-axis, in contrast to Fig. 3.26, the function is not exponential but linear. This can be expressed with (3.55)

Fig. 3.29 Physical volume effect in solids

and is called the life law,

$$E^N t = \text{const.} \Rightarrow \log E = \text{const.} - \left(\frac{1}{N}\right) \log t, \quad (3.55)$$

where  $E$  is the electric field strength and  $t$  the expected life time. The parameter  $N$  depends on the material and represents the gradient of the straight line. For technical applications with solids, the value of  $N$  is between 10 and 15 [3.7].

The performance of solids is usually checked with small test samples. Therefore, the extrapolation of larger volumes of solids should be done carefully considering the so-called volume effect. This effect has two components: the statistical volume effect and the physical volume effect. The statistical volume effect is based on the assumption that with a larger volume also the number of defects in the solid increases. The theoretical evaluation of the breakdown probability can originate from two extreme cases. The first one is that all defects exist in parallel, which means that the breakdown of one of the defects leads to the breakdown of the test sample. The second one is that all defects are connected in series, and that a breakdown of one defect will increase the stress of the rest of the defects at the following stresses, whereby the increase of breakdown probability depends on the number of defects in the series, and the breakdown probability of the test sample should be calculated step by step. The first case is the most critical and should, therefore, be handled in more detail. Assuming similar defects, the breakdown probability for such a single defect can be determined and denoted by  $F$  as function of the applied voltage. The withstand probability  $W$  of one defect can then be expressed as

$$W(u) = [1 - F(u)]. \quad (3.56)$$

If the number of defects in parallel in the test sample is  $n$ , the withstand probability of the complete test sample  $W_n$  can be calculated by the multiplication of the probability of each of  $n$  defects,

$$W_n = [1 - F(u)]^n. \quad (3.57)$$

From (3.57), it can be seen that the withstand probability decreases exponentially with the increase of the number of defects.

The second volume effect is based on the increase of the stressed volume. Figure 3.29 shows the electric field in a solid with space charges. The average electric field is  $E_0$ , but due to space charges in the solid, the maximum electric field at the actual anode (A) can be  $2E_0$ . The reference value should be, for example,  $\Delta E = E_0/2$ . In the left part of Fig. 3.29 the applied voltage should be  $U$  and in the right part  $2U$ , doubling the electrode distance and resulting in the same electric field.

From Fig. 3.29, it can be seen that the highly stressed volume (dashed area) in front of the anode with an electric field of  $E \geq E_0 + \Delta E$  has been increased due to the increase of the electrode's distance, which is equivalent to the increase of the volume.

Both volume effects can be taken into account for the evaluation of the life time of a solid. Figure 3.30 shows the life law for two different volumes  $V_1$  and  $V_2$  (statistical effect) and also for the consideration of the physical volume effect.

For a given material with life time exponent  $N_1$  and a volume  $V_1$ , the life law can be calculated according to (3.55),

$$E^{N_1} t = \text{const.} \Rightarrow \log E = \text{const.} - \left(\frac{1}{N_1}\right) \log t. \quad (3.58)$$

**Fig. 3.30** Influence of statistical and physical volume effects on the life law (adapted from [3.7])

The influence of the volume can be considered by a volume factor  $v$ , because the statistic volume effect complies with the statistic behavior. Then (3.55) will be changed to

$$vE^N t = \text{const.} \Rightarrow \log E = \text{const} - \left(\frac{1}{N}\right) \log(vt), \quad (3.59)$$

with  $v = V_2/V_1$  and  $V_2 > V_1$ .

In Fig. 3.30 it can be seen that an increase of the volume will result in a shift of the life time line to a lower electric field, but the gradient is unchanged. If the phys-

ical effect is added, the life-time line is again shifted to a lower electric field, but in this case, with an increase of the gradient, which means a reduction of the life time for the required electric field strength.

The determination of the characteristics of solids is similar to that of gases and fluids, but only the determination of the breakdown of the electric field or voltage is governed by a larger spread of test results due to the fact that for each breakdown test, a new sample is required, and this already contributes to scatter. Furthermore, the defects within the solid are responsible for the breakdown, and these defects are randomly distributed.

### 3.5 Insulating Materials

Insulating materials have different functions, which determine the choice of the material. The basic purpose is the separation of elements with different potential. Air and gas insulation is unlimitedly available and free of charge, but the electric performance depends on the ambient conditions, which are uncontrollable. Other gases, like nitrogen  $N_2$ , sulfur hexafluoride  $SF_6$ , carbon dioxide  $CO_2$ , or new synthetic gases require a shell. The electric performance can be controlled by the gas pressure within a certain limit, and is partly independent of the ambient conditions. It should be taken into account that gases may have a dew point that is above the lowest service temperature, and then the liquefaction will reduce the remaining partial gas pressure. In any case, fluids require a shell and, besides the electric performance, fluids can be used for

impregnation, typically in combination with paper or, more correctly, with cellulose, and for cooling purposes. Furthermore, the choice of a specific fluid may depend on the fire behavior and environmental compatibility. A typical example is the replacement of a fluid based on mineral oil by a fluid based on ester, synthetic or natural. The combination of a fluid with cellulose has big advantages, because the holes in the cellulose can be filled with the fluid, preventing partial discharges there, and at the same time, the fluid can carry the heat generated, which makes this system particularly suitable for the insulation of transformers. Finally, solids are necessary to take over the mechanical tasks combined with good electric performance but with limited thermal performance. The limitation of the power transmission of a high-voltage cable with solid insula-

tion, e.g., XLPE, is given by the heat transfer of the solid.

### 3.5.1 Gases

Air is an insulation gas that is available anywhere, free of charge, and for many applications has a sufficient electric performance. The breakdown electric field strength in a homogeneous electrode arrangement is about 30 kV/cm, which is little bit higher than the breakdown electric field for nitrogen, due to the fact that air is a combination of nitrogen (about 80%) and oxygen (about 20%), and oxygen belongs to gases with electron affinity. These gases have the characteristic that they attract electrons and detract these from the discharge process. A further gas that has a stronger electron affinity than oxygen is sulfur hexafluoride (SF<sub>6</sub>). Due to its molecular structure, the six fluor atoms are eager to catch an electron to get a so-called inert gas configuration. Therefore, SF<sub>6</sub> is used in gas-insulated substations, and the size of the substations may in some cases be reduced up to a factor of 10. The breakdown electric field strength of SF<sub>6</sub> at a pressure of 1 bar is about 90 kV/cm, which is three times higher than air. With increasing pressure, the electric field strength could be enhanced and, therefore, the dimensions of the SF<sub>6</sub>-insulated substations could be limited even for very high system voltages up to 1200 kV. Furthermore, SF<sub>6</sub> may also be used in circuit breakers due its good performance as a medium for arc quenching. However, the disadvantage of SF<sub>6</sub> is the high greenhouse effect, which is about 23 000 times higher than the effect of CO<sub>2</sub>. Therefore, research was conducted to reduce the amount of SF<sub>6</sub> while retaining the good electric performance of this gas. A technical and economical solution was a mixture of 80% N<sub>2</sub> and 20% SF<sub>6</sub> as the insulation gas for gas-insulated lines [3.20]. With such a mixture, an electric strength of about 80% of pure SF<sub>6</sub> can be reached. With the intention to eliminate SF<sub>6</sub> as the insulating gas in high-voltage equipment, further investigations were carried out and so-called fluoroketones and fluoronitrile with low greenhouse potential were found to replace SF<sub>6</sub> [3.21–23]. However, high boiling points of the given fluoro-organic gas types require a mixture with other gases, like N<sub>2</sub> or CO<sub>2</sub>, in order to keep the partial pressure of the fluorinated component under a certain limit. The chemical formula for the fluoroketone is (CF<sub>3</sub>)<sub>2</sub>CFC(O)CF<sub>3</sub> or the shorter C<sub>5</sub>-FK, and for the fluoronitrile (CF<sub>3</sub>)<sub>2</sub>CFCN or the shorter C<sub>4</sub>-FN. The electric performance of the two fluoro-organic gas types is equal or sometimes better than the mixture of 80% N<sub>2</sub> and 20% SF<sub>6</sub>, but the boiling point should be taken into account.

**Fig. 3.31a–e** Structures of hydrocarbons of mineral oil. (a) Paraffin, (b) iso-paraffin, (c) naphthene, (d) aromatics, (e) olefin (adapted from [3.7])

### 3.5.2 Fluids

The fluid most used in high-voltage apparatus is oil based on mineral oil. The purpose of this fluid is governing the required insulation, impregnation, and heat transfer from the inner part of the apparatus to the walls or the cooling system. Mineral oil is a combination of different kinds of hydrocarbons with different chemical bonds. Figure 3.31 shows the kinds of hydrocarbons [3.7].

Figure 3.31a shows the molecular structure of paraffin with a linear combination of the molecules CH<sub>2</sub>. Figure 3.31b shows the so-called isoparaffin with some branches in the structure, and Fig. 3.31c shows a naphthenic structure sometimes called cycloparaffin. None of the hydrocarbons have a double bond, which results in high stability but less potential to react with other molecules. Figure 3.31d shows the structure of aromatics with double bonds in a cyclic arrangement, and Fig. 3.31e olefin, again with double bonds but in a more linear structure. These two kinds of hydrocarbon with double bonds are less stable but have a higher potential to react with other molecules. In a standard mineral

oil, the content of all kinds of paraffin is about 80–90%, the content of aromatics is in the range of a few percent to 20%, and the content of olefin is only in the range of 1%. The breakdown electric field varies between 200 and 350 kV/cm, which is about ten times higher than air and about three times higher than SF<sub>6</sub> at 1 bar. One of the disadvantages of mineral oil is ageing, supported by oxygen, humidity, high temperature, and catalysts such as copper or other metals. Also, the missing environmental compatibility counts as a disadvantage of mineral oil, even if in any case a protection against environmental contamination for high-voltage apparatus exists. Another disadvantage of mineral oil is the high flammability and, therefore, another kind of fluid generated interest in the 1930s for the insulation of transformers, and this was polychlorinated biphenyl. The advantages were the flame-resistant behavior and a similar relative permittivity to paper. However, the disadvantage of polychlorinated biphenyl is the generation of high toxic components like dioxins, and, therefore, production was stopped in the 1980s.

A replacement for mineral oil, as well as for polychlorinated biphenyl, is an ester fluid, which exists in two types, synthetic ester and natural ester. Besides the advantages of low flammability and environmental compatibility, the water solubility of ester is much higher compared to mineral oil, and, therefore, the influence of moisture in the fluid on the electric breakdown performance is less important. Much research was carried out concerning the behavior of new fluids as a replacement for mineral oil with respect to electric and ageing characteristics. In some cases, further fluids like silicon oil, castor oil, rape seed oil, coconut oil, sunflower oil, or palm oil, were included in the investigations [3.23–26]. In recent years, synthetic ester fluids were used more and more, and also natural esters from different manufacturers are now in service as insulation fluids for high-voltage power transformers [3.27]. Ester fluids are environmentally friendly fluids and belong to the class of fluids that are *slightly hazardous to water*. The increasing use of ester fluids delivers more experience and also more information concerning diagnosis methods, which are well developed for mineral oil and can be probably transferred to ester fluids.

The increase of the requirements on a fluid in a transformer regarding ageing behavior, higher electric stress, the influence of sulfur, and higher system voltages (up to 1200 kV AC and 1100 kV DC) has resulted in a synthetic fluid based on gas-to-liquid technology. The fluid has the structure of an isoparaffin without any defects compared to a natural isoparaffin, and, therefore, the performance is in many characteristics better, such as the higher flashpoint, the low loss factor, and a very low sulfur content [3.28].

### 3.5.3 Solids

Similarly to fluids, solids have several tasks in high-voltage apparatus. The main part is the use as a design element with strong mechanical characteristics. Other tasks are the separation of different fluids or gases and use as dielectric medium with a high relative permittivity. There are various types of solids, and it is not possible to cover them all in this chapter. Therefore, a selection of solids will be handled with particular importance for high-voltage engineering and further information concerning chemical, thermal, and mechanical characteristics is available in the relevant literature, which covers about 100 years of research on solids [3.29, 30].

#### Inorganic Solids

The group of inorganic solids includes porcelain, glass, and mica. All these are characterized by a high temperature resistance and insensitivity to chemical influences, climatic influences, irradiation, and partial discharges. Furthermore, some of these solids have a very high mechanical strength. Porcelain is the main solid for air-insulated systems like overhead lines, substations, surge arrestors, or post insulators. However, in future porcelain will become increasingly replaced by so-called composite insulators. The characteristic of porcelain with respect to thermal strength, electrical strength, or mechanical strength can be modified to a certain limit by a mixture of the three components feldspar, responsible for electrical strength, quartz, responsible for mechanical strength, and kaolin, responsible for thermal strength. Regarding mechanical strength, porcelain has a strong mechanical strength for pressure but a much lower one for bending, and the ratio is about 1/7. For some specific applications, it should be noted that porcelain is sensitive to fast temperature changes. Glass, where the main component is quartz (SiO<sub>2</sub>), can replace porcelain in some applications, for example, as overhead insulators, but for high-voltage applications, glass should have a very low content of alkali, and it should contain boron oxide to reduce the melting point of the mixture. Glass can also be used in the form of fibers to enhance the mechanical strength of polymers. Mica is a natural mineral and is used as mica lamination on tapes or in polymers for the insulation of the windings of rotating machines due to its high resistance to partial discharges, and high mechanical and thermal strength.

#### Polymers

Polymers for high-voltage applications contain a large number of molecules, where the connections of the molecules can be in a line like a thread, in two dimen-

Fig. 3.32 Ethylene (left) and polyethylene (right)

Fig. 3.34 Structure of tetrafluoroethylene (left) and polytetrafluoroethylene (right)

Fig. 3.33 Electric breakdown field strength  $E_b$  as function of thickness  $d$  of polyethylene (adapted from [3.7])

sions like an area, or in three dimensions like a cube. The characteristics are different, and the materials can be grouped into thermoplastics, elastomers, and duroplastics. The preparation of polymers is a poly reaction, where polymerization, polycondensation, and polyaddition are possible. Thermoplastics can be melted and formed again, while duroplastics cannot be melted, and above the glass transition temperature the material remains elastic, and a further increase in temperature leads to thermal destruction. Polyethylene was used at the beginning of the replacement of fluid-impregnated paper insulation for high-voltage cables. Figure 3.32 shows the molecule structure of ethylene and polyethylene.

The connection between the chains of polyethylene leads to so-called cross-linked polyethylene, which has a better thermal performance than polyethylene and is nowadays the standard polymer insulation material for high-voltage cables. Belonging to the same family of polymers, polypropylene in combination with paper and fluid was developed for high-voltage cables for DC transmission in the voltage range up to 700 kV. The electric breakdown field of polymers depends strongly on the thickness of the test sample. As an example Fig. 3.33 shows the electric breakdown field  $E_b$  as function of the thickness of polyethylene.

The manufacturing procedure of polyethylene differs with respect to the low-pressure procedure, which results in a high-density polyethylene (HDPE), and the high-pressure procedure, which results in a low-density

polyethylene. The very high electric performance of polyethylene can be seen in Fig. 3.33, where the electric field strength for 2 mm thickness is about 100 kV/mm or 1000 kV/cm, which is about three to four times higher than mineral oil and about ten times higher than SF<sub>6</sub> at 1 bar. At the beginnings of the application of polyethylene a problem arose, which was called *water treeing*. Conductive structures were built under the influence of the electric field and in combination with diffused humidity, and they looked like a tree. These water trees resulted in so-called *electrical trees*, and finally in a breakdown of polymer insulation. This problem is now solved by a watertight design of high-voltage cables, through the use of very clean polyethylene material and a manufacturing process with threefold extrusion of the inner and outer conductive layers and insulation material.

Polyvinyl chloride (PVC) is another polymer that has been for high-voltage cables up to 30 kV, but it is nowadays mainly used for low voltage cables. PVC requires some addition of a plasticizer to be flexible and tensile, but in combination with Cl molecules the loss factor increases and excludes PVC as an insulating material for high-voltage cables above 30 kV. PVC is still used for cable sheaths. One critical characteristic of PVC is the diffusion of the plasticizer with time.

Polymers with fluorine molecules form another group of polymers. Figure 3.34 shows the polymer polytetrafluoroethylene (PTFE) as an example.

This polymer has a good thermal performance and a very low loss factor, but it is very sensitive to partial discharge, which is of consequence in the low electric field strength for stress endurance. A combination of fluorine containing polymer forms two further so-called copolymers. The copolymer tetrafluoroethylene-hexafluoropropylene (FEP) is a mixture of tetrafluoroethylene (10–50%) and hexafluoropropylene (90–10%) where the characteristics can be modified by the mixture ratio. The copolymer perfluoroalkoxy (PFA) is a combination of tetrafluoroethylene and perfluoropropylvinylether and has the same characteristics as PTFE.

Polymers with only C–H as chemical bonds are limited in their thermal performance, because the continuous service temperature should not be significantly higher than 100 °C. Polymers with benzene rings, oxy-

Fig. 3.35 Chemical structure of bisphenol A-based epoxy resin

gen, nitrogen, and sulfur allow much higher continuous service temperatures. Polyimides (PI) belong to this group of polymers, with a continuous service temperature of 250 °C; polyamides (PA) show a strong mechanical performance with respect to the tensile strength and toughness and abrasion resistance, and their applications are electrical and mechanical stress components in high-voltage apparatus. The different kinds of polyamides are characterized by the length of the carbon strings, for example PA 6 or PA 12.

Polymer compounds of silicone are exceptional elastic, flexible, and nondeformable. Depending on the temperature at the crosslink, two types of silicone exist: RTV silicone with crosslinking at room temperature and HTV with crosslinking at higher temperatures. Silicones are inflammable and resistant against chemicals, climatic influences, and ageing, but swell up and lose their mechanical strength in combination with some kinds of mineral oils. With fillers like titanium oxide or with soot, the characteristics of silicone can be modified, and typical applications are prefabricated cable joints of silicone with an in-built electric field grading by conductive silicone cones. An outstanding characteristic of silicone is its hydrophobicity, which qualifies silicone as insulation material for outside insulators, often in combination with reinforced glass fiber epoxy resin rods to cover both the mechanical and the electric strength. The hydrophobicity characteristic keeps for a long time, and even pollution will not influence this performance.

A polymer with similar characteristics to silicone is the copolymer ethylene propylene (EPR), often modified with diene and known as EPDM. The advantage of this polymer is the resistance to water and electrical treeing [3.31].

In the group of polymer resins, epoxy resin is the dominant material. In general, epoxy resins contain resin and hardener as the main components, but also catalysts, fillers, pigments, and flexibilizers. Therefore, a large number of epoxy resins exist with tailored characteristics for the relevant applications. The combination of bisphenol A and epichlorohydrin is the most-used epoxy resin in high-voltage applications. The chemical structure is shown in Fig. 3.35.

Dicarboxylic anhydrides are often used as hardener in combination with flexibilizers in order to compensate

or at least reduce the mechanical tension for a material combination metal epoxy resin with different expansion coefficients. Examples of dicarboxylic anhydrides are phthalic anhydride (PSA), hexahydrophthalic anhydride (HHPSA), and methylhexahydrophthalic anhydride (MHHPA), and for flexibilizers, polyols and glycidyl ester. For all combinations it should be taken into account that flexibilizers compromise electric performance and heat distortion. Fillers have the task to improve the mechanical characteristics, to reduce the exothermic processes during the manufacture of epoxy resin insulators with a large volume, and to reduce the price. Quartz powder ( $\text{SiO}_2$ ) is a common filler, but in  $\text{SF}_6$ -insulated apparatus aluminum oxide ( $\text{Al}_2\text{O}_3$ ) or dolomite are used, because in the case of discharges in the gas-insulated system, partial discharges, or arcs, the filler will not be attacked by a decomposition product of  $\text{SF}_6$ .

The manufacture of epoxy resin entails a chemical reaction between resin and hardener, and later a processing of the mixed material. Due to the sensitivity of voids within a polymer, the preparation of the material and manufacturing procedure should be done under vacuum. Different technologies exist, like casting, pressure gelation or an injection molding process, or impregnation, whereby the choice of the technology depends on the manufacturing time, the type of object, and the requirements.

The characteristics of epoxy resin concerning the mechanical, thermal, and electrical performance depend on the kind of epoxy resin and the manufacturing processes, for example weathering and UV (ultraviolet) radiation lead to a reduction of the mechanical performance and tracking resistance for bisphenol A-based epoxy resin. Furthermore, the loss factor and the relative permittivity of epoxy resin depend on the glass transformation temperature, and as well as on the service temperature. Figure 3.36 shows the relative permittivity and the loss factor of two types of epoxy resin as a function of the temperature.

It can be seen that a maximum of the polarization mechanism leads to an increase of the relative permittivity, and that with addition of a filler, here quartz powder, a further maximum, area II, appears. The measurement of the loss factor over the temperature allows the determination of polarization mechanism; however,

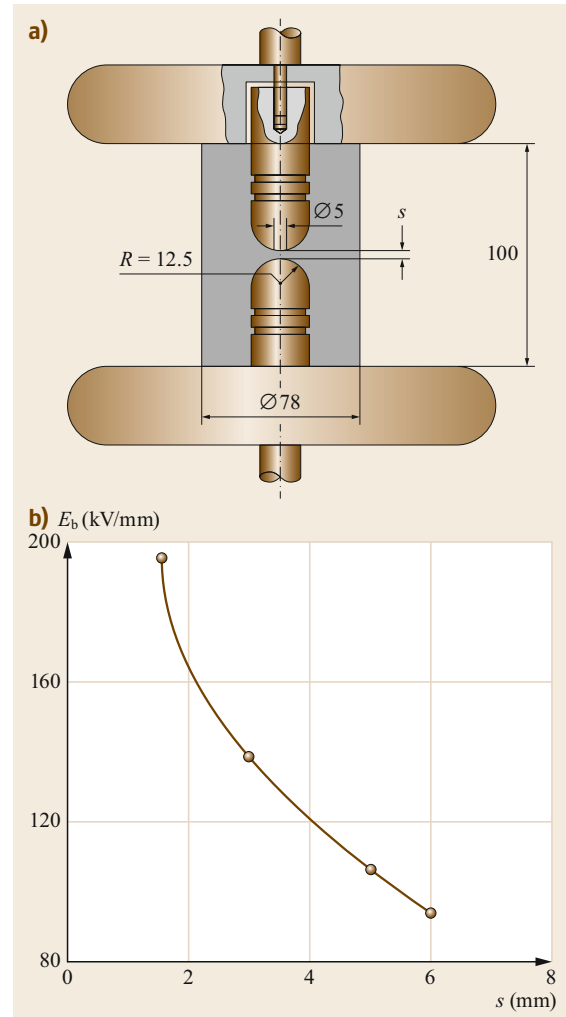

**Fig. 3.36a,b** Relative permittivity  $\epsilon_r$  and loss factor  $\tan \delta$  as functions of the temperature  $T$  (1 – pure epoxy resin, 2 – filled epoxy, I – area of small polar chain segments, II – area of boundary polarization, III – area of larger polar chain segments, IV – area of ion conduction) (adapted from [3.7])

the maxima are not always detectable. Therefore, the measurement of the relative permittivity gives a clearer picture of the polarization effects. The electric field strength also influences the loss factor and the relative permittivity. With an increase of the electric field, the loss factor and the relative permittivity also increase, and the increase is stronger the higher the temperature.

The conductivity of epoxy resin under DC stress is constant up to a certain electric field strength and increases with temperature and the addition of filler. With increasing electric field strength the conductivity increases exponentially, and this effect starts at a lower electric field strength with increasing temperature.

Similarly to the breakdown behavior of fluids, the volume of the tested samples influences the breakdown voltage. Figure 3.37 shows the short time breakdown electric field of a sphere–sphere electrode arrangement

**Fig. 3.37a,b** Breakdown electric field strength  $s$  at 50 Hz AC for a sphere–sphere gap with unfilled epoxy resin as a function of the gap distance  $s$  and gap volume: (a) electrode arrangement, (b) breakdown electric field strength (adapted from [3.7])

as a function of the gap distance and volume under stress, with a pure unfilled epoxy resin. This arrangement represents a more or less uniform electric field distribution. The voltage rise was 3 kV/s to prevent a thermal breakdown.

Unlike a void in a fluid, where the void can possibly move by fluid flow, a void in a solid is locally fixed, and if partial discharges occur in the void, the possible deterioration is always at the same place. The deterioration may erode the solid and finally lead to a total breakdown of the solid. The time for this process may vary from several minutes up to several years, and this effect is called erosion breakdown, as shown in

**Fig. 3.38** Structure of cellulose

Fig. 3.26. Another effect that may influence the interpretation of partial discharge measurements is the fact that in a closed void in solids, partial discharges increase the gas pressure. Then, according to Paschen's law, see Fig. 3.21, the inception voltage for partial discharges increases. As a consequence, partial discharges disappear, assuming that the applied voltage is constant, until the gas pressure in the void is reduced by diffusion, and then partial discharges appear again.

Another group of solids are polyurethanes (PU), which are mainly used in low or medium-voltage applications. The electric performance is lower compared to epoxy resin, but leakage current resistance is high, and viscosity and elasticity are very good. The rheological behavior is also good, and, therefore, polyurethanes are often used for void-free impregnation.

### 3.5.4 Impregnated Solids

Polymers exhibit a high electric performance, and this characteristic can be used if the polymers are thin foils

and impregnated with a gas or fluid. The most-used impregnated solid is paper in combination with a fluid, mineral oil, or ester fluid. Paper is based on cellulose, which is a molecule with a number of elements connected as a string. Figure 3.38 shows the chemical structure of a cellulose molecule.

Cellulose molecules are connected via an oxygen atom. If paper strings are cut, the free oxygen atoms build up together with two hydrogen atoms water molecules  $H_2O$ , and according Fig. 3.23, this may influence the breakdown voltage of the impregnation fluid. The length of the paper string is also a measure of the mechanical strength. New paper for the insulation of power transformers has a string length of about 1200 molecules. The end-of-life for such paper is reached at a string length of about 200. The relative permittivity of cellulose is 6.1, and, therefore, it should be taken into account that the electric field distribution in a paper-fluid combination is given by the relative permittivity of the different materials, and the electric field stress is higher for the fluid than for the paper. As an example, in a cellulose-mineral oil combination, the electric field stress in oil is higher than in paper ( $\epsilon_{r,oil} = 2.2$ ,  $\epsilon_{r,cell} = 6.1$ ). Humidity is a main factor affecting the electrical and mechanical performance of fluid and paper, and, therefore, both paper and fluid should be dry. After generation of cellulose from the raw material wood, for example spruce or pine, the cellulose is cut and macerated. Undesired constituents are removed by washing with water. Afterwards, a careful drying of the cellulose and very often a compression are performed to manufacture paper foils and pressboard elements. The drying

**Fig. 3.39** Water concentration in paper as a function of the water concentration in mineral oil [3.32]

process, as well as the impregnation process, should be done under vacuum in order to remove as much as possible of the remaining humidity and to fill up all voids with impregnation fluid. It is recommended to use more than a layer of paper as an insulation system, because imperfections are unavoidable in paper foils, and these represent weak points in the insulation.

The combination of mineral oil and paper is the dominant insulation system for power transformers, and with respect to the humidity, it is very important to know the humidity concentration in the two components. Figure 3.39 shows the water concentration in the paper as function of the water concentration in the mineral oil with the equilibrium temperature as a parameter.

The water content in paper is in the range of %, but the water in mineral oil is in the range of ppm. Furthermore, it can be seen that water moves from paper to mineral oil if the temperature increases, and vice versa if the temperature decreases. The curves in Fig. 3.39 are only valid for an equilibrium of the temperature, and depending on the size of the transformer, this requires a long time at a constant temperature. However, it is important to realize that in a transformer at 100 °C, water moves from the paper to the mineral oil. If the

transformer is switched off and cools down, the water will move to the paper, but this requires time, and in the meantime the relative water content in the mineral oil is high, and a breakdown may occur if the transformer is switched on again.

Another impregnated solid, mainly used for transformers but also for indoor substations, is resin-bonded paper (RBP). Several layers of paper are bonded with resin, typically phenol or cresol, nowadays also epoxy resin (void-free resin-impregnated paper (RIP)), and manufactured as a preproduct for plates, tubes, and differently shaped pieces. A similar material combination is known as a transformer board. A large number of paper layers are bonded in a hot-pressing procedure. The product is pure cellulose, which can be used and impregnated with fluids. The shaped piece combines the high electrical performance of soft paper with the high mechanical performance of RBP. A further advantage of transformer boards is that also complex elements like angular rings and pipe elbows can be directly manufactured.

A new group of impregnated solids is the combination of aramid fiber with a fluid. Aramid fibers are synthetic and have a lower mechanical performance than paper but can be used at higher temperatures.

## 3.6 Test Techniques

High-voltage equipment is tested at different stages of development and manufacturing. The first step is the test at the design stage, usually on a prototype. Then follows a so-called design test on regularly manufactured equipment in order to check all design criteria and compliance with the relevant standards, national or international. Furthermore, the test results are used to have a record of performance for the relevant equipment. There are many tests for nonelectrical parameters, but only electrical tests will be described in the following chapters. Routine tests are carried out on every piece or, depending on the evaluated quality of manufacturing, on a random or fixed selection of the manufactured pieces. Finally, after transportation and assembly, an on-site test is done in order to detect damage during transportation or failure during assembly. This test is usually called the acceptance test, but the routine test can also be a kind of acceptance test. The test voltages are AC, DC, or impulse voltage, and are in some cases combined with measurements of some parameters that may contain some information about the status of the insulation. The performance of the test voltage sources can be different for factory or on-site tests, depending on the requirement and availability [3.33].

The IEC standard [3.2] defines a test voltage by its amplitude, frequency, and/or shape within specified tolerances. It also describes preferred test voltages, but it may sometimes be necessary to modify the frequency or shape of the test voltage in order to enable testing of the test object.

### 3.6.1 AC Voltage

Alternating voltage is defined by its rms value and/or by its peak value, depending on the purpose. For a pure sinusoidal wave form, the relation between the peak value  $\hat{U}$  and the rms value  $U$  is given by the square root of 2. This relation is also used in the recommendations [3.2] to define the tolerance of the sinusoidal wave shape by the following equation

$$\frac{\hat{U}}{U} = \sqrt{2} \pm 5\% . \quad (3.60)$$

For short time stress, the flashover or breakdown behavior of insulating material depends on the peak value of the voltage supplied. At a longer stress time or under service stress, the rms value is very often the most im-

**Fig. 3.40** A voltage transformer ( $\Phi$  – magnetic flux,  $N$  – number of windings)

**Fig. 3.41** Equivalent diagram of a three-stage transformer cascade (1 – primary winding, 2 – secondary winding, 3 – tertiary winding)

portant parameter for the breakdown. This depends on the thermal behavior of the insulating material and the loss characteristics.

The ratio of the basic frequency and the harmonics of different order define the wave form of AC voltage. For the measurement, the harmonics should be taken into account, particularly because some measurement systems use the peak value in order to evaluate the rms value. This is becoming increasingly important due to the increase of power electronics, which generates a higher harmonic content. AC voltage can be generated by a very simple circuit. Figure 3.40 shows a simplified equivalent diagram of a voltage transformer.

The ratio of the number of windings defines the ratio of the two voltages  $U_1$  and  $U_2$ , and, therefore, theoretically every voltage ratio can be reached by a single-stage transformer. The nonlinear behavior of the insulation performance leads to the generation of high AC voltage by means of a transformer cascade, reducing the cost of the insulating material, and for using a flexible combination of a number of single transformer units. Figure 3.41 shows a typical three-stage cascade arrangement with identical units. Each unit needs only the insulation for a single-stage transformer.

The short-circuit impedance and the harmonic content as functions of the load are the important param-

**Fig. 3.42** AC transformer cascade for 1000 kV with a voltage divider (courtesy of BTU Cottbus-Senftenberg)

eters for an AC voltage generator. The short-circuit impedance, given in percent, represents the voltage drop under full load conditions. It is assumed that the resistive part is negligible in comparison to the inductive part. For a cascade, the short-circuit impedance is higher than the sum of the short-circuit impedances and increases more than linearly with the number of stages.

The combination shown in Fig. 3.41 can also be used with two transformers at the bottom stage and one transformer at the second stage. Thus, giving a higher output current, but at a lower output voltage. The use of each unit as a single transformer or the combination of the units offers a number of possibilities. Concerning the power distribution within a cascade, it is important that the primary winding of the first stage should be designed to carry the full output power of the cas-

**Fig. 3.43** Equivalent diagram of a transformer with capacitive load ( $U_1$  – input voltage, referred to the high-voltage side,  $U_2$  – output voltage, across the capacitive load,  $I$  – transformer current,  $C_T$  – capacitor, representing the transformer capacitance,  $C_P$  – capacitor, representing the load capacitance)

**Fig. 3.44** Vector diagram of a transformer with capacitive load

cade. In all stages, the secondary windings are loaded with the same power. They are calculated by the output power divided by the number of stages, assuming that all transformers are identical. The tertiary winding of the first stage is loaded with two-thirds of the output power. In all other stages, the windings are loaded with the relevant load distribution within the transformer. Figure 3.42 shows an AC transformer cascade with a voltage divider for 1000 kV.

For AC voltage generation by a transformer, another factor is the voltage increase due to the capacitive load. This is usually the case for AC test objects. The vector diagram for a simplified transformer circuit is shown in Fig. 3.43, where all elements are referred to the high-voltage side.

The output voltage  $U_2$  can normally be calculated using the ratio of the windings, but the voltage  $U_2$  is higher than calculated. This is demonstrated by the vector diagram shown in Fig. 3.44.

An increase of the output voltage due to the capacitive load is normally undesirable. Nevertheless, for AC tests, the increasing voltage can be used to reduce the input voltage or the size of the test equipment. If the capacitance of the load including the transformer capacitance and the inductance of the transformer including the circuit inductance are equal, the circuit is in resonance, and the output could theoretically increase up to infinity. Because of the resistance in the circuit, the voltage will be limited. The ratio between the input voltage

**Fig. 3.45** Parameters of DC voltage

and the output voltage can be very high, up to 100, and the necessary active power is very low.

The resonance conditions can be used for voltage tests by changing the inductance of the circuit, which results in resonance conditions at constant frequency. Alternatively, changing the frequency results in resonance conditions at different frequencies. With this type of test equipment, test objects with very high capacitance can be tested with a reasonable size and power of the test equipment. In all cases, the regulation of the test system should be adapted very carefully to the required voltage level to avoid overshooting of the test voltage.

### 3.6.2 DC Voltage

A direct voltage is defined as the mean value between the highest and lowest levels within a time period. The duration of the period depends on the generating system. Figure 3.45 shows a typical example of DC voltage generated by rectification of AC voltage.

The DC voltage  $U_{DC}$  is the arithmetic mean value of the voltage  $u(t)$ . The voltage drop  $\Delta U$  is the difference between the peak voltage of the AC power supply and the DC voltage. This is given by the so-called *internal impedance* of a multiple stage rectifier. The ripple  $\delta U$  is the difference between the highest and lowest values of  $u(t)$ . It represents the charging of the capacitors by an AC source during the conductive period of the diodes and the discharging of the capacitors by the load during the nonconductive period of the diodes. It should be taken into account for the design of the diodes that the charging time is much shorter than the discharging time, and the charging current is much higher than the discharge current. According to [3.2], the value of the ripple  $\delta U$  should be less than 3% of  $U_{DC}$ . The main parameters influencing the ripple are the frequency of the AC supply voltage, the value of the smoothing capaci-

**Fig. 3.46** Equivalent diagram of a multiple-stage rectifier (1 – thyristor controlled voltage regulation, 2 – high-voltage transformer, 3 – rectifier with diodes, charging and smoothing capacitors, 4 – resistive voltage divider with grading capacitors, 5 – discharging and grounding device, 6 – test object,  $C$  – charging or smoothing capacitor,  $C_M$  – grading capacitor of the measuring resistor,  $R_M$  – measuring resistor,  $R_D$  – damping resistor,  $R_E$  – earthing resistor,  $R_G$  – grading resistor of the earthing switch)

tance, and the load current. For small load currents, the ripple can be estimated by

$$\delta U \approx \frac{I}{fC} \frac{N}{4} (N + 1), \quad (3.61)$$

where  $I$  is the load current,  $f$  the frequency of the AC power supply,  $C$  the smoothing capacitance, and  $N$  the number of stages of a multiple-stage rectifier. Equation (3.61) depicts that the ripple increases linearly with the load current and quadratically with the number of stages. It decreases with increasing frequency and smoothing capacitance. The voltage drop  $\Delta U$  influences only the mean value  $U_{DC}$  of a DC generator and also depends on the design of the generator. For a multiple stage generator, the voltage drop can be estimated according to

$$\Delta U \approx \frac{I}{fC} \frac{N}{3} (2N^2 + 1), \quad (3.62)$$

with the same parameters as in (3.61).

**Fig. 3.47** DC generator for 1200 kV and 2 A (courtesy of Haefely Test AG)

Equation (3.62) shows that the increase of the voltage drop  $\Delta U$  is by the cube power of the number of stages  $N$ . This can be accounted for by choosing the adequate no-load voltage of the generator and a fast voltage-regulating system. Therefore, the highest requirements are made in DC pollution tests, where the load current can change very rapidly from some mA up to some A. Thus, the voltage should be kept stable within given limits requiring a strong AC power source, a large smoothing capacitance, and a fast regulation system. A multiple-stage rectifier and its main components are shown in Fig. 3.46. Some measures to reduce the ripple  $\delta U$  can be gained from (3.61). Normally, the voltage drop  $\Delta U$  is no problem for the test generator, because it can be adjusted by proper design and the no-load output voltage. Figure 3.47 shows a DC generator with a three-phase AC supply for 1200 kV DC and a current of 2 A for pollution tests with DC.

During DC voltage tests, the voltage drop on polluted insulators may influence the test results due to the fast change of load. Therefore, the transient behavior of the voltage regulator should be controlled in case of high load current. The energy supply has to be regulated

**Fig. 3.48** Output current  $I$  as a function of the output voltage  $U$  at 3% ripple;  $N$  = number of stages (400 kV rated voltage)

very fast by feeding the current from the smoothing capacitor, from the main power supply, or from both. The dependence of the number of stages, the maximum load current, and the output voltage for a standard multiple-stage rectifier is shown in Fig. 3.48. It has a no-load voltage of 400 kV per stage.

### 3.6.3 Impulse Voltage and Current

The peak value and its time parameter define an impulse voltage or current. For reproducible results in impulse voltage tests, the wave shapes are defined in general recommendations [3.2] or device-related descriptions are given in [3.34, 35]. The generation of an impulse voltage or current as in Fig. 3.2 or Fig. 3.5 is generally accomplished by the charging and discharging of capacitors through resistors. This gives an impulse, which can be described by two exponential functions.

Figure 3.49a shows a simplified equivalent circuit for impulse voltage generation without any inductance.

Figure 3.49b shows a similar circuit but with a different arrangement of the resistors, which is commonly used.

In both circuits, a wave shape that represents the sum of two exponential functions is generated. The ratio of the output voltage or the voltage across the load capacitor  $C_1$  and the input charging voltage  $U_0$  is different. In a circuit of type A, Fig. 3.49a, the voltage across the load capacitor can be calculated with (3.63), neglecting the influence of the inductance of the circuit and the discharge through the resistor  $R_e$  during the charging time of  $C_1$

$$u(t) = U_0 \frac{C_s}{C_s + C_1} \frac{R_e}{R_d + R_e} \quad (3.63)$$

The output voltage is not only given by the ratio of the capacitor but also by the ratio of the resistors. In circuit type B Fig. 3.49b, the output voltage is only determined by the capacitors and is, therefore, higher than in circuit A according to

$$u(t) = U_0 \frac{C_s}{C_s + C_1} \quad (3.64)$$

An empirically-based estimation of the real output voltage  $u(t)$  of the circuit type B) is given by

$$u(t) = U_0 \frac{C_s}{C_s + C_1} 0.95, \quad (3.65)$$

which also uses the damping effect of the resistors.

For a given capacitance of  $C_1$ , the front time is determined by the load capacitance and the damping resistance. The front time can be adjusted by variation of the damping resistance, assuming that the load cannot be changed. The time to half-value is mainly determined by the earthing resistance and the impulse capacitance, assuming that the impulse capacitance is

**Fig. 3.49a,b** Simplified equivalent circuit of an impulse-generating circuit type A (a) and B (b). ( $C_s$  – charging or impulse capacitor ( $C_s \gg C_1$ ),  $R_d$  – damping resistor,  $R_e$  – earthing resistor ( $R_e \gg R_d$ ),  $C_1$  – load capacitor (test object, divider, etc.),  $S$  – spark gap)

much higher than the load capacitance. Then, a reasonably high output voltage is reached. For tests with a standard lightning impulse, the value of the resistance should be calculated depending on the test object and the generator to be used. The mathematical description of the circuit leads to a differential equation whereby the solution of the differential equation is not consistent, and, therefore, assumptions for the time constant  $T_f$  (front time) and the time constant for the tail  $T_t$  (time to half value) are given in the following equations

$$T_f \approx R_d \frac{C_s C_1}{C_s + C_1}, \quad (3.66)$$

$$T_t \approx R_e (C_s + C_1). \quad (3.67)$$

The relations of the time constants  $T_f$  and  $T_t$  to the relevant time parameter for the front time  $T_1$  and the time to half-value  $T_2$  (Fig. 3.2) for a standard lightning impulse  $1.2/50 \mu\text{s}$  are

$$T_1 = 2.96 T_f, \quad (3.68)$$

$$T_2 = 0.73 T_t. \quad (3.69)$$

For a standard switching-impulse voltage  $250/2500 \mu\text{s}$  (Fig. 3.4), the relations to the time to peak  $T_p$  and the time to half value  $T_2$  are

$$T_1 \approx 2.41 T_f, \quad (3.70)$$

$$T_2 = 0.87 T_t. \quad (3.71)$$

Impulse voltages with high amplitude are normally generated with a multistage impulse generator, called the Marx generator after the inventor. The generator's principle is the parallel charging of a number of impulse capacitors followed by discharging of these capacitors in series. The equivalent simplified circuit, again for the type B circuit, is shown in Fig. 3.50.

The most important part for high reproducibility of the impulse shape and amplitude is the behavior of the spark gap S. The breakdown process and time of a spark gap depend on the uniformity of the electrical field. Therefore, sphere gaps are generally used. With an electrode material of tungsten for reduction of surface damage by the arc, it is also necessary that the breakdown of the spark occurs at the same charging voltage to generate impulses with identical amplitude and time parameters. Triggering the spark gap is the method of choice.

Two methods may be used: triggering at a constant distance of the spark gap or triggering at a constant voltage. For the first method, the spark gap should have a distance that is larger than the breakdown distance at the desired voltage. The impulse capacitors are

**Fig. 3.50** Simplified equivalent circuit of a multistage impulse generator ( $C_s$  – charging or impulse capacitor per stage ( $C_s \gg C_1$ ),  $R_d$  – damping resistor per stage,  $R_e$  – earthing resistor per stage ( $R_e \gg R_d$ ), S – spark gap per stage,  $C_1$  – load capacitor (test object, divider, etc.),  $R_p$  – protection resistor)

charged in parallel up to the required charging voltage and reach the full charging voltage at different times, which should be taken into account. When all capacitors are fully charged, the gap is reduced, and the breakdown takes place at the flashover distance, which is constant for a given charging voltage. Then all capacitors are connected in series through the spark gaps and the damping resistors  $R_d$ , and they charge the load capacitor  $C_1$  and generate the impulse by discharging later on through the earthing resistors  $R_e$ .

The second method is more frequently used and is based on a triggering device within the bottom spark gap. The spark gap distance is slightly longer than the required breakdown distance. Then the impulse capacitors are charged up to the preselected voltage and kept constant. A trigger impulse at the bottom spark gap generates a breakdown of the bottom spark gap, and due to natural overvoltage in the other stages, all spark gaps flash over. This method has a high reproducibility and reliability, in particular for transformer impulse tests, where a comparison between impulses at different charging voltages is required.

For the evaluation of the required charging voltage of an impulse generator, the so-called efficiency factor is helpful, which is defined as the ratio of the output voltage to the total charging voltage of the generator. In (3.65), the common efficiency factor for lightning

**Fig. 3.51** 6 MV impulse generator (courtesy of Mitsubishi Electric Corporation)

impulses is about 0.95, whereas this factor can go down up to 0.5 for switching impulses. Figure 3.51 shows an impulse generator with 6 MV charging voltage together with an impulse divider and a chopping device.

Furthermore, the total inductance of the test circuit is also important for lightning impulses. For an aperiodically damped impulse consisting of two exponential functions for the front and the tail, a minimum value of the resistance can be calculated according to

$$R_d = 2 \sqrt{L \frac{\frac{C_s}{n} + C_l}{\frac{C_s}{n} C_l}}, \quad (3.72)$$

with  $L$  as the inductance of the complete circuit,  $C_s$  the charging capacitance per stage,  $n$  number of stages, and  $C_l$  the total load capacitance. With the given impulse and the load capacitor, the damping resistor for an aperiodically damped impulse is determined by the inductance. At a given front time, the required damping resistor may be lower than for an aperiodically damped shape. Then the impulse may show some oscillations if the inductance cannot be reduced due to the size of the test circuit and the inner inductance of the capacitors.

**Fig. 3.52** Example of a lightning impulse with overshoot (adapted from [3.2])

In [3.2], the time parameters and the allowed oscillations or overshoot for lightning-impulse voltages are defined, and an evaluation procedure is also described. As an example, Fig. 3.52 shows a lightning-impulse voltage, where the resistance is lower than for the aperiodically damped case, and an overshoot occurs in the peak area. In order to increase the reproducibility of the evaluation of the test voltage, a so-called test voltage factor  $k$  was introduced to prevent the discontinuity in a former version of [3.2].

The recorded curve has an extreme value  $U_e$  and an overshoot  $\beta$  above the base curve, calculated as the difference between  $U_e$  and  $U_b$ . The allowed relative overshoot magnitude is 10% of the extreme value  $U_e$ . The evaluation of the base curve is given in [3.2] based on the assumption that the impulse voltage is composed of two exponential functions, and that the recorded curve is available in digital form. The difference between the recorded curve and the base curve is shown as a residual curve. Investigations on the breakdown behavior of materials have demonstrated that the frequency content of the oscillation should be taken into account, and from these investigations, the  $k$  factor was developed [3.36, 37]. Figure 3.53 shows the  $k$  factor as a function of the frequency of the overshoot or oscillation and the approximate function.

The  $k$  factor represents a mean value of the influence of overshoot on the breakdown behavior of air, SF<sub>6</sub>, mineral oil, and polyethylene. The filtering of the residual curve with the  $k$  factor function is shown in Fig. 3.54 together with the ascertained test voltage curve, which is the sum of the base curve and the filtered residual curve. The test voltage  $U_t$  is, then, the highest magnitude of the test voltage curve.

The limits for a standard lightning impulse with the tolerances given in [3.2] are physically given by the in-

**Fig. 3.53** The  $k$  factor as a function of the frequency  $f$  of overshoot or oscillation (adapted from [3.2])

**Fig. 3.54** Determination of the test voltage curve (adapted from [3.2])

ductance and the capacitance of the test object and can be approximated as

$$R_d = 2 \sqrt{L \frac{\frac{C_s}{n} + C_1}{\frac{C_s}{n} C_1}} \approx 2 \sqrt{\frac{L}{C_1}} \quad \text{for } \frac{C_s}{n} \gg C_1. \quad (3.73)$$

Usually, the capacitance of the load  $C_1$  varies, and, therefore, the resistance  $R_d$  should be adapted. Large impulse generators may have 20–30 stages, and this also requires 20–30 resistor elements. Therefore, a customized selection of resistors and a clever design of the interconnec-

tion of the resistors within one stage can optimize the impulse generator. For example, with two resistor elements and the possibility of parallel and serial connections, four magnitudes of resistances are possible.

Impulse currents are generated similarly to an impulse voltage [3.38], the main difference being that the capacitors are all connected in parallel, thus increasing the capacitance and reducing the inductance of the circuit. Since the steepness of the current impulse depends on the derivative of the current as shown in (3.74),

$$\frac{di}{dt} = \frac{U}{L}, \quad (3.74)$$

current impulses with short front times need special arrangements of the capacitors. Here,  $U$  is the charging voltage and  $L$  the inductance of the complete test circuit. Although a lower inductance leads to a higher steepness of the current, in many cases, the inductance is fixed, and the steepness can only be adapted by increasing the charging voltage, which should be realized by a sophisticated design of the current generator [3.39].

From the many activities within CIGRE and IEC, the most important ones from the point of view of test techniques for ultra-high-voltage (UHV) equipment are the requirements on the overshoot and front time due to large test circuits, wet tests, the time-to-peak of the switching-impulse voltage due to the breakdown voltage minimum as a function of the time-to-peak for large air-gap distances and the atmospheric and altitude correction factors.

## 3.7 Measuring Techniques

Because the amplitudes are high, and they cannot be measured directly with conventional measuring and recording systems, the measurements of voltage and current in high-voltage tests are difficult to obtain. Furthermore, not only the peak value but also the shape of the signal should be measured and evaluated. This requires an adequate recording system. Generally, a high-voltage or high-current measuring system consists of converting, transmission, and recording devices. A measuring system is as good as the weakest part of the system, and, therefore, it is not necessary to ask for exceptional performance of one of the components. The amplitude of the signal to be measured should be reduced by the converting device to a value suitable for transmission and recording. The output signal of the converting device must be an exact replica of the input signal with respect to the wave shape and time parameters. This requirement is very strong in many cases, and, in addition, measurement uncertainty should be estimated and evaluated carefully.

The converting device is usually the critical component due to its transfer behavior and physical size. The preferred calibration method is by comparison with an approved measuring system under normal operating conditions shown in Fig. 3.55.

The comparison with an approved measuring system results in an uncertainty with respect to the evaluation and output of the system to be calibrated. The calibration should reach at least at 20% of the rated operating voltage of the converting device. For example, a reference measuring divider for impulse voltage with a rated voltage of 500 kV can be used to calibrate a converting device up to 2500 kV. However, the linearity of the converting device between the calibration

**Fig. 3.55** Arrangement for comparison measurements ( $V$  = applied voltage; system  $N$  = reference system; system  $X$  = system to be calibrated) (adapted from [3.40])

voltage level and the rated voltage of the converting device must be checked. This is even more important for the testing of UHV equipment, where lightning-impulse voltages up to 2700 kV and switching-impulse voltages up to 1950 kV are used [3.1].

Stability within the specified range of operating conditions, keeping the scale factor of the measuring system constant over long periods, is a further important requirement for converting, transmission, and recording devices. The dynamic behavior of a converting device should preferably be evaluated by an amplitude/frequency response measurement or by a unit step response measurement.

The performance of an approved measuring system is given by its uncertainty budget [3.40]. The individual uncertainty of the scale factor measurement, the linearity check, the dynamic check, the short and long-time behavior, the ambient temperature effect, and the proximity effect compose the uncertainty budget. If software is used for the evaluation of the parameters, then also the uncertainty of the software should be taken into account. Depending on the voltage shape, the uncertainties may contribute differently to the total uncertainty budget. Therefore, in [3.40], the evaluation procedure for the uncertainty budget of the different types of voltages like DC, AC, and impulse voltage is described.

The transmission device is generally a coaxial cable, which should not influence the amplitude. In special cases, it does influence the transfer behavior of the complete measuring system. The recording device is very often equipped with an additional converting device on its input. Again, this is to reduce the amplitude, but this converting device is small and normally has sufficiently good transfer behavior. The transformation characteristics are normally not critical, but they should be checked and included in the evaluation of the entire system.

Particularly at high voltage or high current, an important problem for all measuring systems, is the sensitivity to electromagnetic interferences. The most critical tests are impulse tests, where the impulse generation is at the same time a radiation source of an electromagnetic wave. This wave penetrates the whole system – the converter, the transmission, and the recording device – and not all components can be properly shielded. Thus, reducing the amplitude of the radiation and increasing the signal level in order to get a very high signal-to-noise ratio is mandatory. Nowadays, recording devices are analog–digital converters instead of analog devices. A careful selection should be made for moving coil instruments (mean average value) or moving iron instruments (RMS value).

**Fig. 3.56** Metal oxide residual voltage measuring circuit ( $U_C$  – charging voltage of capacitor  $C$ ,  $C$  – charging capacitor,  $R$  – damping resistor,  $S$  – spark gap,  $MO$  – metal oxide surge arrester,  $U_r$  – representing the residual voltage across the surge arrester,  $U_s$  – voltage across the shunt, representing the current  $I$ ,  $I$  – current through the surge arrester,  $H$  – magnetic field in the residual voltage measuring loop)

Another source of electromagnetic interference are voltages and currents floating within the test object and measuring cables, because they can induce voltages by capacitive or inductive coupling or by loops of the measuring cable. Proper shielding, or in special cases, double shielding of the measuring and control cables, prevention of loops by a star connection of all measuring and control cables and compensation of unwanted effects like magnetic fields can reduce the electromagnetic interference. The residual voltage measurement of a metal oxide arrester is a typical example. In this case, the high magnetic field induces a voltage in the loop, which is superimposed on the residual voltage. Figure 3.56 shows the schematic diagram.

If the earth connection of the divider cannot be changed for some reason, a suitable connection of the voltage divider is necessary, because the magnetic field  $H$  induces a reasonable voltage in the residual voltage measuring loop. A simple check is the replacement of the surge arrester by a metallic tube with the same geometry and the application of a current impulse. In this case, the measured residual voltage across the metallic tube should be close to zero.

Variations of the scale factor or of a parameter of a measuring device, due to proximity effects, should be considered and can be determined by measurements performed for different distances of the device from earthed walls or energized structures.

The simplest device for voltage measurement are standard air gaps [3.3], but they have some disadvantages. First of all, the information about the magnitude of the voltage can only be reached if a breakdown of the air gap occurs. Furthermore, at impulse voltages only the peak value can be evaluated but not the time parameter. In [3.3], tables showing the breakdown voltage as a function of the gap distance and in the case of spheres

as electrodes of the sphere radius. For DC, a rod–rod electrode arrangement is a requirement, for all other voltage forms a sphere–sphere arrangement. With the tables and a tape measure, the applied voltage can be evaluated and with certain care, an uncertainty of 3% can be reached, if the atmospheric correction factors are carefully used.

### 3.7.1 Voltage Measurement

#### DC Voltage

The main parameter of a DC voltage is the amplitude, but often the deviation from the ideal DC voltage, defined as ripple, is important (Fig. 3.45). The uncertainty for the amplitude measurement is 3%, for the ripple less than 10% of the ripple amplitude or 1% of the arithmetic mean value of the DC voltage, whichever is larger.

A simple measuring device is a high ohmic resistor and a current measuring device in series. The current through the resistor is proportional to the applied voltage, and it is recommended that the current be as high as 0.5 mA at the rated voltage to ensure that the influence of leakage current is negligible. For safety reasons, it is necessary to have a surge protective device in parallel to the measuring device, because in the case of disconnection of the measuring cable or flashover of the high-voltage resistor, the full voltage will be applied to the measuring device. A high-voltage resistor normally consists of many elements that are connected in series. The resistance of each element has a voltage and temperature coefficient, and both influence the magnitude of the resistance and, therefore, the uncertainty of the measurement. Under normal conditions, the voltage and temperature coefficients do not play an important role. However, for very small measuring uncertainties, the temperature coefficient must be taken into account, because it has a greater influence than the voltage coefficient. Figure 3.57 shows the relative change of the resistance as function of the temperature for a carefully selected number of resistor elements. The relative change of the total resistance is less than 0.05% in the temperature range between  $-20^\circ\text{C}$  and  $+50^\circ\text{C}$ , but each resistor element may have a larger coefficient than that allowed for the complete chain.

Another way for compensation of the effect of the voltage and temperature is by the use of voltage dividers. Since the elements in the high-voltage and low-voltage part are subject to the same voltage and temperature stress, this type of measuring device is commonly used as a high-voltage DC measuring technique. Figure 3.58 shows the simplified equivalent circuit diagram.

In the case of fast transient voltages, the distribution is important because even in DC test systems

**Fig. 3.57** Relative resistance change as a function of temperature

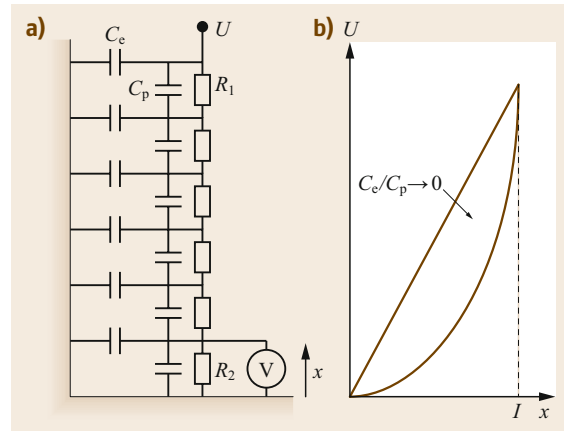

**Fig. 3.58** DC voltage divider ( $U$  – DC voltage,  $I$  – DC current,  $R_1$  – high-voltage arm resistor,  $R_2$  – low voltage arm resistor, SPD – surge protective device,  $V$  – voltage measuring device with very high resistance)

a breakdown with a very fast voltage change may occur. A resistive divider as shown in Fig. 3.59 has a linear voltage distribution as long as the frequency is near zero for DC or AC at very low frequency. When the stray capacitances  $C_e$  start influencing the voltage distribution, e.g., in the case of higher frequency content in the voltage, the voltage distribution is no longer linear.

The voltage distribution is strongly influenced by the ratio of the stray capacitances. The voltage distribution becomes more and more nonlinear, if the parallel stray capacitance decreases, or the earth stray capacitance increases. When designing a pure resistive voltage divider, this phenomenon should be taken into account. Adding capacitors in parallel to the resistors can keep the ratio  $C_p/C_e$  high is one of the measures.

### AC Voltage

The main parameter of AC voltage is amplitude, but here also the rms value is often used, particularly for the evaluation of energy and thermal aspects. In some

**Fig. 3.59a,b** Resistive divider with stray capacitances (**a**) and shape of voltage distribution (**b**) ( $U$  – DC voltage,  $R_1$  – high-voltage resistor,  $R_2$  – low voltage arm resistor,  $C_p$  – parallel stray capacitance,  $C_e$  – earth stray capacitance,  $V$  – voltage measuring device with very high resistance,  $x$  – distance from ground potential)

**Fig. 3.60** AC voltage divider ( $U$  – AC voltage,  $I$  – AC current,  $C_1$  – high-voltage arm capacitor,  $C_2$  – low voltage arm capacitor,  $V$  – voltage measuring device with very high impedance, SPD – surge protective device)

cases, the frequency should be taken into account, but for electric energy systems, 50 or 60 Hz are the common frequencies. If the voltage shape is purely sinusoidal, the relation between the peak value and the rms value is given by

$$\frac{\hat{U}}{U} = \sqrt{2}. \tag{3.75}$$

This ratio can be changed if the AC voltage contains higher frequencies than the operating frequency, and the allowed deviation is 5%. The uncertainty for AC voltage measurement is 3%.

A capacitive voltage divider, which is not influenced by the temperature and voltage coefficient of the capacitors, will normally be used for AC measurements. Figure 3.60 shows the simplified equivalent circuit diagram.

**Fig. 3.61** AC peak value measuring circuit with a capacitive divider ( $u(t)$  – AC voltage,  $i(t)$  – AC current,  $C_1$  – high-voltage arm capacitor,  $C_2$  – low-voltage arm capacitor,  $R_e$  – earthing resistor,  $R_m$  – measuring resistor,  $C_m$  – measuring capacitor,  $u_2(t)$  – measured voltage, V – voltage measuring device with very high impedance, SPD – surge protective device)

The divider output voltage is given by the ratio of the capacitors according to

$$V = U_2 = U \frac{C_1}{C_1 + C_2 + C_i}, \quad (3.76)$$

with  $C_i$  the capacitance of the measuring instrument.

The measured voltage is the rms value. In some cases, the peak value is of interest, or the rms value is evaluated from the peak value measurement according to (3.75), which is only correct if the applied voltage is sinusoidal. In any case, an additional uncertainty should then be accepted. The peak value of a voltage can also be measured with a capacitive voltage divider similar to what is depicted in Fig. 3.60 and with a supplement shown in Fig. 3.61.

The measuring instrument shows the peak value of the voltage when the measuring capacitor  $C_m$  is charged up to the peak value of  $u_2(t)$ . This is only a part of the high voltage  $u(t)$  given by the divider ratio. It is desirable that the series resistance of the diode is small and, thus, gives a negligible voltage drop across the diode. Mainly three parameters influence the uncertainty of measuring the peak voltage measuring circuit. The transformation ratio is influenced by resistor  $R_e$ , the resistor  $R_m$  discharges the measuring capacitance  $C_m$ , and during the charging time, the capacitor  $C_m$  is in parallel with the capacitor  $C_2$  and changes the capacitive transformation ratio. The latter two factors are, additionally, frequency dependent. Fortunately, for all these influences, compensation measures exist.

Nowadays, the measurement of the peak value is only carried out by an analog digital converter as the recording device. The integrated computer can make more calculations, e.g., fast Fourier transformation (FFT) and can evaluate the amplitudes of the relevant harmonics. With the 12-bit resolution of a commercially available digital recorder, the measurement uncertainty of the recording device is negligible compared

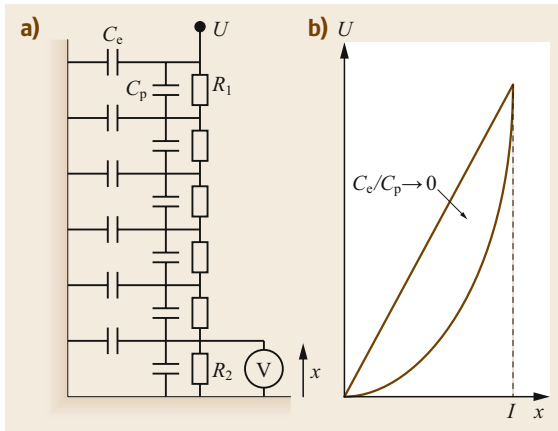

with the other components of the measuring system. IEC recommendations for DC and AC measurements with digital recorders are under preparation [3.3].

### Impulse Voltage

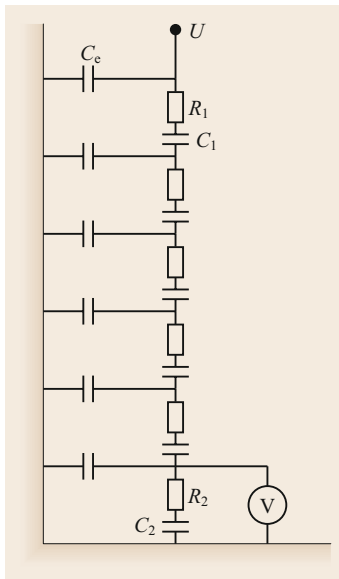

Impulse voltages require a measurement system having a known scale factor and an adequate dynamic behavior. This is because not only the peak value but also the wave shape should be recorded and evaluated. Under certain conditions for impulse measurements, resistive dividers can be used. If the resistance is low enough, the transfer behavior is not influenced by the stray capacitance. A good estimation of the time constant  $T$  of the unit step response characterizing the transfer behavior is given by  $T = (RC_e)/6$ , where  $C_e$  is the stray capacitance and  $R$  the resistance of the divider. The stray capacitance and the resistance should be as small as possible. Because of the low resistance of the measuring system with resistive dividers, the wave shape of the impulse may be changed so that no switching impulses can be measured. Therefore, resistive–capacitive dividers are the common divider type for the measurement of impulse voltages. Figure 3.62 shows the schematic, which is the same as for DC measurements (Fig. 3.59) regarding fast voltage changes.

If the time constants in the high-voltage  $R_1 C_p$  and the low-voltage arm  $R_2 C_p$  are identical, the divider is frequency independent. Nevertheless, the inductance caused by the high-voltage lead, and the capacitance of the divider built up of a series resonance circuit may cause oscillations. A combination of resistors and capacitors in series, in particular for high-voltage dividers with large dimensions, is a solution that is used very often. Figure 3.63 shows a so-called damped capacitive divider.

It is obvious that the divider is frequency independent if the time constants  $R_1 C_1$  and  $R_2 C_2$  are equal. Two types of damped capacitive dividers exist, the optimum damped divider and the slightly damped divider. For an

**Fig. 3.62a,b** Resistive–capacitive voltage divider (a) and voltage distribution (b) ( $U$  – impulse voltage,  $R_1$  – high-voltage resistor,  $R_2$  – low-voltage arm resistor,  $C_p$  – parallel stray capacitance;  $C_e$  – earth stray capacitance,  $V$  – voltage measuring device with very high impedance,  $x$  – distance from earthed floor)

**Fig. 3.63** Damped capacitive voltage divider ( $U$  – impulse voltage,  $R_1$  – high-voltage resistor of the  $n$ -element,  $R_2$  – low-voltage arm resistor,  $C_1$  – high-voltage capacitor of the  $n$ -element,  $C_2$  – low-voltage arm capacitor,  $C_e$  – earth stray capacitance,  $V$  – voltage measuring device with very high impedance)

optimum damped divider, the total resistance  $R$  can be estimated by

$$R \approx 0.2 \sqrt{\frac{L}{\frac{C_1}{n}}} \quad (3.77)$$

and leads to a resistance of 60–100  $\Omega$  for a divider in the MV range.

If the damped capacitive voltage divider is completed by a parallel column of resistors with the same

voltage distribution as the capacitive–resistive column, then this divider will be called a *universal* voltage divider because it can DC, AC, and impulse voltage measure.

For impulse voltage measurements, the measuring cable must match with its characteristic impedance. Recording devices such as oscilloscopes or analog digital converters show very high input impedance if the cable is directly connected to the deflecting system or the input divider. Then the characteristic impedance of the standard transmission system is at the beginning of the measuring cable. The equivalent circuit diagram for the low-voltage side of a capacitive divider is shown in Fig. 3.64, together with a compensated measuring circuit for a constant ratio at high and low frequencies [3.41, 42]. For a correct measurement, the requirement is given by

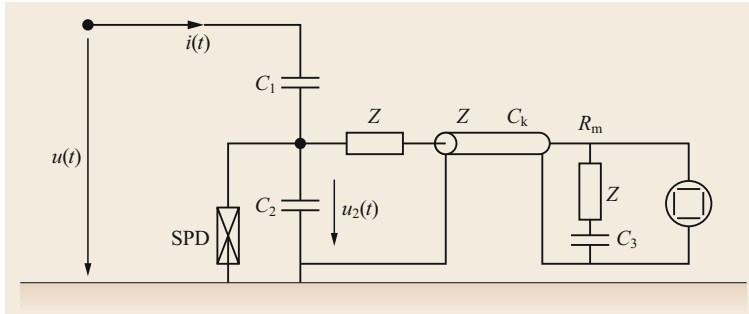

$$C_1 + C_2 = C_k + C_3 . \quad (3.78)$$

An oscilloscope, a peak voltmeter, or a digital recorder can be used for the evaluation or measurement of the peak value. The determination of the mean curve through oscillations according to the relevant recommendations is best accomplished by an oscillogram or digital record evaluation. In many cases, the highest amplitude recorded by a peak voltmeter is not sufficient, and the wave shape must be checked by an oscilloscope or a digital recorder. With an analog digital converter as the recording device, the full data set, amplitude, front time, and time to half-value can be evaluated, stored, and treated, depending on the need of the test.

An indirect voltage measurement is the use of sensors like electro-optical sensors based on the so-called Pockels or Kerr effect. The sensitivity of these sensors is based on the polarization effect on light by the applied electric field. A further sensor is the capacitive electric field sensor, which can be three-dimensional in order to measure the electric field in space. If such a sensor is connected via fiber optics with the recording device, it can be placed anywhere in the high-voltage laboratory. The disadvantage of this sensor is the requirement to calibrate the sensor with another voltage measuring device at the precise and fixed position of the sensor, because any position change will change the relation between the measured electric field and the applied voltage.

### 3.7.2 Current Measurement

When the influence of the high magnetic field is considered, the measurement of an impulse current can be accomplished by measuring the voltage across a de-

**Fig. 3.64** Equivalent circuit of a capacitive divider with compensation of a long measuring cable ( $u(t)$  – impulse voltage,  $i(t)$  – impulse current,  $u_2(t)$  – impulse voltage across the low voltage capacitor,  $C_1$  – high-voltage arm capacitor,  $C_2$  – low-voltage arm capacitor,  $C_3$  – compensation capacitor,  $C_k$  – measuring cable capacitance,  $Z$  – characteristic impedance, SPD – surge protective device)

**Fig. 3.65** Impulse current measurement with a shunt ( $u(t)$  – impulse voltage;  $i(t)$  – impulse current;  $R$  – shunt resistor;  $L$  – shunt inductor;  $u_m(t)$  – measured impulse voltage representing the impulse current;  $u_R(t)$  – resistive part of the measured impulse voltage;  $u_L(t)$  – inductive part of the measured impulse voltage)

finer resistor. Current testing and measurements are described in [3.3]. Figure 3.65 shows a simplified measuring arrangement of the voltage drop across a resistor or shunt and considering the voltage induced by the magnetic field of the current flowing through the shunt.

The measured voltage  $u_m(t)$  consists of  $u_R(t)$  and  $u_L(t)$ . The part  $u_R(t)$  is proportional to the current  $i(t)$  but the part  $u_L(t)$  is proportional to the derivative of the current  $i(t)$  over time  $t$ . This should be compensated by the design of the shunt or by other means. The loss power and the mechanical forces, on the other hand, must be coped with by the proper design of a high impulse current shunt.

The so-called Rogowski coil is another technique for impulse current measurement. The measuring method is rather simple and is based on the induction of a voltage in a winding through changing magnetic field. The voltage is proportional to the change of the current. This needs integration, and it is necessary to obtain the current that can be gained by an RC circuit.

The advantage of the Rogowski coil is the potential-free measurement of the current [3.43].

An indirect current measurement is the use of sensors like Hall-probe or magneto-optical devices. The measurand is the magnetic field generated by a current and with calibration, these devices can be also used for current measurement.

### 3.7.3 Partial Discharge Measurement

A localized electrical discharge is called a partial discharge (PD). It bridges the insulation between conductors, which may or may not occur adjacent to a conductor [3.44]. Partial discharges are, in general, a consequence of local electric stress in the insulation or on the surface of the insulation. Usually, the discharges appear as pulses with durations of less than 1  $\mu$ s. Partial discharges are a sensitive measure of local electric stress, and, therefore, the measurement is very often used as quality check of the insulation. Before a complete discharge between conductors occurs, the inception of partial discharges gives information about the limit of the electric strength of the insulating material. Therefore, the insulating material can be tested without damaging or reducing its performance. Partial discharge measurements also imply that every stress of the insulation will influence the life expectancy of the material. A reasonable compromise between stress during measurement and the influence on lifetime should be found and fixed in the relevant standards for particular equipment, such as transformers, cables, switchgears, etc. As a typical nondestructive test, the partial discharge measurement can be used to examine the insulation's performance at the beginning of its service time. This includes the reduction of the performance during the service time by ageing, depending on numerous parameters such as electrical, thermal, and

**Fig. 3.66** Equivalent circuit for partial discharges ( $U$  = applied voltage at power frequency,  $C_1$  = capacitor representing the cavity,  $C_2$  = capacitor representing the insulating material around the cavity,  $C_3$  = capacitor representing the remaining insulating material,  $S$  = spark gap representing the discharge of the capacitor  $C_1$ )

mechanical stress. Different kinds of insulating material have different limits for the allowed partial discharge value at a given stress level. They are defined in the relevant recommendations. Particularly for solid insulators, where a complete breakdown damages the test object seriously, PD measurement is a tool for quality assessment.

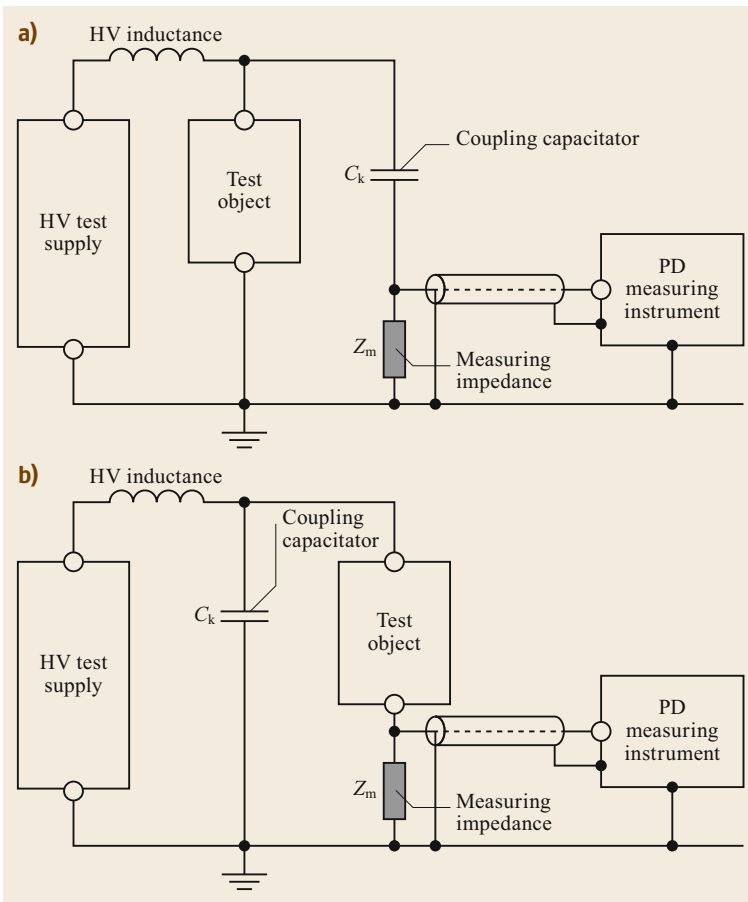

It is assumed that small cavities exist in the insulating material where discharges take place, which are the basis for the detection and measurement of PDs. This discharge causes a charge transfer in the whole circuit by an impulse-shaped current, which can be detected and measured. The relation of the discharge event and the phase angle of the applied voltage at power frequency are also important for the measurement. A simplified equivalent circuit for the PD is shown in Fig. 3.66.

The voltage across the capacitor  $C_1$  is given by

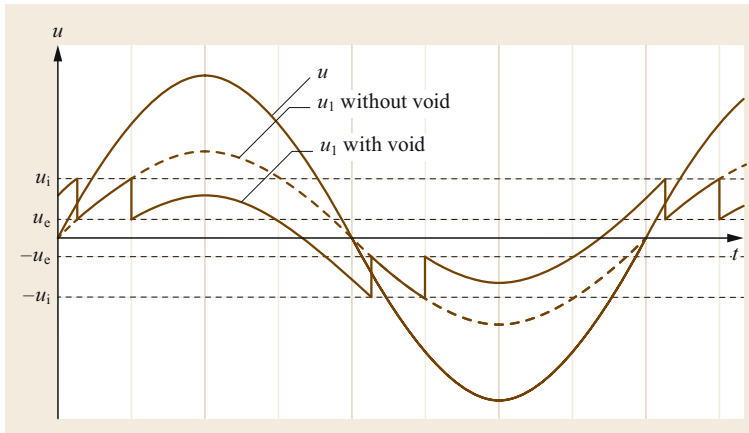

$$u_1 = U \frac{C_2}{C_1 + C_2}. \quad (3.79)$$

The capacitor  $C_3$  represents the part of the test object where no partial discharge occurs. In a real test setup, the capacitances of  $C_1$  up to  $C_3$  are within the test object, and a coupling capacitor  $C_k$  is added, as shown in Fig. 3.67.

The discharge of the spark gap  $S$  in Fig. 3.66 represents partial discharge, and this takes place when the

**Fig. 3.67a,b** Basic partial discharge measurement circuits: (a) measuring impedance  $Z_m$  in series with coupling capacitor  $C_k$ , common circuit; (b) measuring impedance  $Z_m$  in series with test object, not always possible (adapted from [3.45])

**Fig. 3.68** Voltage behavior of a void in a solid insulation system ( $u_i$  – inception voltage,  $u_e$  – extinction voltage)

voltage  $u_1$  has reached the so-called inception voltage. Under ideal conditions, the discharge process of the spark gap  $S$  needs no time, but for real arrangements, the discharge process is still very fast but can be neglected with regard to the timescale of the applied voltage. Due to the discharge of the capacitor  $C_1$ , the capacitor  $C_2$  is now stressed with the applied voltage  $U$ , and this causes a change of the charges. According to Figs. 3.66 and 3.67 there are three sources for the allocation of charges. The first source is the high-voltage test supply, but the inductance prevents the fast delivery of charges. The second source is the capacitor  $C_3$  in Fig. 3.66, but the capacitance and, therefore, the amount of charges which can be delivered is unknown. The third source is the coupling capacitor  $C_k$ , which is well known, and the delivered charges can be measured via the measuring impedance  $Z_m$ . It should be mentioned that the applied AC test voltage also charges the coupling capacitor  $C_k$ , but this happens with power frequency. The partial discharge effects are, however, in the range of ns or  $\mu$ s, and the separation from the power frequency occurs in the measuring impedance  $Z_m$ . In order to measure the charge of the partial discharge correctly, as much as possible, the charges delivered from the coupling capacitor should be much larger than the charges delivered from the voltage supply and the internal capacitor  $C_3$ , the capacitance of the coupling capacitor should in this respect be as high as possible. However, on the other hand, the coupling capacitor is a capacitive load of the high-voltage test supply, and this limits the magnitude of the capacitance.

Figure 3.68 shows the voltage behavior for the simplified capacitive equivalent circuit and a void in a solid insulation system.

Assuming that the applied voltage  $u$  is sinusoidal, the inception voltage for partial discharges  $u_i$  and the extinction voltage  $u_e$  are the same for positive polarity and negative polarity. According to (3.79), the voltage

$u_1$  across the capacitor  $C_1$  depends on the capacitance of  $C_1$  and  $C_2$ , which are both unknown. If there is no void, the voltage  $u_1$  follows the voltage  $u$ , but with a lower amplitude. If there is a void, and the voltage  $u_1$  is above the inception voltage  $u_i$ , then a discharge occurs, and the voltage drops to the extinction voltage  $u_e$ . After that, the voltage  $u_1$  increases again with the shape of the applied voltage  $u$ , until the inception voltage  $u_i$  is reached again. Finally, it can be seen in Fig. 3.67 that the discharges occur around the zero crossing of the applied voltage  $u$ , and this is a typical behavior of partial discharges in a void of solids. The simple capacitive model of a void in a solid is replaced by the so-called dipole model, which is described in detail in [3.45], with a view to explaining, for example, partial discharges in crosslinked polyethylene cables more precisely.

The electrical partial discharge measurement described is based on the assumption that the frequency content of partial discharges is high at much higher frequencies compared to the power frequency of 50 or 60 Hz. The PD measuring instrument in Fig. 3.67 should be able to record the high frequencies, and there is a differentiation between so-called narrow-band and wide-band partial discharge measuring systems. For a narrow-band system, the recommended middle frequency is between 50 kHz and 1 MHz, depending on the noise frequencies. The bandwidth is in the range of 9–30 kHz. For wide-band recording devices, the lower frequency limit is between 30 and 100 kHz, the upper limit between 130 kHz and 1 MHz, and the bandwidth in the range from 100 to 970 kHz [3.45]. These frequency ranges should be taken into account if a calibration of the test circuit is to be done. An impulse with a known charge is injected at the point where the partial discharge measuring circuit is connected with the test object. The frequency content of such an impulse should cover the frequency range of the recording de-

vice. The readout of the measuring instrument is then equivalent to the injected charge, and this has a relation to the signal that appears on the same accessible place of the test object and is called the apparent charge. The apparent charge is a charge generated by partial discharge within the test object and appears on the accessible points for measurement but may be influenced in amplitude and shape by traveling from the point of generation to the point of measurement.

The analog measuring devices for partial discharge usually delivers a mean value of the periodically appearing signals; and all the requirements in the actual recommendations are based on this performance and also on the experience. For example, an apparent charge of 10 pC for crosslinked cables at a voltage of  $1.5U_0$ , whereby  $U_0$  is the voltage between conductor and ground, is a convention based on scientific researches and on practical experience of the operators of cable systems [3.46]. With an analog digital recorder for partial discharge measurements, modifications of the existing recommendations are necessary due to the fact that now every partial discharge signal is recorded, and the question is how to handle this information. Partial discharge measurements generally suffer from noise and random noise signals, but their influence on the indication disappears when only the average is shown, which is reasonable from the test point of view. Furthermore, a digital record of partial discharges allows many more evaluations, which supply additional information [3.44].

Besides the detection of partial discharges, very often the location of the partial discharge source is also important. With acoustic or ultra-high-frequency sensors, the location of a partial discharge source, for example in a transformer, is possible by triangulation [3.47]. Another method is the calculation of the partial discharge signal behavior on the way from the source to the measuring point via a transfer function. With the measurement of the same partial discharge signal on bushing and the neutral point of a transformer, locating of the partial discharge source is possible [3.48]. For extensive equipment like cables, the partial discharge location can be found by evaluation of the traveling time, because a partial discharge signal travels from the source to the measuring point and to the end of the cable. Then the reflected signal also travels to the measuring point but with a delay depending on the length of the cable and the traveling speed within the cable. The partial discharge location can be calculated from the time difference.

There are also other technologies for partial discharge measurement or detection, like acoustic methods, ultra-high-frequency (UHF) measurements, optical measurements, and chemical analysis, for example dissolved gas analysis (DGA) measurements whose ap-

Fig. 3.69 Equivalent circuit for a solid

plications depend on the test object and the design. General information about acoustic and UHF methods for partial discharge measurements are available in [3.49].

### 3.7.4 Measurement of Dielectric Characteristics

In contrast to partial discharge measurement and detection, which reveal local defects, the measurement of dielectric characteristics gives information about the integral characteristic of the insulation. This is, in general, less important for gas insulation but more important for fluids and solids, and the expectation from these measurements is the evaluation of ageing and rest-of-life time, whereby the test voltage and frequency can differ from the service conditions.

#### Response Measurements

A solid insulation can be described by a number of R-C combinations, representing the different kinds of polarization effects. If such a solid is stressed by a DC voltage, dipoles are oriented, and the resulting current is now caused by the conductivity of the material and the polarization effects. Figure 3.69 shows the equivalent circuit of a solid.

The procedure for the response measurement is to charge the test sample with DC for a certain time, then the DC source is disconnected, and the test sample short-circuited to discharge the main capacitor  $C_0$ . Afterwards, the voltage, called return or recovery voltage, can be measured as a consequence of the relaxation of the dipoles, oriented by the former DC voltage. The shape, the peak value, and the peak time can be used to evaluate the condition of the solid, for example the moisture of oil-impregnated paper insulation, by comparison with former measurements, but it is not possible to determine the absolute moisture content from only one measurement. Figure 3.70 shows the procedure and the relevant parameters.

**Fig. 3.70** General procedure for recovery voltage measurements

Instead of the recovery voltage, the so-called relaxation current can be measured, which also delivers some information about the condition of the solid, but also here a comparison with former measurements is necessary, and the temperature should be taken into account for both procedures.

**Loss Factor and Capacitance**

The loss factor has already been described in Sect. 3.4.5, and, therefore, only the measurement of the loss factor and the capacitance of a solid will be listed here. Figure 3.71 shows the classic Schering bridge, which is commonly applied for such measurements.

The equivalent circuit for the solid is the series connection of capacitor  $C_x$  and resistor  $R_x$ . The capacitor  $C_N$  is a reference capacitor that is very often called a standard capacitor, which should have a very low/negligible loss factor, usually a gas-filled capacitor. The elements in the dotted area are at high potential, whereas the others are at low potential, and this allows an operator to adjust the resistor  $R_3$  and the capacitor  $C_4$ . Protection devices against high voltage in the case of a breakdown of the test sample are not shown in Fig. 3.71.

If the zero indicators shows zero, then the left and right branches are in balance, and this can be expressed by the ratio of the impedances

$$\frac{Z_x}{Z_3} = \frac{Z_N}{Z_4} \quad \text{with} \quad Z_x = R_x + \frac{1}{j\omega C_x}$$

$$Z_N = \frac{1}{j\omega C_N}, Z_3 = R_3, \quad (3.80)$$

$$Z_4 = \frac{R_4 + \frac{1}{j\omega C_4}}{\frac{R_4}{j\omega C_4}}.$$

**Fig. 3.71** Schering bridge ( $R_x$  – unknown resistor of solid;  $C_x$  – unknown capacitor of solid,  $C_N$  – reference capacitor,  $R_3$  – variable resistor,  $R_4$  – fixed resistor,  $C_4$  – variable capacitor,  $Z_1$  – zero indicator) (adapted from [3.50])

After some calculations and a comparison of real and imaginary parts, the loss factor can be expressed as

$$\tan \delta = \omega C_4 R_4. \quad (3.81)$$

With a fixed resistance of 318.3  $\Omega$  for the resistor  $R_4$ , the loss factor  $\tan \delta$  can be expressed at an applied test frequency of 50 Hz as

$$\tan \delta = \frac{C_4}{10 \mu\text{F}}. \quad (3.82)$$

Some precautions are necessary if the current through the test object is high and may damage the resistor  $R_3$ . A defined resistor parallel to  $R_3$  may solve this problem.

For test objects with a very low loss factor, for example crosslinked polyethylene cables, further measures like an auxiliary branch are required. Nowadays, automatic Schering bridges are available, which adjust the bridge without the help of an operator, and digital signal processing allows the use a Schering bridge without an exact balance.

Ernst Gockenbach has 40 years of experience in high-voltage engineering, including several years as Chief Engineer for high-voltage test and measuring equipment in Switzerland and 24 years in teaching high-voltage engineering and insulation systems at university level. He was Chair of the CIGRE Study Committee D1 on Materials and Emerging Test Techniques and Chairman of IEC TC 42 High-Voltage and High Current Test Techniques.

# 4. High Currents and Contact Technology

Steffen Großmann

Section 4.1

Electrical power systems and transport systems are subject to profound changes all around the world. This is accompanied by higher requirements for the components of stationary or mobile equipment of electrical power engineering. Especially a compact design, a higher current load under normal operating conditions, and in the case of a fault, disparate environmental conditions and the demand for higher availability, reliability, and safety are great challenges for designers, manufacturers, constructors, and operators.

This chapter gives an overview of current-conducting arrangements (conducting systems) whose load is caused by electric current and ambient conditions, the resulting thermal and mechanical stress, and the long-term and reliably necessary strength of the conducting components.

Fundamentals on the thermal behavior of equipment and analytical approaches to the calculation of temperatures at relevant spots are presented that have proven themselves over decades in practice. If necessary, they can be supplemented by numerical methods, which will not be explicitly discussed here. Regarding the mechanical-dynamical behavior of current-conducting arrangements exposed to short-circuit currents or thermal elongation due to current load, methods for determining the strain and the necessary strength are presented with regard to the material properties in the elastic range and the

plastic range. Stationary electrical contacts and connections have been the subject of scientific research at TU Dresden for more than four decades and will be discussed here in an overview in terms of design, operating, and long-term behavior.

All results presented in this chapter are, to a great extent, results of scientific research at TU Dresden and have been taken from the course material presented to the students.

## 4.1 Current-Conducting Arrangements (Conducting Systems)

During the conversion, transport, and distribution of electrical energy, *current-carrying configurations* consisting of the *electrical conductor*, its contacts, its *electrical insulation*, and its *external mounting* in a wide variety of designs form the core of the electrical power system [4.1–3]. Driven by a voltage  $U$ , carriers  $Q$  move in a conductor with a resistance  $R$  and, thus, form a current  $I$ . This current leads, depending on the conductor cross section  $A$ , to a current density  $J$ , which

causes thermal losses  $P_{\text{vth}}$  in the conductor and, thus, will increase the conductor temperature by  $\Delta\vartheta$ . In addition, each current-carrying conductor is subjected to a magnetic field  $H$  that is responsible for eddy-current and hysteresis losses,  $P_{\text{vW}}$ ,  $P_{\text{vH}}$  (Sect. 4.2) and also has a mechanical-force effect  $F$  (Sect. 4.3.2). Particularly at very high voltages, dielectric losses  $P_{\text{D}}$  can lead to heating of the current-conduction arrangement. However, the mechanical and electrical properties of

a current-conducting device are largely determined by its temperature. Temperatures must be maintained within a limited range to ensure long-term reliable and economical operation of electrical power systems.

Conductor arrangements must be designed so that the requirements for reliability and availability, as well as plant and personal safety, are guaranteed for all loads possible in the respective case.

Depending on the technical requirements and the operating conditions, conductor arrangements can be divided into the following:

#### 4.1.1 Concerning Conductor Material

In electrical power engineering, copper and aluminum are the preferred conductor materials due to their good electrical conductivity, adequate mechanical properties, machinability, availability, and acceptable price. An improvement in mechanical properties can be achieved by copper or aluminum alloys, but this always leads to a reduction in conductivity (Table 4.1).

Due to its low price and low specific weight, and despite its lower electrical conductivity, aluminum is becoming increasingly important for selected applications (Fig. 4.1). In addition to traditional power cables and overhead-line and switchgear construction, aluminum is now also used successfully as a conductor material in the automotive and aviation industries, in transformer construction and in the equipment industry. However, the different electrical and mechanical properties, as well as the different technologies for installing and connecting aluminum conductors, must be taken into account when designing and dimensioning (Sect. 4.3.3) equipment or systems.

Composite materials or material systems are used, e.g., copper-coated aluminum conductors, Al-Cu sheets, aluminum-steel cables, or high-temperature overhead-line conductors made of aluminum alloys with a mechanically supporting carbon-fiber core. Moveable conductor arrangements, e.g., in rotating electrical machines (collectors, slip rings) or in the overhead contact lines of electrical railways and cranes, are usually implemented with carbon-copper (alloy) systems.

#### 4.1.2 Concerning the Structure of the Conductor

The level of the operating and short-circuit current to be conducted, the required mechanical strength and the necessary flexibility and mobility, fastening and support conditions, as well as application-related requirements, determine the appropriate design of the electrical conductors (Table 4.2).

**Table 4.2** Structure of electric conductors

Rigid Solid, massive	Tubular	Moveable Stranded, laminated	Flexible Thin-wire
Characteristics: Low volume	High flexural rigidity and high short circuit currents Low skin effect Large heat-emitting surface	Bendable Compensation of thermal expansion	High flexibility Compensation of mechanical vibration
Examples: Bus bars	Bus bars	Overhead line conductors Power cable Expansion clamps	Flexible line

**Fig. 4.1a-d** Relations between conductors from aluminum and copper for equal electric resistance. (a) Cross section of aluminum related to copper for equal resistance, (b) aluminum has half weight of copper for equal resistance, (c) larger thermal extension of aluminum has to be taken in account for bus bar length and for sag of overhead lines, (d) larger heat capacity of aluminum is an advantage in case of short circuits

### 4.1.3 Concerning Conductor Connections

In an electrical system, conductors made of different conductor materials and with different conductor structures must be joined together for the purpose of:

- Conductor connections
- Equipment connections
- Branching points or tap-offs.

Depending on the function of the connection, they can be designed as permanent, nondetachable closed, detachable, or as movable or pluggable connections.

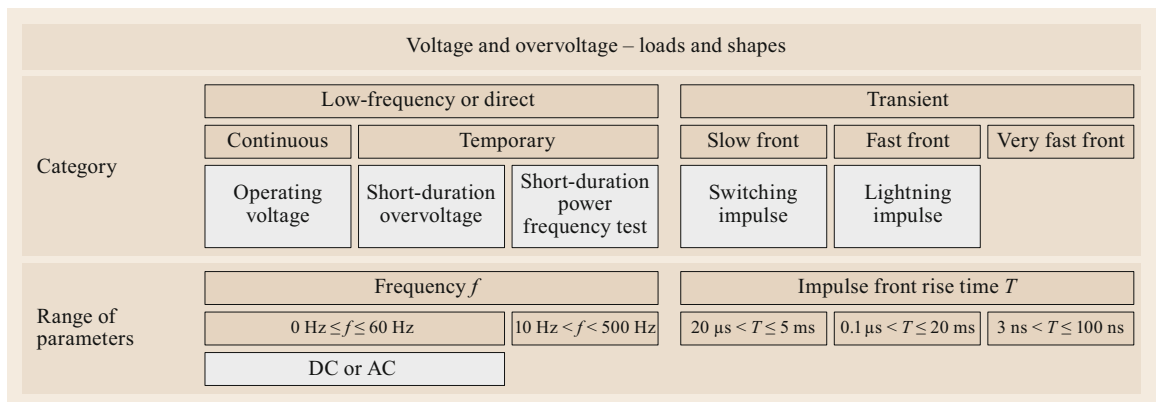

Electrical connections are exposed to a multitude of loads (Table 4.3) that stress the connection and, thus, lead to aging of the connection over time (Sect. 4.3.3). The load-dependent aging of the connection must, therefore, already be known during installation in order to ensure a reliable connection over the projected

service life of the system through suitable joining of the conductors. Occasionally, little attention is paid to electrical connections in the planning, design, and installation of systems, which can lead to considerable long-term problems with reliability and related very high costs.

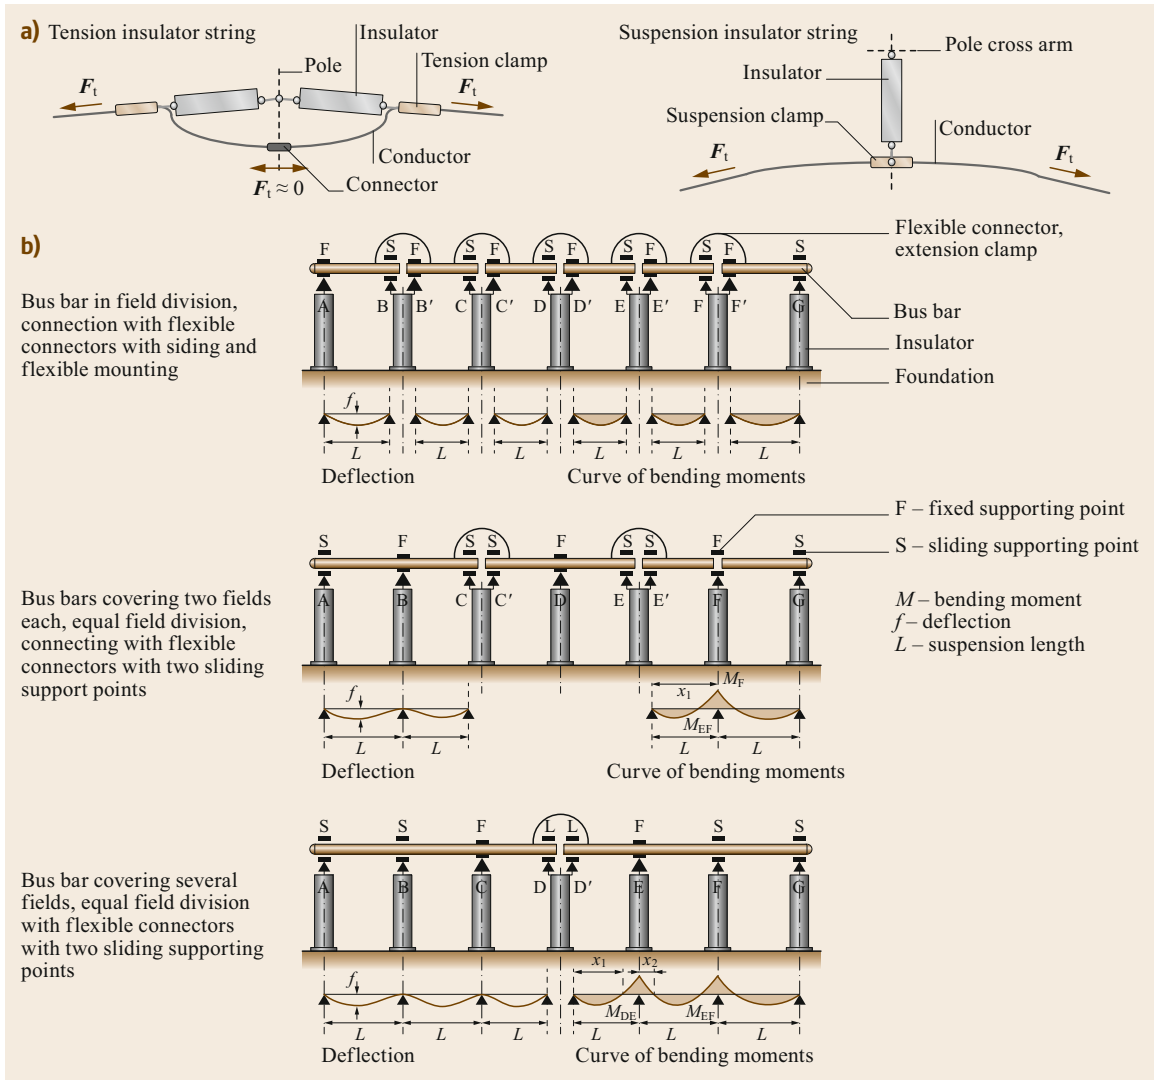

#### 4.1.4 Concerning Insulation Arrangement and Insulation Material

The conductor arrangement must reliably separate the electrical potentials between the conductors and between the conductor and earth. The insulation is exposed to various loads, which lead to permanent and

transient stresses on the insulation arrangement (Table 4.4, Fig. 4.2 [4.4]).

Whether electrical conductors are used bare (i.e., insulated with air) or insulated with a suitable solid or liquid insulating material to each other, to ground and against touch contact depends on the specific application, the operating voltage, the space requirements, the ambient conditions, the costs, etc. A distinction is made between the type of insulation arrangement and the insulation material (Figs. 4.2 and 4.3).

The type of insulation closely interacts with the current-carrying capacity, design, installation, and flexibility of the system during operation, maintenance, and system losses.

**Fig. 4.5a,b** Fastening of electric conducting systems. (a) Conductor with mechanical tensile stress, (b) conductor without mechanical tensile stress

**4.1.5 Concerning Mechanical Properties**

Conductor arrangements must be designed in such a way that the requirements for reliability and availability, as well as plant and personal safety, are guaranteed for all possible loads. This includes the fittings, the insulators, and the supports.

The type of mechanical fastening to be selected depends on the operating current and the resulting lon-

gitudinal expansion of the conductor arrangement, as well as the short-circuit forces acting on the conductor, the insulators, and the support. The criterion here is that neither conductors, insulation, nor fastening may be permanently distorted and that the striking distance of insulation sections must not fall below the values specified to avoid puncture or flash-over (Table 4.5, Figs. 4.4 and 4.5).

## 4.2 Current-Carrying Capacity

Conductor arrangements must be able to reliably and safely carry operating and fault currents over the entire projected service life, usually several decades [4.1, 2, 5]. This means that the functions of conducting current, insulating electrical potentials, connecting, branching, and fixing conductors must be guaranteed for a long time under all operating conditions. The temperature of the current path plays a central role. In the event of a fault, electrodynamic forces and power arcs must also be withstood. With the associated physical processes, the operating states, namely:

- Normal operation: continuous and alternating load (Table 4.6a)
- Short circuit: outside (Table 4.6b) and inside (Table 4.6c) of the network considered

pose different challenges and technical objectives (Table 4.6), which must be equally taken into account in the design of power-distribution systems.

### 4.2.1 Load

Conductor arrangements with their components (conductors, insulations, connections, fasteners) are loaded by *external effects*, the current flow, and the ambient conditions:

Thermal loads caused by power-heat losses are:

- Continuous current load
- Intermittent current load
- Short-circuit current load.

Mechanical loads are caused by:

- Bending moments and line loads on conductors and forces on support and fastening points in the event of a short circuit.  
Examples: bus bars, conductors, insulators, fittings, parallel single-core cables.
- Deflection of nonrigid conductors due to the effect of the wind. Examples: overhead lines with single or bundled conductors, field spacers, separators.

Loads due to ambient conditions are caused by:

- Ambient temperature
- Heat generation through solar and sky radiation
- Humidity and air pollutants
- Snow and ice loads as additional weight loads
- Wind inducing conductor vibrations and constituting an additional mechanical load.

The relevant standards contain the design-relevant ambient conditions. On the other hand, it is not feasible to incorporate in the standards all climatic conditions for all regions of the globe, which might differ substantially. Thus, for extreme ambient conditions, specific long-time tests, e.g., for connections and contacts, are required [4.6].

### 4.2.2 Stresses

The external loads of a conductor arrangement lead to *internal stresses* of the same arrangement. The interaction of different, mostly temperature-dependent loads leads to the aging of the components of a conductor arrangement, which, depending on the strength of the construction, may lead to partial or complete failure after a period.

Examples (Table 4.6):

1. The dielectric strength of various insulations decreases over time. Higher temperatures can accelerate this process. In particular, transient overvoltages can become critical.
2. The long-term behavior of electrical contacts and connections reacts very sensitively to elevated temperatures, since most aging mechanisms follow Arrhenius' law (4.1),

$$k = ae^{-\frac{E}{RT}}, \quad (4.1)$$

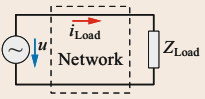

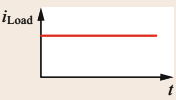

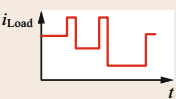

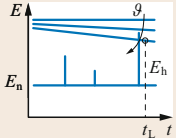

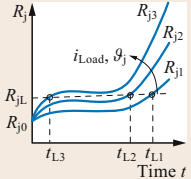

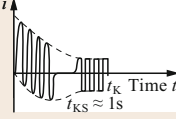

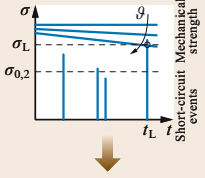

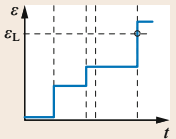

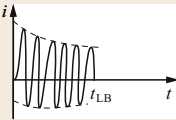

where  $k$  = aging rate,  $a$  = factor of proportionality,  $E$  = activation energy,  $R$  = universal gas constant, and  $T$  = absolute temperature.

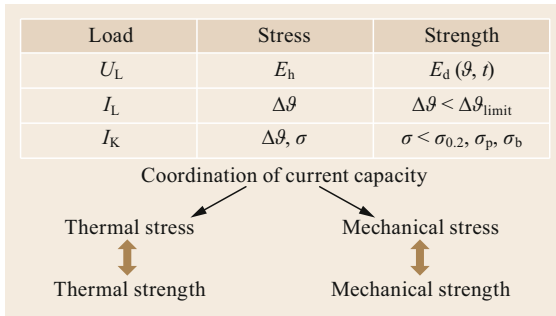

The higher the initial resistance of a connection  $R_{J0}$ , the faster it ages at higher temperatures, and thus the sooner it will fail. Higher current loads and higher ambient temperatures, therefore, have an accelerating effect on the aging of electrical connections (Sect. 4.3.3).

3. The mechanical strength of many materials decreases over time, which is accelerated by increased temperatures (Arrhenius' law). Especially under short-circuit currents, high electromagnetic forces occur, which will cause higher permanent plastic deformations, which accumulate with each short-circuit event (Sect. 4.3.2).

The permissible thermal stress of the conductor arrangements is, therefore, limited and is specified in standards as the *limit temperatures* for various materials and applications. A distinction is made between normal operation (continuous or alternating current) and short-circuit

**Table 4.6** Current-carrying capacity

**Fig. 4.6** Electrical load, stress, and strength of conducting systems

operation (Sect. 4.3.1). Electrical power equipment constitutes capital goods that are designed for a service life of several decades and must, therefore, be dimensioned not only for new conditions but also taking aging into account. This is often difficult in practice, because the loads can change during operation, and their patterns are not always known. There is still a need for research in this area, since suitable diagnostic methods are not available for all stresses and are also not always practical and economical. Rather, comparatively simple technical systems, such as power conductor arrangements, should be so robustly dimensioned and designed that a diagnosis is only necessary in special cases.

For mechanical stress (Sect. 4.3.2), the permissible limits are not to be defined trivially with general limit values. Rather, suitable calculations based on models or corresponding experiments are required. The technical criterion is the *permanent deformation*, which should not exceed values that have been agreed upon and are based on design and material properties. This affects bending, tensile, compressive, and torsional stresses in the electrical conductor, in connections and fasteners, as well as in technical insulations that are in the glass state (e.g., porcelain, insulating resins) or in the elastic state (e.g., silicone rubber, PVC, PE, VPE).

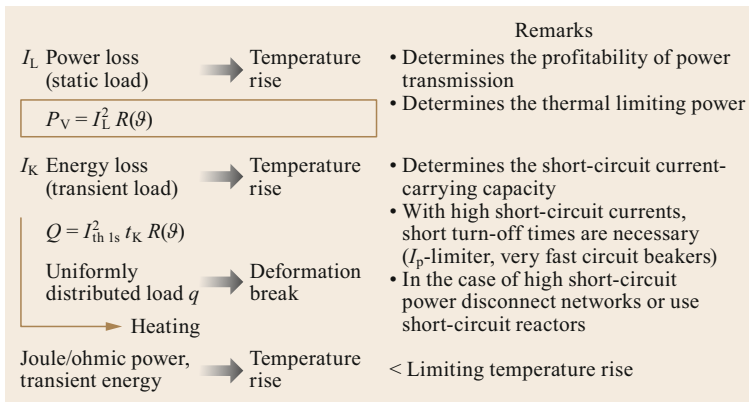

### 4.2.3 Strength

The strength of a current-conducting device is the ability to withstand the electrical, mechanical and environmental stresses to such an extent that its function is ensured under all possible external and internal loads (Figs. 4.6 and 4.7). Aspects of technical requirements, reliability, personnel and plant safety, economic efficiency, and occasionally also the quality of appearance must be taken into account.

In order to guarantee the required thermal strength, the limit temperatures specified in standards must be observed. This makes sense from a technical point of view, as they ideally take into account the new condition of the equipment, its aging, its normal and extraordinary (e.g., under fault) operation, as well as the expected environmental loads. Compliance with the limit temperatures is provided by tests or analytical calculations, insofar as this is accepted by the user. For practical application, it is essential to question whether the boundary conditions specified in the standards for the verification of the limit temperatures also correspond to those to be expected in the respective application.

Example: low-voltage switchgear is tested according to uniform, easily comparable criteria. However, this test arrangement does not roughly correspond to the many installation cases of low-voltage switchgear and control-gear assemblies [4.7], which can be found in practice. Due to the much shorter connecting cables and the significantly worse conditions for heat dissipation, significantly higher temperatures occur in practice than in the standard test, or the current-carrying capacity in the actual application will generally be significantly lower than indicated on the nameplate of the switching device. In this case, it is the responsibility of the system manufacturer to prove compliance with the limit temperatures.

The temperature of the current path is the essential criterion for the current-carrying capacity. Compliance

**Fig. 4.7** Influence of power loss, energy loss, and mechanical load on current-carrying capacity and heating

with limit temperatures must be proven in standardized heating tests. Temperature is decisive for mechanical strength and aging. It serves as an indirect but measurable criterion for meeting the technical objectives with regard to electrical, dielectric, thermal mechanical, and safety-related tasks.

The level of the permissible limit temperature depends on the materials of the conductors, the insulation, the connections and the fasteners, as well as on the time variation of the load current, and is determined on the basis of practical experience and systematic aging

tests. If these limit temperatures are maintained during a temperature-rise test, a service life of several decades can very probably be expected for mature equipment from the point of view of current-carrying capacity.

Examples:

1. ACSR conductors for overhead lines are designed for a maximum conductor temperature of 80 °C. This is based on an ambient temperature of 35 °C, a wind speed of 0.6 m s<sup>-1</sup>, and solar radiation of 1000 W m<sup>-2</sup>. In the case of deviating ambient con-

ditions, the current load can be temporarily adapted while maintaining the specified limit temperature. It should be noted that accelerated aging of the connections must be taken into account when the current load is increased, although the limit temperature of the conductor is not exceeded [4.13, 14].

2. High-temperature, low-sag (HTLS) conductors may be operated at temperatures up to 210°C. This results in temperatures at the connectors of 120–150°C [4.15, 16].
3. Selected examples of limit temperatures in low and high-voltage switchgear (Table 4.7).

It should be noted that the boundary conditions for heating tests are not always uniformly specified in the various standards. Therefore, the limit temperatures and their boundary conditions for individual components and for the entire system must always be taken as a basis for the design of conductor arrangements.

Most of the limit temperatures specified in the standards are based on knowledge of physical laws, electrical, thermal, and mechanical material properties, and operating experience over several decades and have generally proven themselves as accepted technical certainties. The increasing need to allow for higher limit temperatures for certain new applications compared to those which have been proven over a long period of time requires special care and responsibility in their usage and is often associated with additional preliminary long-term investigations (Sect. 4.3.3).

## 4.3 Design Principles

### 4.3.1 Thermal Design

Current-conducting arrangements must be dimensioned in such a way that the limit temperatures for the conductor, the insulation, the contact and connecting elements and the fasteners, and for the operator are maintained under the expected loads in normal operation and in the event of a fault (short circuit). Permissible limit temperatures are specified in standards or must be determined experimentally or analytically for special applications (Sect. 4.2). In order to meet this requirement, design principles are required that have been successfully applied for decades. In addition, modern calculation methods (e.g., the finite element method (FEM), etc.) are useful, with the help of which partial solutions can be determined even more precisely and displayed clearly where this is necessary [4.1, 2, 5, 19].

Examples:

1. Investigations on the long-term behavior of bolted connections with copper bus bars in low-voltage switchgear and control-gear assemblies up to 140°C [4.17]
2. Investigations on the electrical contact and long-term behavior of compression connectors with HTLS conductors up to 210°C [4.18]

In the near future, it will be a challenge to additionally investigate the influence of nonsinusoidal currents or currents with higher frequencies on the heating of current paths and the aging of connections and to describe them in test standards. The increasing integration of renewable energy sources (wind-energy plants, photovoltaic plants) and the associated ever-broader use of the advantages of power electronics are major motivations for this.

The proof of the mechanical strength against the effect of the electrodynamic forces in the event of a short circuit outside the equipment under consideration (Table 4.6b) must be provided in a short-circuit test in an electrical power test field or by suitable calculations.

The proof of the strength against the thermal and pressure effects in the case of an arc fault in the equipment under consideration (Table 4.6c) must be performed in an arc-fault test in a high-performance test field or by suitable calculations.

### Thermal Balance Equation for a Current Path

During the transport of electrical energy, part of the power to be transmitted in the current paths of the equipment is converted into heat losses,  $P_v$ . This leads to an increased temperature of the current path itself and other components (insulation, connections, contacts, fasteners) in the equipment. This creates a thermal stress for the current-conducting arrangement (Sect. 4.2). Between heat losses  $P_v$ , heat dissipation along the electrical conductor by heat conduction  $P_L$ , heat dissipation radially outwards by convection  $P_K$ , heat radiation  $P_S$ , and the heat stored in the current path  $P_C$ , thermal equilibrium is reached. For a differentially small-volume elements in a homogeneous, long conductor inside (Fig. 4.8), the *heat balance equation* can be given as a second-order differential equation, with spatial and temporal depen-

**Fig. 4.8** Balance of thermal power in a homogeneous, straight conductor ( $dP_V$  joule, ohmic power loss,  $dP_C$  stored thermal power,  $dP_{L,IN}$  heat conduction in the element,  $dP_{L,OUT}$  heat conduction out of the element,  $dP_K$  radially dissipated heat power by convection,  $dP_S$  radially dissipated heat power by radiation)

dence

$$dP_V - dP_C - dP_L - dP_K - dP_S = 0. \quad (4.2)$$

For example, for a bus bar, these terms can be described as follows:

- Heat dissipation generated in the volume element  $dP_V$

$$\begin{aligned} dP_V &= kI^2 \frac{\rho(\vartheta) dx}{A} \\ &= kI^2 \frac{\rho_{20}}{A} dx [1 + \alpha T(\vartheta_L - 20^\circ\text{C})], \end{aligned} \quad (4.3)$$

where  $k$  = current displacement factor,  $\rho$  = resistivity,  $\rho_{20}$  = specific electrical resistance at  $20^\circ\text{C}$ ,

$A$  = conductor cross section,  $\alpha_T$  = temperature coefficient of electrical resistance, and  $\vartheta_L$  = conductor temperature.

- Heat stored in the volume element

$$dP_C = Ac\delta \frac{\partial \vartheta}{\partial t} dx \quad (4.4)$$

with  $c$  = specific thermal capacity of the conductor material (Table 4.8), and  $\delta$  = density of the conductor material.

- Heat entering the volume element at position  $x$  and exiting at position  $x + dx$  conducted out heat conduction (heat flow rate)

$$dP_L = \underbrace{\left(-\lambda A \frac{\partial \vartheta}{\partial x}\right)}_{\text{In}} + \underbrace{\left[-\lambda A \frac{\partial \vartheta}{\partial x} \left(\vartheta + \frac{\partial \vartheta}{\partial x} dx\right)\right]}_{\text{Out}}, \quad (4.5)$$

where  $\lambda$  = thermal conductivity of the conductor material.

- Heat dissipated radially over the surface of the volume element by convection

$$dP_K = \alpha_K(\vartheta) U_K(\vartheta_L - \vartheta_0) dx, \quad (4.6)$$

where  $\alpha_K$  = heat transfer coefficient for convection.  $U_K$  = convective heat-emitting circumference of the conductor over the length  $dx$ ,  $\vartheta_L$  = conductor temperature, and  $\vartheta_0$  = ambient temperature.

- Heat dissipation radially over the surface of the volume element by thermal radiation

$$dP_S = \alpha_S(\vartheta) U_S(\vartheta_L - \vartheta_0) dx \quad (4.7)$$

where  $\alpha_S$  = thermal transfer coefficient for radiation, and  $U_S$  = heat-emitting circumference of the conductor over the length  $dx$ .

**Table 4.8** Thermal characteristic of selected materials: specific electric resistance (at  $20^\circ\text{C}$ ), temperature coefficient electric resistance, density at  $20^\circ\text{C}$ , specific thermal capacity, and thermal conductivity

**Table 4.9** Demand depending current load and thermal behavior;  $I_r$  – rated current load,  $I_L$  – current load,  $I_{th\ 1s}$  – thermal equivalent 1-second short circuit current,  $\vartheta_0$  – ambient temperature,  $\vartheta_L$  – conductor temperature,  $\Theta$  – overtemperature,  $\vartheta_{Gr}$  – limiting temperature, and  $\vartheta_a$  – origin temperature in normal operation (adapted from [4.5])

	Permanent current load	Flexible current load	Short-term current load Short-circuit current
Current and thermal behavior			
Equivalent thermal network			
Thermal power losses	$P_{IN} = P_{OUT} = P_K + P_S + P_L$ $P_V = I_L^2 R_{el}(\vartheta)$	$P_{IN} = P_{OUT} + \frac{dQ}{dt}$	$P_{IN} = \frac{dQ}{dt}$ $Q = \int_0^{t_K} P_{IN}(\vartheta) dt = mc \Delta \vartheta$ $= \int k I_{th\ 1s}^2 R_{el}(\vartheta) dt$

If the circumference transmitting heat through radiation and convection  $U$  is the same, the following applies in simplified form

$$dP_K + dP_S = [\alpha_K(\vartheta) + \alpha_S(\vartheta)]U(\vartheta_L - \vartheta_0)dx$$

$$= \alpha(\vartheta)U(\vartheta_L - \vartheta_0)dx, \quad (4.8)$$

with

$$\alpha = \alpha_K + \alpha_S. \quad (4.9)$$

Inserting (4.3)–(4.9) into (4.2) results in

$$\frac{kI^2 \rho(\vartheta)}{A} - Ac\delta \frac{\partial \vartheta}{\partial t} + \lambda A \frac{\partial^2 \vartheta}{\partial x^2} - \alpha(\vartheta)U(\vartheta_L - \vartheta_0) = 0. \quad (4.10)$$

This differential equation for the heat balance of the homogeneous, long conductor is solved for four special cases:

1. Stationary heating – continuous load (Table 4.9, left column)

A constant current flows, which causes the heat losses  $P_V$ . Those increase the conductor temperature to  $\vartheta_L$  (4.3). Since the current  $I$  is assumed to be constant with time, there is no storage of heat (4.4). In addition, it is assumed that there is no axial heat

transfer in the conduct. Thus, the following boundary conditions apply:

- $dP_C = 0$  no heat storage
- $dP_{LIN} = dP_{LOUT}$  no heat flow along the conductor.

Because of this all heat losses,  $P_V$  have to be radially transmitted to the surroundings via radiation  $P_S$  and convection  $P_K$

$$dP_V = dP_K + dP_S. \quad (4.11)$$

With (4.9) and (4.10), it follows that

$$\frac{kI^2 \rho(\vartheta)}{A} = \alpha(\vartheta)U(\vartheta_L - \vartheta_0). \quad (4.12)$$

The permissible continuous current  $I_r$ , at which the conductor temperature  $\vartheta_L$  is less than or equal to the permissible limit temperature of the conductor  $\vartheta_{Gr}$  is given by (4.12) to be

$$I_r = \sqrt{\frac{\alpha(\vartheta)UA(\vartheta_L - \vartheta_0)}{k\rho_{20}[1 + \alpha_T(\vartheta_L - 20^\circ\text{C})]}}. \quad (4.13)$$

Thereby, the current  $I_L$ , which depends on the conductor temperature  $\vartheta_L$  and the ambient temperature  $\vartheta_0$ , should not exceed the permissible continuous current  $I_r$ , so that the limit temperature  $\vartheta_{Gr}$  of the conductor will be observed.

2. Transient heating – short-term load (Table 4.9, right column)

During a short-term current flow up to 1 s, there is practically no heat conduction or convection and radiation, because these are relative slow physical processes. Thus, the following boundary conditions apply:

- $dP_K = dP_S = 0$ , i.e., no convection and no radiation
- $dP_{LIN} = dP_{LOUT}$  no heat flow along the conductor.

The total power losses  $P_V$  in the conductor must, therefore, be stored in the conductor itself during the duration of the current (adiabatic heating)

$$dP_V = dP_C. \quad (4.14)$$

From (4.14), the following differential equation is obtained

$$\frac{kI^2\rho(\vartheta)}{A} = Ac\delta \frac{\partial\vartheta}{\partial t}. \quad (4.15)$$

Its solution is the thermally permissible short-term current  $I_{th}$  for a time duration  $t_K$  in (4.15),

$$I_{th} = \sqrt{\frac{c\delta A^2}{k\rho_{20}\alpha_T t_K} \ln \left[ \frac{1 + \alpha_T(\vartheta_{Gr} - 20^\circ\text{C})}{1 + \alpha_T(\vartheta_a - 20^\circ\text{C})} \right]}. \quad (4.16)$$

Here, the current  $I_{th}$  depends on the time duration  $t_K$ , the temperature of the conductor  $\vartheta_a$  before the onset the short-term load, and the permissible limit temperature of the conductor  $\vartheta_{Gr}$  for the short-term load. Usually, this limit value is higher than for a continuous current load and is specified in the standards.

When the short-term thermal current  $I_{th}$  or the short-term current density  $J_{th}$  are known, the conductor temperature can be calculated  $\vartheta_L$  as a function of the time duration  $t_K$  of the short-term current

$$\vartheta_L = \frac{1}{\alpha_T} \left\{ [1 + \alpha_T(\vartheta_a - 20^\circ\text{C})] \exp \frac{kJ^2\rho_{20}\alpha_T}{c\delta} t_K - 1 \right\} + 20^\circ\text{C}, \quad (4.17)$$

where  $J$  = current density

3. Variable heating – variable load (Table 4.9, middle column)

The most frequent load case is probably a variable load for which both the ambient temperature and

the current load change over time. Because of the heat-storage capacity of the conductor, the conductor temperature  $\vartheta_L$  always lags behind the current  $I_L(t)$ . Assuming that there is no heat transfer along the conductor, the following boundary condition applies

$$dP_{LIN} = dP_{LOUT}$$

(no heat flow along the conductor), where the radial heat transfer by convection  $P_K$  and by radiation  $P_S$ , as well as the heat storage  $P_C$ , enter the heat balance equation

$$dP_V - dP_C - dP_K - dP_S = 0. \quad (4.18)$$

With (4.9) and (4.10), one obtains

$$\frac{kI^2\rho(\vartheta)}{A} - Ac\delta \frac{\partial\vartheta}{\partial t} - \alpha(\vartheta)U(\vartheta - \vartheta_0) = 0. \quad (4.19)$$

For a transient situation and for a lower ambient temperatures  $\vartheta_0$ , a temporary overcurrent,  $I_L$ , higher than the rated current  $I_r$  can be sustained without the limit temperature of the current path being exceeded. Knowledge of the thermal time constants of all related components is indispensable for the practical use of this effect.

The time dependence of the temperature (heating) of a conductor  $\vartheta_L(t)$  [4.20] after switching a current  $I_L(t)$  on (Fig. 4.9a) is obtained by solving (4.19)

$$\vartheta(t) = \Delta\vartheta_{\text{end}} \left( 1 - e^{-\frac{t}{\tau}} \right) + \vartheta_0, \quad (4.20)$$

where

$$\tau = \frac{c\delta A}{\alpha(\vartheta)U}, \quad (4.21)$$

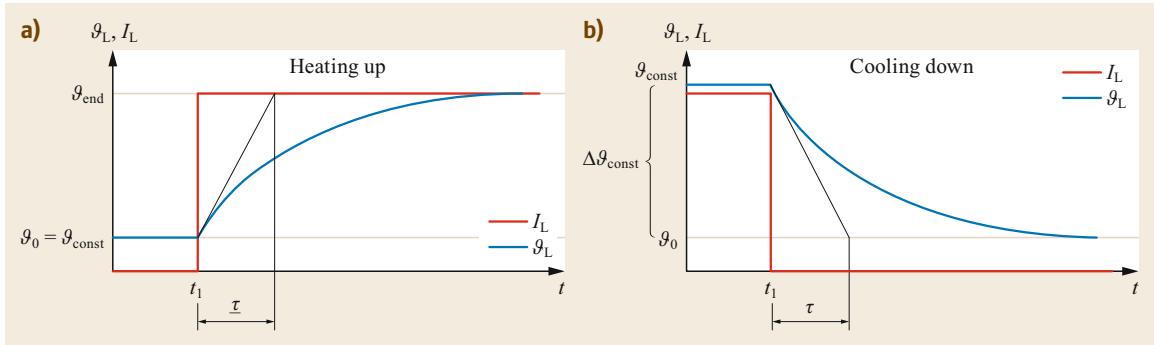

and  $\tau$  = thermal time constant, and  $\Delta\vartheta_{\text{end}}$  = final temperature value in the stationary state after heating.

Cooling a conductor after switching a current  $I_L(t)$  off (Fig. 4.9b) follows as

$$\vartheta(t) = \Delta\vartheta_{\text{const}} e^{-\frac{t}{\tau}} + \vartheta_0. \quad (4.22)$$

Examples: the thermal time constant  $\tau$  amounts to:

- 15–25 min with air-cooled copper conductors
- 2–3 min for oil-cooled conductors
- 1 min for water-cooled conductors
- 10 min for aluminum overhead-line conductors.

**Fig. 4.9a,b** Conductor temperature  $\vartheta_L(t)$  after switching on and off a current  $I_L$ . After  $3\tau$  the temperatures deviate only by 5% of the final value  $\vartheta_{end}$ . **(a)** Temperature rise after switching on, **(b)** temperature fall after switching off

4. Heating of a long, linear conductor with additional temperature distribution along the conductor from a heat source (Fig. 4.10).

When there are points along a conductor with additional power losses  $P_V$ , these result in hot spots with a temperature of  $\vartheta_V$ . The heat conduction  $P_L$  along the conductor, though, reduces such local temperature rises  $\Delta\vartheta_V$  until their effect is no longer noticeable, i.e., until  $\vartheta_{endL}$ .

Examples:

- Damaged or highly-aged connections with a high resistance (Sect. 4.3.3); these impose a hot spot.
- Local reduction of the conductor cross section.

- Additional losses in components with hysteresis and eddy current losses (old type dead-end clamps from malleable cast iron in overhead lines, steel bushings, and fasteners).

From the heat balance equation (4.9), one obtains under the boundary condition that there is no heat storage, as this process is time invariant, i.e.,  $dP_C = 0$ ,

$$dP_V - dP_L - dP_K - dP_S = 0, \tag{4.23}$$

which leads to

$$\frac{kI^2\rho(\vartheta)}{A} + \lambda A \frac{\partial^2\vartheta}{\partial x^2} - \alpha(\vartheta)U(\vartheta - \vartheta_0) = 0, \tag{4.24}$$

or

$$\frac{d^2\vartheta}{dx^2} - \frac{\alpha(\vartheta)U}{\lambda A}\vartheta + \frac{\alpha(\vartheta)U}{\lambda A}\vartheta_0 + \frac{kI^2\rho(\vartheta)}{\lambda A} = 0, \tag{4.25}$$

with the homogeneous part

$$\frac{d^2\vartheta(x)}{dx^2} - \frac{1}{b^2}\vartheta(x) = 0. \tag{4.26}$$

Assuming

$$\vartheta(x) = e^{ax}, \quad \ddot{\vartheta}(x) = a^2e^{ax}, \tag{4.27}$$

and inserting in (4.26), one obtains

$$a^2e^{ax} - \frac{1}{b^2}e^{ax} = 0,$$

**Fig. 4.10** Distribution of the conductor temperature  $\vartheta_L(x)$  with unequal dissipation of power loss along the conductor. After  $3b$  the temperatures deviate only by 5% of the final value  $\vartheta_{end}$

with the solution

$$a^2 - \frac{1}{b^2} = 0, \quad a^2 = \frac{1}{b^2}, \quad a = \sqrt{\frac{1}{b^2}} = \pm \frac{1}{b}. \tag{4.28}$$

Thus, the temperature distribution along the conductor becomes (Fig. 4.10)

$$\vartheta(x) = \Delta\vartheta_{\text{ve}} e^{-\frac{x}{b}} + \vartheta_{\text{endL}}, \tag{4.29}$$

where  $b$  is the thermal local constant

$$b = \sqrt{\frac{\lambda A}{\alpha(\vartheta)U}}. \tag{4.30}$$

This means that the temperature difference  $\Delta\vartheta$  (higher or lower) along a conductor subsides after a distance of three times the thermal local constant  $b$  to about 5% of its original value.

Examples: the thermal local constant  $b$  is approximately:

- 30–35 cm for a copper bus bar 100 mm × 10 mm
- 20–25 cm for an aluminum bus bar 40 mm × 10 mm
- 22 cm for an aluminum overhead conductor 240 mm<sup>2</sup>.

### Calculation of Temperature Distribution

In order to calculate the spatial temperature distribution of a device, knowledge of the relevant heat sources, i.e., the heat conduction along the current path, is required according to the thermal balance equation;  $P_L$  the heat dissipation by convection  $P_K$ , the radiation  $P_S$  radially to the current path and with dynamic processes and also the heat capacities  $P_C$  are required. The necessary information on the design, dimensions, and materials must be known. Even if these often have to be procured laboriously or determined experimentally, they are indispensable.

Heat sources in electrical equipment can usually be the following (Fig. 4.11):

- Electrical heat losses  $P_V$  in the conductor,  $P_{VL}$  and in the electrical contacts and connections  $P_{Vj}$ ,

$$P_{VL} = kI_L^2 R_{\sim}(\vartheta) = kI_L^2 \frac{\rho_{20}l}{A_L} [1 + \alpha_{T20}(\vartheta_L - 20^\circ\text{C})], \tag{4.31}$$

where

$$k = \frac{P_{\sim}}{P_{=}} = \frac{R_{\sim}}{R_{=}}, \tag{4.32}$$

and  $P_{\sim}$  = alternating current (AC) power,  $R_{\sim}$  = AC resistance of the conductor,  $P_{=}$  = direct current (DC) power, and  $R_{=}$  = DC resistance of the conductor.

The skin effect factor  $k$  is a measure of the higher resistance for alternating current (AC) (skin effect for single conductors, proximity effect for the mutual influence of parallel conductors) than for direct current, for common current paths and can be taken as an example for rectangular conductors from Table 4.10 (Fig. 4.12). For common rectangular, round, tubular, and profile conductors, these factors are already taken into account when specifying the current-carrying capacity [4.19, 21, 22].

The current heat losses in electrical connections  $P_{Vj}$  result in

$$P_{Vj} = I^2 R_j(\vartheta, t), \tag{4.33}$$

and

$$R_j(\vartheta, t) = R_m(\vartheta) + R_c(t) + R_f(t), \tag{4.34}$$

where  $P_{Vj}$  = heat or dissipation in one connection,  $I$  = current flowing in the connection,  $R_j(t)$  = joint

**Fig. 4.11** Thermal power losses in an electric power circuit;  $P_{VL}$  = electric heat losses in conductors,  $P_{Vj}$  = electric heat losses in connectors,  $P_D$  = dielectric losses (in cables  $\geq 200$  kV),  $P_{Ka}$  = losses in encapsulation and concentric external conductor,  $P_W$  = eddy-current losses,  $P_H$  = hysteresis losses, and  $P_{SH}$  = thermal power from solar and sky radiation

**Table 4.10** Current displacement factor  $k$  for rectangular flat bus bars ( $k = R_{\sim}/R_{=}$  for rectangular flat bus bars with subconductors;  $f = 50\text{ Hz}$ ;  $\vartheta_L = 70^\circ\text{C}$ ; space between subconductors = 10 mm)

**Fig. 4.12** Related current density distribution  $J$  in a  $2 \times (60 \times 10)\text{ mm}^2$  rectangular flat bus bar (schematically)

resistance (time-dependent quantity  $\rightarrow$  aging),  $R_m =$  metallic lead resistance/self-resistance,  $R_c(t) =$  constriction resistance (time-dependent variable  $\rightarrow$  aging), and  $R_f(t) =$  impurity film resistance (time-dependent variable  $\rightarrow$  aging).

Just like the losses in the conductor, the losses in the joints also depend on the current load  $I_L$  and, thus, the temperature of the conductor. In addition, in this case, the time variation of the joint resistance  $R_v(t)$  by aging processes (Sect. 4.3.3) has to be considered:

- Dielectric losses  $P_D$  have to be considered in high-voltage cables with operating voltages  $\geq 220\text{ kV}$  and are calculated as

$$P_D = U_B^2 \omega C_B \tan \delta, \quad (4.35)$$

where  $U_B =$  operating voltage,  $\omega =$  angular frequency,  $C_B =$  electrical capacity of the equipment, and  $\tan \delta =$  loss factor.

- Eddy current losses  $P_W$  occur when alternating magnetic fields penetrate components made of non-ferromagnetic materials

$$P_W = \frac{1}{24} \kappa \omega^2 d^2 \hat{B}_m^2 V F(x), \quad (4.36)$$

with

$$F(x) = \frac{3 \sinh x \sin x}{x \cosh x \cos x}, \quad (4.37)$$

$$x = \beta d, \quad (4.38)$$

$$\beta = \sqrt{\pi f \kappa \mu}, \quad (4.39)$$

where  $\kappa =$  conductance,  $\omega =$  angular frequency,  $f =$  power frequency,  $\mu =$  permeability,  $d =$  thickness of the sheet,  $\hat{B}_m =$  peak value of the mean magnetic induction, and  $V =$  volume.

- If components made of ferromagnetic materials, e.g., steel parts, are penetrated by alternating magnetic fields, hysteresis losses  $P_H$  occur

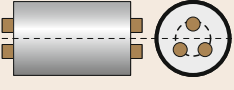

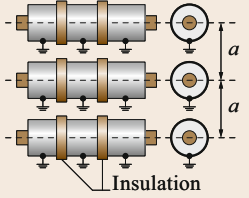

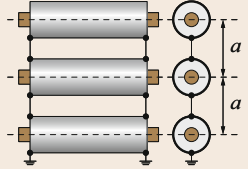

$$P_H = \frac{8}{3} \nu f \hat{H}_m^3 V, \quad (4.40)$$

where  $\nu =$  material constant, determined by the hysteresis of the material,  $f =$  power frequency,  $\hat{H}_m =$  peak value of the mean magnetic field strength, and  $V =$  volume.

- Losses  $P_{Ka}$  in the enclosure of modern switchgear and in concentric outer conductors of cables are generated by induction or eddy currents. The driving voltage required for this is induced by the alternating magnetic field of the conductor currents in the enclosure. The smaller the distance between the conductor and the concentric outer conductor and the larger the conductor current, the greater these losses become. In three-phase systems, a distinction must be made between single-pole and three-pole enclosure. In single-pole insulated systems, the arrangement *side-by-side* must also be distinguished from the *triangular* arrangement, since the magnetic fields of the three conductors in the three-phase system compensate each other in different ways, which affects the losses (Table 4.11). Thereby the individual segments of the enclosure

**Table 4.11** Typical configurations for encapsulated bus bars or cables

Three-phase encapsulation	Single-phase encapsulation	
Triangular ( $3 \times 120^\circ$ )	Side-by-side	Triangular ( $3 \times 120^\circ$ )
	Not electrically connected	Electrically connected through
		

can be electrically connected through or insulated from each other (not connected for  $l < 10\text{ m}$ ) and individually/each one earthed [4.2].

– Single-pole encapsulation

In a symmetrical three-phase system with single-pole insulated current paths, the mean enclosure losses of a concentric outer conductor are calculated as

$$P_{Ka} = mKI_L^2 \frac{\rho_{20}}{A_K} l [1 + \alpha_T (\vartheta_{Ka} - 20^\circ\text{C})], \tag{4.41}$$

where  $A_K$  = conductor cross section of the enclosure,  $a$  = conductor spacing,  $d_{Ka}$  = enclosure diameter,  $I_{Ka}$  = capsule current,  $I_L$  = conductor current,  $K$  = enclosure power-loss factor (Fig. 4.14a),  $k'$  = enclosure factor (Fig. 4.14a),  $l$  = length of the enclosure,  $m$  = correction factor (0.9–1.04) (Fig. 4.14b), and  $R_{Ka}$  = enclosure resistance, which are dependent from the temperature, and where the enclosure power-loss factor  $K$  represents the ratio of the actually generated heat output to the output that arises when the enclosure current  $I_{Ka}$  is equal to the phase current  $I_L$  (Fig. 4.16).

If the individual segments of the current path are not connected (Table 4.11, column 2, Fig. 4.13), the enclosure power-dissipation factor becomes  $K < 1$  for nonferromagnetic materials and for a ratio of the enclosure diameter to the conductor distance  $d_{Ka}/a < 0.82$ . For  $0.82 < d_{Ka}/a < 0.9$   $K$  becomes 1.5 (Fig. 4.14a). This diagram applies for an enclosure factor  $k' = 20$  according to the relationship (4.42) is calculated to

$$k' = \omega \kappa \mu_0 b_{Ka} r_{Ka}, \tag{4.42}$$

with  $b_{Ka}$  = thickness of enclosure,  $r_{Ka}$  = enclosure diameter,  $\omega$  = angular frequency of the network, and  $\kappa$  = electrical conductivity of the enclosure material.

For enclosure factors deviating from  $k' = 20$ , correction factors  $m$  must be taken into account, which use the geometric and electrical conditions in accordance with (4.42) (Fig. 4.14b).

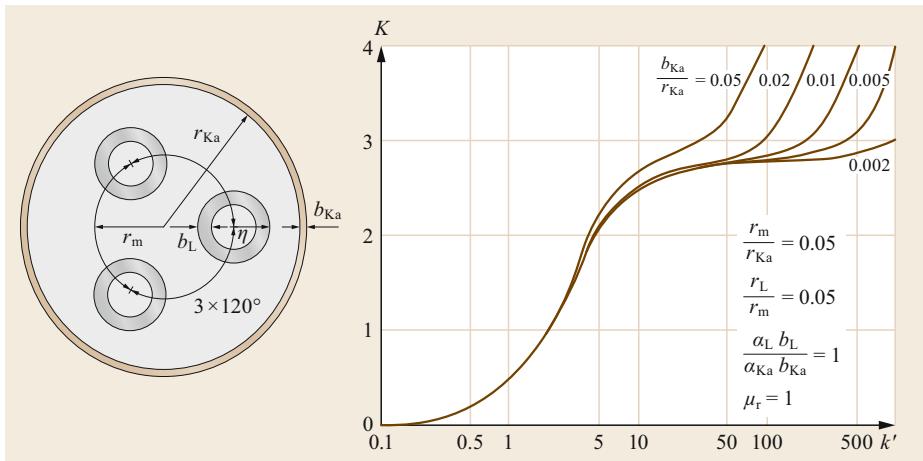

With a smaller conductor distance  $a$  and more compact design, the enclosure power-loss factor  $K$  and, thus, the losses  $P_{Ka}$ , are larger. The enclosure losses of the concentric outer conductor also increase with poorer conductivity of the enclosure material.

**Fig. 4.13** Power losses  $P_{Ka}$  in encapsulated bus bars and a concentric external conductor, GIL with a single pole, not connected encapsulation, side-by-side, length of segments  $l < 10\text{ m}$ , symmetrical current load in three phases (adapted from [4.2])

**Fig. 4.14** (a) Encapsulation power factor  $K$  for calculation of power losses in all three capsules in the case of symmetric current load (single-pole, unconnected encapsulation) (b) correcting factor  $m$  for encapsulation factor  $k'$  if  $k' \neq 20$  (adapted from [4.2])

**Fig. 4.15** Encapsulation power-loss factor  $K$  with three-pole cylindrical encapsulation (adapted from [4.2])

If the individual segments of an enclosure are electrically connected along the current path ( $l > 10$  m) (Table 4.11, columns 3 and 4), then for practically relevant applications, the conductor ( $I_L$ )- and the enclosure currents ( $I_{Ka}$ ) have about the same magnitude, i.e.,

$$K = \left( \frac{I_{Ka}}{I_L} \right)^2 \approx 1, \tag{4.43}$$

thus, the enclosure losses  $P_{Ka}$  can be computed as

$$P_{Ka} = I_{Ka}^2 R_{Ka}(\vartheta). \tag{4.44}$$

- Three-pole enclosure If the three conductors of a symmetrical three-phase system are arranged together in an equilateral triangle in a cylindrical enclosure of nonferromagnetic material (Ta-

ble 4.11 column 1), the mean enclosure losses can be calculated with (4.41) with  $m = 1$ . The enclosure power factor  $K$  depends on the enclosure factor  $k'$  and the ratio of wall thickness  $b_{Ka}$  of the encapsulation to the mean radius of the three conductors  $r_m$  (Fig. 4.15).

- Heating capacities  $P_{SH}$  by *solar and celestial radiation*, to be taken into account in outdoor installations, especially in countries with intensive solar radiation. The maximum daily output is

$$P_{SH} = ik'\alpha'P_{SH}^*(h) \sin \gamma A \quad (4.45)$$

$$h = (90^\circ + \delta) - \phi, \quad (4.46)$$

where  $i$  = pollution factor (Fig. 4.16c),  $k'$  = correction factor for height above sea level (Fig. 4.16d),  $\alpha'$  = absorption coefficient,  $\gamma$  = inclination of the surface to the incidence of the Sun,  $A$  = illuminated surface,  $h$  = sun elevation (Fig. 4.16a),  $\phi$  = latitude, and  $\delta$  = declination of the Sun (Fig. 4.16b)

For the time variation of the heat output caused by solar and celestial radiation, the day and year movement of the Sun must be taken into account (Fig. 4.16e)

$$P_{SH} = ik'\alpha'P_{SH}^*(h) \sin \gamma A \cos \alpha, \quad (4.47)$$

where  $A$  = azimuth,  $h$  = solar elevation,  $t$  = hour angle,  $WOZ$  = true local time,  $\alpha$  = angle between the position of the surface in relation to the azimuth and the position of the Sun, and  $\beta$  = surface azimuth.

Example: the daily variation of the directly and diffusely irradiated heat  $P_{SH}$  on an equipment enclosure with the dimensions length  $\times$  width  $\times$  height = 1 m  $\times$  1 m  $\times$  1 m on 21 June at a location  $51^\circ$  N latitude, at sea level  $NN = 0$  depending on true local time must be determined.

The maximum Sun elevation is calculated taking into account the declination  $\delta = 23.5^\circ$  on 21 June, the day with the highest position of the Sun

$$h_{\max}(90^\circ + 23.5^\circ) - 51^\circ = 62.5^\circ. \quad (4.48)$$

This allows the maximum possible solar power of approximately  $980 \text{ W m}^{-2}$  to be absorbed (Fig. 4.17). At this solar elevation, the pollution factor  $i$  is 0.8 (Fig. 4.16c).

The altitude of the Sun  $h(t)$  changes during the day with

$$h(t) = 90^\circ - [\arccos(\sin \delta \sin \phi \cos \delta \cos \phi \cos t)], \quad (4.49)$$

where the hour angle  $t$  results from

$$t = -(12 \text{ h} - WOZ)\omega, \quad (4.50)$$

with

$$\omega = \frac{2\pi}{d} = \frac{360^\circ}{24 \text{ h}} = 15 \frac{\text{deg}}{\text{h}}. \quad (4.51)$$

The azimuth  $a$  is calculated by

$$a = \arctan \frac{\cos \delta \sin t}{\sin \phi \cos \delta \cos t - \cos \phi \sin \delta}. \quad (4.52)$$

The angle  $\alpha$  is the difference between the position of the surface in relation to the direction  $\beta$  and the Sun's azimuth  $a$

$$\alpha = (\beta - a). \quad (4.53)$$

The result of this calculation (Fig. 4.17) shows the temporally and spatially uneven thermal load of the individual surfaces on the north, east, south, and west locations as caused by solar and celestial radiation. The normal surface experiences the largest heat load. Such calculations can be helpful in optimizing the thermal design, construction, and installation of thermally highly loaded equipment [4.2, 23].

### Thermal Storage

For dynamic thermal processes, the *heat energy*  $Q_C$  stored in the conductor, in the insulation and in the connectors must be taken into account during dimensioning

$$Q_C = mc\Delta\delta = mc(\vartheta - \vartheta_0) = C_{th}(\vartheta - \vartheta_0), \quad (4.54)$$

where  $Q_C$  = stored heat energy,  $m$  = mass of the heat-storing volume,  $c$  = specific heat (Table 4.8),  $\Delta\vartheta$  = temperature difference,  $\vartheta$  = temperature of the volume to be heated,  $\delta_0$  = initial temperature before heating, and  $C_{th}$  = thermal capacity.

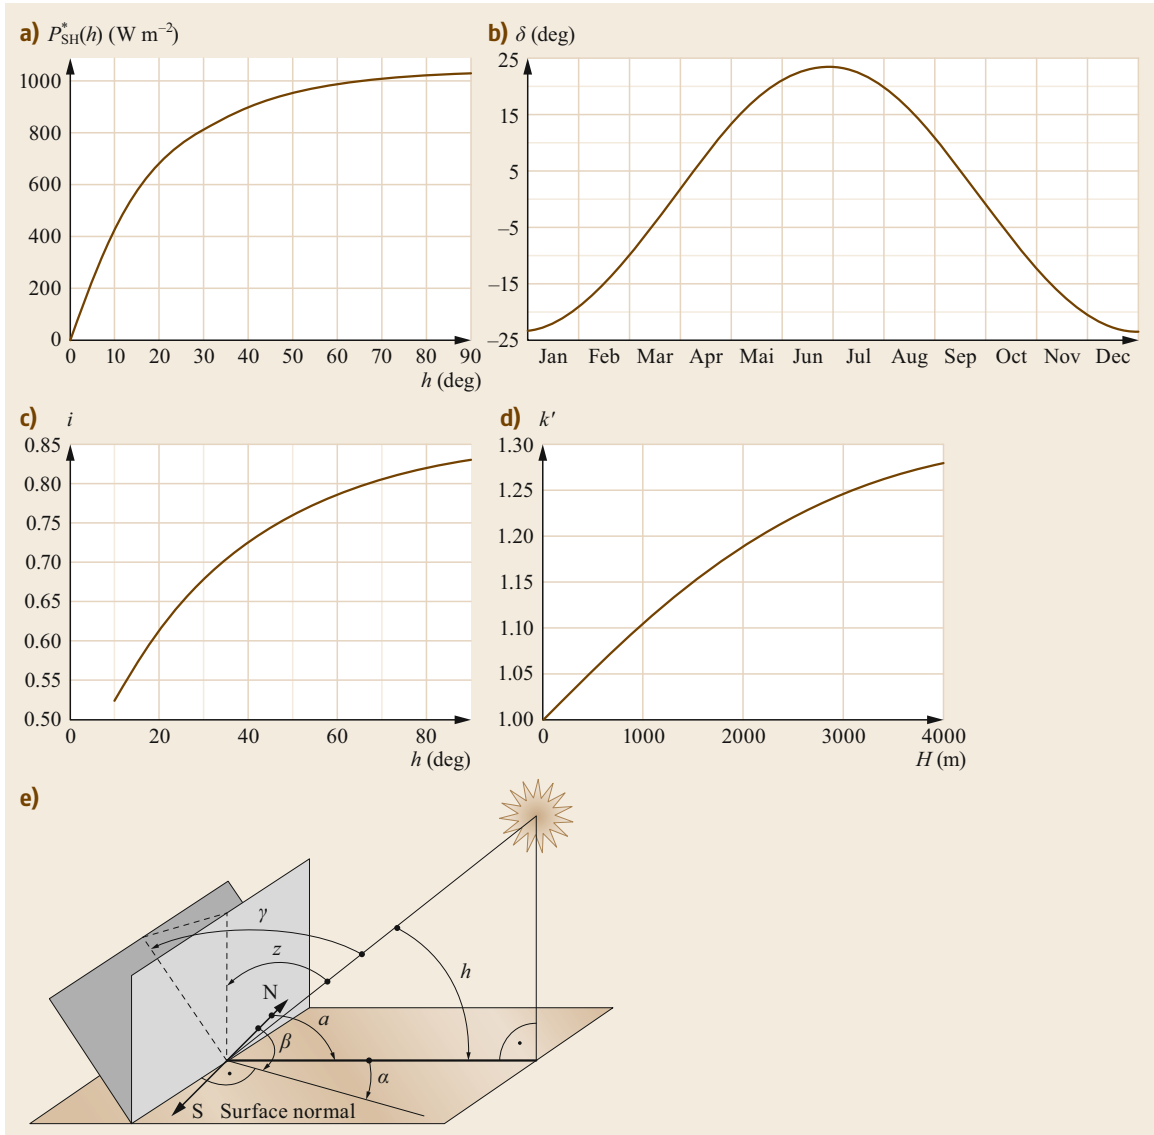

### Heat Transfer

Heat is transferred from high-temperature to low-temperature regions by means of different physical processes, which depend on the materials involved.

*Heat conduction*  $P_L$ :

- In solids: by lattice vibrations, electron movement
- In liquids: by lattice vibrations, diffusion
- In gases: by diffusion.

Heat flow flows through a body during heat conduction  $P_L$ . According to the Fourier law of heat conduction, this can be calculated as (stationary heat

**Fig. 4.16a–e** Heat output from solar and sky radiation. (a) Power consumption of a normal area ( $1 m^2$ ) at NN due to global radiation as a function of the solar altitude  $h$  in clean air ( $a' = 1$ ), (b) declination  $d$  of the Sun depending on the course of a year ( $50^\circ N$  latitude), (c) pollution factor  $i$  of a normal area ( $a' = 1$ ) at NN due to global radiation as a function of the altitude of the Sun, (d) correction factor  $k'$  depending on  $H$ , the altitude above sea level NN, (e) the influence of the position of the Sun on the power curve

conduction)

$$P_L = -\lambda A \frac{d\vartheta}{dx}, \tag{4.55}$$

where  $\lambda$  = specific thermal conductivity (Table 4.8),  $A$  = surface perpendicular to heat flow, and  $d\vartheta/dx$  = thermal gradient.

The negative sign considers that heat flow takes place from the higher to the lower temperature.

Examples:

1. Stationary heat conduction through a flat wall (one-dimensional) (Fig. 4.18a)  
 From (4.55) it follows that

$$-\int_{\vartheta_i}^{\vartheta_a} d\vartheta = P_L \int_0^d \frac{dx}{\lambda A}, \tag{4.56}$$

**Fig. 4.17** Example of thermal power absorbed by solar and celestial radiation. Power consumption by direct and diffuse radiation on the side surfaces of a cube (1 m × 1 m × 1 m) on 21 June, 50° N latitude depending on the true local time (WOZ) [4.2, 23]

with the solution

$$\vartheta_i - \vartheta_a = \Delta\vartheta = P_L \frac{d}{\lambda A}, \tag{4.57}$$

which can also be written as

$$\Delta\vartheta = P_L R_{th,w}, \tag{4.58}$$

or in analogy to electrical engineering as *Ohm's law* of thermal fluid mechanics

$$R_{th,w} = \frac{d}{\lambda A}, \tag{4.59}$$

where  $\vartheta_i, \vartheta_a$  = temperature on the inside or outside of the flat wall,  $d$  = wall thickness, and  $R_{th,w}$  = thermal resistance of a flat wall.

2. Stationary heat conduction through a coaxial cylinder (one-dimensional) (Fig. 4.18b)

From (4.55), it follows that

$$-\int_{\vartheta_i}^{\vartheta_a} d\vartheta = P_L \int_{r_i}^{r_a} \frac{dr}{\lambda 2\pi r l}, \tag{4.60}$$

with the solution

$$\vartheta_i - \vartheta_a = \Delta\vartheta = P_L \frac{1}{\lambda 2\pi l} \ln\left(\frac{r_a}{r_i}\right), \tag{4.61}$$

which can also be written as

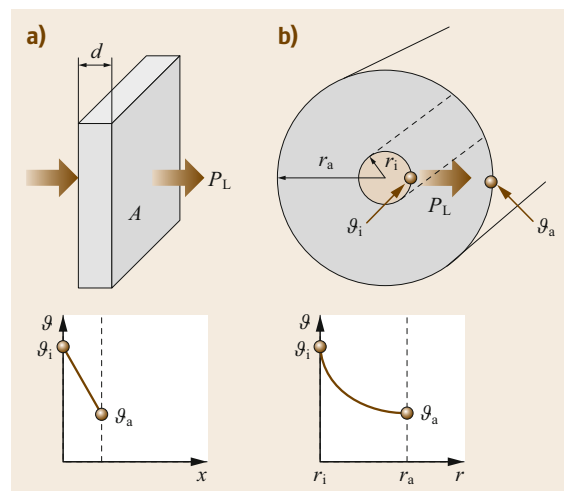

$$\Delta\vartheta = P_L R_{th,koax}, \tag{4.62}$$

or in analogy to electrical engineering as *Ohm's law* of thermal fluid mechanics

$$R_{th,koax} = \frac{1}{2\pi\lambda l} \ln\left(\frac{r_a}{r_i}\right), \tag{4.63}$$

where  $l$  = length of coaxial cylinder,  $r_a, r_i$  = outer and/or inner radius of the coaxial heat flow field, and  $R_{th,koax}$  = thermal resistance of the coaxial cylinder.

Heat transfer after Newton comprises convective heat transfer  $P_K$  and heat radiation  $P_S$  by electromagnetic waves from a solid through the surrounding gas

**Fig. 4.18a,b** Stationary heat conduction: (a) through a plane wall, (b) through a coaxial cylinder

**Fig. 4.19** Heat transfer from a warm surface with temperature  $\vartheta$  to the cooler environment by radiation and convection according to Newton

or liquid (Fig. 4.19), where  $\vartheta_0$  = ambient temperature,  $\vartheta_W$  = temperature of opposite wall,  $P_S$  = heat transfer by radiation, and  $P_K$  = heat transfer by convection.

$$P_U = \alpha O \Delta \vartheta, \quad (4.64)$$

whereby

$$\alpha = \alpha_S + \alpha_K, \quad (4.65)$$

and, therefore,

$$P_U = P_S + P_K = \alpha_S O_S (\vartheta - \vartheta_W) + \alpha_K O_K (\vartheta - \vartheta_0), \quad (4.66)$$

with the thermal radiation resistances

$$R_S = \frac{1}{\alpha_S O_S} \quad (4.67)$$

and the thermal convection resistance

$$R_K = \frac{1}{\alpha_K O_K}, \quad (4.68)$$

where  $P_U$  = heat transfer by radiation and convection,  $\alpha$  = heat-transfer coefficient,  $\alpha_S$  = heat-transfer coefficient for radiation,  $\alpha_K$  = heat-transfer coefficient for convection,  $O_S$  = surface for heat radiation,  $O_K$  = surface for heat convection,  $\vartheta_0$  = temperature of the surrounding medium (for convection),  $\vartheta_W$  = temperature of the opposite wall (for radiation),  $R_S$  = thermal radiation resistance, and  $R_K$  = thermal convection resistance.

*Heat radiation*  $P_S$  takes place between the surfaces of solid bodies with different temperatures by electromagnetic waves in vacuum or in transparent materials (e.g., air) with wavelengths  $\lambda$ :

- At  $100^\circ\text{C} \Rightarrow \lambda = 7.76 \text{ mm}$  (infrared)
- At  $6000 \text{ K} \Rightarrow \lambda = 0.48 \text{ mm}$  (visible).

According to Wiens's law, the following applies

$$\lambda_{\max} T = 2896 \text{ mm K}, \quad (4.69)$$

where  $\lambda$  = wavelength of the electromagnetic wave, and  $T$  = absolute temperature.

**Fig. 4.20** Heat transfer by convection

The radiated power is calculated according to the Stefan–Boltzmann law

$$P_S = \varepsilon_{1,2} C_S O_S [(T_S)^4 - (T_W)^4], \quad (4.70)$$

with  $T_S$  = absolute temperature of the surface emitting heat through radiation  $O_S$ , and  $T_W$  = absolute temperature of the wall absorbing heat through radiation  $O_W$ .

The resulting emission number  $\varepsilon_{1,2}$  is based on the ratio of the radiating and the receiving surfaces, i.e.

- Parallel surfaces

$$\varepsilon_{1,2} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}. \quad (4.71)$$

- Surrounding bodies with the surfaces  $O_{S1}$  and  $O_{S2}$

$$\varepsilon_{1,2} = \frac{1}{\frac{1}{\varepsilon_1} + \frac{O_{S1}}{O_{S2}} \left( \frac{1}{\varepsilon_2} - 1 \right)}, \quad (4.72)$$

where  $C_S = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$  = radiation coefficient of an ideal black body,  $\varepsilon_1, \varepsilon_2$  = emission number of areas 1 and 2, and  $O_{S1}, O_{S2}$  = size of the mutually emitting surfaces 1 and 2.

*Thermal convection*  $P_K$  is a mass transport taking place in liquids and gases along the surface of a solid body at a higher temperature  $\vartheta$  than the ambient temperature  $\vartheta_0$  (Fig. 4.20).

*Convection:*

- Heat transfer between solid body and fluid (gas/liquid)
- Bound to a motile medium
- Transfer of heat output in the boundary layers by heat conduction
- Transfer of heat output outside the boundary layers by mass transport.

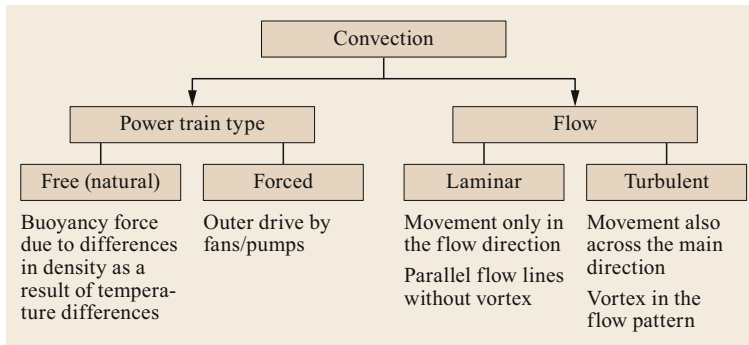

Fig. 4.21 Types of convection

Depending on the type of mass transport and the type of flow, different convection types can be distinguished (Fig. 4.21), which is reflected in the different heat-transfer coefficients  $\alpha_K$  (4.65) and (4.66). Because of the complexity of the physical processes involved, an analytical description is generally not available.

Nevertheless, according to *similarity theory*, it becomes possible to use *similarity criteria* to determine the relationship between the physical parameters involved, i.e.:

- Temperature  $\vartheta$ , position and dimensions of the heat-emitting surface  $O_K$
- The physical properties of the ambient cooling medium, e.g., its thermal conductivity  $\lambda$ , density  $\delta$ , specific heat capacity  $c$ , kinematic viscosity  $\nu$
- The type of convection (laminar or turbulent flow) (Fig. 4.21)

on the basis of experimental investigations of typical arrangements and to generalize this to similar arrangements within a range of validity (Tables 4.12–4.14).

For free convection

$$\text{Nu} = f(\text{GrPr}) = c_1 (\text{GrPr})^{n_1} \quad (4.73)$$

For forced convection

$$\text{Nu} = f(\text{Re}' \text{Pr}) = c_2 (\text{Re}')^{n_2} \quad (4.74)$$

$\text{Re}'$  takes into account the superposition of free and forced convection, e.g., in outdoor substations with low wind speed  $v \leq 1.0 \text{ m s}^{-1}$ . It is calculated from the superposition of forced flow with  $\text{Re}^*$  and free flow with  $\text{Re}$  to

$$\text{Re}' = \sqrt{\text{Re}^2 + \text{Re}^{*2}}, \quad (4.75)$$

where  $\text{Re}^*$  results from

$$\text{Re}^* = c^3 (\text{GrPr})^{n_3}, \quad (4.76)$$

with

$$c_3 = \left( \frac{c_1}{c_2} \right)^{\frac{1}{n_2}}, \quad (4.77)$$

and

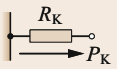

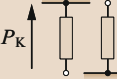

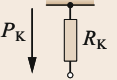

$$n_3 = \frac{n_1}{n_2} \quad (4.78)$$

**Table 4.12** Similarity criteria (characteristic values) for convective heat transfer

Nusselt number Nu	Determination of the heat-transfer coefficient for convection	$\text{Nu} = \frac{\alpha_K}{\lambda_{\text{med}}} l_w$ (Nusselt criterion) $\alpha_K = \text{Nu} \frac{\lambda_{\text{med}}}{l_w}$
Grashof number Gr	Free convection	$\text{Gr} = \frac{g \beta l_w^3}{\nu^2} (\vartheta - \vartheta_0)$
Reynolds number Re	Forced convection	$\text{Re} = \frac{v}{\nu} l_w$
Prandtl number Pr	Free convection	$\text{Pr} = \frac{\nu}{\alpha}; \alpha = \frac{\lambda_{\text{med}}}{c \delta}$

$\alpha_K$  = heat transfer coefficient for convection,  $\alpha$  = thermal diffusivity,  $l_w$  = characteristic length (Tables 4.13 and 4.14),  $\lambda_{\text{med}}$  = thermal conductivity of the medium (Fig. 4.22),  $g$  = gravity,  $\beta$  = coefficient of expansion of the medium,  $\nu$  = kinematic viscosity (Fig. 4.23),  $v$  = flow velocity.

**Table 4.13** Similarity functions to free convection,  $Nu = c_1(GrPr)^{n_1}$

Arrangement	Application (example)	Schema	$c_1$	$n_1$	Range of validity
Vertical plate	Vertical wall of switchgear housing		0.15	0.33	$1.7 \times 10^7 < GrPr < 2 \times 10^{10}$
Horizontal plate (convection upside)	Roof of switchgear housing, inside and outside		0.17	0.33	$2.3 \times 10^8 < GrPr < 2.1 \times 10^9$
Horizontal plate (convection downside)	Channel bottom		0.095	0.33	$1.7 \times 10^8 < GrPr < 1.2 \times 10^9$
Horizontal cylinder	Cable, round conductor		0.56	0.25	$5 \times 10^2 < GrPr < 2 \times 10^7$
Bus bar, rectangular, single, twin, triple placed upright	Space between subconductors is equal to thickness of bus bar, free in air		0.60	0.25	$9 \times 10^4 < GrPr < 4.6 \times 10^6$

**Table 4.14** Similarity functions to forced convection in air,  $Nu = c_2(Re)^{n_2}$

Arrangement	Application (example)	Schema	$c_2$	$n_2$	Range of validity
Vertical plate, flowed along	Vertical wall of switchgear housing, forced cooled		0.16	0.66	$Re < 10^5$
Horizontal cylinder, flowed across	Forced cooled cable or round conductor		0.170	0.62	$10^3 < Re < 10^4$
Bus bar, rectangular, placed upright, flowed across	Forced cooled bus bar		0.400	0.60	$1.5 \times 10^3 < Re < 4.2 \times 10^4$

**Fig. 4.22** Thermal conductivity  $\lambda$  of gases at normal pressure

**Fig. 4.23** Kinematic viscosity  $\nu$  of gases

**Fig. 4.24** Coefficient of material value  $k_s$  for air at normal pressure (adapted from [4.5])

For this calculation, the physical properties of the cooling medium (Figs. 4.22 and 4.23) are adequately combined, taking into account their temperature dependence, in a material value coefficient  $k_s$  [4.2, 5] (Fig. 4.24).

$$k_s(\vartheta_m) = \frac{g\beta}{v^2} \text{Pr} = \frac{g\beta c\delta}{v\lambda_{\text{med}}}, \quad (4.79)$$

where  $k_s(\vartheta_m)$  = temperature-dependent material value coefficient, and  $\vartheta_m$  = average temperature.

Thereby the relevant temperature is the average temperature  $\vartheta_m$  between the heat-emitting surface  $O_K$  with temperature  $\vartheta$  and the temperature of the cooling medium  $\vartheta_0$

$$\vartheta_m = \frac{\vartheta + \vartheta_0}{2}. \quad (4.80)$$

Therefore,

$$(\text{GrPr}) = k_s l_w^3 (\vartheta - \vartheta_0),$$

where the heat-transfer coefficient  $\alpha_K$  can be calculated using the equations in Table 4.12 and (4.73)–(4.74). The values for  $c_1, c_2, c_3$  or  $n_1, n_2, n_3$  in (4.73), (4.74), and (4.76) must be determined experimentally. For typical arrangements, these values and their ranges of validity are available (Tables 4.13 and 4.14) [4.2].

Example: heat emission of a vertical surface 1.0  $\times$  1.0 m at a temperature of  $\vartheta = 70^\circ\text{C}$  and ambient air with  $\vartheta_0 = 30^\circ\text{C}$  by radiation (surface bare or coated) and by free or forced convection (Fig. 4.19, Table 4.15).

Results, depending on the combination of possible heat emission by radiation and convection are shown in Table 4.16.

The example shows the great influence of the surface treatment of the heat-emitting surface as well as of

**Table 4.15** Example calculation for the heat emission of a vertical surface  $O_S = O_K = 1 \text{ m}^2$ ,  $\vartheta = 70^\circ\text{C}$  ( $T_S = 273.15 \text{ K} + 70^\circ\text{C} = 343.15 \text{ K}$ ) to the ambient air at  $\vartheta = 30^\circ\text{C}$  and the surrounding walls with  $\vartheta_W = 30^\circ\text{C}$  ( $T_W = 273.15 \text{ K} + 30^\circ\text{C} = 303.15 \text{ K}$ )

forced air flow, e.g., by fans on the heat emission of the same surface.

Heat transfer by a *coolant flow*  $P_{\dot{V}}$  is the heat transport in enclosed systems by convection from the current path via a fluid (air, insulating gas) directly to the enclosure, such as in *ventilated current conducting arrangements* (air flow rate). The heat emitted from the heated components results in

$$P_{\dot{V}} = c\delta\dot{V}(\vartheta_a - \vartheta_e). \quad (4.81)$$

The air flow rate depends on the temperature-dependent pressure difference  $\Delta p$  and the sum of all flow resistances  $S$

$$\dot{V} = \sqrt{\frac{\Delta p}{S}}, \quad (4.82)$$

where the driving pressure difference depends on the mean temperature  $\vartheta_m$  between inlet and outlet openings and on the coefficient of expansion  $\beta$  of air

$$\vartheta_m = \frac{\vartheta_e + \vartheta_a}{2}, \quad (4.83)$$

$$\Delta p = gh\delta \left( \frac{1}{1 + \beta\vartheta_0} + \frac{1}{1 + \beta\vartheta_m} \right), \quad (4.84)$$

where  $P_{\dot{V}}$  = heat flow through the coolant,  $\dot{V}$  = volume flow rate between inlet and outlet,  $c$  = heat capacity of air,  $\delta$  = specific mass of air,  $\vartheta_e$  = temperature of air at the inlet,  $\vartheta_a$  = temperature of air at the outlet,  $\Delta p$  = pressure difference, and  $S$  = flow resistance.

This means that heat can only be transferred through a coolant flow if there are both air inlet and air outlet openings, and these are at different heights.

The flow resistance  $S$  is determined by the air inlet and outlet openings, as well as by cross-sectional narrowings

$$S = S_e + S_a + S_q. \quad (4.85)$$

Flow resistance at the air inlet opening  $S_e$

$$S_e = \frac{\delta(1 + \beta\vartheta_e)}{2A_e^2} \left[ \zeta_e + \left( 1 - \frac{A_e}{A_{Ka}} \right)^2 \right]. \quad (4.86)$$

Flow resistance at the air outlet opening  $S_a$

$$S_a = \frac{\delta(1 + \beta\vartheta_a)}{2A_a^2} (\zeta_a + 1). \quad (4.87)$$

Flow resistance at a cross-sectional narrowing  $S_q$

$$S_q = \frac{\delta_0(1 + \beta\vartheta_q)}{2A_q^2} \zeta_q, \quad (4.88)$$

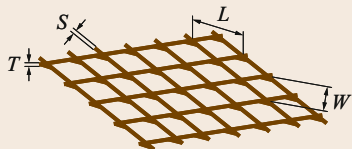

where  $A_{Ka}$  = cross section of the flow channel,  $A_e$  = cross section of the air inlet opening,  $A_a$  = cross section of the air outlet opening,  $A_q$  = cross section of the cross section's narrowing,  $\zeta_a$  = coefficient of resistance of the air flow at the inlet opening,  $\zeta_e$  = coefficient of resistance of the air flow at the outlet opening,  $\zeta_q$  = coefficient of resistance of the air flow at the cross section's narrowing, and  $\delta_0$  = specific mass of air at  $0^\circ\text{C}$ .

The resistance coefficients of the air flow  $\xi$  must be determined experimentally. Selected typical values are given in Tables 4.17–4.23.

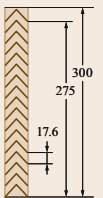

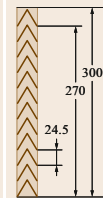

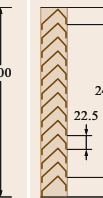

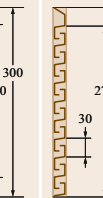

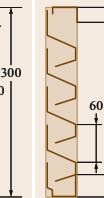

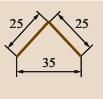

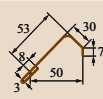

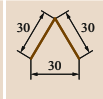

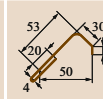

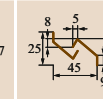

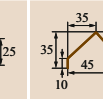

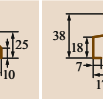

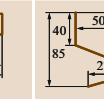

#### Thermal-Network Method

For the thermal calculation of simple, but extensive and complex arrangements, the heat-network method has proven to be very effective. The increased efforts for a necessary manual creation of the network are compensated by very short calculation times and a simple variation of the input parameters for comparative studies. The accuracy of the calculation depends on the correct selection of the design and material input parameters and the appropriately selected structure of the thermally simulated plant components and, generally, fully satisfies engineering requirements [4.2, 5, 23].

The heat-network method is based on the analogy (Table 4.24) between the electric and the thermal field and uses known solution algorithms in freely available software for network calculations in electrical engineering.

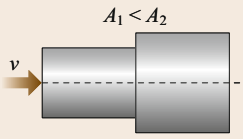

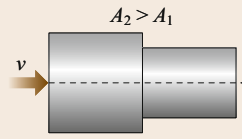

This makes it possible to display the thermal behavior of a device, which is a heat network, in an analog electrical network and to calculate its behavior for both stationary and transient operation (for examples, see Figs. 4.25–4.29), where  $P_V$  = power losses in the bus bar,  $P_{ca}$  = power losses in the capsule,  $C_{bar}$  = thermal capacity of bus bar,  $C_{ca}$  = thermal capacity of capsule,  $\vartheta_i$  = air temperature inside capsule, and  $\vartheta_{ca}$  = temperature of capsule.

For larger devices and systems, it makes sense to combine the different heat networks into modules for recurrent components, store them in a library, and then, depending on the respective application, only connect the finished modules.

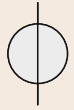

### Heating Test

During the heating test, it is necessary to assure that the limits of permissible excessive temperature  $\vartheta_{0,max}$  for the electrical conductors, the connections and the insulation, as well as the fastening and control elements at *continuous current load* or at the short-circuit current load are observed. In the short-circuit thermal test, a distinction must be made whether the short-circuit current is applied to the test object at no-load or when it has reached its operating temperature at normal load. These limit temperatures are specified in national and international standards (Sect. 4.2). The temperature-rise test is an energy test (4.2), which makes it clear that the temperature of the test object depends on several parameters:

**Table 4.23** Experimentally determined resistance coefficients  $\zeta$  for ventilation openings and cross-section changes, cross-section variations in flow channel (all dimensions in mm) (adapted from [4.5, 23])

Cross-section variation			
$\zeta (A_1/A_2)$	0.1	0.81	0.44
$\zeta (A_1/A_2)$	0.2	0.66	0.42
$\zeta (A_1/A_2)$	0.4	0.38	0.35
$\zeta (A_1/A_2)$	0.6	0.17	0.26
$\zeta (A_1/A_2)$	0.8	0.05	0.14

		$W \text{ (Ws)}$	$E_{th} \text{ (Ws) or (J), (1 Ws = 1 J)}$

- Ambient conditions (temperature, air flow)
- Adjacent walls (temperature, distance to the test object, emission behavior)
- Power supply to the test object (cross section, conductance, length)
- Arrangement of the test object (free, on test table, close to other test objects)
- Mounting (heat transfer or heat conduction on mounting)
- Temperature measurement (measuring method, measuring point, time variation).

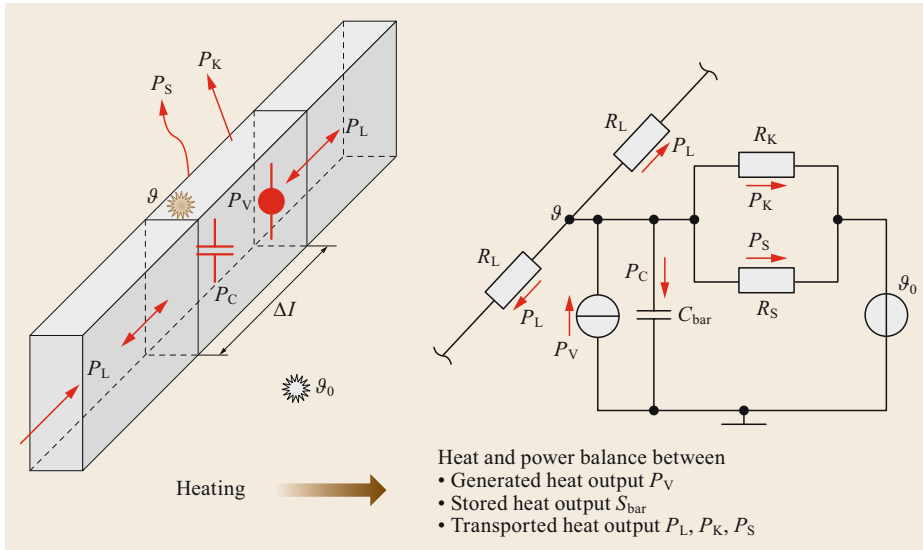

In order to make the test results comparable, standards for individual equipment groups define the ambient conditions and their permissible deviations. How-

ever, it should be noted that these conditions are not identical in different standards (Table 4.25).

The ambient conditions of the test chamber influence the test result, e.g., as follows.

- The ambient temperature  $\vartheta_0$  determines the heat transfer from the test object to the environment by convection.
- The temperature of the wall or lacquered steel doors  $\vartheta_w$  determines the heat transfer from the test object to the wall by radiation.

For  $\vartheta_0 \neq \vartheta_w$ , heat can be emitted uncontrollably by radiation to the wall. In this way, cold walls can influence the test result towards lower temperatures or apparently

**Fig. 4.25** Thermal network of a current-carrying bus conductor

**Fig. 4.26** Thermal network of a current-carrying encapsulated bus bar

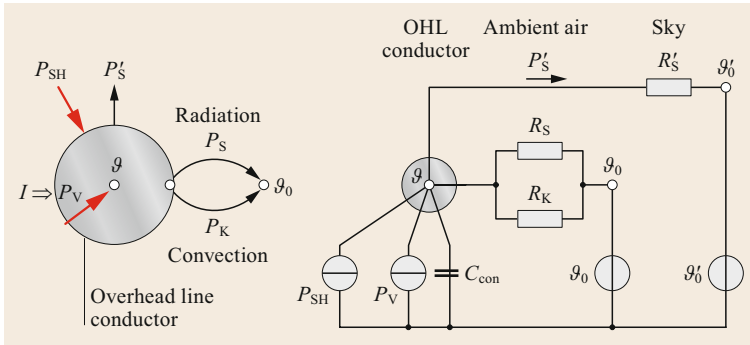

**Fig. 4.27** Thermal network of an air-installed cable;  $P_V$  = power losses in the bus bar,  $P_{\text{ex}}$  = power losses in the external concentric conductor,  $C_{\text{con}}$  = thermal capacity of cable conductor,  $C_{\text{ins}}$  = thermal capacity of cable insulation,  $C_{\text{ja}}$  = thermal capacity of cable jacket,  $\vartheta_{\text{ex}}$  = temperature of the external concentric conductor, and  $\vartheta_{\text{ja}}$  = temperature of cable jacket

higher current-carrying capacity of the test object (Table 4.26). This is possible despite observing the ambient air temperature through more intensive heat radiation, depending on the emission behavior of the test object.

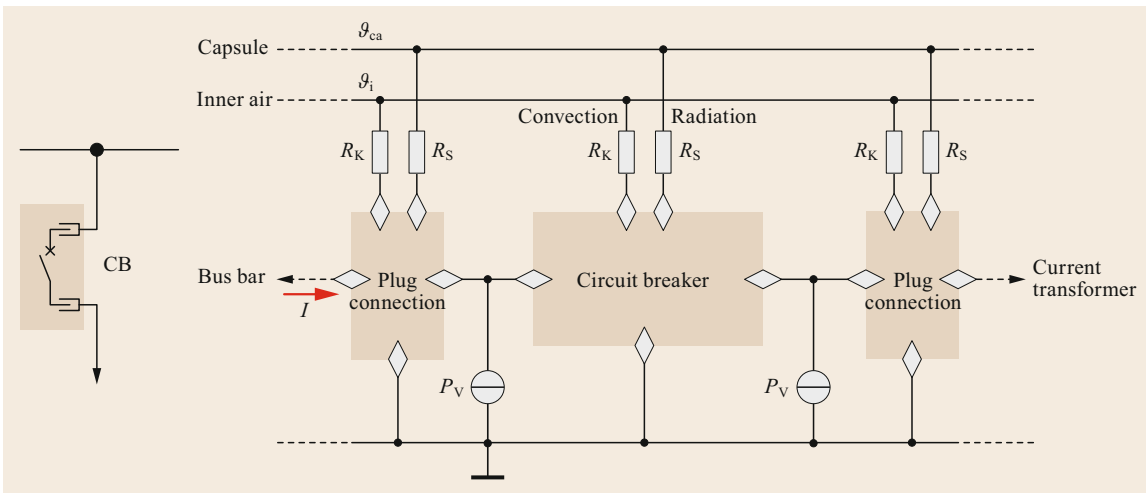

The permissible current-carrying capacity  $I$  of a test object becomes particularly clear for free, i.e., without enclosure, test arrangements, even at very low flow ve-

locities, influenced by the air flow in the test chamber (Fig. 4.30 and (4.78)).

It is particularly important to ensure that the temperature of the test object has reached its stationary final value when all thermal capacities are saturated, which can take many hours, especially in enclosed systems, such as equipment with insulating oil or solid insulation

**Fig. 4.28** Thermal network of an overhead line conductor;  $P_V$  = power losses in the OHL conductor,  $P_{SH}$  = power input from solar radiation,  $P'_S$  = heat transfer by radiation to sky,  $C_{con}$  = thermal capacity of OHL conductor, and  $\vartheta'_0$  = air temperature in the sky

Air flow in the test room ( $\text{m s}^{-1}$ )	–	–	$v_{air} \leq 0.5$
Wall temperatures in test room	No information in the standard		

((4.21) and Fig. 4.31). Standards usually accept that the stationary final value is reached when the temperature rise  $\Delta\vartheta < 1 \text{ K h}^{-1}$  [4.9, 10, 12].

The type of power supply, its cross section, conductance, and length are responsible for whether power is supplied or dissipated to the test object by heat conduc-

tion, which can strongly influence the temperature of the test object. The aim is to select the supply line in such a way that neither significant heat input nor output can occur. However, this is not always stipulated, especially in the standards for low-voltage switchgear. An oversized power supply cable draws far more heat

**Table 4.26** Heat test, influence of wall-temperature  $\vartheta_w$  on heat transfer  $P$

**Fig. 4.30a–c** Heat test, operating current of a free (a) and an encapsulated conductor (b) depending on air flow velocity  $v$  in the test chamber (c)

from the device under test than in practical use in a low-voltage switchgear and control gear. This means that, in practice, depending on the installation conditions, a low-voltage device may only be subjected to considerably less load than the value indicated on its rating plate (Figs. 4.32 and 4.33)

$$|P_L| = \frac{\lambda A}{d} \Delta\vartheta = \frac{\lambda A}{b} \Delta\vartheta, \tag{4.89}$$

$$b = \sqrt{\frac{\lambda A}{\alpha(\vartheta)U}}, \tag{4.90}$$

with Al:  $b \approx 0.3 \text{ m}$  and Cu:  $b \approx 0.4 \text{ m}$ .

Example: determine the influence of the power supply line on the thermal power dissipated from a 1000 A switchgear during the heating test. The temperature gradient along the feed line can vary significantly, i.e., from  $\Delta\vartheta = 70 \text{ K}$  at the connections of the test object to  $\Delta\vartheta = 50 \text{ K}$  at the power supply line (Fig. 4.34a); this depends on the cross section of the copper bus bars (here,  $2 \times (60 \times 5) \text{ mm}^2$ ). Assuming a permissible excess temperature at the connections of  $\Delta\vartheta = 70 \text{ K}$ , the power dissipated by heat conduction in the power supply line results in  $P_L = 70 \text{ W}$  with a load current of  $I = 1000 \text{ A}$  (Fig. 4.34b). While in this example painted bus bars ( $\epsilon = 0.9$ ) are used, a bare bus bar would only have a thermal

**Fig. 4.31** Heat test, heating curve dependent on the time constant  $\tau$  ( $\tau = C_{th}R_{th} = c\delta VR_{th}$ )

**Fig. 4.33** Dissipated heat output through heat conduction in the power supply conductors

output of  $P_L = 56$  W (Fig. 4.34c). Here, it becomes clear what influence the choice of the current-supply line has on the temperature of the test object.

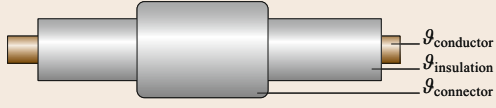

**Fig. 4.34a-c** Example: influence of the power supply conductor on the heat output dissipated from a switching device for  $I_n = 1000$  A. (a) Temperature distribution along the power supply conductor for different conductor cross sections ( $\Delta\vartheta =$  overtemperature), (b) dissipated heat output for each power supply conductor, (c) influence of the emission factor  $\varepsilon$  of the power supply conductor

### On the Temporary Current Overload Ability of Power Control Systems and Installations

Occasionally, it is intended to load existing bus bar arrangements and equipment with higher current than stationarily permissible, without exceeding the limit temperature.

**Table 4.27** Electric devices as a dynamic system

General	Input ( $x_{IN}(t)$ ) $\Rightarrow$	Dynamic system weighting function $\Rightarrow$	Output ( $x_{OUT}(t)$ )
Electrotechnical system	Current square $P_V \propto I^2$	Electric device	Temperatures at critical points $\vartheta_1$ $\vdots$ $\vartheta_n$
Example: solid insulated bus bar	$I^2$		$\vartheta_{\text{conductor}}$ $\vartheta_{\text{insulation}}$ $\vartheta_{\text{connector}}$

For *electrical equipment and drives*, ten corresponding operating modes – S1–S10 – for periodically recurring load cycles and short-term loads are defined in standards and are taken into account in the design and operation of the equipment by utilizing its heat capacity [4.24].

For *equipment and systems*, two possibilities can be used for current overload capability:

- The temperature signal follows the current signal with a time lag (Table 4.9, middle column).
- The ambient conditions (temperature, wind speed, solar radiation) determine the temperature of the equipment with their magnitude and time dependence.

For example, a low ambient temperature makes it possible to take advantage of the higher temperature difference up to the limit temperature. Also at higher wind speeds, forced convection results in better heat dissipation, which also permits a higher current load. Since the current load of conductors and equipment, as well as the heat output due to radiation and convection and the heat storage (input variables), vary over time, knowledge of the past is always required in order to determine the current load (output variable) permitted in the next time interval (Table 4.27). For not necessarily periodic, pulse-shaped input variables [4.14, 20],  $x_{IN}$  is the weight function,  $g(\tau)$  is a measure of how strong the input variables at the time  $t$  and at the period before ( $t - \tau$ ) influence the output variables  $x_{IN}$ ; this is expressed by the convolution integral

$$x_{OUT} = \int_0^t g(\tau)x_{IN}(t - \tau)d\tau. \quad (4.91)$$

Since the weight function  $g(\tau)$  is constant over a time interval  $\Delta T$ , the convolution integral for a time  $k$  can be

expressed as

$$x_{OUT}(k\Delta T) = \Delta T \sum_{l=0}^n g(l\Delta T)x_{IN}[(k-l)\Delta T] + x_{OUT0}, \quad (4.92)$$

where  $x_{IN}$  = input variable, e.g., current load, wind velocity,  $x_{OUT}$  = output variable, e.g., temperature at a critical location,  $g$  = weight function,  $t$  = time variable,  $\tau$  = runtime in convolution integral,  $\Delta T$  = time interval,  $k$  = time after measurement of the output variable during memory time,  $l$  = time difference +  $(l\Delta T)$  from time  $k$ , and  $x_{OUT0}$  = value of the output variable at the operating point  $x_{IN} = 0$ .

The weight functions  $g$  for the memory time of the conductor, the insulation, and the connection in Table 4.27 can be determined experimentally or by means of the heat-network method and, thus, serve to predict the temperature to be expected in the future depending on the future load current and the load history of the equipment. This way, in the next time interval  $(k + 1)\Delta T$ , the permissible current that does not violate the limit temperature  $\vartheta_{Gr}$  can also be calculated [4.20].

If one considers, initially in stationary operation, the influence of the ambient conditions, e.g., air temperature, wind velocity, etc., a significant influence on the temperature of the device can be determined. Using the example of an ACSR 380/50 overhead-line conductor (382-AL1/49-ST1A, outer diameter 27.0 mm) with the standardized boundary conditions [4.25], i.e.:

- Ambient temperature:  $\vartheta_0 = 35^\circ\text{C}$
- Wind velocity perpendicular to the line:  $v = 0.6\text{ m s}^{-1}$
- Permissible maximum conductor temperature:  $\vartheta_{Gr} = 80^\circ\text{C}$ .
- Permissible continuous current:  $I = 840\text{ A}$

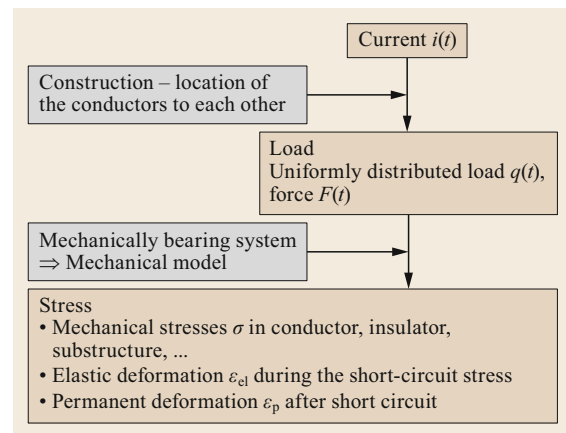

**Fig. 4.35a,b** Current-carrying capacity of a transmission-line conductor and of a high-voltage circuit breaker depending on ambient temperature and wind velocity (global radiation  $P_{SH} = 1000 \text{ W m}^{-2}$ , transverse flow with  $v = 0$  to  $5 \text{ m s}^{-1}$ , and ambient temperature  $\vartheta_0 = -10$  to  $+40^\circ\text{C}$ ). (a) Current-carrying capacity of a transmission-line conductor at a limiting temperature  $\vartheta_{Gr} = 80^\circ\text{C}$ , (b) current-carrying capacity of a high-voltage circuit breaker at a limiting temperature on contact elements  $\vartheta_{Gr} = 105^\circ\text{C}$  in comparison to the overhead line in (a)

its thermal rating can be determined by means of the heat-network method or by experiments in the wind tunnel (Fig. 4.35a). It should be noted that, for the rather unlikely case of wind velocities  $v < 0.6 \text{ m s}^{-1}$ , the thermal rating will decrease, while for wind velocities  $v > 0.6 \text{ m s}^{-1}$  and at ambient temperatures  $\vartheta_0 < 35^\circ\text{C}$  a higher thermal rating of the conductor is theoretically possible in the case the same ambient conditions apply along the line, and the limit conductor operating temperature  $\vartheta_{Gr} = 80^\circ\text{C}$  is not exceeded, and, therefore, the admissible sag limits are not violated [4.14]. However, these apparent reserves are reduced to a temporary *overload capacity of the conductor* by accelerated aging of connectors and clamps at higher temperatures (Sect. 4.3.3).

Furthermore, the thermal behavior of all other equipment in the current path must also be considered, which can differ considerably from that of the overhead conductor. For example, the influence of the wind on a high-voltage circuit breaker is comparatively much less than on an overhead-line conductor, so that the reserve calculated above can only be used to a limited extent (Fig. 4.35b); nevertheless, a certain temporary overload capacity may exist, taking into account the actual ambient temperature.

### 4.3.2 Mechanical Dimensioning

Current-conducting arrangements are stressed by the electric current  $i(t)$  not only thermally, but also mechanically, depending on the design and position of the conductors relative to each other. External mechanical loads may cause line loads  $q(t)$  and forces

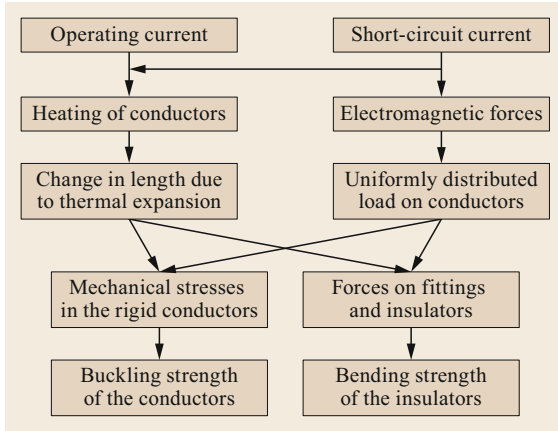

**Fig. 4.36** Emergence of mechanical stress

$F(t)$ , which lead to mechanical stresses in the conductors themselves and their support points, such as clamps, tap-offs, and insulators (Figs. 4.36 and 4.37). It goes without saying that these mechanical loads must not exceed the damage and deformation limits of the components of the electrical equipment [4.1, 26–33].

#### Load: Forces Due to Thermal Expansion

Forces due to thermal expansion result from a constrained expansion due to the heating of a current-carrying conductor and its insulation, especially under a short-term load. These forces can occur longitudinally and radially and be of static nature. They act so slowly that inertial forces caused by moving masses do not have to be taken into account.

**Fig. 4.37** Effects of electrical load on mechanical stress

The longitudinal expansion of a pinned but, flexurally stiff conductor (Fig. 4.38b) is

$$\Delta l = l \alpha_{th} \Delta \vartheta \Rightarrow \varepsilon_{th} = \alpha_{th} \Delta \vartheta, \quad (4.93)$$

where  $l$  = conductor length,  $\Delta l$  = thermal linear expansion,  $\alpha_{th}$  = coefficient of linear expansion (Table 4.28),  $\Delta \vartheta$  = heating of the conductor in relation to the initial state at  $\vartheta_0$ , where the conductor temperature is  $\vartheta > \vartheta_0$  at operating current, and  $\vartheta \gg \vartheta_0$  at short circuit current, and  $\varepsilon_{th}$  = relative elongation of the conductor ( $\Delta l/l$ ) by thermal expansion.

With a fixed conductor (Fig. 4.38c), a mechanical stress occurs in the conductor.

$$\sigma_{th} = E \alpha_{th} \Delta \vartheta = \varepsilon_{th} E = \frac{F_{th}}{A}, \quad (4.94)$$

where  $\sigma_{th}$  = mechanical stress in the conductor,  $E$  = modulus of elasticity (Table 4.28),  $F_{th}$  = compressive force in the conductor, and  $A$  = conductor cross section.

**Table 4.28** Modulus of elasticity  $E$ , coefficient of linear thermal expansion  $\alpha_{th}$ , and the limit elastic stress  $\sigma_{0.2}$  of selected conductor materials

Material	$E$ (kN mm <sup>-2</sup> )	$\alpha_{th}$ ( $\times 10^{-6}$ K <sup>-1</sup> )	$\sigma_{0.2}$ (N mm <sup>-2</sup> )
Aluminum (Al) F7	60–65	23.8	34
Aluminum (Al) F9			62
Copper (Cu)	110	16.5	> 220
Brass (Ms)	85	20.2	60–100
Steel (St)	210	11.5	200–400

This will cause a compression load on the conductor and a corresponding bending load  $F_{th}$  on the insulator at the support.

$$F_{th} = AE \alpha_{th} \Delta \vartheta. \quad (4.95)$$

Example: fixed bus bar made from aluminum alloy (AlMgSi)  $A$  (40 × 10) mm<sup>2</sup>;  $\Delta \vartheta = 70$  K;  $E = 69$  kN/mm<sup>2</sup>, and  $\alpha_{th} = 23.4 \times 10^{-6}$  K<sup>-1</sup>,

$$\begin{aligned} \sigma_{th} &= E \alpha_{th} \Delta \vartheta = 69 \frac{\text{kN}}{\text{mm}^2} \cdot 23.4 \times 10^{-6} \frac{1}{\text{K}} \cdot 70 \text{ K} \\ &= 113 \frac{\text{N}}{\text{mm}^2}, \end{aligned} \quad (4.96)$$

$$\begin{aligned} F_{th} &= AE \alpha_{th} \Delta \vartheta = 400 \text{ mm}^2 \cdot 113 \frac{\text{N}}{\text{mm}^2} \\ &= 45.21 \text{ kN}. \end{aligned} \quad (4.97)$$

The top of the support insulator is subjected to an upheaval bending force of  $F_{th} = 45.21$  kN.

With straight, flexurally stiff conductors, such as tubular bus bars, the compressive force leads to buckling  $\Delta s$  of the conductor, depending on the type of clamping at the support (Fig. 4.39). If the elastic limit

**Fig. 4.38a,b** Thermal expansion forces on a rigid conductor

**Fig. 4.39** Bending  $\Delta s$  of conductors and reduction of the effective length  $l_v$  depending on the type of clamping/fixing

**Fig. 4.40** Thermal expansion forces in encapsulated bus bar systems (GIL, GIS)

of the conductor material is exceeded, the maximum buckling load depends on the reduced length  $l_v$  of the conductor, the slenderness ratio  $s_r$ , and the radius of inertia  $i$ , and if exceeded will cause excessive plastic deformation by abrupt buckling.

$$s_r = \frac{l_v}{i}, \tag{4.98}$$

$$i = \sqrt{\frac{I}{A}}, \tag{4.99}$$

$$\sigma_{Gr} = \pi \sqrt{\frac{E}{\sigma_{0.2}}} \tag{4.100}$$

$$\Delta s_p = \sqrt{\frac{3}{8}} l_v \Delta I_o, \tag{4.101}$$

where  $S_r$  = slenderness ratio,  $l_v$  = reduced length according to type of clamping (Fig. 4.39),  $i$  = radius of gyration,  $I$  = moment of inertia of the cross section (Table 4.29),  $A$  = area of the cross section,  $\sigma_{GR}$  = limit buckling stress, and  $\Delta s_p$  = buckling (plastic deformation).

Comparable loads result from thermal expansion in encapsulated gas-insulated switchgear (GIS) and lines (GIL). In this case, the different temperature increases of the conductor and the enclosure ( $\Delta\theta_L > \Delta\theta_{ca}$ ) and, thus, their differing elongations have to be considered (Fig. 4.40).

In order to reduce such mechanical loads on the conductors and support points, sliding bearings, expansion bands, or expansion clamps are used in practice (Figs. 4.5 and 4.41).

**Table 4.29** Moments of inertia and resistance of different conductor cross sections in the direction of uniformly distributed load  $q$

Cross section	Moment of inertia	Moment of resistance
	$I = \frac{bh^3}{12}$	$W = \frac{bh^3}{6}$
	$I = \frac{BH^3 - bh^3}{12}$	$W = \frac{BH^3 - bh^3}{6H}$
	$I = \frac{\pi d^4}{64}$	$W = \frac{\pi d^3}{32}$
	$I = \frac{\pi(D^4 - d^4)}{64}$	$W = \frac{\pi(D^4 - d^4)}{32D}$

**Table 4.30** Comparison of coefficients of linear thermal expansion  $\alpha_{th}$  for conductor and insulation materials

Conductor material	$\alpha_{th}$ ( $\times 10^{-6} K^{-1}$ )	Insulation material	$\alpha_{th}$ ( $\times 10^{-6} K^{-1}$ )
Aluminum	23.8	Epoxy resin	30
Copper	16.5	Quartz	0.5
Brass	11.5	Glass	4–10
Steel	10.5	Porcelain	3.8–7
Cast iron	18.4	Polyethylene	$\approx 200$

Thermomechanical stresses in current-conducting arrangements also occur when conductor and insulation materials with different coefficients of thermal linear expansion  $\alpha_{th}$  are used and are firmly connected (cast-resin insulation, cables) (Table 4.30).

For solid insulated conductors, especially for insulation made of filled epoxy resin (insulating material in the *glass state*, and, thus, not elastic), the *radial thermal compressive stresses*  $\sigma_r$  can cause considerable hoop stresses  $\sigma_t$  at the circumference of the insulation which, in turn, can cause the insulation to burst and, thus, fail (Fig. 4.42) [4.27].

In low and medium voltage systems at *uninterrupted operation*, it is critical to consider that the supporting and clamping components also heat up and expand, thus, the differences in extension shall be used for the calculation. In the *case of a short circuit*, adiabatic heating of the conductor can be assumed, which is considered particularly critical for high short-circuit-currents and long short-circuit periods.

**Fig. 4.41** Examples for bus bar supports and expansion clamps

**Fig. 4.42** Radial pressure, tangential, and tensile stresses in a heated solid-insulated conductor;  $\sigma_r$  = radial compressive stress,  $\sigma_t$  = tangential tensile stress,  $\sigma_z$  = axial tensile stress,  $\vartheta_L$  = temperature of conductor,  $\vartheta_1$  = temperature of insulation depends on radius  $r$ ,  $r$  = radius, and  $\vartheta_0$  = ambient temperature

#### Loads Due to Electromagnetic Forces on Conductors – Individual and Distributed Forces on Conductors and Supports

Conductors through which current flows are surrounded by a magnetic field  $\mathbf{B}$ , whereby a force  $\mathbf{F}$  or a line load  $q$  is created on adjacent, parallel conductors that are also current-carrying (effect). Depending on whether the currents of the parallel conductors flow in the opposite or in the same direction, the conductors will repel or attract each other (Fig. 4.43 and Table 4.31).

The differential force  $d\mathbf{F}$  depends on the current  $i$ , the effective length  $dx$  of the conductor, and the magnetic induction  $\mathbf{B}$  at this location (Fig. 4.44).

$$d\mathbf{F} = i(dx \times \mathbf{B}) . \tag{4.102}$$

In the case where  $dx$  and  $d\mathbf{B}$  are orthogonal to each other, which is true for many applications, this relationship is simplified to

$$dF = iBdx . \tag{4.103}$$

Dividing the force  $d\mathbf{F}$  by the length  $dx$  one obtains the related line load  $q$

$$q = \frac{dF}{dx} = iB . \tag{4.104}$$

The Biot–Savart law enables the calculation of the magnetic field strength  $dH_{21}$  caused by current  $i_1$  in one

**Fig. 4.43** Electromagnetic forces on current-carrying, parallel conductors – right-hand rule. Carrying conductors arise between current-electromagnetic forces that have a static and/or dynamic stress result

conductor at a distance  $r$  of conductor point P on the adjacent conductor 2 (Figs. 4.44 and 4.45)

$$dH_{21} = \frac{i_1}{4\pi} \frac{r \times dy}{r^3} \tag{4.105}$$

With

$$dy \times r = r dy \sin \delta \quad \text{and} \quad B = \mu H \tag{4.106}$$

one obtains

$$dB_{21} = i_1 \frac{\mu_0}{4\pi} \frac{\sin \delta}{r^2} dy, \tag{4.107}$$

and by integration over  $dy$

$$B_{21} = i_1 \frac{\mu_0}{4\pi} \int_{y_1}^{y_2} \frac{\sin \delta}{r^2} dy, \tag{4.108}$$

**Fig. 4.44** Electromagnetic forces on current-carrying conductors;  $i$  = reason,  $B$  = mediation,  $F$  = effect

**Fig. 4.45** Magnetic field strength  $H_{21}$  in conductor point P at distance  $r$  from conductor 1. The following parameters must be taken into account: time curve of the currents  $i_1$  and  $i_2$ , geometry of the arrangement, characterized by  $y_1, y_2, r$ , and  $\delta$  (or  $a$ )

and with (4.104) the line load  $q$  can be calculated as

$$q = \frac{dF}{dx} = i_1 i_2 \frac{\mu_0}{4\pi} \int_{y_1}^{y_2} \frac{\sin \delta}{r^2} dy. \tag{4.109}$$

The load  $F$ , which acts on the supports of a current path, becomes

$$F = i_1 i_2 \frac{\mu_0}{4\pi} \int_{y_1}^{y_2} \frac{\sin \delta}{r^2} dy dx, \tag{4.110}$$

**Table 4.31** Electromagnetic forces on current-carrying parallel conductors

Application of the right-hand rule (R-M-E rule)		
	Opposite currents $+I_1; -I_2$	Parallel currents $+I_1; +I_2$
Reason R		
Mediation M	Overlay of the magnetic fields $H_1$ and $H_2$ ⇒ Field enhancement between the conductors	Overlay of the magnetic fields $H_1$ and $H_2$ ⇒ Compensation of the magnetic fields between conductors ⇒ Fields outside the conductors determine the effect of $F$
Effect E	Effect of forces ⇒ conductors repel	Effect of forces ⇒ conductors attract/approach

where  $y$  or  $dy =$  conductor, from which  $B_{21}$  is generated,  $x$  or  $dx =$  conductor on which the line load acts, and  $\mu_0 = 4\pi \times 10^{-7} \text{Vs/Am}$  – magnetic permeability.

For the time dependence of the line load  $q(t)$  between parallel conductors and the force  $F(t)$ , the type of short circuit and the time dependence of the short-circuit current  $i(t)$  must be observed.

*Steady-state short-circuit current.*

$$i = \hat{I}_K \sin \omega t, \tag{4.111}$$

and

$$\hat{I}_K = \sqrt{2}I_K \tag{4.112}$$

gives a line load  $q(t)$  of

$$q(t) = \frac{\mu_0}{2\pi a} \hat{I}_K^2 \sin 2\omega t.$$

Which, with

$$\sin 2x = \frac{1}{2}(1 - \cos 2x) \tag{4.113}$$

becomes

$$q(t) = \frac{\mu_0}{2\pi a} \left(\sqrt{2}I_K\right)^2 \frac{1}{2}(1 - \cos 2\omega t), \tag{4.114}$$

$$q(t) = \frac{\mu_0}{2\pi a} I_K^2 (1 - \cos 2\omega t) \tag{4.115}$$

with a DC and a AC component (Fig. 4.46)

$$q_+(t) = \frac{\mu_0}{2\pi a} I_K^2, \tag{4.116}$$

$$q_-(t) = -\frac{\mu_0}{2\pi a} I_K^2 \cos 2\omega t. \tag{4.117}$$

*Remote generator short circuit with decaying DC component and symmetrically driving voltage without tran-*

**Fig. 4.46** Uniformly distributed load  $q(t)$  between parallel conductors at a continuous short-circuit current  $i(t)$

**Fig. 4.47** Short circuit remote from generator, time course of short-circuit current  $i(t)$  and voltage  $u(t)$  with impedance angle  $\varphi_z$  (phase displacement  $u$  and  $i$  at stationary short-circuit current  $\varphi_z = \arctan(X/R)$ ) and phase angle of voltage at the time of short-circuit  $\varphi_u$

sient component due to decay processes in the generator ( $I''_K = I_K$ ) (Fig. 4.47)

$$i = \sqrt{2}I''_K \left[ \underbrace{e^{-\frac{R}{X}\omega t} \sin \alpha + \sin(\omega t - \alpha)}_{\text{for crest factor } \kappa \text{ see Fig. 4.48}} \right], \tag{4.118}$$

with  $R/X =$  ratio of resistance to reactance of the short-circuit current path, where

$$\alpha = \varphi_z - \varphi_u. \tag{4.119}$$

The maximum current (Fig. 4.49) takes place at:

- Phase angle  $\varphi_u = 0$  (short circuit in voltage zero crossing)
- Impedance angle at short-circuit entry  $\varphi_z \approx 90^\circ$  ( $R/X \rightarrow 0$ ).

**Fig. 4.48** Crest factor  $\kappa$  for a remote short-circuit depending on the  $R/X$  ratio of the upstream network

**Fig. 4.49** Short-circuit remote from generator, short-circuit current  $i(t)$ , voltage  $u(t)$ , and uniformly distributed load  $q(t)$  with phase angle  $\varphi_u = 0$  and  $R/X = 0.05$

The maximum current over time takes place at

$$t - \varphi_Z \approx \frac{\pi}{2} \rightarrow \omega t = \frac{\pi}{2} + \varphi_Z = \pi, \quad (4.120)$$

which, at a mains frequency of  $f = 50$  Hz, corresponds to a time of

$$t = \frac{\pi}{2\pi f} = \frac{1}{2f} = \frac{1}{100} = 10 \text{ ms}. \quad (4.121)$$

For a real high-voltage network with  $R/X = 0.05$  and, thus,  $\varphi_Z = 87.1$ , and, therefore  $\sin \alpha \approx 1$  a decaying DC component as per (4.118) with:

- $R/X = 0.05 \rightarrow X/R = 20$
- $e^{-t/\tau}$  with a time constant,

$$\tau = \frac{L}{R} = \frac{X}{\omega R} = \frac{20 \text{ s}}{2\pi 50} = 64 \text{ ms}. \quad (4.122)$$

Thus, the maximum current over time at  $t = 10$  ms, the value of the decaying exponential function becomes

$$e^{-\frac{10 \text{ ms}}{64 \text{ ms}}} = 0.855, \quad (4.123)$$

which means that, at this point in time, the DC component has dropped to a value of 85.5% due to the damping. With the crest factor  $\kappa$ , the peak short-circuit current  $i_p$  can be calculated as

$$i_p = \sqrt{2} \kappa I_K'', \quad (4.124)$$

where (with (4.123))

$$\kappa = 0.855 + 1 = 1.855. \quad (4.125)$$

The crest factor cannot, theoretically, exceed the value  $\kappa = 2$ ; in practical cases it is usually  $\kappa \leq 1.8$ .

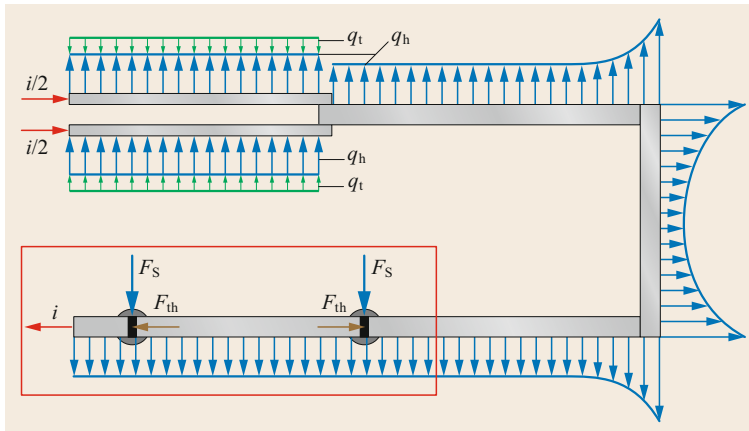

The peak short-circuit current  $i_p$  is the maximum amplitude occurring immediately after the short circuit and is decisive for the design of the mechanical strength of the current-conducting arrangement. The stress over time curve due to the line load  $q(t)$  depends on the  $R/X$  ratio of the feeding network and, thus, on the time function of the short-circuit current  $i(t)$  (Table 4.32) as well as the phase angle of the voltage  $\varphi_u$  at the instant the short-circuit occurs (Fig. 4.47).

Selected practical examples of electromagnetic forces  $F$  on support points (insulators) and line loads  $q$  on conductors in electrical installations (Figs. 4.50 and 4.51) or on contacts in electrical connections and on switching contacts can be calculated with the equations in Table 4.33 (maximum values) [4.1, 26].

For conductors with rectangular cross section, a mechanically effective main conductor spacing of  $a_m$  is considered, which depends on the conductor height  $d$ , its width  $b$ , and the geometric center distance  $a$  (Fig. 4.52)

$$\frac{1}{a_m} = \frac{1}{b} \left[ \varphi \left( \frac{b}{a} \right) + \frac{d^2}{a^2} \eta \left( \frac{b}{a} \right) \right], \quad (4.126)$$

**Table 4.32** Short-circuit remote from generator, short-circuit current  $i(t)$  and uniformly distributed load  $q(t)$ , and examples for several  $R/X$ -ratios

**Fig. 4.50** Electromagnetic forces  $F$  and uniformly distributed load  $q(t)$ . (Top view).  $q_h$ : uniformly distributed load between main conductors;  $q_t$ : uniformly distributed load between subconductors;  $F_S$ : electromagnetic force at fittings and insulators;  $F_{th}$ : thermal expansion force

**Fig. 4.51** Electromagnetic and thermal expansion force on supports (fittings and insulators), side view.  $F_S$ : electromagnetic force on fittings and insulator;  $F_{th}$ : thermal expansion force;  $M_S(z)$ : moments at insulator caused by electromagnetic force;  $M_{th}(z)$ : moments at insulator caused by thermal expansion force

**Table 4.33** Uniformly distributed load and force for selected arrangements

Arrangement and application	Schema	Uniformly distributed load or force
Parallel, endless long conductors e.g., overheadline conductors, substation bus bar (opposing currents, conductors repel each other)		$q = \frac{i_1 i_2 \mu}{2\pi a}$
Bundled conductors, subconductors in bus bars (parallel conductor, conductors attract)		
Conducting arrangement with 90°-angles e.g., bus bar derivation, cross connection of parallel conductors		$q = \frac{i^2 \mu}{4\pi x}$
Circular ring e.g., winding of a coil (radial forces to the outside)		$q_r = \frac{i_2 \mu}{2\pi R} \left( \ln \frac{8R}{r} - 0.75 \right)$ applies for: $R \gg r$
Circles next to each other e.g., uniformly distributed load between windings of a coil (conductors repel each other)		$q = \frac{i_1 i_2 \mu}{2\pi a}$ $F = i_1 i_2 \mu \frac{R}{a}$ applies for: $\frac{R}{a} > 2$
Conducting arrangement with several corners e.g., MV-insulator, MV-circuit breaker with trolley, NH-fuse links (forces try to open the current path)		At both corners each $q = \frac{i^2 \mu}{4\pi x}$
Contact point in a connection e.g., plug-in connectors, switching contacts (lift-off force)		$F \approx \frac{i^2 \mu}{4\pi} \ln \frac{r_2}{r_1}$

**Fig. 4.52** Parallel main conductors with rectangular cross section

whereby

$$\varphi\left(\frac{b}{a}\right) = 2 \arctan\left(\frac{b}{a}\right) - \frac{a}{b} \ln\left[1 + \left(\frac{b}{a}\right)^2\right], \quad (4.127)$$

$$\eta\left(\frac{b}{a}\right) = \frac{bd^2}{6a(a^2 + b^2)}. \quad (4.128)$$

For bus bars with several subconductors ( $a_s < b$ ) (Fig. 4.53), the line load is calculated as

$$q_s = \left(\frac{\hat{i}}{2}\right)^2 \frac{\mu_0}{2\pi a_s}, \quad (4.129)$$

where

$$\frac{1}{a_s} = \frac{1}{b} \left[ \varphi\left(\frac{b}{a_t}\right) + \left(\frac{d}{a_t}\right)^2 \eta\left(\frac{d}{a_t}\right) \right]. \quad (4.130)$$

In symmetrical three-phase systems, different currents flow in the three conductors when a three-pole short circuit occurs:  $i_{L1}$ ,  $i_{L2}$ , and  $i_{L3}$ , whose mechanical load effects overlap. Two typical cases in the praxis are the arrangement of the three conductors in one plane with a distance  $a$  and the arrangement of the conductors in an equilateral triangle.

*Conductors in one plane.* Line currents  $i_L$  (Fig. 4.54)

$$i_{L1} = \sqrt{2I''_{K(3)}} \left[ e^{-\frac{R}{X}\omega t} \sin \alpha + \sin(\omega t - \alpha) \right], \quad (4.131)$$

$$i_{L2} = \sqrt{2I''_{K(3)}} \left\{ e^{-\frac{R}{X}\omega t} \sin\left(\alpha + \frac{2\pi}{3}\right) + \sin\left[\omega t - \left(\alpha + \frac{2\pi}{3}\right)\right] \right\}, \quad (4.132)$$

$$i_{L3} = \sqrt{2I''_{K(3)}} \left\{ e^{-\frac{R}{X}\omega t} \sin\left(\alpha + \frac{4\pi}{3}\right) + \sin\left[\omega t - \left(\alpha + \frac{4\pi}{3}\right)\right] \right\}. \quad (4.133)$$

Static line loads  $q_{pe}$

$$q_{L1(3)} = \frac{\mu_0}{2\pi a} \left( i_{L1}i_{L2} + \frac{i_{L1}i_{L3}}{2} \right), \quad (4.134)$$

$$q_{L2(3)} = \frac{\mu_0}{2\pi a} (i_{L2}i_{L1} - i_{L2}i_{L3}), \quad (4.135)$$

$$q_{L3(3)} = \frac{\mu_0}{2\pi a} \left( -i_{L2}i_{L3} - \frac{i_{L1}i_{L3}}{2} \right). \quad (4.136)$$

This results in:

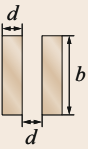

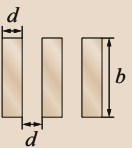

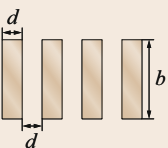

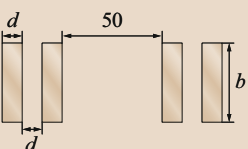

- Phase conductors L1 and L3 moving outwards by the resulting line load.
- The resulting line load on phase conductor L2 is zero.
- The sum of all line loads is zero at all times.

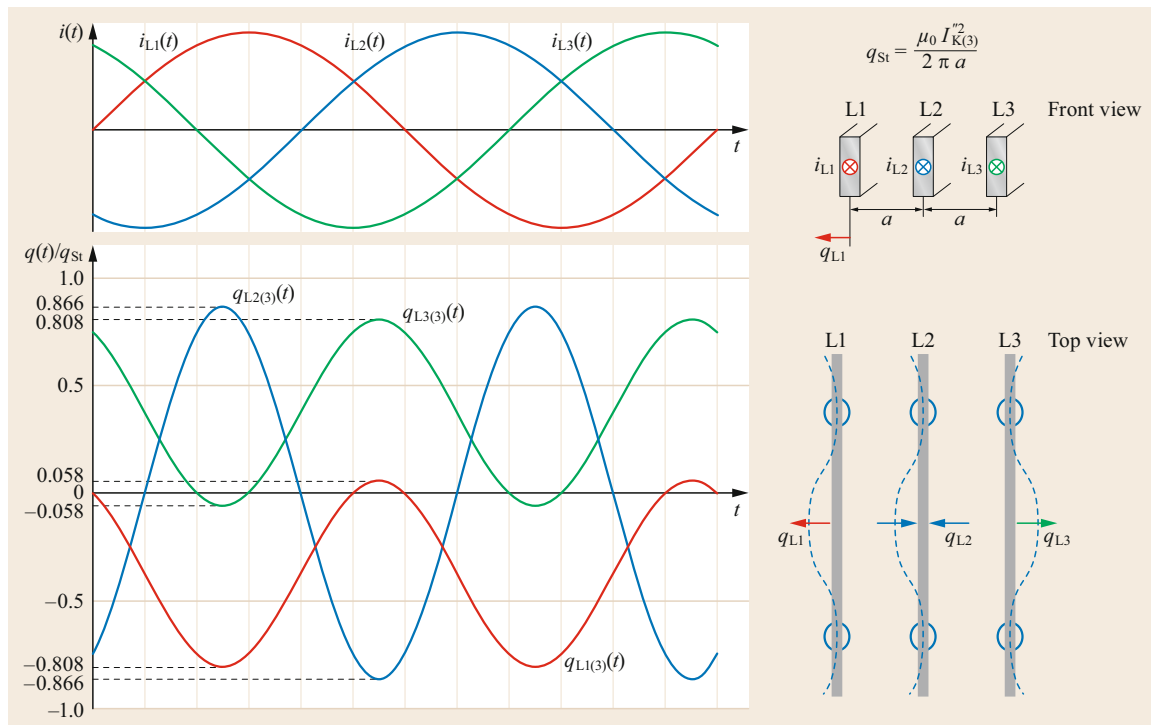

*Conductors in an equilateral triangle.* The vectors of the forces act in different directions (attracting and repulsive) depending on time, and they have to be added for every time instant  $t$  vectorially, resulting in a lo-

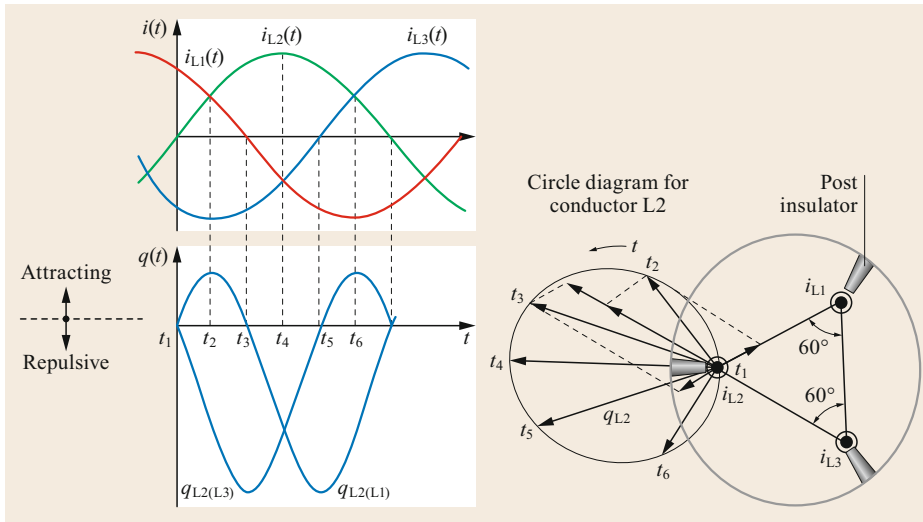

**Fig. 4.53** Uniformly distributed load at main and subconductor arrangements ( $a$  = geometric center-to-center distance of the main conductors,  $a_t$  = geometric center-to-center distance of the subconductors,  $a_m$  = effective main conductor spacing,  $a_s$  = effective subconductor spacing (Table 4.34),  $b$  = width of the rectangular conductor,  $d$  = height of the rectangular conductor,  $i/2$  = current per subconductor (with two subconductors),  $q_m$  = line load due caused by the main conductors,  $q_s$  = line load by the subconductors)

**Table 4.34** Effective subconductor spacing  $a_s$  for a rectangular cross section (all dimensions given in mm)

**Fig. 4.54** Short-circuit current – uniformly distributed load profiles with three-pole short circuit – one-level arrangement

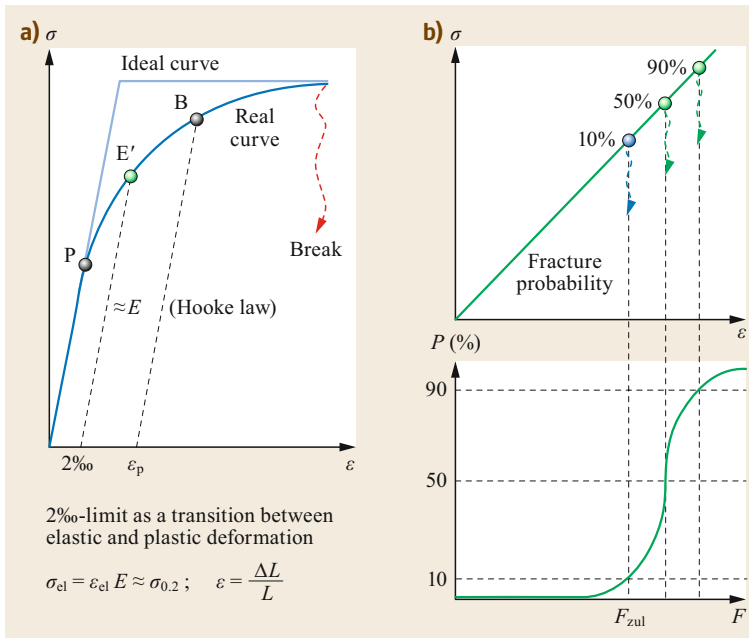

**Fig. 4.55** Short circuit current – uniformly distributed load profiles with three-pole short circuit – arrangement in triangle

cus curve that is run through once in each half-wave of the current. The resulting forces always act outwards, so that the support insulators should ideally be arranged in such a way that they are subjected to compression. The sum of all line loads is zero at all times (Fig. 4.55).

**Mechanical Stress**

*Elastic and plastic deformation of current paths under short-circuit current load.* The load of current-conducting arrangements by short-circuit currents leads to mechanical stresses  $\sigma$  on the conductors

(L), the insulators (I), and the structural substructure (U). With metals (conductor, substructure), this leads to elastic deformation ( $\sigma < \sigma_{el} \approx \sigma_{0.2} \Rightarrow \epsilon < \epsilon_{el}$ ) or, for larger stresses, to permanent plastic deformation ( $\sigma = \sigma_p > \sigma_{0.2} \Rightarrow \epsilon = \epsilon_p > \epsilon_{el}$ ). When the material strength is exceeded ( $\sigma_b$ ), the metal will fail (Fig. 4.56a). In the case of brittle insulating materials in the glass state, the failure occurs directly after the slightly elastic state without prior permanent deformation (Fig. 4.56b). Depending on the material structure, its strength is subject to  $\sigma_b$  scatters and is described by a distribution function for the probability of failure.

**Fig. 4.56a,b** Behavior of materials under mechanical stress. (a) Conductors/metals, (b) insulating materials in vitreous state

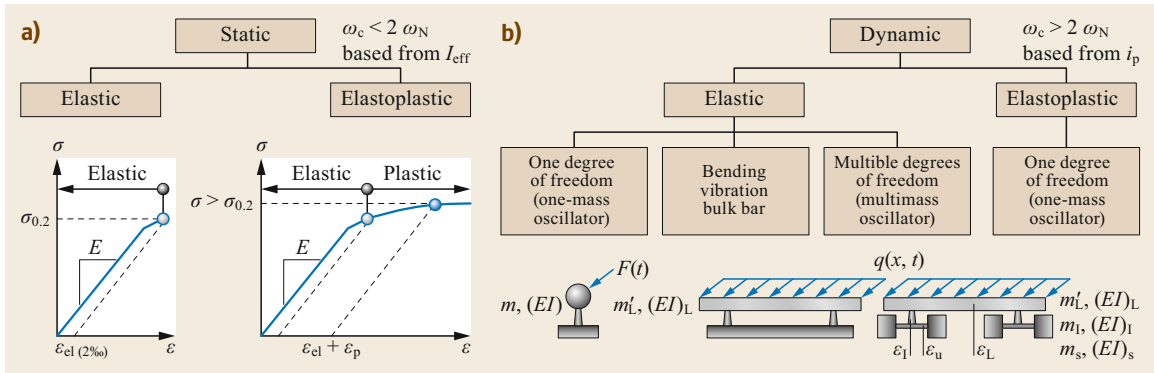

Fig. 4.57 (a) Static and (b) dynamic models for mechanical stress due to short-circuit currents

Fig. 4.58 Models for mechanical stress due to short-circuit currents, flexibility of conducting systems

If the mechanical natural frequencies  $f_c$  – which is caused by the line load  $q(t)$  or the force  $F(t)$  – of the stressed conductors – insulators and the substructure are considerably lower than twice the electrical mains frequency  $f_n$  (based on the current peak load  $\hat{I}_{max}$ ), said components cannot follow the line load time curve  $q(t)$ , which oscillates with a frequency of  $2 f_n$  (Fig. 4.46), and thus a static model can be used for the calculation of the mechanical stresses (spatial problem). If, on the other hand, the natural frequencies are significantly greater than twice the mains frequency, a dynamic stress (spatio-temporal problem) must be assumed (Fig. 4.57), whereby, taking into account the flexibility (elasticity) (Fig. 4.58), a distinction must be made between single-mass oscillators, mass-covered beams, and multimass oscillators, which are to be treated differently.

That *elastostatic model* (Fig. 4.57) can be used under the following conditions:

- The arrangement can follow the load without delay  $\rightarrow f_c \gg 2f_n$  (very high bending stiffness of the supporting elements or insulators  $(EI)_I$  and torsional stiffness of the substructure  $(GI)_U$ ).
- Step-like load changes are not considered.
- Application of mechanical equivalents (Fig. 4.59):
  - Beam fixed on both sides (central field of a bus bar)
  - Beam fixed on one side and pinned on the other (edge field of a bus bar)
  - Beam fixed on one side (support insulator).

For an elastically deformable beam with transverse oscillations, this partial differential equation applies

$$\frac{\partial^2}{\partial x^2} \left( EI \frac{\partial^2 v}{\partial x^2} \right) + \frac{\partial}{\partial x} \left( m \frac{\partial^2 v}{\partial t^2} \right) + \frac{\partial}{\partial x} \left( 2\delta m \frac{\partial v}{\partial t} \right) = q(t, x), \quad (4.137)$$

where  $m$  = mass, and  $\delta$  = density,  $v$  = deflection.

Under the conditions of a constant mass per unit of length, a constant bending stiffness  $(EI)$  and a constant line load  $q$ , (4.54) is simplified to

$$EI \frac{\partial^4 v}{\partial x^4} + m \frac{\partial^2 v}{\partial t^2} + 2\delta m \frac{\partial v}{\partial t} = q(t). \quad (4.138)$$

For the static case ( $\partial/\partial t = 0$ ), the differential equation of elastic bending (Table 4.35) results.

The constants  $C_1$  to  $C_4$  result from the boundary conditions for the static model (clamping conditions) (Table 4.36).

Table 4.35 Differential equation of elastic bending

Mechanical quantity	Differential equation
Line load	$EI \frac{\partial^4 v}{\partial x^4} = q$
Shear force	$EI \frac{\partial^3 v}{\partial x^3} = FQ(x) = qx + C_1$
Bending moment	$EI \frac{\partial^2 v}{\partial x^2} = M(x) = q \frac{x^2}{2} + C_1 x + C_2$
Bending angle	$EI \frac{\partial v}{\partial x} = EI v'(x) = q \frac{x^3}{6} + C_1 \frac{x^2}{2} + C_2 x + C_3$
Deflection	$EI v = EI v(x) = q \frac{x^4}{24} + C_1 \frac{x^3}{6} + C_2 \frac{x^2}{2} + C_3 x + C_4$

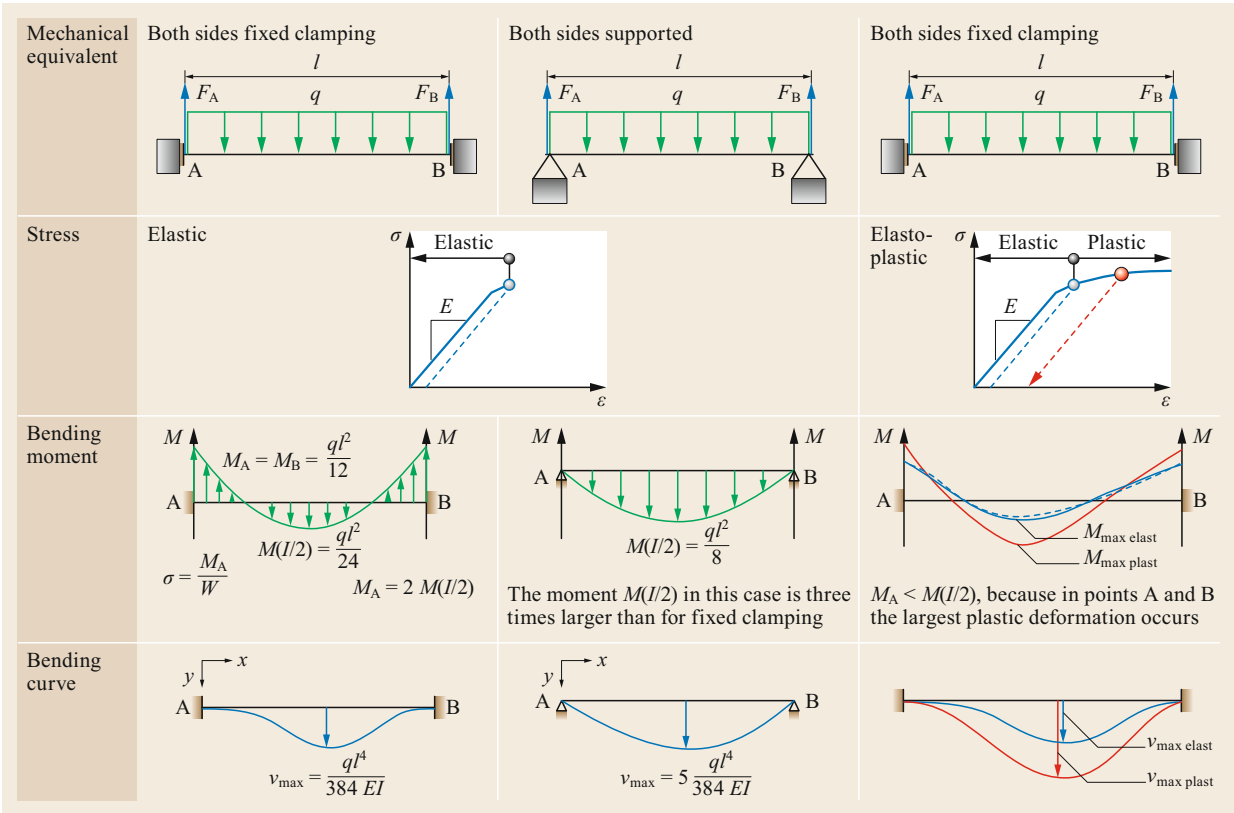

Fig. 4.59 Reactions of a conductor rail to the static load

Table 4.36 Clamping conditions in the static models

Clamping conditions	Seriousness	Stipulation	Constant
Fixed	No deflection	$v = 0$	$C_3 = 0$
	No deflection angle	$\frac{dv}{dx} = 0$	$C_4 = 0$
Pinned	No deflection	$v = 0$	$C_2 = 0$
	No bending moment	$\frac{d^2v}{dx^2} = 0$	$C_4 = 0$
Free	No bending moment	$\frac{d^2v}{dx^2} = 0$	$C_1 = 0$
	Zero shear force	$\frac{d^3v}{dx^3} = 0$	$C_2 = 0$

The *elastoplastic model* (Fig. 4.57) can be applied under the following conditions:

- The application is similar to the elastostatic model, however, the plastic properties of the conductor materials are also taken into account.
- The model describes the behavior of the flexurally stiff conductors in the overall system.

- Common materials for support insulators (e.g., porcelain, epoxy resin) are practically not plastically deformable. From this it follows that they will fail at the end of their elastic range (Fig. 4.56b).

The following ideas are behind the elastoplastic model:

- Materials can be subjected to higher loads, in which the limit loads are derived from their plastic behavior and the permanent deformation.
- Permanent deformation must not inadmissibly reduce the functionality of the device and/or the breakdown voltage between deflected conductors.
- The calculation of the maximum permanent deflection depends on the load.
- Edge stresses of the bending beam are smaller, and edge strains are higher than calculated for the elastic case.
- The permanent deformation is calculated numerically as a function of the line load using experimentally determined stress-strain curves.

Dynamic models (Fig. 4.57) apply under the following conditions:

- After displacement from the equilibrium position following a damped oscillation with eigenfrequency, the mechanical stresses return to zero.
- Preferred application when a large mass is supported by an elastically deformable element, and a time-varying force acts on the mass (e.g., elastic support insulator  $I$  fixed on one side and carrying a conductor  $L$ ).
- System elements behave elastically:
  - Applies in good approximation to support insulators up to failure.
  - Applies to metals (conductors, substructure), as they can deform plastically.
  - Only qualitative comparison between elastostatic and elastodynamic models are possible.
- Eigenfrequency  $\omega_c$  and damping constant  $\delta$  can be determined experimentally (decay test) or analytically (dynamic model with several degrees of freedom).

**Typical application case 1 – Stresses on support insulators.** The mechanical equivalent is a spring-mass oscillator as a first-degree oscillating element with the mechanical eigenfrequency  $\omega_c$  and the damping constant  $\delta$  with a transfer function  $G(s)$

$$G(s) = \frac{\omega_0^2}{\omega_0^2 + 2\delta\omega_0s + s^2}, \tag{4.139}$$

where

$$\omega_0^2 = \sqrt{\omega_c^2 + \delta^2}, \tag{4.140}$$

where  $G$  = transfer function,  $s$  = Laplace operator,  $\delta$  = damping constant, and  $\omega_c$  = eigenfrequency of the mechanical oscillating system.

With this model, it is possible to calculate the mechanical stress depending on the load. The input

variable for the model is the time-dependent force  $F(t)$ , which acts at the head of the support insulator and emerges from the line load  $q(t)$  or the quadratic current curve  $i^2(t)$ . The output variable can, for example, be the deflection  $y(t)$ , the edge strain  $\varepsilon(t)$ , or other mechanical quantities, which can then be compared with the permissible strength values of the respective material. The solution of the transfer function  $G(s)$  takes place in the Laplace domain and is then transformed backwards into the time domain.

Example: the behavior of a support insulator  $I$  on rigid ground  $U$  under load with a 50 Hz short-circuit current and the resulting line load curve at the top of the insulator  $q(t)$  is illustrated in Fig. 4.60 for four different mechanical eigenfrequencies ( $f_c = 25, 50, 100,$  and  $150$  Hz) and discussed with regard to its DC and AC components. The dominant loads for the individual natural frequencies are marked with an arrow.

**Typical application 2 – Vibrations of electrical conductors.** The mechanical equivalent are bending vibrations of mass-covered beams with rigid subsoil under the following conditions:

- Mass, bending stiffness, and elasticity along a conductor or insulator are continuously distributed.
- The profile of the cross section is double-symmetrical (e.g., rectangle, circle) (Table 4.29).
- The oscillating beam is fixed or pinned on one or both sides. This means that the conductors oscillate independently of the overall system (Fig. 4.61 and Table 4.37).

The mechanical natural frequency  $f_c$  of the oscillating conductor is mainly determined by its length  $l$  between the clamping points

$$f_c = \frac{22.4}{2\pi l^2} \sqrt{\frac{EI}{\delta A}}, \tag{4.141}$$

**Table 4.37** Bending waves of mass-compounded beam, types of natural oscillations (adapted from [4.1])

Fixed/supported	$k = 1$	$k = 2$	$k = 3$	$\lambda_k$ in Table 4.35
One side fixed	 $\lambda_1^2 = 3.52$	 $\lambda_2^2 = 22.4$	 $\lambda_3^2 = 61.7$	$\lambda_k^2 = \left(k - \frac{1}{2}\right)^2 \pi^2$
Fixed/supported	 $\lambda_1^2 = 15.4$	 $\lambda_2^2 = 50$	 $\lambda_3^2 = 104$	$\lambda_k^2 = \left(k + \frac{1}{4}\right)^2 \pi^2$
Both sides fixed	 $\lambda_1^2 = 22.4$	 $\lambda_2^2 = 61.7$	 $\lambda_3^2 = 121$	$\lambda_k^2 = \left(k + \frac{1}{2}\right)^2 \pi^2$

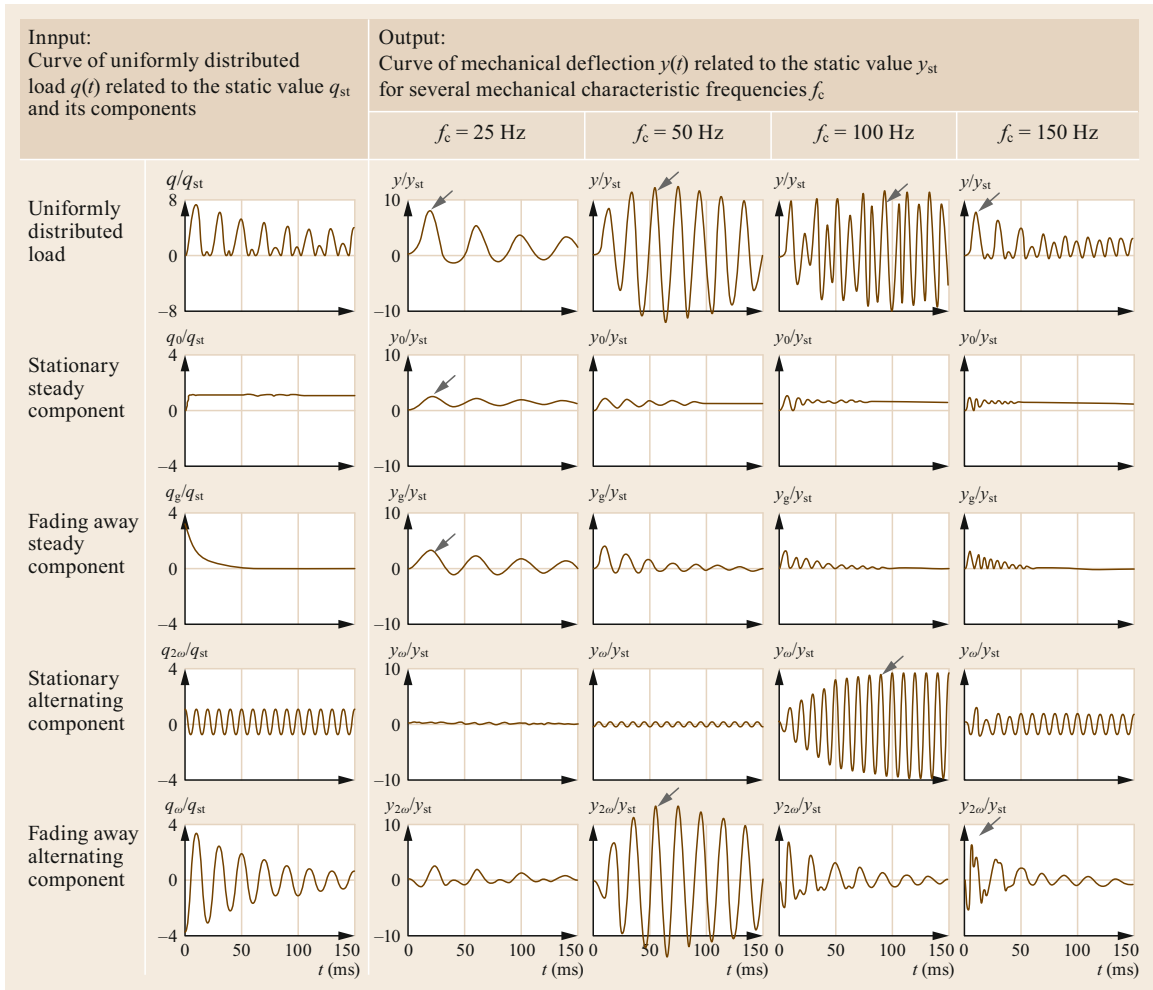

Fig. 4.60 Typical oscillation behavior of a spring-mass system, e.g., elastic post insulator ( $I$ ) in a rigid system

Fig. 4.61 Oscillation of an electric conductor ( $L$ ) with rigid substructure ( $U$ ) and insulator ( $I$ )

where  $E$  = modulus of elasticity,  $I$  = moment of inertia (Table 4.29),  $\delta$  = specific mass,  $A$  = conductor cross section,  $l$  = length between clamping points, and

$22.4 = \lambda^2$ -factor for first natural frequency with fixed clamping (Table 4.37,  $k = 1$  bottom).

For the elastically deformed beam with lateral oscillations, the partial differential equation for the line load applies

$$\frac{\partial^2}{\partial x^2} \left( EI \frac{\partial^2 v}{\partial x^2} \right) + \frac{\partial}{\partial x} \left( m \frac{\partial^2 v}{\partial t^2} \right) + \frac{\partial}{\partial x} \left( 2\delta m \frac{\partial v}{\partial t} \right) = q(t, x) \quad (4.142)$$

With the assumptions of constant mass  $m$ , constant bending stiffness  $EI$ , and no damping ( $\delta = 0$ ), and without line load ( $q = 0$  results) in the differential equation for the free oscillation

$$EI \frac{\partial^4 v}{\partial x^4} + m \frac{\partial^2 v}{\partial t^2} = 0 \quad (4.143)$$

The solution for the deflection  $v(x,t)$  becomes

$$v(x,t) = \sum_{k=1}^{\infty} a_k v_k(x) \sin(\omega_k t + \beta_k), \quad (4.144)$$

with the integration constants  $\alpha_k$  and  $\beta_k$ . The deflection  $v(x,t)$  is a superposition of oscillations with a multitude of natural frequencies  $\omega_k$  (Table 4.37)

$$\omega_k = \lambda_k^2 \sqrt{\frac{EI}{\delta A l^4}}. \quad (4.145)$$

Special cases:

- The mechanical natural frequency  $f_c$  is significantly greater than twice the mains frequency  $f_n$  ( $f_c \gg 100$  Hz). The conductor follows the load without delay, and the stresses on the conductor can be determined as with a statically loaded conductor. This means that the highest line load that occurs leads to maximum mechanical stress  $\sigma_{\max}$ .
- The mechanical natural frequency  $f_c$  is twice the mains frequency  $f_n$  ( $f_c = 100$  Hz). The system resonates in the elastic range; at higher loads, plastic deformation occurs, and the resonance frequency is detuned, i.e., the system *heals* itself.
- The mechanical natural frequency  $f_c$  is significantly smaller than twice the mains frequency  $f_n$  ( $f_c \ll 100$  Hz); the electrical conductor cannot follow the load due to its inertia (elastostatic load case).

**Typical application 3 – Electrical conductor with elastic substructure.** The dynamic model with several degrees of freedom (multimass oscillator) (Fig. 4.57) serves as the mechanical equivalent. In real switchgear systems, the short-circuit current load on the conductor also causes the insulating support points and the supporting substructure to deform. The lowest natural frequencies (fundamental frequency) of the overall system is smaller than, for example, the natural frequencies of a rigidly fixed conductor bus bar (flexibility). High and short-term loads due to surge currents can cause smaller loads in the system than can be expected from static models. Prerequisites and objectives for calculations with this model are:

- It must be possible to derive a multimass model with known distribution of masses and bending stiffness from the design in order to be able to calculate the characteristic dynamic properties (fundamental frequency).
- The system is assumed to be linear, i.e., no plastic deformations are taken into account. Damping plays a subordinate role or is completely neglected.

- The system load can be estimated for periodic loads (continuous short-circuit current) and short-term loads (surge short-circuit current).

The vibration of the system, i.e., conductor (L), support insulator (I), and substructure (U), depends on the displacement of the bus bar  $d_L$  and of the insulator  $d_I$ , as well as the elasticity (property of a body loaded with a force to give way by deformation, elasticity) of the substructure  $d_U$ . The maximum occurring forces  $F_{\max}$  during this process are calculated: for three-pole short circuit; conductors are in a plane arrangement

$$F_{\max} = V_F \frac{\mu_0 \sqrt{3} l}{4\pi a_m} \left( \kappa \sqrt{2} I''_{K(3)} \right)^2. \quad (4.146)$$

for a bipolar short circuit ( $I''_{K(2)} = 0.866 I''_{K(3)}$ )

$$F_{\max} = V_F \frac{\mu_0 l}{2\pi a_m} \left( \kappa \sqrt{2} I''_{K(2)} \right)^2, \quad (4.147)$$

where  $V_F$  = factor for comparing dynamic to static force ( $F_{\text{dyn}}/F_{\text{stat}}$ ) (Fig. 4.62),  $l$  = length between clamping points,  $a_m$  = effective conductor spacing, and  $\kappa$  = crest factor.

In the practical case where the flexibility of the conductor  $d_L$  and the support insulator  $d_I$  clearly distinguish ( $d_L/d_I$ ), the model can be simplified as a vibrating conductor with the mass  $m_L$  and an oscillating support insulator with a top mass  $m_I$  (dual-mass model). The frequency of the system related to the frequency of the clamped conductor ( $f_{\text{sys}}/f_L$ ) results from the ratio of the vibrating masses ( $m_I/m_L$ ) and the related deflections ( $d_L/d_I$ ) (Fig. 4.63).

The maximum possible load current  $\hat{i}_{\max}$  for a conductor fixed at both ends of length  $l$  and distance  $a$  to the adjacent conductor is the current at which the permissible mechanical stress remains in the elastic range of the conductor material, i.e.,  $\sigma_{\text{zul}} = \sigma_{0.2}$  is not exceeded. This stress is calculated as

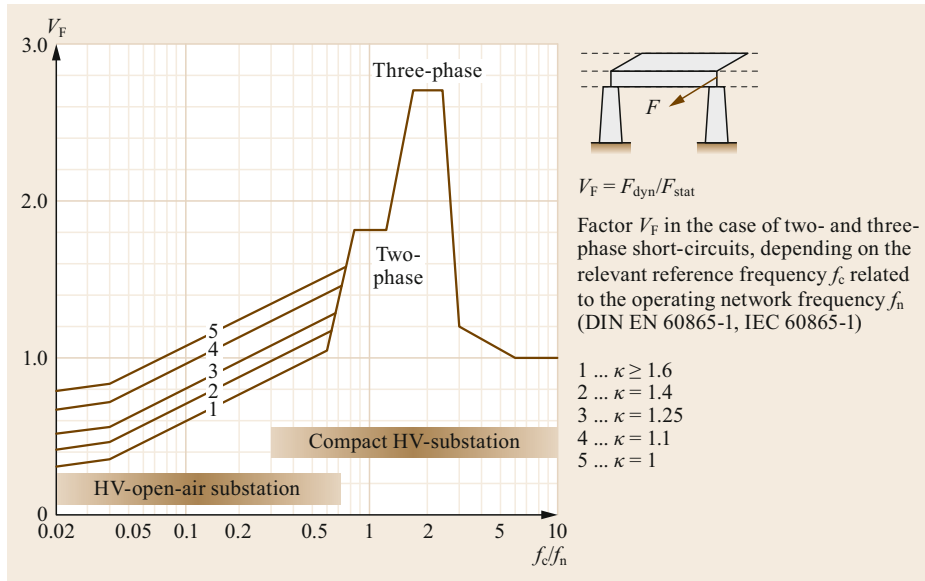

$$\sigma_{0.2} = \frac{M}{W} V_{\sigma}, \quad (4.148)$$

where with  $i_1 = i_2$  in (4.111) and

$$M = \frac{q l^2}{12} \quad (4.149)$$

insertion into (4.148) results in

$$\sigma_{0.2} = \frac{\mu_0 l^2 \hat{i}_{\max}}{2\mu q a 12 W} V_{\sigma}. \quad (4.150)$$

**Fig. 4.62** Ratio of dynamic force to static force on the support (adapted from [4.28])

**Fig. 4.63** Dynamic model – diagram-related natural frequencies for a two-mass model (adapted from [4.28])

With this equation, one obtains the maximum permissible current as

$$\hat{i}_{\text{max}} = \sqrt{\frac{4\pi abh^2\sigma_{0.2}}{\mu_0 l^2 V_\sigma}}, \quad (4.151)$$

where  $a$  = center distance of the conductors,  $b$  = conductor width (Table 4.30), and  $h$  = conductor height (Table 4.30),  $V_\sigma$  = factor for comparing the dynamic to static conductor bending stress ( $\sigma_{\text{dyn}}/\sigma_{\text{stat}}$ ) (Fig. 4.64).

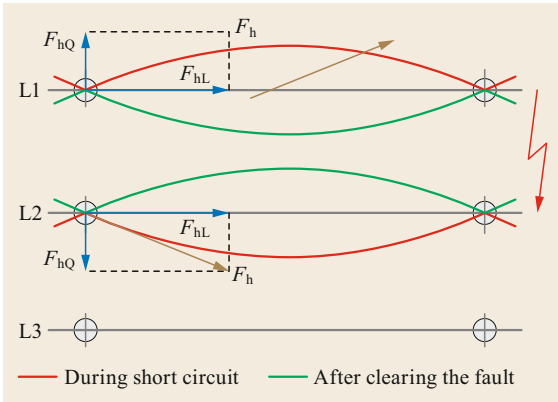

**Flexible conductors.** For example, overhead line conductors, can move relatively freely in contrast to flexurally stiff conductors. The mechanical natural frequency

of a sagging conductor is approximately  $f_c \approx 0.3$  Hz, compared to the force of the short-circuit current, which oscillates with double mains frequency  $2f_n = 100$  Hz; thus, the issue becomes a quasi elastostatic problem. In the case of a two-pole short circuit (Fig. 4.65), the affected conductors are repelled during the short circuit (currents in the opposite direction). In the case of a three-pole short circuit (Fig. 4.66), this affects the two outer conductors, while the middle conductor remains mechanically neutral. In both cases, the peak short-circuit current (acting like an impulse relative to the natural frequency of the rope) stimulates the conductors to oscillate slowly, causing them to move towards each other. Due to the very large distances between the main conductors, es-

Factor  $V_\sigma$  for two- and three-pole short circuits, depending on the relevant reference frequency  $f_c$  related to the operating network frequency  $f_n$  (DIN EN 60865-1, IEC 60865-1)

**Fig. 4.64** Factor  $V_\sigma$  to determine the conductor

**Fig. 4.65** Mechanical stress on stranded overhead line conductors (main conductor) in the phase-to-phase fault

**Fig. 4.66** Mechanical stress on stranded overhead line conductors (main conductor) in the three-phase fault

pecially with high-voltage overhead lines, the line loads on the main conductors are usually negligibly small.

These issues are significantly different for bundled conductors (Fig. 4.68) in which the short-circuit current is divided between two, three, four, or more subconductors of a bundle, which are, however, only a few decimeters apart. This leads to a strong contraction of

**Fig. 4.67** Mechanical stress on stranded overhead line conductors (bundled conductors) during and after short circuit

**Fig. 4.68** Quad-bundled conductors with spacer dampers

the bundle between spacer locations along the bundle (Fig. 4.67) and subsequent expansion. This can lead to clashing of the conductors at the instant of the short-circuit, as well as to high compressive and tensile forces at the spacers. The resistance of the spacers to short circuits must, thus, be verified. Only very short distances

**Fig. 4.69** Curve of tensile force in a span with bundled conductors. Maximum force  $F_b$  after short-circuit entry due to contraction of the bundle conductors, depending on the short-circuit current  $i_p$  and the rope elongation; force effect between the main conductors is built up, due to the large inertia of a span (natural frequency  $f_c < 1$  Hz), comparatively slow ( $F_h$  depending on the rms value of the short-circuit current); initial force  $F_0$  before short-circuit

between the spacer frames (5–10 m) could prevent the conductors from clashing even with high short-circuit currents, which is at best possible in open air substations. Furthermore, the high bending stress at the spacer clamps can lead to plastic deformation of the individual wires in the outer conductor layer (birdcaging, which will cause disturbing acoustic emissions).

The contraction of the bundle conductors after the short circuit occurs (at  $t_1$ ) results in a large increase in the conductor tensile force  $F_b$  (depending on the peak short-circuit current  $i_p$  and the rope elongation) (Figs. 4.67 and 4.69). Moreover, this force is partially reduced by decreasing the sag and, possibly, by a time-dependent plastic elongation of the conductors. After that (at  $t_2$ ), a force is comparatively slowly applied between the main conductors (because of the high inertia of the span with a natural frequency  $f_c \approx 0.3$  Hz). ( $F_h$  depends on the rms value of the short-circuit current.)

### 4.3.3 Connections in Current Paths

*Electrical connections* are used to connect, terminate, and branch electrical conductors. *Electrical connectors* are hardware components, which are suitable for making such connections in current paths [4.3, 17, 18, 34–42]. The *electrical contact* is a physical state in which two or more electrical conductors are joined together in such a way that a current can be conducted from one to the other. Electrical contacts are the physically necessary prerequisite for the function of electrical connections.,

#### Theory of Electrical Connections and Contacts

When connecting electrical conductors, within the apparent contact area  $A_a$  there exist either single or multiple contact points that can be of a point or a linear

shape. In these contact points, the electric current flow is constricted to microscopically small metallic surfaces  $A_m$  (*metallic contact area*). This results in an additional electrical *constriction resistance*  $R_c$ . Since there is always an impurity layer (usually an oxide layer) with a higher specific electrical resistance on every metallic surface, the resulting *impurity film resistance*  $R_f$  must be taken into account. Constriction and impurity film resistance result in the *contact resistance*  $R_k$ , which, in addition to the metallic lead resistance  $R_m$  of the conductive path, represents an additional heat source. Contact and material resistance can be determined analytically and experimentally as *joint resistance*  $R_j$  (Figs. 4.70 and 4.72) [4.43]:

- Contact resistance

$$R_k(t) = R_c(t) + R_f(t), \quad (4.152)$$

- Joint resistance

$$R_j(t) = R_k(t) + R_m = R_c(t) + R_f(t) + R_m. \quad (4.153)$$

In the case of plastic deformation due to high contact forces, the size of the metallic contact surface  $A_m$  and the resulting constriction resistance  $R_c$  are dependent on the effective contact force  $F_j$  and the material properties, i.e., hardness  $H_k$  and specific electrical resistance  $\rho$  of the contact partners to be connected, and can be based on the *Holm* contact model (4.154) to (4.156), (Fig. 4.71). The contact hardness is determined experimentally (Table 4.38 [4.34, 44]).

$$A_m = \frac{F_j}{H_k}, \quad (4.154)$$

$$r_m = \sqrt{\frac{A_m}{\pi}}, \quad (4.155)$$

$$R_c = \frac{\rho}{2} \sqrt{\pi \frac{H_k}{F_j}}, \quad (4.156)$$

where  $F_j$  = joint force,  $r_m$  = radius of metallic, load bearing area,  $A_m$  = metallic, load bearing area,  $H_k$  = contact hardness, and  $\rho$  = specific electric resistance of contact material.

**Table 4.38** Contact hardness

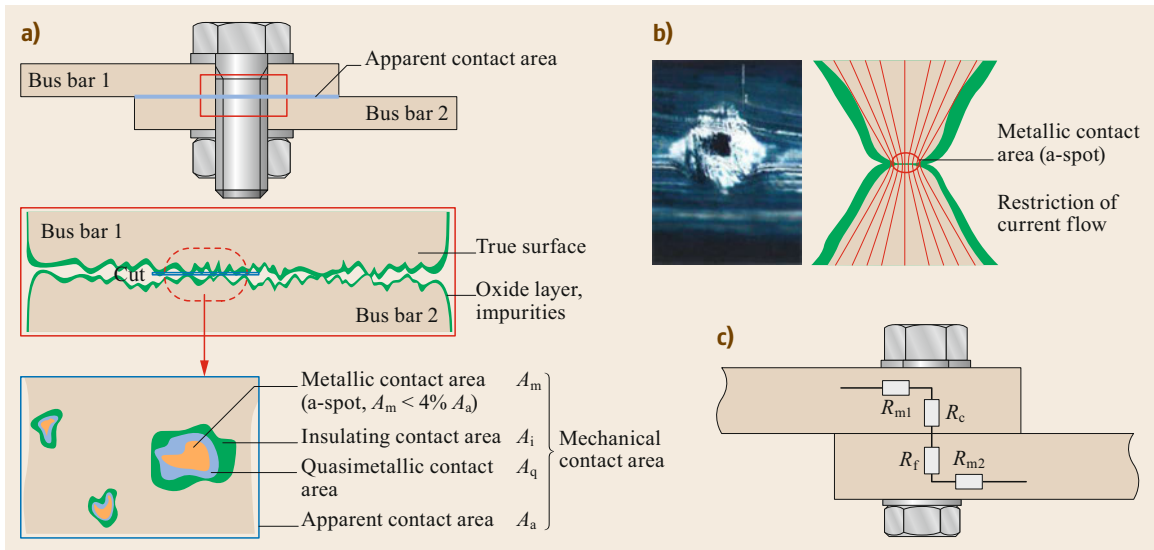

Fig. 4.70a-c Bolted connection of two bus bars. (a) Contact areas, (b) a-spot in detail, (c) joint and contact resistance

Fig. 4.71 Contact surface and constriction resistance depending on material and force – plastic deformation

With high contact forces, as is usual in most electrical power engineering connections, several parallel contact points are created. Assuming a power-law relationship (with an exponent  $m$ ) between the number  $n$  of the parallel contact points  $A_{mn}$  and the contact force  $F_c$ , one obtains, after Babikow [4.45], constriction resistance  $R_c$  of

$$R_c = \frac{10^{-3} C \rho}{(0.1 F_c / N)^m} \quad [\Omega] \quad (4.157)$$

with empirically determined values for  $C$  and  $m$  (Tables 4.39 and 4.40).

The connection resistance  $R_j$  can be evaluated independently of the dimensions and contact material of

Table 4.39 Coefficient  $C\rho$  for clean surfaces in (4.157)

a linearly shaped connection, consisting of identical conductors, with the help of the quality factor  $k_u$

$$k_u = \frac{\Delta U_j}{\Delta U_{\text{cond}}} = \frac{R_j}{R_{\text{cond}}} = \frac{P_j}{P_{\text{cond}}}, \quad (4.158)$$

where  $k_u$  = quality factor,  $\Delta U_j$ ,  $\Delta U_{\text{cond}}$  = voltage drop across the connection or over a conductor of equal

**Fig. 4.72** Characteristic criteria for connections: performance factor  $k_u$

length,  $R_j$ ,  $R_{cond}$  = resistance of the connection or a conductor of equal length,  $P_j$ , and  $P_{cond}$  = power loss in the connection or in a conductor of equal length.

The quality factor of a bolted bus bar connection amounts to:

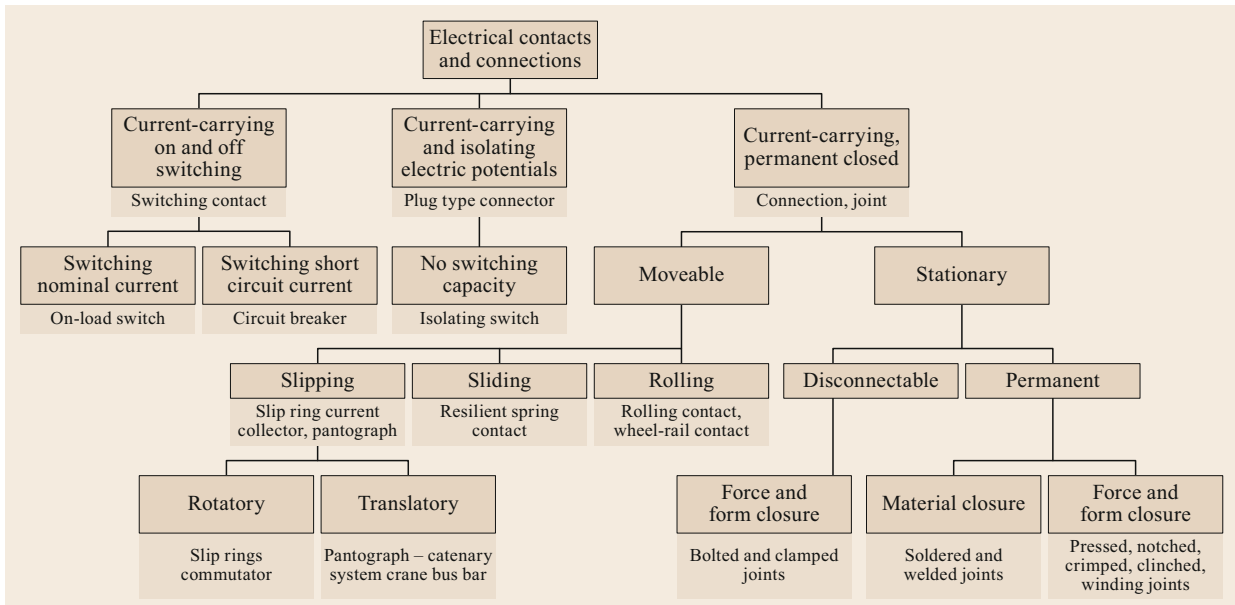

- $k_u = 1$  for the same losses in the connection as in the conductor of equal length, i.e., no additional losses through the connection.
- $k_u = 0.5$  for the theoretical, smallest possible value, since the conductor cross section in the area of the connection is twice as large as in the bus bar.
- $k_u = 1.5$  for approximately the same temperature in the connection and in the conductor due to the larger, heat-emitting surface.

A good electrical bolted connection ( $k_u < 1.5$ ), thus, always has a lower temperature than the connected conductors. Only poor connections ( $k_u > 1.5$ ) become hot

spots. This applies analogously to most other types of connections. The heat dissipation in the joint causing a temperature rise can be calculated with (4.33) in Sect. 4.3.1. The local temperature distribution along a conductor around a connection (Fig. 4.10) results from (4.29).

### Electrical Connections and Their Properties

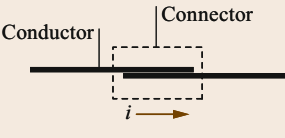

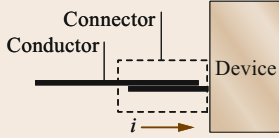

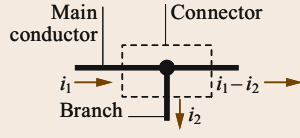

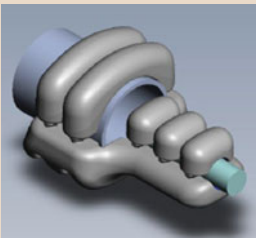

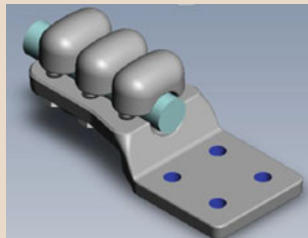

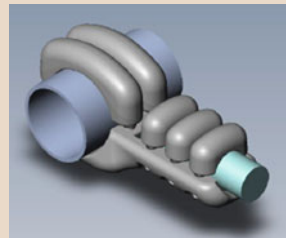

According to their function, electrical contacts and connections can be divided into those that are closed during operation and which can be opened to separate electrical potentials (isolating sections), and those that are suitable for interrupting (switching off) or establishing (switching on) the current flow (Fig. 4.73). According to design requirements, a distinction is made between connecting of conductors, connecting of conductors to equipment, and branching off conductors for the purpose of current distribution (Table 4.41).

**Fig. 4.73** Overview of electrical connections

**Table 4.41** Examples of electrical connection functions

Connection	Terminal	Derivation
		
		
Straight connector	Straight flat terminal connector	T-connector

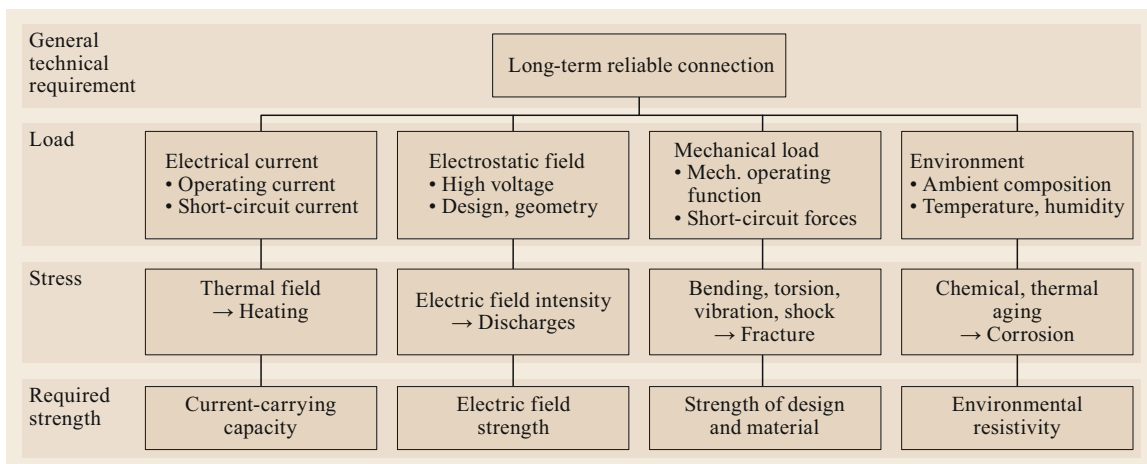

In *stationary electrical connections*, the contact points created during the joining of the contact pieces remain in first approximation during the current flow and do not change their position. In the case of thermal load cycles or aging, changes in the contact points can also be expected. Depending on the joining process, these can be *separable* (terminal and bolted connections, plug-in connections, disconnection points for plug-in connectors or disconnectors), or *fixed* (rivet, solder, weld connections) (Table 4.42).

For *moving electrical connections*, the contact pieces can move relative to each other during the current flow. These include, for example, slip rings on rotating electrical machines, crane conductor lines, and current collectors for electrical trains on the contact wire. While the contact pieces move towards each other, new electrical contacts must be permanently formed to maintain the current flow (Table 4.43).

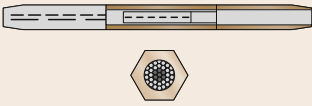

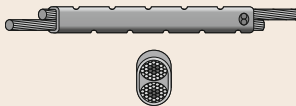

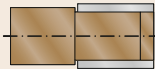

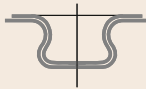

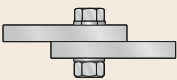

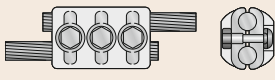

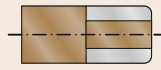

Depending on the joining process, the electrical contact is established within connections through:

- Adhesion (e.g., bolted connections)
- Form-fit and force-fit connection (e.g., plug connection)
- Material-fit (e.g., soldered, friction and welded connections).

Electrical connections must meet the *requirements* by all electrical, thermal, mechanical, and environmental stresses (Fig. 4.74). This should be verified by suitable, mostly standardized tests and additional long-term investigations. With regard to the load duration, recommended long-term tests go far beyond the requirements of standardized tests not only to prove compliance with minimum requirements, but also to confirm part of the planned service life under practical conditions.

**Fig. 4.74** Electrical connection requirements

Standards for testing electrical connections (Table 4.44) usually take into account the many years of experience of the respective users and represent the state-of-the-art in the related industry. These standards are not consistent in all cases with regard to their technical contact requirements. From the point of view of contact physics, long-term safe and reliable current-carrying capacity is independent of the voltage level in which the connection is used.

Connections must be designed in such a way that their joint resistance will only increase, under consideration of all loads during the planned service life, to such

an extent that thermal damage or destruction of the connection itself, the current path, and adjacent insulations and fittings – under-rated and short-circuit currents – is ruled out. The effects of the mechanical loads, e.g., by tensile force in overhead lines, mechanical vibrations in moving equipment components, thermal expansion and friction between the contact pieces, on the long-term behavior must also be investigated. Special ambient conditions, e.g., high ambient temperatures, aggressive pollutants, high SO<sub>2</sub>-content or salinity of the air, extreme climates, etc., can also increase the connection resistance in the long term. In addition, connections

**Table 4.44** Overview of selected standards for testing electrical connections

Norm	DIN EN 61284: 1998	DIN EN 61238-1: 2004	DIN EN 60999: 2000
Application	Overhead lines – requirements and tests for fittings > 45 kV	Compression and mechanical connectors for power cables for rated voltages up to 36 kV	Connecting devices – electrical copper conductors; safety requirements for screw-type and screwless-type clamping units up to 1 kV (AC)/1.5 kV (DC)
Number of test samples	4	6	10
Number of cycles $n$	1000/500/100 additionally $I_k$	1000 additionally $I_k$	196
Arrangement	Distance between samples > $3b$ , free convection	Free arrangement, no retroactive effects from floor, ceiling, and walls to the test circuit	No movement of samples during test
$\Delta\vartheta$ or $\vartheta$ (partial reference conductor)	70 K/100 K/130 K < 180 °C (short term)	120–140 °C < 250–270 °C (short term)	Heat cabinet with test current
$\vartheta_0$ (°C)	15–30	15–30	Heat cabinet 20–40
Plateau phase	30 min (VL)	10 min median connector	Heat cabinet, thermal stability 10 min, $\Delta\vartheta$ max. 5 K
Measuring of resistance	DC, max. 10% $I_p$	DC, max. 10% $I_p$	DC or AC $I_p$
Criteria for resistance	$R_{j0}$ (30% Str.) $R_{j<0.1n} < 0.75R_{j,VL}$ $R_{j>0.5n} < 1.5R_{j0}$	$k_{u0}$ (30% Str.) $k_{u,1000} < 2k_{u0}$	Voltage drop ( $I_p$ ) < 22.5 mV or $1.5R_{j,n=24}$

$I_k$  short-term current,  $R_j$  joint resistance,  $k_u$  performance factor,  $I_p$  test current,  $b$  local constant,  $n$  number of cycles, VL reference conductor.

in high-voltage installations must be designed in such a way that the electric field in the vicinity of the connection does not adversely affect the insulation, e.g., through partial discharges (avoiding small radii and sharp edges, providing shielding).

**Design and Dimensioning.** During the *design and dimensioning* of the current path equal power losses in the connection and the current path outside the connection (quality factor  $k = 1$ ) should be targeted. This means that the connection will not reach a higher temperature than the rest of the current path and, therefore, does not represent a hot spot. This is achieved by the following:

- Suitable *conductor materials* (copper, aluminum and their alloys), *surface coating* with selected contact materials (silver, nickel, tin), as well as the design and dimensions of the contact pieces, the joining process and the assembly technology.

For pressed, notched, and clinched connections, the forming of the conductors and the fittings must be coordinated with the assembly tools to ensure an optimum balance between the mechanical and electrical requirements, even in long-term behavior. Compression connectors for high-temperature conductors (operating temperatures up to 240 °C) in high-voltage overhead lines and switchgear for which conventional compression

connectors are not stable over the long-term deserve special attention.

Bolted and clamped connections must be dimensioned so that at least the required conductor cross section is also available within the connection and the heat-emitting surface of the connection is larger than in the conductor itself in order to dissipate the additional heat losses occurring in the contact points. The mechanical connecting elements (screws, washers, nuts, pressure plates, springs) for high-current connections, particularly for highly-loaded connections, should consist of nonferromagnetic material to reduce additional hysteresis and eddy-current losses (Fig. 4.75) [4.38]:

- *Parallel contact points* distribute the total current  $i$  at  $n$  parallel current paths.

In the case of bolted or clamped connections, this can be achieved, for example, by grooving the contact surfaces in the connection. The connection resistance or the quality factor of such multipoint contacts can, thus, be significantly reduced (Fig. 4.76) [4.46].

Thus, the power dissipation of  $n$  parallel, similar contact points with a resistance ( $R/n$ ), related to the power dissipation  $P$  of a single contact with the connection resistance  $R$ , in simplified form is

$$\frac{\sum P_n}{P} = \frac{n[(i/n)^2(R/n)]}{i^2R} = \frac{1}{n^2} \quad (4.159)$$

Fig. 4.75 Influence of ferromagnetic design elements on the resistance of highly-stressed connections

For plug connections with parallel contact fingers or multilamella contacts (Table 4.43), the total connection force is limited due to friction in order to still be able to move the plug [4.3]. The connection force is distributed almost evenly among the  $n$  parallel contact points. The ratio total connection resistance  $R_n$  to a single-point

connection resistance  $R_1$  (Fig. 4.77), becomes, under consideration of (4.157) a constant connection force

$$\frac{R_n}{R_1} = \frac{C\rho/(n(F/n)^m)}{C\rho/F^m} = n^{(m-1)}. \tag{4.160}$$

The losses in the plug connection with  $n$  parallel contact points are reduced to

$$\frac{\sum P_n}{P_1} = n^{(m-2)}. \tag{4.161}$$

Since it is generally not possible to assume that the parallel partial resistances will be of equal size, further individual investigations, in particular into the aging mechanisms, are required for specific arrangements [4.3].

- In addition to the *design of the connection*, a basic prerequisite for their long-term reliable operation (Fig. 4.78) is the professional and careful *assembly* of the connection.

It is essential to ensure that only suitable conductors and connectors are joined using the prescribed assembly tools and technologies. Prior to assembly, the contact surfaces of the conductors and connectors must be thoroughly cleaned and any oxide layers removed. Dirt and grease are removed with a chemically neutral solvent. For decades, clean, sharp wire brushes have proven their utility on aluminum surfaces of conductors, bus bars, and equipment connections. These remove the hard, insulating aluminum oxide layer with about 30 brush strokes and simultaneously roughen the conductor surface in such a way that a large number of parallel contact points are formed as a microstructure. Once cleaned, contact surfaces must not be touched again with a dirty hand and should be installed as soon as possible (Fig. 4.79) [4.47]. Surfaces of copper conductors can be easily cleaned of foreign layers with

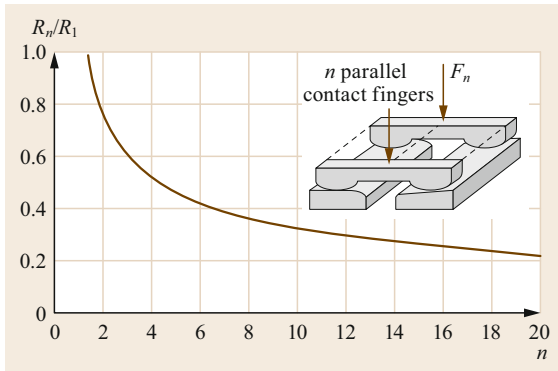

Fig. 4.76 Influence of the surface structure on the quality factor of aluminum connection surfaces (adapted from [4.46])

**Fig. 4.77** Relative resistance of a connector depending on the number of parallel contact fingers;  $F = nF_n = \text{const.}$ ,  $R_n/R_1 = n^{(m-1)}$ , with  $R_n$  = joint resistance of  $n$  parallel fingers,  $R_1$  = joint resistance of on finger, and  $m = 0.5$ , (Table 4.40 point-to-flat contact) [4.3]

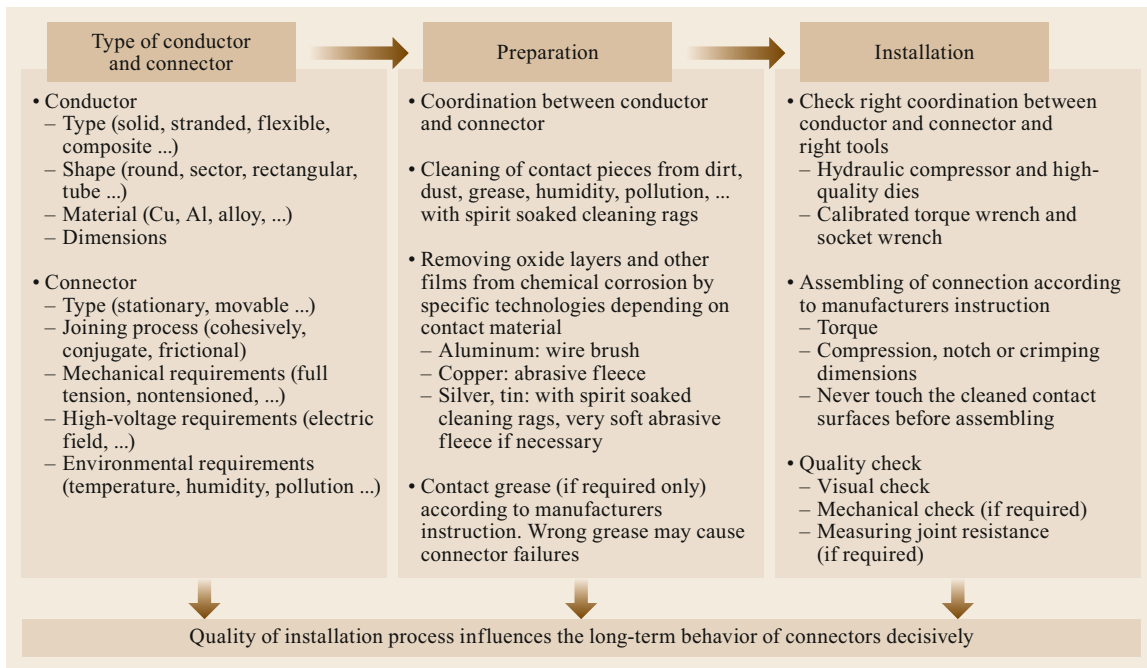

abrasive fleece to minimize the connection resistance (Fig. 4.80) [4.38]. For silver-plated, tinned, or nickel-plated surfaces, cleaning with a clean rag and spirit is usually sufficient. Heavily soiled or oxidized surfaces can also be gently cleaned with a soft abrasive fleece. The initial quality factor  $k_{uo}$  resulting from the quality of the installation is decisive for the long-term behavior of a connection in operation.

Contact pastes may only be used for the applications specified by the manufacturer; otherwise, e.g., particles

mixed into contact pastes for press connections, if used for bolted connections, can lead to catastrophically poor connection resistances due to the lower degree of deformation of the latter. The connection resistance of a frictional connection is determined by the number and size of the true contact points within the apparent contact surface and depends on the surface condition and the connection force (4.157).

The bolt force (or the bolt tightening torque) essentially determine the connection resistance (quality factor) of a force-fit *bolted joint* (Fig. 4.81) or a *clamp connection*. The connection force should be selected so large that the stable range of the connection is reached. The resistance-force-hysteresis behavior guarantees a low connection resistance even during force degradation (see the subsequent section on the *aging and long-term behavior of electrical connections*), especially with aluminum connections. However, a minimum force (approximately 5 kN) must not be reduced in order to prevent the contacts from breaking open under mechanical loads (short-circuit forces, vibrations, or shock). If an aged joint is to be refurbished, simply retightening the bolts is usually not sufficient, as thicker oxide layers have formed around the contact points, which are often not broken open during retightening. In this case, the connection must be opened and the contact surfaces cleaned and reassembled.

To connect or to terminate multiwire underground cables, insulated wires, or overhead line conductors,

**Fig. 4.80** Influence of surface preparation on the joint resistance and hysteresis of bolted copper bus bar joints (adapted from [4.38])

the *circumferential compression* (often with hexagonal presses) (Fig. 4.82, left column) in special fittings (compression cable lugs, compression sleeves) has been established as the preferred joining method for both nontension-proof and tension-proof connections (Fig. 4.82, first row, left column). The electrical and mechanical behavior of a compression fitting is determined by the proper material selection, the dimensioning, and the assembly. The high degree of deformation produced during compression causes impurity layers to be ruptured. The contact force (Fig. 4.82) remaining after the assembly process ensures the integrity of the large contact areas [4.18].

From the geometric conditions (Fig. 4.83), the space factor  $f$  of the conductor is calculated as

$$f = \frac{A_{Al} + A_K}{\frac{\pi}{4} d_L^2}, \quad (4.162)$$

**Fig. 4.81** Hysteresis behavior of aluminum screw connections

**Fig. 4.82** Principle phases of the joining process of hexagonal compression connections (adapted from [4.18])

where  $A_{Al}$  = total cross-section aluminum,  $A_K$  = total cross-section core,  $d_L$  = total diameter of a stranded conductor, and  $f$  = space factor.

The fit factor  $p$  of a compression fitting is the ratio of the nominal outside diameter  $d_L$  to the inner diameter of the press sleeve  $d_i$

$$p = \frac{d_L}{d_i}. \quad (4.163)$$

The compression factor  $K_F$  describes the compaction of the aluminum cross sections  $A_{Al}$  and  $A_H$  in the cross section of the hexagon  $A_3$ , assuming that the core  $A_K$  is incompressible

$$K_F = \frac{A_{Al} + A_H}{A_3 - A_K}. \quad (4.164)$$

In analogy to the quality factor  $k_u$  for bolted connections (4.158), a resistance ratio  $k'$  between the real and

**Fig. 4.83** Dimensions of stranded conductor (overhead-line conductor), compression sleeve, and compression hexagon;  $A_1$  = single-aluminum-wire cross section,  $A_2$  = single-core-wire cross section,  $A_3$  = cross section of the hexagonal compression,  $A_H$  = total cross section of the aluminum compression sleeve,  $A_K$  = total cross-section core,  $d_a$  = outer diameter of the compression sleeve,  $d_i$  = inner diameter of the compression sleeve,  $d_3$  = corner distance of a regular hexagon, and  $S_3$  = edge distance of a regular hexagon (adapted from [4.18])

**Fig. 4.84** Equivalent network for a differential part of a compression joint (adapted from [4.18])

the ideal connection resistance is used for evaluating the electrical properties of compression connections. From this and with the help of the specific transverse resistance  $R'_q$ , a generally-valid electrical model for compression connections is derived, which uses the differential resistance per unit length in order to analyze the connection (Fig. 4.84).

Assuming that the material resistances do not change along the compression and that the microcontact points are equally large and equidistantly distributed over the apparent contact surface, a differential equation can be solved from the mesh equation of the model, from which the connection resistance  $R_j$  can be calculated

$$R_j = \frac{R'_{m1}}{R'_{m1} + R'_{m2}} \left[ R'_{m2}s + \frac{R'_{m1} - R'_{m2}}{\alpha} \tanh\left(\frac{s\alpha}{2}\right) \right] + \frac{R'_{m1} + R'_{m2} \cosh(s\alpha)}{\alpha \sinh(s\alpha)}, \quad (4.165)$$

and

$$\alpha = \sqrt{\frac{R'_{m1} + R'_{m2}}{R'_q}}, \quad (4.166)$$

where  $R_j$  = joint resistance of compression type connector,  $R'_{m1}$ ,  $R'_{m2}$  = metallic lead (material) resistance of conductor 1 and 2, per unit length,  $R'_q$  = joint cross (link) resistance, related to the length, and  $s$  = compression length.

The ideal connection resistance  $R_{j\text{ideal}}$ , which would theoretically be the smallest possible resistance without contact resistance, is calculated as follows

$$R_{j\text{ideal}} = \frac{R'_{m1}R'_{m2}}{R'_{m1} + R'_{m2}} K_F s. \quad (4.167)$$

This enables the real connection resistance to be compared with the ideal connection resistance

$$k' = \frac{R_j - R_{j\text{ideal}}}{R_{j\text{ideal}}}. \quad (4.168)$$

The current distribution along the compression joint depends mainly on the material resistances  $R_{m1}$  and  $R_{m2}$ . If the current transfer between the two contact partners mainly takes place at the two ends of the compression, while the cross current in the middle of the connection is low, the specific cross resistance is calculated as

$$R'_q = \left(\frac{c}{a} k'\right)^2, \quad (4.169)$$

and

$$a = \frac{R'_{m1}}{R'_{m2}} + \frac{R'_{m2}}{R'_{m1}}, \quad (4.170)$$

$$c = s\sqrt{K_F (R'_{m1} + R'_{m2})}. \quad (4.171)$$

**Fig. 4.85** Test arrangement and measurement of joint resistance (adapted from [4.18])

Experimental investigations of compression joints made of two different materials such as ACSR and HTLS conductors for overhead lines (Fig. 4.85) show the effect of different design parameters on the specific transverse resistance (Fig. 4.86).

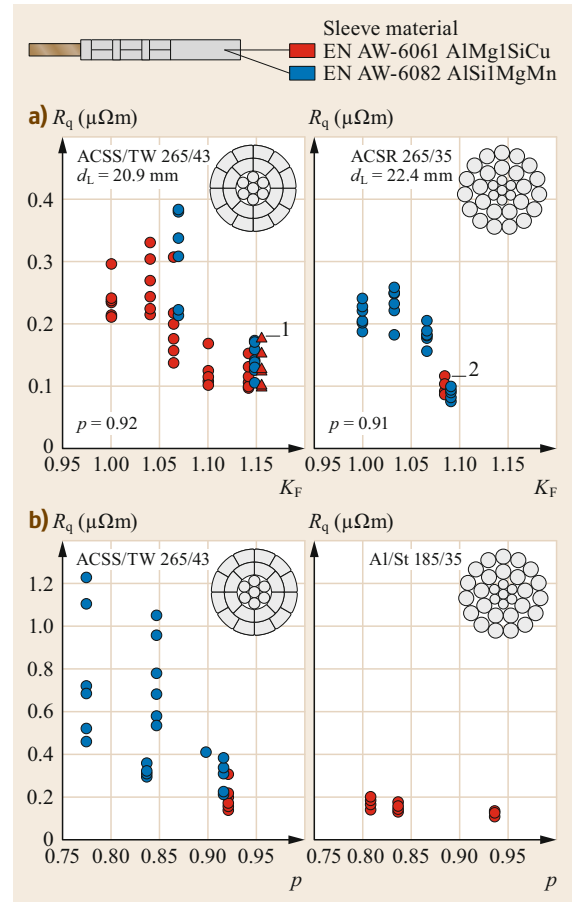

This demonstrates the general relationship between design and electrical operating behavior of compression joints (Fig. 4.87).

Figure 4.88 schematically shows the effect of the compression force  $F_{\text{press}}$  when mounting the connection on the apparent contact area  $A_s$  for conductors with trapezoidal individual wires and the on-load-bearing, mechanical contact area  $A_m$  for conductors with round wires, as well as on the constriction resistance  $R_c$  and the film resistance  $R_f$ .

For compression connections subject to high electrical loads, in particular for full-tension compression joints and dead end clamps on high-temperature overhead line conductors, the long-term electrical behavior can be significantly influenced already during the design stage of the fitting and also during installation. Nevertheless, long-term experiments that clearly exceed the duration of a standard-type test are indispensable for proving a stable connection resistance even under high current loads.

*Plug-in-type connectors* (Table 4.43) [4.3, 36, 41] are used in electrical power applications:

- For operational disconnection of electrical potentials (disconnection points).
- For connecting of factory-made, exchangeable modules on site (e.g., in low-voltage switchgear equipment, transformer plugs).
- For connecting movable components (e.g., railway wagons).
- For extending or connecting cables.
- To compensate for thermal expansions of conductors and encapsulations (e.g., modules in GIS and GIL). The mobility of the contact partners relative to each other means that new microcontacts will

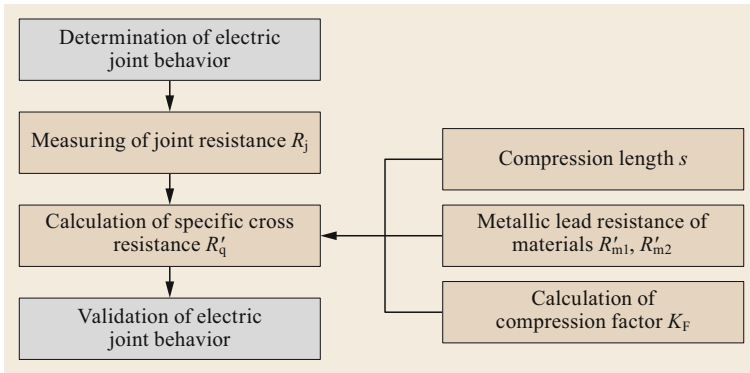

**Fig. 4.86a,b** Specific cross resistance  $R_q$  of compression joints at ACSR and ACSR conductors, experimentally determined. (a) Depending on compression factor  $K_F$ , (b) depending on fit factor  $p$  (adapted from [4.18])

carry the current and, thus, after each movement, the contact resistance will vary.

To close a plug connection (e.g., a disconnection point or during assembly) and to move the contact pieces of a connection in the closed state, axially-acting plug forces  $F_S$  are required, which are sometimes, depending on the application, limited, so that the connection can still be plugged in. Depending on the effective static and sliding friction  $F_R$  between the contact pieces, also the radially acting connection forces  $F_j$  and, thus, the contact forces  $F_c$  on the individual contact points are limited. The design of the contact pieces has a significant influence on the required insertion forces, while the tensile unplug forces  $F_Z$  when opening a plug connection are usually subordinate for the dimensioning of a connection (Fig. 4.89).

**Fig. 4.87** Principal influence of compression joint design on electric contact behavior (adapted from [4.18])

To compensate for smaller contact forces, compared to bolted, clamped, or compression joints, many parallel contacts are arranged in plug connections, e.g., as contact pins, coil springs, or multilamellae, onto which the current is to be distributed as evenly as possible. Under this assumption, the current-density distribution, the current heat losses, and the temperature distribution, based on the Wiedemann–Franz law, can be calculated for known contact geometries and material properties. The analogy between electrical conductivity and thermal conductivity is taken into account, since both the heat flow and the electrical current are transported in the metal as a function of temperature [4.34, 41, 48]

$$\frac{\lambda}{\kappa} \approx LT = L(\vartheta + 273 \text{ K}), \quad (4.172)$$

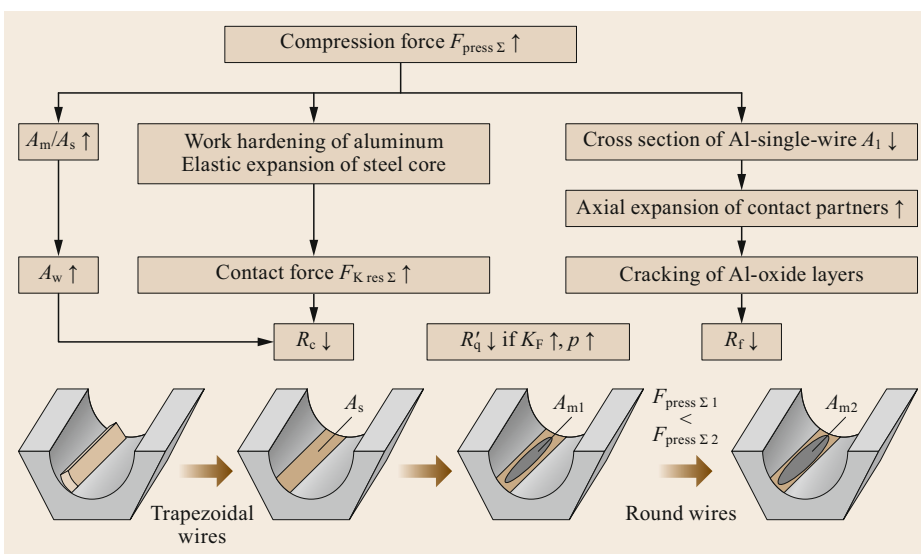

where  $L$  = Lorenz-number =  $2.44 \times 10^{-8} \text{ V}^2/\text{K}^2$ ,  $T$  = absolute temperature,  $\vartheta$  = temperature,  $\kappa$  = specific electric conductivity, and  $\lambda$  = specific thermal conductivity.

For thermally symmetrical contact arrangements, the following relationship between the electrical voltage drop  $u$  across the contact point, the temperature in the contact  $\vartheta$  and the material parameters  $\kappa$  and  $\lambda$  applies (Fig. 4.90)

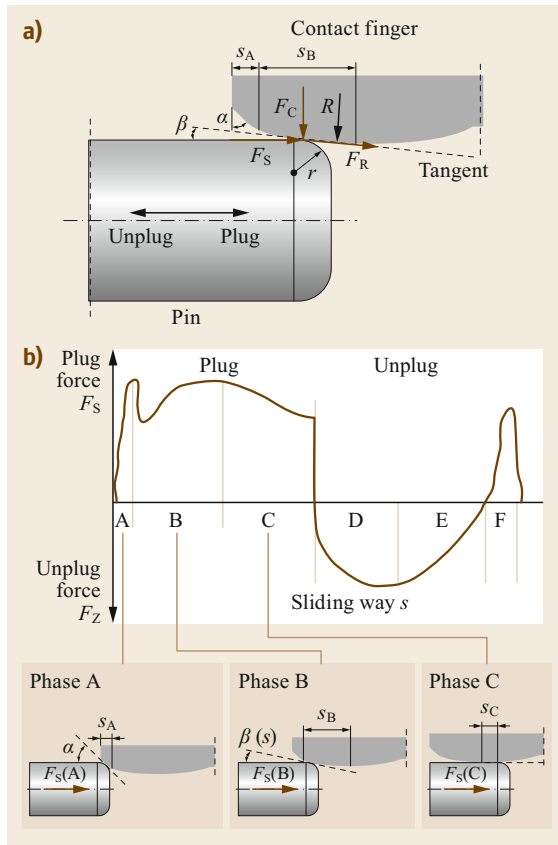

$$u^2 = 8 \int_{\vartheta_1}^{\vartheta_{\max}} \frac{\lambda}{\kappa} d\vartheta, \quad (4.173)$$

where  $u$  = contact voltage drop,  $\vartheta_1$  = temperature of contact pieces 1 and 2 (if symmetrically), and  $\vartheta_{\max}$  = maximum temperature.

For electrically and thermally highly-loaded plug-in connectors with many small parallel contact pieces, the temperature dependence of the specific electrical and thermal conductivity due to the higher internal heating in the contact point must be taken into account. This model enables, based on the actually measured connection resistance  $R_j$ , calculation of the contact voltage

**Fig. 4.88** Influence of the compression force on the electric contact behavior (adapted from [4.18])

**Fig. 4.89a,b** Plug-in-type finger connector, axial plug force – principal behavior. **(a)** Arrangement of plug (contact finger) and pin, **(b)** behavior of axial plug force;  $F_C$  = contact force,  $F_R$  = friction force,  $F_S$  = axial plug force,  $F_Z$  = axial unplug force,  $s_A$  = friction distance in phase A (positioning of contact partners),  $s_B$  = friction distance in phase B (spreading of contact fingers),  $s_C$  = friction distance in phase C (sliding of plug and pin),  $\alpha$  and  $\beta$  = tangent angles between pin and finger, depending on positions A, B, and C (adapted from [4.3])

$u$  also of the temperature distribution in the contact for stationary and transient operation using the material properties. This is particularly necessary for the design of high-current connectors with lamellae, coil springs, or other slender contact elements [4.41].

In addition to the thermal load of the parallel contact points of a plug connection, the electrodynamic lift-off forces in the event of a short circuit must be taken into account for dimensioning (Table 4.33, bottom), as these counteract the comparatively small contact force in the case of an impulse current. In the event of a lift-off, arcs may form, and the contact pieces may subsequently be welded together. This means that the plug connection is no longer movable (Fig. 4.91)

**Quality Assurance Tests.** *Quality assurance tests* are indispensable in the manufacture and assembly of connections. Proof that the design and dimensioning of live electrical connections meet the relevant requirements in long-term stationary operation and in the event of a short circuit must be verified in type tests and is required in most cases. In addition, measurements of the resistance of highly-loaded connections after assembly in the factory or on the construction site are strongly recommended as a routine or random test for quality assurance (see the subsequent section on measuring electrical connections). For bolted connections with long-term stability, output quality factors of  $k_{u0} \leq 1.5$  are required. In order to gain knowledge about the long-term behavior of electrical connections, long-term investigations (possibly during their field operation) with significantly longer test duration than provided for in the type tests are indispensable.

#### Aging and Long-Term Behavior of Electrical Connections

The *aging and long-term behavior of electrical connections* are dependent on the design, dimensioning, and installation of the connection itself and on the in-

**Fig. 4.90** Thermal-electrical model of a contact point (adapted from [4.41])

**Fig. 4.91** Electrodynamic short-circuit forces between contact pieces

teraction of the various loads (electrical, thermal, and environmental) to which the connection is exposed during operation. Accordingly, various aging processes are effective, which superimpose each other and determine the time curve of the connection resistance or of the quality factor (Fig. 4.92). All aging processes (except fretting) are temperature-dependent and can generally be described with Arrhenius' law.

$$k_u = Ce^{Q_a/(R'T)}, \tag{4.174}$$

where  $C$  = factor,  $Q_a$  = activation energy,  $R'$  = gas constant ( $8314 \text{ J K}^{-1} \text{ mol}^{-1}$ ), and  $T$  = absolute temperature.

This shows that for all aging mechanisms, a higher temperature will generally lead to a rise of the connection resistance or of the quality.

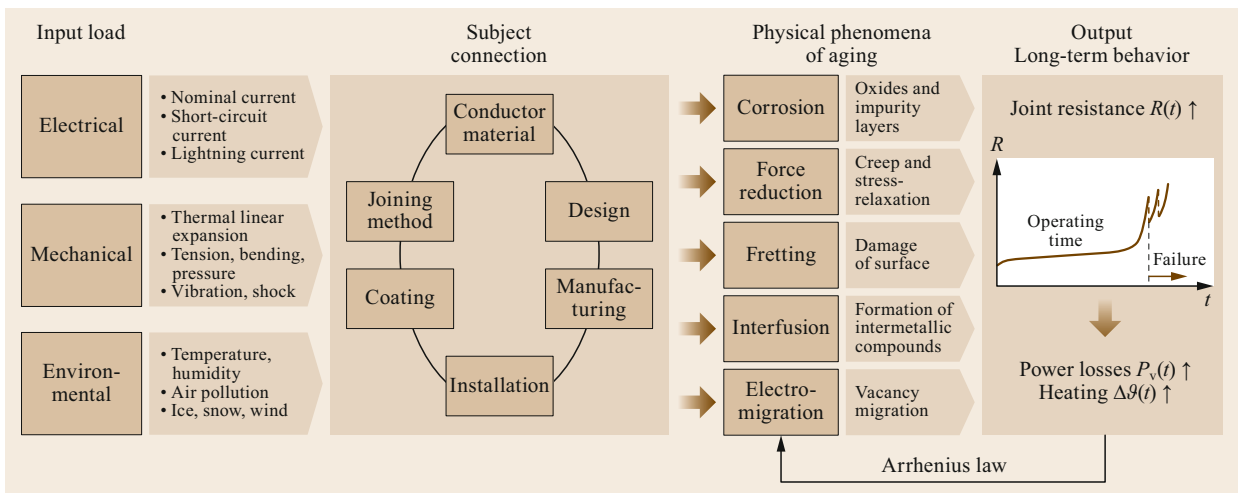

The basic time development of the quality factor  $k_u(t)$  (Fig. 4.93) can be described with the four phases [4.35]:

- *Formation phase*, depending on the contact materials (takes days to weeks).
- *Relative stability phase*, the actual operating time (should take several decades).
- *Accelerated aging*: an increased temperature at contact points causes a clearly faster reaction in one or more aging processes, thus increasing quality factor, power dissipation, and heating in the contact points (upward spiral) up to the melting point. Then, at the latest, the service-life limit of the connection is reached.
- *Intermittent failure*: newly-welded contact points repeatedly lead to a decrease of the performance factor (intermittent). However, these melting points do not have the required current-carrying capacity and burn out until the entire connection is destroyed.

From the aforesaid, a mathematical model can be derived that can describe the long-term behavior of a specific connection type, based on experiments. This makes it possible to estimate an extrapolation beyond the duration of the test [4.3, 35, 49, 50]

$$k_u(t + \Delta t) = k_u(t) + \frac{[k_u(t) - k_{ui}]de^{-[b/(R'T_E)+1/2]}}{t_0(t/t_0)^m} \Delta t, \tag{4.175}$$

where  $k_u$  = measured performance factor at time  $t$ ,  $k_{ui}$  = ideal performance factor ( $R_k = 0$ ),  $T_E$  = absolute temperature at constriction point,  $t_0$  = reference time (e.g., 1 h),  $m$  = exponent, empirically determined from the experiments,  $d$  = factor, empirically determined from the experiments, and  $b$  = factor, empirically determined from the experiments.

**Fig. 4.92** Complexity of contact and long-term behavior of electric connections under superposition of several load conditions and aging phenomena

**Fig. 4.93** Time dependency of performance factor  $k_u$  (schematic).  $k_{u0}$  = initial performance factor directly after construction ( $t = 0$ ),  $k_{u,crit}$  = critical (limiting) performance factor ( $t = t_{failure}$ )

**Table 4.45** Empirically determined parameters  $b$ ,  $d$ , and  $m$  from the experiments (preparation before installation: cleaning with spirit and wire brush) with bolted bus bar connections (example) (adapted from [4.35])

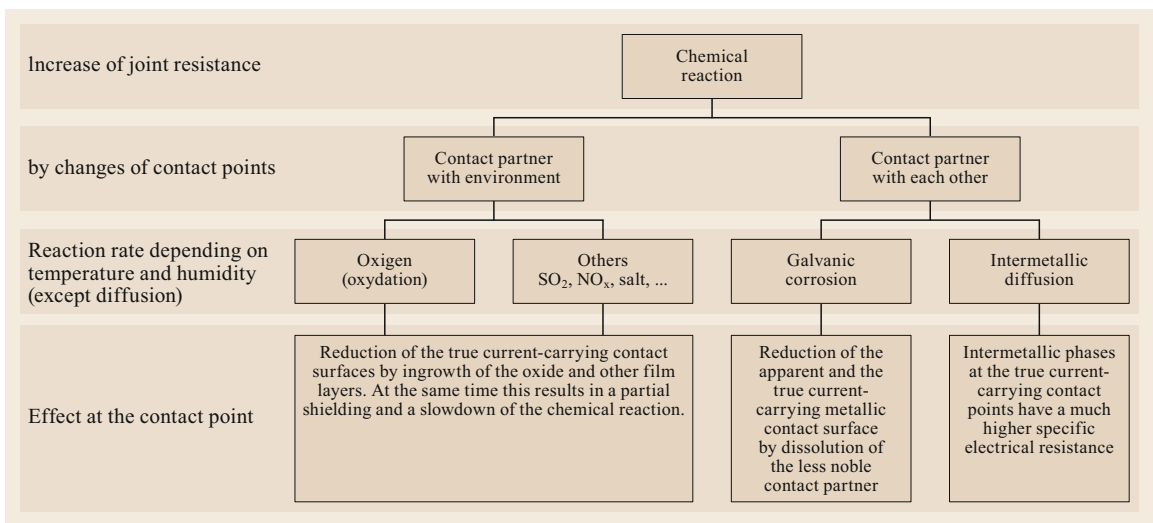

Material	$\vartheta$ (°C)	$m$	$b$ (J mol <sup>-1</sup> )	$d$
Al99.5F7	90–150	0.478	9709	0.1
Al99.5-Cu-ETP	90	0.616	14432	5

In this approach, the effects of all aging processes are superimposed without one being able to consider them separately. It is further assumed that the physical aging processes do not change during the period under consideration.

The parameters  $b$ ,  $d$ , and  $m$  must be determined experimentally for specific arrangements and operating conditions in long-term tests (duration of at least 1 year, but better 3 years). As an example, Table 4.45 shows the values for two bus bar bolted connections [4.35].

**Aging Due to Chemical Corrosion.** Aging due to chemical corrosion can be based on various processes that cause different effects at the contact location [4.42, 49] (Fig. 4.94).

Oxidation of the contact materials produces an oxide layer. Its specific electrical resistance is several orders of magnitude greater than that of the contact materials and, therefore, causes a film resistance  $R_f$ , which increases the connection resistance  $R_j$  considerably and, thus, the power dissipation in the connection. It is, therefore, essential that the related oxide layer be removed before assembly, particularly in the case of connections subject to high electrical loads. While the metallic contact points should be almost free of oxide layers, an oxide layer will form again after assembly in the joints between the contact partners as oxygen is adsorbed on the surface. If sufficient oxygen is available, oxide nuclei are formed, from which a closed, protective oxide layer grows. This, in turn, hinders the access

**Fig. 4.94** Overview on influences of chemical reactions on the aging of electric connections

**Table 4.46** Physical properties of aluminum and copper and their oxides (adapted from [4.42, 51, 52])

Property	Cu-ETP CW004A	Al99.5 EN AW-1350A	Cu <sub>2</sub> O	Al <sub>2</sub> O <sub>3</sub>

**Fig. 4.95** Chemical reactions in the oxidation of copper. 1 Oxidation of copper, 2 adsorption and reduction of oxygen, 3 diffusion of copper ions and electrons through the oxide layer (adapted from [4.42])

of further oxygen and, thus, slows down the reaction. However, higher temperatures accelerate the growth of thicker oxide layers (Figs. 4.95–4.98).

Mechanical stresses, e.g., due to the different coefficients of thermal expansion from the metal to the oxide layer or due to mechanical stresses perpendicular to the contact area within a joint can tear open the oxide layer, and further oxygen or moisture can infiltrate into the cracks.

The physical properties of copper(I) oxide Cu<sub>2</sub>O and aluminum oxide Al<sub>2</sub>O<sub>3</sub> are, in particular, their specific electrical conductivities  $\kappa$ , which are by a factor of tens smaller, and their much greater hardness  $H$  compared to the related metals leads over time to an in-

crease in the film resistance  $R_f$  (Table 4.46, Figs. 4.98–4.100) [4.35, 36, 42, 54].

**Dependence on time and temperature.** For bimetallic connections with a large difference in the standard potentials within the electrochemical voltage series (e.g., Al (–1.66 V)/Ag (+0.80 V) or Al (–1.66 V)/Cu (+0.34 V)) (Table 4.47) and the presence of moisture, electrochemical corrosion occurs in which electrons of the less noble metal migrate to the more noble metal at the contact points. The result is that the less noble metal is gradually deteriorated and the contact points are destroyed (Fig. 4.101). At temperatures slightly below 100 °C and at very low humidity (dry interior), the electrolyte is hardly present, and the chemical reactions become slower. In contrast, moist, high-salinity atmosphere (near the sea, industrial atmosphere, roads) significantly accelerates electrochemical corrosion.

**Fig. 4.96** Influence of temperature and time on the growth of oxide layers Cu<sub>2</sub>O on copper (adapted from [4.17])**Table 4.47** Electro-potential series of selected contact materials with ion layer in front of the electrode surface at 25 °C (adapted from [4.41])

For this reason, preventive measures must be taken. Long-term stable bimetallic connectors can be produced by suitable, usually material-locking connection technologies and subsequent sealing of the connection point against moisture. Alternatively, AlCu sheets, sleeves, and washers (thickness ratio Al/Cu: 70/30) have also proven themselves suitable for some applications. These rolled AlCu bimetallic sheets with a large surface and a material-locking aluminum-copper connection are placed between the aluminum and copper contact pieces to be joined. This way, electrochemical corrosion only occurs in the peripheral areas. For this

reason, these AlCu sheets and sleeves are always dimensioned a few millimeters larger than the apparent contact surface, and thus the material loss at the edge is taken into account (Fig. 4.102a,b). Special washers based on the described effects: – defined contact lines (real metallic contacts) instead of big apparent contact areas and – using designs creating elasticity, are an additional solution for e.g., Al-Cu connections. This solution, plastic housing in combination with contact protection grease, has been used successfully over the last 40 years in millions of applications worldwide (Fig. 4.102c,d).

**Fig. 4.103** Force reduction by various mechanisms (adapted from [4.17])

**Fig. 4.104a,b** Force reduction in bolted connection: (a) test sample and distribution of mechanical tension, (b) time dependence of mechanical tension  $\sigma$ , joint force reduction  $F_j$  and increasing joint resistance  $R_j$  for two different temperatures, where  $T_1 < T_2$  (adapted from [4.17, 49])

In addition, the surfaces of contact pieces made of copper, aluminum, or their alloys are coated with silver, nickel, or tin, especially for moving joints, because the oxides of these materials have a higher electrical conductivity and a lower hardness than the oxides of copper and aluminum (Tables 4.46 and 4.48). This allows the oxide layer to be destroyed and a current-carrying contact to be established with every relative movement of

the contact pieces. However, the electrochemical series (Table 4.47) must also be considered when selecting the material pairings.

**Intermetallic Diffusion.** Another aging process to be considered in electrical contacts is the *intermetallic diffusion* during joining of different metals. Due to differences in the atomic density of the metals, a particle transportation to free locations of the atomic lattice takes place at the interface layer. This process is accelerated by increasing temperature. The intermetallic phases (IMP) thus created show a significant higher conductivity than the initial materials (Tables 4.49 and 4.50).

**Reduction of the Mechanical Connection Force.** Besides the chemical reactions, the *reduction of the mechanical connection forces* has a significant influence on the long-term behavior of a joint (Fig. 4.92). The contact force  $F_j$  has a great influence on the contact resistance  $R_k$  and, thus, on the connection resistance  $R_j$  (4.156) and (4.157), Figs. 4.80 and 4.81). The connection force applied during joining is reduced over time by setting (leveling surface roughness of mechanically supporting contact surfaces by plastic deformation) and by stress relaxation in the primary area (dynamic primary recrystallization) and in the secondary area (secondary recrystallization with grain coarsening) (Figs. 4.103 and 4.104).

This process is considerably accelerated at higher temperatures. Due to the hysteresis behavior of copper and, especially, of aluminum (Figs. 4.80 and 4.81), the loss of contact force, which only occurs when it falls below a critical value  $F_{min}$  causes a rapid increase in connection resistance  $R_j$ . Tests for force reduction on bolted connections with copper bus bars at 105 and 140 °C (Fig. 4.105) and for clamps on high-temperature aluminum conductors at 23–100 °C clamp temperature (Fig. 4.106) clearly show the temperature dependence of setting and stress relaxation and the associated force reduction.

**Fig. 4.105** Related force reduction of bolted copper bus bar connections (adapted from [4.49])

**Fig. 4.106** Related force reduction of bolted connectors with stranded aluminum conductors TAL 550/70 (adapted from [4.55])

Since the microcontact points, which have been reduced or augmented by the force reduction, have over time oxidized in their environment at high temperatures, and pollution layers have been formed, retightening of bolted connections is often not very successful. If there is a risk that the connection force will reach the critical value  $F_{\min}$ , which is indicated, for example, by an increased temperature of the connection, it is advisable to completely open the connection, clean the contact surfaces, and remove the pollution layers before reassembling the connection and tightening it to the specified torque or the necessary contact force. A measurement of the resistance of the bolted or clamped connection after reassembly proves that the inspection was successful.

**Aging Due to Friction.** With electrical connections whose contact pieces move relative to each other (plug-type connectors, insulators, moveable connections), friction wear can lead to a further aging mechanism by removal of coatings or destruction of the surface of contact pieces. Mechanical load can be caused, for example, by oscillating movements with a frequency of 100 Hz (in high-current systems with 50 Hz alternating current); gradual, periodically recurring thermal linear expansion of the current path; switching operations; or mechanical vibrations or shocks acting from outside. The stress of the contact pieces during sliding or rolling friction is dependent on structural and environmental influences and can lead to various impermissible changes in the shape, size, and material properties of the contact pieces and their coating (Fig. 4.107) and, thus, adversely affect the connection resistance and the required plug-in force.

The simultaneous interaction of the many influencing variables makes a mathematical model for the description of aging very difficult to create, so that the experiment is recommended for concrete applications. Examples are shown in Figs. 4.108 and 4.109.

In the following, some experiments on the long-term behavior of electrical connections are presented, in which the various aging mechanisms act simultaneously (Table 4.51).

**Experiments – A Small Selection.** Experiments with bolted connections of aluminum, aluminum alloy, and copper show that reliable connections can be produced over decades even under high thermal loads and harsh climatic conditions (Figs. 4.110 and 4.111a). Aluminum-copper connections already show a signif-

icant increase in the quality factor after a few months, especially at high humidity. AlCu sheets can slow down the rapid aging process considerably, but cannot completely prevent it (Fig. 4.111b). The quality of the connection after assembly has a very significant influence on the long-term behavior of highly-stressed bolted connections (initial quality factor  $k_{u0}$ ). Especially with aluminum and aluminum alloys, it is essential to thoroughly remove the hard, electrically insulating aluminum-oxide layer before assembly (Fig. 4.79, Table 4.46). The time dependency of the quality factor  $k_u(t)$  reacts extremely sensitively to the quality of the assembly (target:  $k_{u0} < 1.5$  by proper assembly). For connections that had a quality factor  $k_{u0} = 1.2$  just af-

**Fig. 4.110** Long-term behavior of bolted connections under indoor laboratory conditions, experimental results; influence of the initial performance factor  $k_{u0}$  ( $1.2 < k_{u0} < 2.7$ ) on the long-term behavior of current-carrying bolted aluminum bus bar connections (bolts M12, 8.8, joint force after installation  $F_j$  16–30 kN, initial joint temperature  $\vartheta_{j0}$  100–160  $^{\circ}\text{C}$ ), experiments over 8.2 yr,  $k_{u0} = 1.2$  (ca. 100  $^{\circ}\text{C}$ )  $\rightarrow$  1.7 after 20 000 h,  $k_{u0} = 2.1$  (160  $^{\circ}\text{C}$ )  $\rightarrow$  12 after 20 000 h (adapted from [4.56])

ter assembly, after 20 000 h the quality factor rose to  $k_u$  (20 000 h) = 1.7. Already with a quality factor of  $k_{u0} = 2$ –3, a failure is to be expected after about 1 yr of continuous high-current loading of the connections. For uncleaned connections (Fig. 4.79,  $k_{u0} \geq 10$ ), operation with high current loads is not possible.

The long-term behavior of connections with stranded-aluminum conductors, e.g., overhead line conductors, is also very much dependent on the thorough pretreatment of the conductors and the associated initial quality factor (in the example,  $k_{u0} = 0.76$ –1.40) (Fig. 4.112). The long-term experiments carried out over several years with continuous-current loads also clearly show the influence of the current load (in the example 60, 100, and 130% of the rated current of the overhead-line conductor). While properly manufactured and installed connections in overhead lines function for decades at lower than rated loads, which corresponds to practical experience, a continuous high load or overload drastically reduces the service life.

Plug-in-type connectors are influenced significantly by the environment because of their predominantly single-point contacts. Their chemically induced aging

**Fig. 4.111a,b** Long-term behavior of bolted connections under harsh environmental conditions, experimental results. **(a)** Aluminum and Copper. **(b)** Bimetallic aluminum-copper connections with and without AlCu-sheets (adapted from [4.42, 49])

can be considerably reduced by suitable coatings with low chemical reaction potential with the environment or with low-resistivity coatings (e.g., silver plated), (Fig. 4.113). Lubricants reduce the static and rolling friction during contact movement and can, thus, reduce the undesirable abrasion process. However, when the coating has been worn down or when it does not even exist, the lubricant alone cannot prevent the aging process (Fig. 4.114).

#### Measurement and Evaluation of Connection Resistances

Measuring the connection resistance is essential for developing and testing, as well as for quality control and condition assessment of electrical connections. Connections in electrical power engineering usually have connection resistances in the range of less than  $1 \mu\Omega$ . This means that special attention must be paid to measuring this quantity by means of four-point measurement (current-voltage measurement). The following basic options are available:

- Measurement with high alternating current (AC), e.g., the rated current. For voltage measurement,

a sensitive voltmeter is sufficient. However, the values in the measuring circuit must be determined by the magnetic field in and around the current-carrying conductor-induced voltages compensated (see the subsequent section on AC measurements, voltage compensation, Fig. 4.121). The conductor and the connection heats up during operation at high current. The connection temperature and the connection resistance must be measured, and the latter converted to  $20^\circ\text{C}$ .

- Measuring with high direct current (DC) is the simplest method, but DC high-current sources with low ripple of the current are usually not available or are not transportable, and, therefore, are only suitable for special applications. As with AC, the heating of the conductors must be considered.
- Measuring with low DC current (20–100 A DC) is possible with consideration of the previously mentioned disadvantages and is the most frequently used method. Here, however, the values of the voltage drop measured are in the microvolt range. Systematic measurement errors due to thermoelectric or other external voltages must be compensated. Microohmmeters with small DC measuring currents usu-

**Fig. 4.112** Long-term behavior of connectors for stranded-Al conductors under indoor laboratory conditions; influence of initial performance factor and permanent current load; 3 yr experiment and estimated lifetime according to (4.175). Initial performance factor  $k_u$  after installation (conductor AL/St 185/30): min.: 0.76, average: 0.94, max.: 1.40 (adapted from [4.57])

ally show the measured and corrected resistance value and, because of their mobility, are suitable for a wide variety of applications in practice.

For all measurement methods, the choice of the current-injection and the voltage-drop locations has to ensure a current flow as homogeneous as possible (Fig. 4.114).

**Measuring with Small DC Currents.** When measuring with small DC currents  $I_m$ , e.g., with a  $\mu\Omega$ -meter,

**Table 4.52** Thermoelectric voltage (excerpt) (adapted from [4.58])

Material	Thermal constant $K_{ptM}$ ( $\mu\text{V K}^{-1}$ ) at 0 °C (relative to platinum)

<sup>a</sup> Reference material.

(Fig. 4.115a), thermoelectric voltages  $U_{th}$  are generated in the voltage-measuring circuit when different conductor materials (test object, connecting leads, electronic processing of the measured variable) and different temperatures occur within the measuring arrangement. These can be of the same order of magnitude as the actual measured value  $U_j$  and are superimposed on it (Fig. 4.115b).

The magnitude of the thermoelectric voltages results from the thermal constants  $K_{ptM}$  (Table 4.52) and the absolute temperature  $T$  at the point of contact of two metallic conductors M1 and M2

$$U_{th} = K_{ptM1M2} \Delta T, \tag{4.176}$$

with

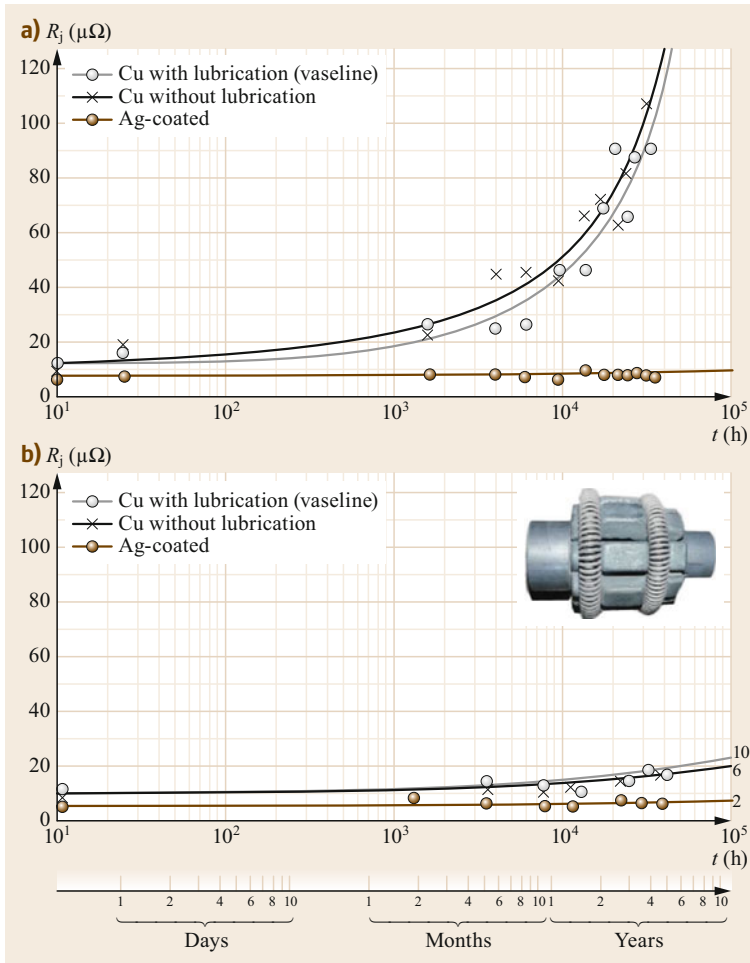

$$K_{ptM1M2} = K_{ptM1} - K_{ptM2}, \tag{4.177}$$

where  $U_{th}$  = thermoelectric voltage,  $K_{ptM}$  = thermal constant with reference to platina, M1 and M2 = metallic conductors 1 and 2, and  $\Delta T$  = absolute temperature difference.

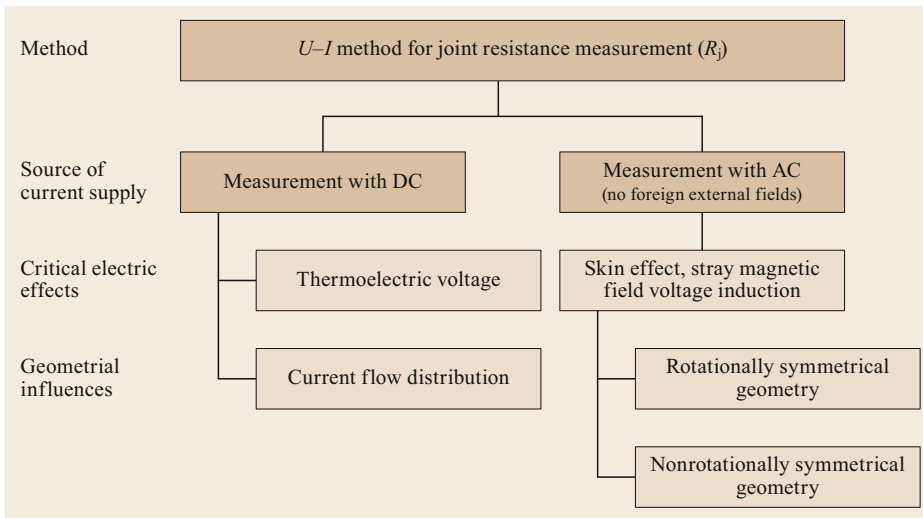

With  $n$  bimetallic contact points in a measuring circuit, the individual thermoelectric voltages add up to the total voltage  $U_{th\text{total}}$ .

$$U_{th\text{total}} = \sum_1^n U_{th\ n}. \tag{4.178}$$

The compensation of these thermoelectric voltages  $U_j$  can be achieved by measuring the voltage drop across the connection, i.e., in two steps with reversal of the current direction and subsequent averaging (Fig. 4.116a). In an alternative method, the voltage drop across the connection without external current flow ( $I_m = 0$ ) is caused by the sum of the thermoelectric voltages  $U_{th}$  in the measuring circuit. Only in a second step of the measuring process is the measuring current  $I_m$  switched on,

**Fig. 4.113a,b** Long-term behavior of plug-in-type connectors (tulip-type); experimental results; influence of the atmosphere (indoor switchgear compared to  $\text{SO}_2$  outdoor switchgear) on the joint resistance  $R_j$  with a silver-plated and plain copper surface. **(a)**  $\text{SO}_2$ -air atmosphere ( $0.75 \text{ mg/m}^3$ , wet) and **(b)** switchgear room (indoor). Fig. 4.119 DC measurement of joint resistance at stranded conductors around the wires

and from the difference between the two measurements, one can determine the true value of the connection resistance  $R_j$  (Fig. 4.116b). Reversible direction of measuring current

$$R_j = \frac{\Delta U_j}{I_m} = \frac{\overbrace{(\Delta U_j + U_{th})}^{\text{phase 1}} - \overbrace{(-\Delta U_j + U_{th})}^{\text{phase 2}}}{2I_m}, \quad (4.179)$$

and separation of thermoelectric voltages

$$R_j = \frac{\Delta U_j}{I_m} = \frac{\overbrace{U_{th}}^{\text{phase 1}} - \overbrace{(-\Delta U_j + U_{th})}^{\text{phase 2}}}{I_m}. \quad (4.180)$$

Resistance measurements in the  $\mu\Omega$ -range by carrying out a current–voltage measurement and applying Ohm’s law assume that the current flow fields in the proximity of the voltage-drop location is as homogeneous as possible. This is reasonable for long, slender conductors with their connections. For bulky test objects though (Fig. 4.117), such as connectors with high lateral dimensions compared to their length or to the length of the related conductor (Fig. 4.118) [4.59], an inhomogeneous current flow field has to be taken into account. In this case, the current-injection and the voltage-drop measurement point have to be carefully selected so that measurement occurs in a mostly homogenous region of the flow field. Possibly multiple measurements at the circumference of the connector and subsequent averaging can deliver a useful result.

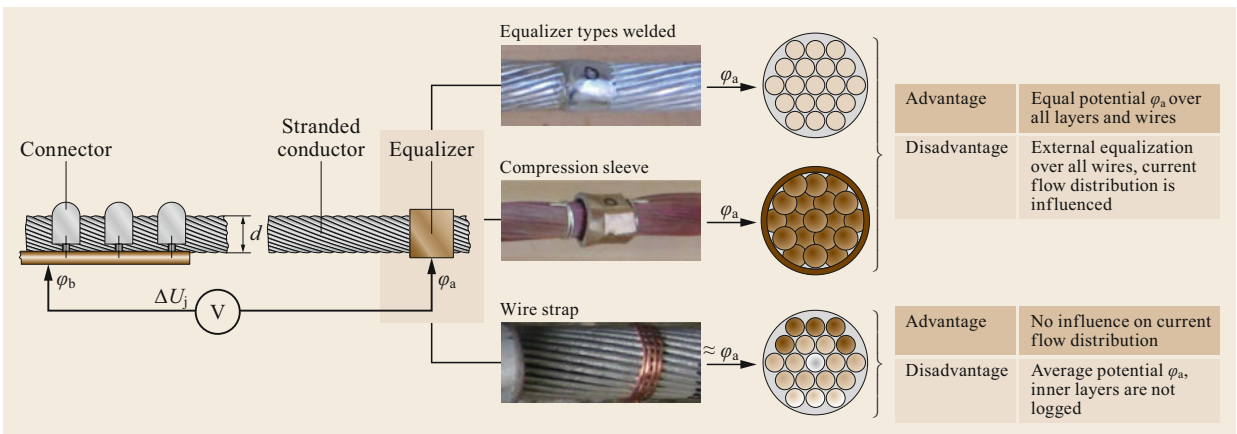

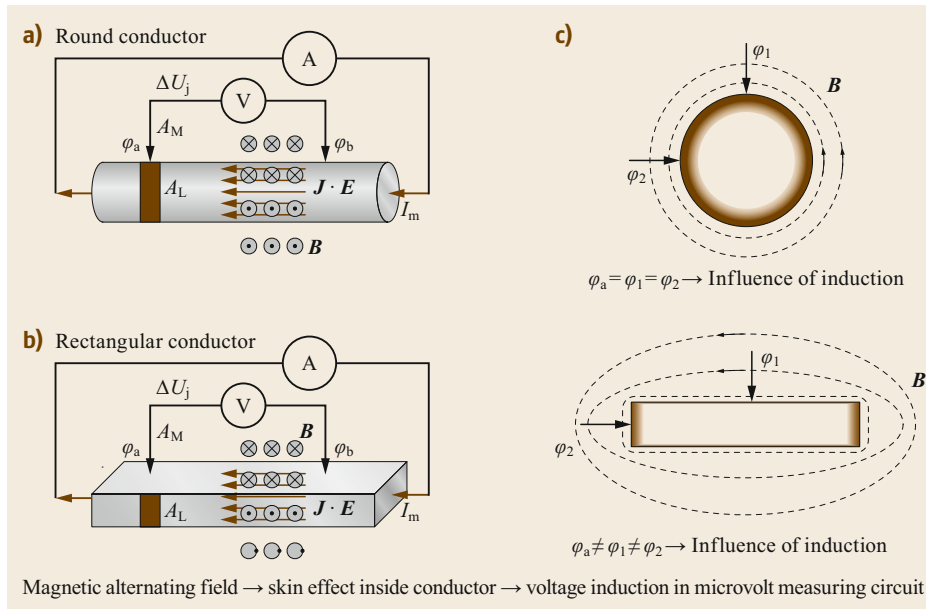

Fig. 4.120 DC measurement of joint resistance at stranded conductors, potential tap

**Fig. 4.121a–c** AC measurement of joint resistance, influence of magnetic field and geometry. (a) Rotationally symmetrical geometry, (b) non-rotationally symmetrical geometry, (c) influence of current density distribution and connector geometry on measured voltage drop  $\Delta U_j = \varphi_a - \varphi_b$  in section  $A_L$

When measuring connection resistances on stranded conductors, it must be assumed that depending on the contact arrangement, not all individual wires conduct the same partial current and have different potentials in the area of the voltage tap (Fig. 4.119). Equalizers in the form of welded joints, ferrules, or wire coils can largely solve this problem (Fig. 4.120). However, with welded and pressed equalizers, an idealized current distribution is forced, which does not correspond to the distribution in the connector in practice.

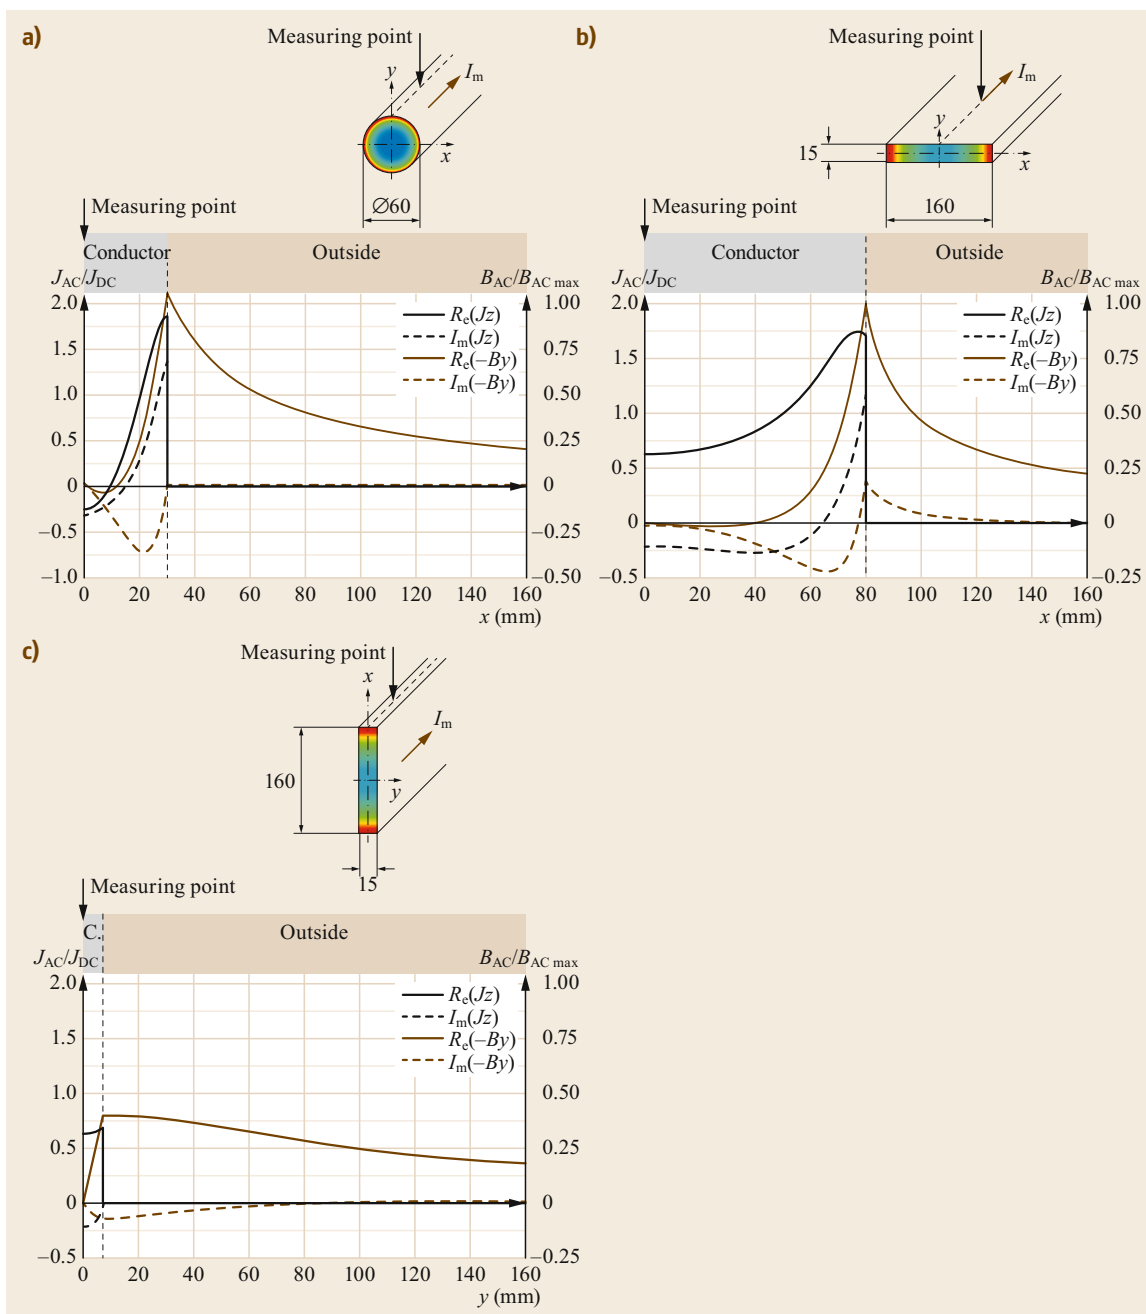

**Measuring with AC Current.** If the connection resistance must be measured with AC, the effect of the electromagnetic field depending on the conductor geometry must be taken into account (Fig. 4.114). While the skin effect of rotationally symmetrical, round conductors is evenly distributed over the circumference of the conductor, the current density  $J$  in rectangular conductors, and, thus, the measured potential, depends on the measuring point (Fig. 4.121).

In addition, in the measuring loop, to determine the voltage drop  $\Delta U_j$ , a surface  $A_L$  in the conductor and a surface  $A_M$  outside the conductor are created, which are permeated by the alternating internal and external magnetic field  $B$ . An electromagnetic voltage is induced and is superimposed on the measured variable. While the outer surface can be reduced to a minimum by clever arrangement and twisting of the measuring conductors, the inner surface with the highest magnetic flux density  $B$  remains, namely, at the boundary layer between conductor and environment in the measuring circuit (Fig. 4.122). Through an *outcrossing* measuring loop

two surfaces  $A_1$  and  $A_2$  of different sizes (Fig. 4.123a) are created, in which the magnetic flow is in opposite directions. The induced voltages, therefore, result in  $e_1$  and  $e_2$ , which are opposite and ideally complement each other to zero, if the two surfaces are matched to the minimum of the voltage to be measured (by trial and error). In this case, the induced voltages are compensated, and the measured variable  $\Delta U_m$  corresponds to the true value of the real proportion of the voltage drop  $\Delta U_j$  over the connection (Fig. 4.123b).

Another way to evaluate live electrical connections is to measure the connection temperature using infrared thermography. Here, the measured temperature is a mediating variable for the connection resistance. Prerequisites for correct measurement of the connection temperature include:

- A sufficiently high, constant current load before and during the measurement.
- The power dissipation generated by the connection and the resulting excess energy.
- The temperature of the connection depends on the square of the current (4.33). For example, if only half the rated current flows, then only about a quarter of the heating can be expected. This can lead to critical misjudgments of the condition of a connection.
- The current distribution within the equipment and on parallel current paths must be known and taken into account.
- The emission coefficient  $\varepsilon$  of the surface under consideration must be known and must be considered (4.70).

**Fig. 4.122a–c** Examples for AC measurement of resistances, finite element simulation of current density inside the conductor  $J_{AC}/J_{DC}$ , and magnetic flux density inside and outside conductor  $B_{AC}/B_{AC\ max}$ , influence of geometry ( $x$  and  $y$ : distance from measuring point). **(a)** Rotationally symmetrical geometry, round conductor; **(b)** nonrotationally symmetrical geometry for rectangular conductor, flat, and **(c)** rectangular conductor, edgewise

**Fig. 4.123a,b** AC measurement of joint resistances, elimination of magnetic induced voltages in the measuring circuit. (a) Arrangement of measuring circuit with crossed measuring leads to compensate induced voltages in area  $A_1$  (conductor inside and outside) by area  $A_2$  (larger loop outside), (b) phasor diagram for ideal compensated induced voltage

- Knowledge and consideration of all ambient conditions, particularly outdoors (ambient temperature, precipitation, air speed, solar and sky radiation). This way, conspicuous connections can be identified and hot spots can be detected quickly.

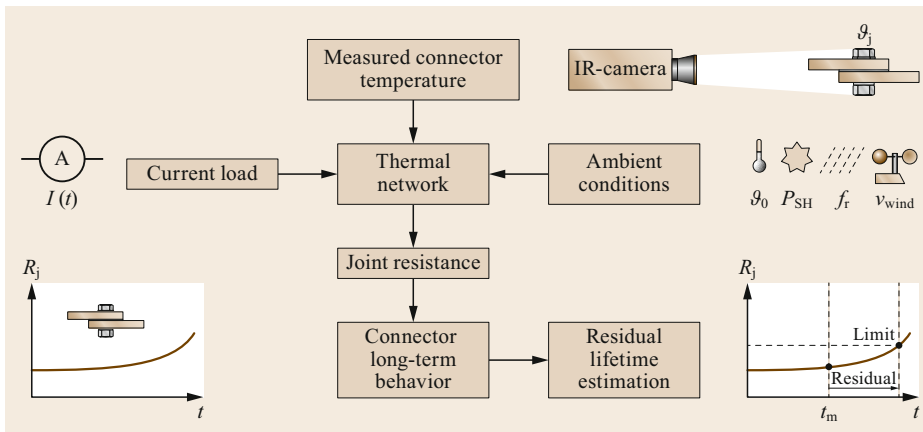

It is possible to estimate the remaining service life of connectors in operation if the fundamental long-term behavior of such connectors is known from experiments. With the help of a thermal network and using the already measured temperature rise and the known test parameters (current environment) (Sect. 4.3.1) the connection resistance of the connector can be calculated and compared with the known long-term performance of this type of connector. Taking into account past and future current loads the remaining life-time of the connector can then

be estimated (Fig. 4.124). This way, inspections can be planned long in advance, and urgent maintenance actions can be initiated without delay [4.60].

**IR Measurement.** Using IR measurement can result in more precise analysis doing a so-called fingerprint measurement.

After installation of a new line or a substation there are used hundreds of same connections. For example, 1 year after starting operation a first measurement on a group of samples is made. The above-mentioned influencing parameters like current, ambient temperature, . . . , should be recorded. After some period of operation e.g., 5 years, the IR measurement is repeated with parameters similar to the initial ones. The evaluation of this recording compared to the starting values allows a statement concerning the state of quality of the connection.

**Acknowledgments.** The author would like to thank the current and former staff of the Institute for Electrical Power Supply and High Voltage Technology at Dresden University of Technology for their kind support while he was working on this chapter; in particular, special thanks go to PD Dr.-Ing. habil. Helmut Löbl, Dr.-Ing. Stephan Schlegel, Dr.-Ing. Robert Adam, and Dr.-Ing. Christian Hildmann for providing related documents and reviewing this material. Thanks also go to the companies RIBE SubCon GmbH, Austria, Pfisterer Kontaktsysteme, Germany, and Werner Industrielle Elektronik Kreischa, Germany for providing illustrations. This chapter could not have been published in English if it had not been for the editor of the book, Prof. Konstantin O. Papailiou, whom I also would like very much to thank.

### Steffen Großmann

Institute of Electrical Power and High Voltage Engineering  
Technische Universität Dresden  
Dresden, Germany  
[steffen.grossmann@tu-dresden.de](mailto:steffen.grossmann@tu-dresden.de)

Steffen Großmann (VDE, CIGRE) received the Dr.-Ing. degree in Electrical Engineering from the Technische Universität Dresden, Germany (1988). In 1990, he started working at RIBE-Richard Bergner GmbH, dealing with the electrical and mechanical behavior of fittings for substations and overhead lines. In 1997 he became Product Team Manager for substations and low-voltage materials. He is Full Professor at the institute for Electrical Power Systems and High-Voltage Engineering at TU Dresden.

# Basics of Power Systems Analysis

Carlo Alberto Nucci , Alberto Borghetti , Fabio Napolitano , Fabio Tossani 

This chapter provides the background required to understand the main aspects of power systems analysis and operation under steady-state and transient or dynamic conditions. It is intended for senior undergraduate or graduate students of electrical engineering as well as practitioners, so readers are assumed to have a solid background knowledge of electrical engineering.

The main technical issues associated with power systems analysis are addressed, focusing in particular on alternating current (AC) transmission lines, networks, load-flow and short-circuit calculations, stability analysis, frequency control, and electromagnetic transient appraisal. The chapter also references the most important and popular model frameworks and calculation/modeling tools that have been developed by researchers and engineers working within the electric power systems area in the last few decades. It is emphasized in this chapter that an understanding of the issues dealt with here is required to comprehend other chapters of this handbook devoted to distributed generation and smart grids, and this knowledge will also be needed to be able to operate upcoming power systems.

The chapter is divided into sections focusing on the following topics:

1. Power systems evolution, from the origins to the traditional structure
2. Transmission lines in steady state, transmitted active and reactive power
3. Power flow analysis (load-flow equations and resolution methods)
4. Short-circuit calculations for unbalanced faults (symmetrical components, fault equations, and sequence networks)
5. Stability (states of operation, classification, P-delta curves, rotor angle stability, equal area criterion, multi-machine stability and voltage stability)
6. Generators reserve and dynamics, frequency dependence of the load, control structure for frequency control

7. Traveling waves in a lossless line, reflection and transmission coefficients, multiple reflections in a line of finite length; electromagnetic transients (classification of transients, EMTP)
8. Power systems in the future (why we need a smart(er) grid, microgrids and energy communities)

Additional information and supplementary exercises for this chapter are available online.

In this chapter, we present a succinct summary of the fundamentals of power systems analysis and operation under steady-state, dynamic, and transient conditions. We consider the main technical issues that are relevant to the transmission of electric energy, focusing mainly on AC transmission lines and networks and addressing load-flow and short-circuit calculations, stability, frequency control, voltage control, and electromagnetic transient appraisal. However, it should be noted that there are a number of excellent books that cover these subjects in a far more comprehensive manner than possible in this chapter (e.g., [5.1–32]).

In the context of this handbook, an understanding of the subjects covered by this chapter is useful for comprehending Chap. 15 on distributed generation and smart grids, and thus how modern power systems work, given that renewables are increasingly being con-

nected to networks through power electronic converters. It should, however, be noted that HVDC (high-voltage direct current) and DC (direct current) applications, modeling, analysis, and operation are deliberately overlooked in this chapter, as these topics are covered in Chap. 12.

This chapter is intended for use by senior undergraduate or graduate electrical engineering students and practitioners who are familiar with the theory of electrical circuits and of electrical machines. We therefore assume that the reader has a solid background knowledge of electrical engineering, along with an understanding of the per unit method.

After some sections or paragraphs, there are web-links to files that contain illustrative examples, exercises, or even animations, which are generally accompanied by the input file of the relevant program codes.

## 5.1 Electric Power System Evolution

### 5.1.1 The Dawn of Electric Power Systems

In its simplest form, an electric power system consists of an electric power generator, a distribution system consisting of one or more distribution lines connecting the generator to users, and some protection/maneuver devices (see Fig. 5.1). Nowadays, this simple configuration is used for off-grid power systems or microgrids operating under islanded conditions, but it is also the configuration that was employed for the first power systems built at the end of the nineteenth century to provide lighting in New York City [5.33].

The history of electric power systems is commonly considered to have begun in the year 1882, when a power station on Pearl Street in New York was inau-

gurated by Thomas Alva Edison (Fig. 5.2). This plant, which generated DC power using 175 HP high-speed steam engines, was designed to supply electrical energy to 400 lamps belonging to 82 customers in the business district of Wall Street.

The construction of the first power station was hugely important: although Volta had invented the first primary cell a century earlier, and more efficient primary cells had been constructed since then (such as the one devised by George Leclanché in 1865), these modest electrochemical power sources were not able to provide the amount of energy needed to power a whole district.

Immediately after the discovery of electromagnetic induction by Faraday in 1831, a variety of generators

**Fig. 5.1** The simplest configuration of an electric power system

were proposed. In 1869, not only was the first DC dynamo revealed in Vienna by Gramme and Pacinotti, but its working principle was also discovered to be reversible, resulting in the creation of the motor.

Furthermore, following the invention of the arc lamp by Foucault in 1841, it was subsequently improved by others until a satisfactory design was devised by Jablochkov in 1876. While the resulting lamp was suitable for generating the large luminous intensities required for public lighting (indeed, it was used along the Avenue de l'Opéra in Paris from 1879 to 1881), it was too bright for private use. Edison's lamp, consisting of a filament housed in a glass vacuum bulb, was far more appropriate for this purpose.

Thus, in summary, two types of light sources and two types of power sources (direct current and alternating current) were available in 1882, but the transformer was yet to be invented.

Table 5.1 summarizes the advances discussed above as well as subsequent developments that are discussed in the next section.

## 5.1.2 From the War of the Currents to the Twenty-First Century

There is no general consensus concerning the year in which the transformer was invented, although it seems fair to ascribe its invention to the Hungarian engineers Zipernowski, Blàthi, and Dèri in 1984. However, there is little doubt that the introduction of transformers was the factor that ultimately caused AC power systems to become more convenient and therefore popular than DC power systems, even though Edison was a passionate supporter of the use of DC (which is as convenient as AC for powering filament lamps, and more convenient than AC for powering arc lamps).

We now consider some of the main steps that shaped the evolution of power systems towards those that are used today. In 1889, René Thury developed the first commercial HVDC transmission system in Europe. This system used hydroturbines on the Gorzente River to supply Genoa in Italy. The generators were connected in series to attain the high transmission voltages needed. When loads were added to the system, more generators were added to maintain the voltage at the load. The first long-distance transmission of DC electricity in the US occurred in 1889 at Willamette Falls Station in Oregon. A flood destroyed this station in 1890, but it was quickly rebuilt, and the Falls Electric Company replaced the DC generators with experimental AC generators from Westinghouse in the same year. In 1896, the construction of the first AC generation and transmission system was completed at Niagara Falls using Westinghouse equipment. Nikola Tesla's work, such as his invention of the induction motor in 1888, helped to make AC power systems increasingly attractive. But the event that marked the success of alternating current was a few years before 1896: The Frankfurt ex-

**Fig. 5.2** Thomas Edison's power station on Pearl Street (adapted from [5.34])

**Table 5.1** Key scientific advances and events (including dates and relevant scientists) that facilitated the development of power systems engineering

Primary cells	Generators
1800 – Volta (pile)	1831 – Faraday (electromagnetic (EM) induction)
1830 – Grove (Zn-Pt)	1832 – Pixii (rudimentary alternator)
1841 – Bunsen (Zn-C)	1856 – Siemens & Alliance
1877 – Leclanché (Zn-Mn)	1860 – Pacinotti (dynamo)
1881 – Thiebaut and Gassner	1869 – Gramme (dynamo)
Light sources (lamps)	Transformers, AC, and three-phase
1841 – Foucault (first arc lamp)	1884 – Zipernowski, Blàthi, and Dèri (transformer)
1876 – Jablochkov (arc lamp)	1888 – Ferraris (AC rotating field)
1878 – Edison (1879 Menlo Park)	1888 – Tesla (induction motor)
	1889 – Blàthi (induction meter)
	1891 – Dobrowolski (three-phase systems)

hibition in August 1891: three-phase transmission line (42 Hz) at 25 000 V, which started from the hydroelectric plant built for a cement factory in Lauffen, on the Neckar river and with a distance of 175 km reached Frankfurt. Promoted by industrialists such as George Westinghouse, the major advantages of AC electric utility services soon became obvious, so DC systems declined in popularity towards the end of the nineteenth century. The advent of the transformer, three-phase circuits, and the induction motor all helped to drive the adoption of AC electric systems as the global standard [5.35].

There are objective advantages of operating electric power systems using AC rather than DC. First, only AC systems can make use of transformers, which allow the same power to be transported at higher voltages and lower current amplitudes—thus minimizing power losses and voltage drops along power lines—and different voltage levels to be used for generation, transmission, distribution, and utilization. With AC, it is possible to implement three-phase networks, allowing smooth, nonpulsating power flows and easy interruption of current in high-voltage equipment. Also, induction motors—which are inexpensive, rugged, and can serve most of the needs of industrial and residential users—can be employed with AC power systems. Further, the advent of steam turbines (which work best at high speeds) made AC generators highly advantageous, as

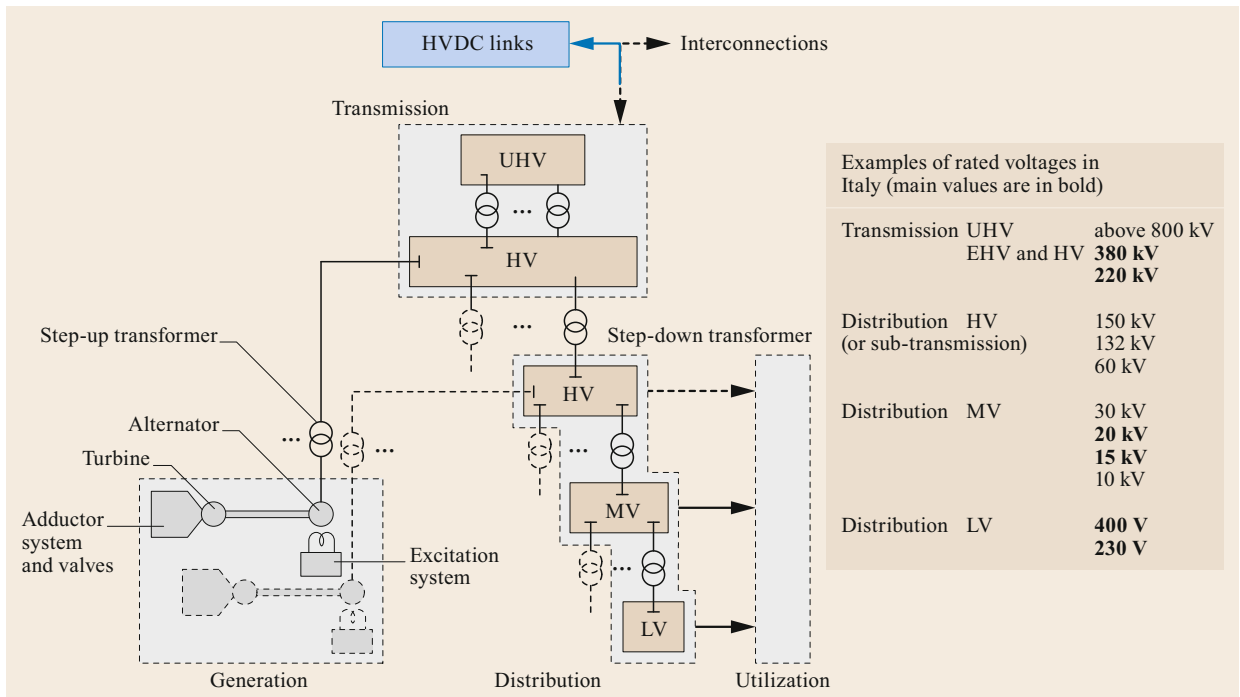

the commutators of DC motors and generators impose limitations on the voltage, size, and especially the speed of those machines.

Inventors such as Galileo Ferraris, Nicola Tesla, William Stanley, Michael von Dolivo-Dobrowolsky, Elihu Thomson, Lucien Gaulard, John Gibbs, and others working in Europe and North America all contributed to advances in AC technology. Much has been written about the so-called *War of the Currents* in the late 1880s, but it was more of a media fight; it was not a significant factor in the subsequent dominance of AC power systems [5.35]. The final decision on the type of system to be applied in a particular scenario has always been made based largely on technical aspects, and AC systems offered more advantages than DC systems given the system requirements and the technology available at that time. It should be noted, however, that although AC power systems have dominated around the world since the late nineteenth century, some DC distribution systems are still used in electric traction systems (trolley bus, railways, or subways). Also, some cities continued to use DC well into the twentieth century: Helsinki had a DC network until the late 1940s, Stockholm lost its dwindling DC network as late as the 1970s, London had some DC loads until 1981, and certain locations in Boston still used 110 V DC in the 1960s. The last DC circuit—a vestige of the nineteenth-century DC system of New York City—was shut down in 2007 [5.35].

## 5.2 Mission and Traditional Structure

The traditional mission of a power system is to provide electricity at the rated frequency and the rated voltage to customers. While the frequency is the same in all parts of the system, the rated voltage can differ depending on the part of the network of interest. The rated voltages of alternators located at power stations typically

range between 15 and 25 kV. Such voltages need to be substantially increased to 66–1000 kV or more by the step-up transformers that connect power stations to high-voltage (HV) and extra-high voltage (EHV) transmission networks (which are relatively well meshed) if the power is to be transmitted with minimal line losses

**Fig. 5.3** Basic elements of an electric power system in its traditional form (EHV, HV, MV, and LV refer to extra-high, high, medium, and low voltage, respectively; adapted from [5.9])

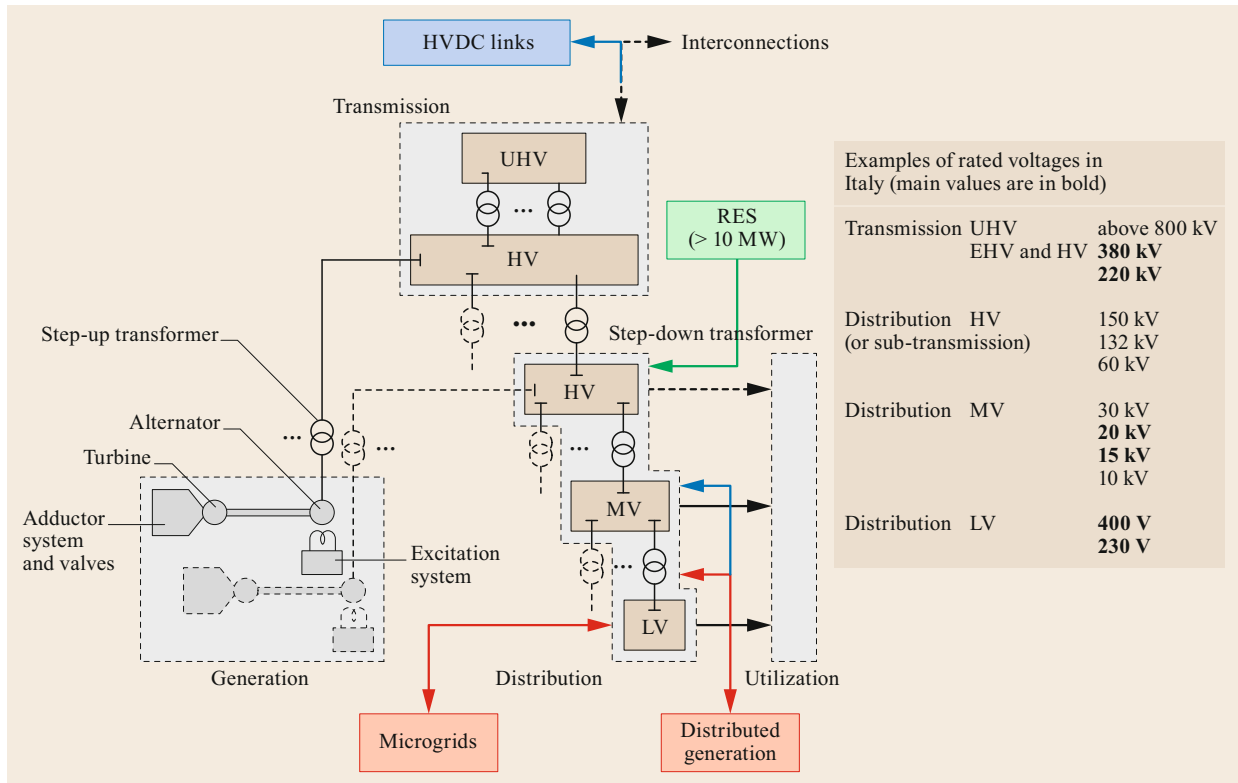

and voltage drops. A single generic HV or EHV line of the transmission network carries hundreds or even thousands of megawatts, possibly in both directions, depending on its operating conditions. Very large power systems (e.g., those of neighboring countries) are generally interlinked through their transmission networks. In some cases, HVDC links are employed to interconnect systems that are not synchronized with each other, to transmit power over very long distances, and for long underground/submarine links. The high-voltage part of the network is then connected to the *high-voltage distribution network*, which is frequently referred to as the *subtransmission network*, to carry power towards a load area. The geographical extent of the subtransmission network depends on the user density in the load area (the power typically ranges from a few megawatts to tens of megawatts for each HV distribution line). Electric power is then carried to each user via *medium-voltage (MV) distribution networks*, where each line can carry around a megawatt of power, and by *low-voltage (LV) distribution networks*. Such a structure is depicted in Fig. 5.3, which also shows possible interconnections with other networks.

We now consider the power system scenario in Italy, which is representative of the situation in quite a few

other countries. The aim of the power system in Italy is to meet the demand for electricity 24 h a day, 365 days a year. This demand arises from:

- 700 HV users (20%)
- 100 000 MV users (35%)
- 35 000 000 LV users (20% domestic, 25% others).

Up to the end of the twentieth century, this aim was accomplished using a number of thermal power plants equipped with steam turbines driven by traditional fuels (coal, oil, gas, etc.) or with gas turbines and/or hydroelectric plants (with a reservoir or basin, or the fluent-water type). Over the last couple of decades, however, the increasing popularity of so-called *distributed generation*, which often utilizes renewable energy sources, has led to some significant changes to the traditional power system structure. In Italy, as well as in many other countries, a considerable amount of power has been connected to the distribution network (LV and MV). To realize large power values (e.g., larger than 10 MW), renewable energy sources (RESs) must be connected directly to the HV network, which is in turn interconnected to the synchronous grid of continental Europe. This structure is depicted in Fig. 5.4; note the presence of *microgrids*—small networks of electricity

**Fig. 5.4** Basic elements of a modern electric power system; note the inclusion of distributed generation, which is connected to the MV and LV distribution networks, as well as the presence of microgrids and a massive amount of renewable energy sources (RES) that is connected to the HV network (adapted from [5.9])

users with a local source—that are usually attached to the centralized national grid but are also able to function independently. The relatively complex operation of modern networks such as this will be briefly addressed in Sect. 5.9.

In Italy, there are over 560 000 power plants (including thermal, hydro, and RES plants), one transmission system operator – Terna (<https://www.terna.it>), which is part of the European Network of Transmission System Operators for Electricity, ENTSO-E –, and 150 entities that are involved in distribution.

If an electric power system is to accomplish its mission, a number of classical issues must be addressed:

- Planning
- Unit commitment and economic dispatch (according to market constraints)
- Power flow
- Fault analysis and protection system design
- Frequency control and voltage control
- Stability
- Insulation coordination and protection against the effects of lightning and overvoltages
- Power quality.

Due to its introductory nature, this chapter will ignore all aspects relating to the planning of power systems and those concerning the generation of power (i.e., traditional power station or RES generating plant design, operation and control, unit commitment, and economic dispatch). Nor are power system relays, insulation coordination, protection against overvoltages, and power quality covered here; most of these topics are dealt with in other chapters of this handbook.

In what follows, we shall focus on the fundamentals of transmission line theory in both the steady-state and transient regimes, on power flow and fault analysis, on stability assessment, and on frequency (and voltage) control, in order to impart the technical background required to understand and develop modern power systems as well as upcoming power systems (the topic covered in the last section of the chapter).

### 5.3 Transmission Line Equations in the Steady State

#### 5.3.1 The Telegrapher's Equations

Let us consider a symmetrical, balanced, three-phase line in a sinusoidal steady state. By making these assumptions, we can refer to the positive-sequence single-phase equivalent model of the line. The relevant distributed parameter circuit is represented in Fig. 5.5. The infinitesimal element  $dx$  is located a distance  $x$  from the origin of the line. Therefore, the reference frame is oriented in the positive direction from the start of the line—where we can imagine a power source to be located (indicated by the subscript p)—to the end of the line, where the power arrives (indicated by the subscript a).

In Fig. 5.5,  $r$  and  $l$  are the resistance and inductance of the line per unit length, while  $c$  and  $g$  are the capacitance and conductance per unit length.

We define the primary parameters of the line as follows:

- Longitudinal impedance per unit length

$$\bar{z} = r + j\omega l \quad [\Omega \text{ m}^{-1}] \quad (5.1)$$

- Transverse admittance per unit length

$$\bar{y} = g + j\omega c \quad [\text{S m}^{-1}]. \quad (5.2)$$

#### Derivation and Integration of the Equations

Utilizing Steinmetz's symbolic notation and setting  $e(x, j\omega) = \bar{E}_x$  and  $i(x, j\omega) = \bar{I}_x$ , the line equations can be derived by applying Kirchhoff's voltage law to the positive-oriented loop in Fig. 5.5, thus obtaining (5.3) below, and Kirchhoff's current law to the bus, thus obtaining (5.4). In these equations, higher-order infinitesimals are neglected.

$$\frac{d\bar{E}_x}{dx} + \bar{z}\bar{I}_x = 0 \quad (5.3)$$

$$\frac{d\bar{I}_x}{dx} + \bar{y}\bar{E}_x = 0. \quad (5.4)$$

Differentiating (5.3) and (5.4) with respect to  $x$  yields the differential equations

$$\frac{d^2\bar{E}_x}{dx^2} + \bar{z}\frac{d\bar{I}_x}{dx} = 0 \quad (5.5)$$

$$\frac{d^2\bar{I}_x}{dx^2} + \bar{y}\frac{d\bar{E}_x}{dx} = 0. \quad (5.6)$$

Upon combining (5.5) with (5.4) and (5.6) with (5.3), we obtain

$$\frac{d^2\bar{E}_x}{dx^2} - \bar{z}\bar{y}\bar{E}_x = 0 \quad (5.7)$$

$$\frac{d^2\bar{I}_x}{dx^2} - \bar{z}\bar{y}\bar{I}_x = 0. \quad (5.8)$$

We define the following secondary parameters of the line:

- Propagation constant

$$\bar{\gamma} = \sqrt{\bar{z}\bar{y}} = \alpha + j\beta = \sqrt{(r + j\omega l)(g + j\omega c)} \quad [\text{m}^{-1}] \quad (5.9)$$

- Characteristic impedance

$$\bar{Z}_0 = \sqrt{\frac{\bar{z}}{\bar{y}}} = \sqrt{\frac{r + j\omega l}{g + j\omega c}} \quad [\Omega]. \quad (5.10)$$

The real and imaginary parts of the characteristic impedance are the *attenuation constant*  $\alpha$  and the *phase or distortion constant*  $\beta$ , which are given by the expres-

**Fig. 5.5** Single-phase representation of a three-phase line in a symmetrical, balanced, sinusoidal steady state

sions

$$\alpha = \sqrt{\frac{1}{2} \left[ \sqrt{(r^2 + \omega^2 l^2)(g^2 + \omega^2 c^2)} + rg - \omega^2 lc \right]} \quad (5.11)$$

$$\beta = \sqrt{\frac{1}{2} \left[ \sqrt{(r^2 + \omega^2 l^2)(g^2 + \omega^2 c^2)} - rg + \omega^2 lc \right]} \quad (5.12)$$

It is worth noting that  $\alpha = 0$  and  $\beta = \omega \sqrt{lc}$  for a lossless line.

Under steady-state conditions and at a frequency of 50 Hz, typical values for the phase constant are as follows:

- Overhead line:  $\beta = 1 \times 10^{-6} \text{ rad m}^{-1}$
- Cable line:  $\beta = (3-5) \times 10^{-6} \text{ rad m}^{-1}$ .

When there are losses, typical values for the attenuation constant are as follows:

- Overhead line:  $\alpha = (0.05-0.5) \times 10^{-6} \text{ m}^{-1}$
- Cable line:  $\alpha = (0.2-2) \times 10^{-6} \text{ m}^{-1}$ .

If the primary line parameters are constant, the general integrals of (5.7) and (5.8) are

$$\bar{E}_x = \bar{K}_1 e^{\bar{\gamma}x} + \bar{K}_2 e^{-\bar{\gamma}x} \quad (5.13)$$

$$\bar{I}_x = \frac{1}{\bar{Z}_0} (-\bar{K}_1 e^{\bar{\gamma}x} + \bar{K}_2 e^{-\bar{\gamma}x}). \quad (5.14)$$

Alternatively, using hyperbolic functions, the solutions to (5.7) and (5.8) can be expressed as

$$\bar{E}_x = (\bar{C}_1 \cosh \bar{\gamma}x + \bar{C}_2 \sinh \bar{\gamma}x) \quad (5.15)$$

$$\bar{I}_x = \frac{1}{\bar{Z}_0} (-\bar{C}_1 \sinh \bar{\gamma}x - \bar{C}_2 \cosh \bar{\gamma}x). \quad (5.16)$$

The constants in (5.13)–(5.16) can be determined by setting appropriate boundary conditions; for instance, by fixing the conditions at the left termination of the line ( $\bar{E}_x|_{x=0} = \bar{E}_p$  and  $\bar{I}_x|_{x=0} = \bar{I}_p$ ).

If we impose these conditions and introduce (5.13) and (5.14), we obtain the system

$$\bar{E}_p = \bar{K}_1 + \bar{K}_2 \quad (5.17)$$

$$\bar{I}_p = \frac{1}{\bar{Z}_0} (-\bar{K}_1 + \bar{K}_2), \quad (5.18)$$

which yield

$$\bar{E}_x = \frac{1}{2} (\bar{E}_p - \bar{Z}_0 \bar{I}_p) e^{\bar{\gamma}x} + \frac{1}{2} (\bar{E}_p + \bar{Z}_0 \bar{I}_p) e^{-\bar{\gamma}x} \quad (5.19)$$

$$\bar{I}_x = \frac{1}{2} \left( \bar{I}_p - \frac{\bar{E}_p}{\bar{Z}_0} \right) e^{\bar{\gamma}x} + \frac{1}{2} \left( \bar{I}_p + \frac{\bar{E}_p}{\bar{Z}_0} \right) e^{-\bar{\gamma}x}. \quad (5.20)$$

On the other hand, if we use (5.15) and (5.16), we obtain

$$\bar{E}_p = \bar{C}_1 \quad (5.21)$$

$$\bar{I}_p = \frac{1}{\bar{Z}_0} (-\bar{C}_2), \quad (5.22)$$

which give

$$\bar{E}_x = \bar{E}_p \cosh \bar{\gamma}x - \bar{Z}_0 \bar{I}_p \sinh \bar{\gamma}x \quad (5.23)$$

$$\bar{I}_x = \bar{I}_p \cosh \bar{\gamma}x - \frac{\bar{E}_p}{\bar{Z}_0} \sinh \bar{\gamma}x. \quad (5.24)$$

It is worth noting that (5.19) and (5.20) are equivalent to (5.23) and (5.24), respectively.

Choosing a reference frame oriented in the opposite direction (i.e., with  $x$  increasing from the right terminal of the line to the left), the solutions to the line equations can be expressed by introducing a change of variable of the type  $\tilde{x} = -x$  into (5.19) and (5.20). Moreover, the boundary conditions for the left-hand side of the line ( $x = 0$ ) become  $\bar{E}_x|_{x=0} = \bar{E}_a$  and  $\bar{I}_x|_{x=0} = \bar{I}_a$ , leading to the equations

$$\bar{E}_x = \frac{1}{2} (\bar{E}_a + \bar{Z}_0 \bar{I}_a) e^{\bar{\gamma}x} + \frac{1}{2} (\bar{E}_a - \bar{Z}_0 \bar{I}_a) e^{-\bar{\gamma}x} \quad (5.25)$$

$$\bar{I}_x = \frac{1}{2} \left( \bar{I}_a + \frac{\bar{E}_a}{\bar{Z}_0} \right) e^{\bar{\gamma}x} + \frac{1}{2} \left( \bar{I}_a - \frac{\bar{E}_a}{\bar{Z}_0} \right) e^{-\bar{\gamma}x}. \quad (5.26)$$

Using hyperbolic functions, the expressions become

$$\bar{E}_x = \bar{E}_a \cosh \bar{\gamma}x + \bar{Z}_0 \bar{I}_a \sinh \bar{\gamma}x \quad (5.27)$$

$$\bar{I}_x = \bar{I}_a \cosh \bar{\gamma}x + \frac{\bar{E}_a}{\bar{Z}_0} \sinh \bar{\gamma}x. \quad (5.28)$$

### Direct and Inverse Waves

Let us consider the solutions to the line equations (5.25) and (5.26), where the positive  $x$  direction is oriented from the load to the generator (from right to the left). These equations show that either the voltage distribution or the current distribution can be considered the

**Fig. 5.6** Voltage distribution along an infinitely long lossless line in the steady state and at 50 Hz (adapted from [5.36])

result of two components. The first component, proportional to  $e^{\bar{\gamma}x}$ , is called the *direct wave*, which increases in the positive  $x$  direction. The second component, proportional to  $e^{-\bar{\gamma}x}$ , is called the *inverse wave* and decreases in the positive  $x$  direction. Similar considerations are valid for (5.27) and (5.28), where the positive  $x$  direction is oriented from the generator to the load.

With reference to (5.25), we set

$$\bar{E}_d = \frac{\bar{E}_a + \bar{Z}_0 \bar{I}_a}{2} \quad (5.29)$$

$$\bar{E}_r = \frac{\bar{E}_a - \bar{Z}_0 \bar{I}_a}{2}, \quad (5.30)$$

where the symbols have obvious meanings. The voltage at a generic point  $x$  along the line can then be expressed as

$$\bar{E}_x = \bar{E}_d e^{\bar{\gamma}x} + \bar{E}_r e^{-\bar{\gamma}x}. \quad (5.31)$$

The superposition of the direct and inverse waves determines the line operation and consequently the voltage and current distributions along the whole line.

Intuitively, all of these considerations for the voltage can also be applied to the current, which leads us to

$$\bar{I}_x = \frac{\bar{E}_d}{\bar{Z}_0} e^{\bar{\gamma}x} - \frac{\bar{E}_r}{\bar{Z}_0} e^{-\bar{\gamma}x}. \quad (5.32)$$

Finally, it should be noted that the inverse wave (i.e., the second terms of (5.19) and (5.20) or (5.25) and (5.26)) is equal to zero in the case of an infinitely long line.

### Propagation Wavelength and Propagation Speed

Let us consider the voltage distribution along a lossless line of infinite length under steady-state conditions and a frequency of 50 Hz. The propagation wavelength is defined as the distance  $\lambda$  such that

$$\lambda\beta = 2\pi \Rightarrow \lambda = \frac{2\pi}{\beta} \quad [\text{m}], \quad (5.33)$$

i.e., such that two measured voltage phasors separated by a distance of  $\lambda$  are in phase (i.e., the distance between two consecutive maxima in Fig. 5.6).

In the additional material for this chapter, there is an animation that demonstrates the voltage and current propagation (sinusoidal waveforms at the utility frequency) for a matched line and for a line terminated at a resistance that differs from the characteristic impedance.

The wave propagation speed as a function of the frequency  $f$  is

$$v = \lambda f = \frac{2\pi f}{\beta} = \frac{\omega}{\beta} \quad [\text{m s}^{-1}]. \quad (5.34)$$

For a lossless overhead line, the propagation speed is

$$v_a = \frac{\omega}{\beta} = \frac{1}{\sqrt{LC}} = \frac{1}{\sqrt{\mu_0 \epsilon_0}} = 3 \times 10^8 \quad [\text{m s}^{-1}]. \quad (5.35)$$

Therefore, the propagation speed is equal to the speed of light in vacuum and is not dependent on the line geometry. If losses cannot be ignored, the speed will be slightly lower.

The wavelength is inversely proportional to the frequency, so

$$\text{At 50 Hz: } \lambda_a = \frac{v}{f} = \frac{3 \times 10^8}{50} = 6 \times 10^6 \text{ m}$$

$$\text{At 60 Hz: } \lambda_a = \frac{v}{f} = \frac{3 \times 10^8}{60} = 5 \times 10^6 \text{ m}.$$

If losses are considered, these values will be slightly lower.

For a lossless cable line with a relative permittivity  $\epsilon_r = 3.5$ , the propagation speed and wavelength are calculated as

$$v_c = \frac{1}{\sqrt{3.5\mu_0\epsilon_0}} = 1.6 \times 10^8 \quad [\text{m s}^{-1}] \quad (5.36)$$

$$\lambda_c = \frac{v_c}{f} = \frac{1.6 \times 10^8}{50} = 3.2 \times 10^6 \quad [\text{m}]. \quad (5.37)$$

Let us consider a voltage wave with a generic profile for a generic angular frequency  $\omega$ . If the Heaviside condition  $r/g = l/c$  is respected, then  $\alpha = \sqrt{rg}$  and  $\beta = \omega\sqrt{lc}$ , therefore  $v = 1/\sqrt{lc}$ , which means that both  $\alpha$  and  $v$  are independent of  $\omega$ ; the transmitted voltage waveform along the line is not distorted, only attenuated. Although this fact is not relevant for power transmission lines at the utility frequency, it is important for telecommunication lines.

### Line Terminated with its Characteristic Impedance

Let us now consider a line with a load equal to the characteristic impedance  $\bar{Z}_0$ , such that

$$\bar{Z}_2 = \frac{\bar{E}_a}{\bar{I}_a} = \bar{Z}_0. \quad (5.38)$$

In this case, we obtain the important relationships

$$\begin{cases} \bar{E}_x = \bar{E}_a e^{\bar{y}x} \\ \bar{I}_x = \bar{I}_a e^{\bar{y}x} \\ \frac{\bar{E}_x}{\bar{I}_x} = \frac{\bar{E}_a}{\bar{I}_a} = \bar{Z}_0. \end{cases} \quad (5.39)$$

The propagation of voltage and current waves along a line that terminates on its characteristic impedance is equivalent to the case in which the line is infinitely long, since the ratio of the voltage to the current is the same at every point along the line. As a consequence, voltage and current waves that are directed to the load are not affected by any reflection.

For a lossless line, the characteristic impedance is a real quantity, and its value is expressed as

$$\bar{Z}_0 = \sqrt{\frac{l}{c}}. \quad (5.40)$$

In this particular case, the characteristic impedance is called the *surge impedance*.

Figures 5.7 and 5.8 show the value of the surge impedance in some practical cases.

### Natural Power

The complex power at the termination in the case where the line terminates on its characteristic impedance is given by

$$\begin{aligned} \bar{S}_{0a} &= P_{0a} + jQ_{0a} = 3\bar{E}_a\bar{I}_a^* = 3\bar{E}_a\frac{\bar{E}_a^*}{\bar{Z}_a} \\ &= \frac{V_a^2}{Z_0(\cos\psi - j\sin\psi)} = \frac{V_a^2}{Z_0}(\cos\psi + j\sin\psi). \end{aligned} \quad (5.41)$$

Fig. 5.7 Formulas for the positive sequence line parameters of lossless overhead transmission lines

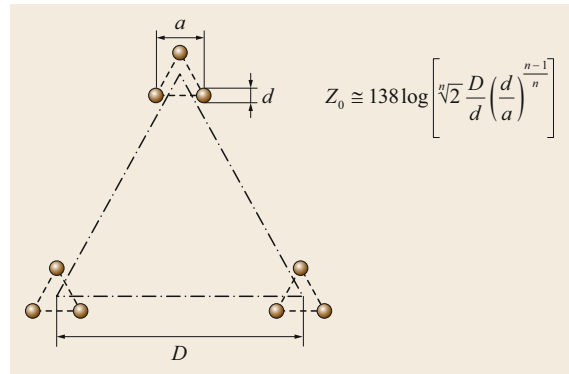

Fig. 5.8 Formulas for the positive sequence line parameters of lossless overhead transmission lines with bundle conductors

For a lossless line, we obtain

$$P_0 = \frac{V_a^2}{Z_0}, \quad (5.42)$$

which is called the *natural power*.

Under these conditions, the line transmits active power to the load without absorbing reactive power (the power factor is equal to 1), i.e.,

$$Z_0^2 = \frac{E_x^2}{I_x^2} = \frac{\omega dx}{\omega c dx}. \quad (5.43)$$

For each infinitesimal element of the line, we can observe that

$$\omega dx I_x^2 = \omega c dx E_x^2. \quad (5.44)$$

This equation gives perfect compensation between the electromagnetic energy and the electrostatic energy of the line (i.e., the line is compensated regarding the reactive power). Therefore, the voltage magnitude is

**Table 5.2** Typical surge impedance and characteristic power values for overhead lines

Voltage (kV)	Overhead line	
	$Z_0$ (P)	$P_0$ (MW)
20	400	1
50	400	6
132	400	44
220	390	124
380	260	560
700	240	2000
1000	240	≈ 4000

constant along the line. This represents ideal operating conditions for an overhead line (not for a cable line, as surge impedances are one order of magnitude lower in that case, so current values would be too high). Table 5.2 shows typical values of the surge impedance and characteristic power for overhead lines.

### 5.3.2 The Line as a Two-Port Network

A single conductor line in steady state can be represented as two port passive network as shown in Fig. 5.9, therefore voltage and currents at one port can be expressed as

$$\begin{aligned} \bar{E}_p &= \bar{A}\bar{E}_a + \bar{B}\bar{I}_a \\ \bar{I}_p &= \bar{C}\bar{E}_a + \bar{D}\bar{I}_a \end{aligned} \tag{5.45}$$

The system considered has two degrees of freedom, which are characterized by two independent relationships between four quantities (voltages and currents) that identify the electric states of the two pairs of terminals.

Using hyperbolic functions, the constants  $\bar{A}$ ,  $\bar{B}$ ,  $\bar{C}$ , and  $\bar{D}$  can be expressed as

$$\begin{cases} \bar{A} = \bar{D} = \cosh \bar{\gamma}L \\ \bar{B} = \bar{Z}_0 \sinh \bar{\gamma}L \\ \bar{C} = \frac{1}{\bar{Z}_0} \sinh \bar{\gamma}L \end{cases} \tag{5.46}$$

The constants  $\bar{A}$ ,  $\bar{B}$ ,  $\bar{C}$ , and  $\bar{D}$  are called *chain matrix parameters*. It is easy to verify that the two-port network is symmetric ( $\bar{A} = \bar{D}$ ) and reciprocal ( $\bar{A}\bar{D} - \bar{B}\bar{C} = 1$ ).

The chain matrix parameters have the following characteristics:

- Constant  $\bar{A}$ : the ratio between the input and output voltages of the open line or between the input and output currents of the short-circuited line. This constant is a pure number and can be expressed via

**Fig. 5.9** Two-port network representation of a transmission line

the Cartesian coordinates  $a_1 + ja_2$  ( $a_1 < 1; a_2 \ll 1$ ) or the polar coordinates  $Ae^{j\alpha_A}$ .

- Constant  $\bar{B}$ : the ratio of the input voltage to the output current of the short-circuited line. This ratio has the dimensions of an impedance and can be expressed via the Cartesian coordinates  $b_1 + jb_2$  ( $b_1 \approx rL = R; b_2 \approx xL = X$ ) or the polar coordinates  $B e^{j\beta_B}$  ( $\bar{B} \approx \bar{Z}$ , the total longitudinal impedance of the line).
- Constant  $\bar{C}$ : the ratio between the input current and the output voltage of the open line. It has the dimensions of an admittance and can be expressed via the Cartesian coordinates  $c_1 + jc_2$  ( $c_1$  is really small and usually negative when the line is really long, and  $c_2 \approx B$  is the susceptance of admittance  $Y$ ) or the polar coordinates  $C e^{j\gamma_C}$  ( $\bar{C} \approx \bar{Y}$ , the total transverse admittance of the line). A passive reciprocal two-port network can always be represented by three impedances or admittances that are connected to form a  $\Pi$  circuit, as represented in Fig. 5.10, or a T circuit. The equations relevant to the equivalent  $\pi$  circuit of a generic line are

$$\begin{aligned} \bar{Y}_L &= \bar{Y} \frac{\tanh(\bar{\gamma}L/2)}{\bar{\gamma}L/2} \\ \bar{Z}_m &= \bar{Z} \frac{\sinh \bar{\gamma}L}{\bar{\gamma}L} \end{aligned} \tag{5.47}$$

For lines with typical lengths (i.e.,  $50 \text{ km} < L < 200 \text{ km}$ ) in the steady state, we can assume that  $\sinh \bar{\gamma}L \approx \bar{\gamma}L$  and  $\tanh(\bar{\gamma}L/2) \approx \bar{\gamma}L/2$ , which in turn yield

$$\begin{aligned} \bar{Y}_a &= \bar{Y}_b = \bar{Y} \\ \bar{Z}_m &= \bar{Z} \end{aligned} \tag{5.48}$$

In this case the calculation of the parameters of the equivalent circuit is simplified, as shown in Fig. 5.11.

Fig. 5.10 Equivalent  $\pi$  circuit of a transmission lineFig. 5.11 Equivalent  $\pi$  circuit of a short transmission line

### 5.3.3 Transmitted Active and Reactive Power Expressions

Let us consider the equations

$$\begin{aligned}\bar{E}_p &= \bar{A}\bar{E}_a + \bar{B}\bar{I}_a \\ \bar{I}_p &= \bar{C}\bar{E}_a + \bar{D}\bar{I}_a\end{aligned}\quad (5.49)$$

which are relevant to the phasor diagram of Fig. 5.12. This phasor diagram is known as a Perrine–Baum diagram.

When the line is open, we can see that  $E_p < E_a$  (known as the Ferranti effect).

The voltage drop along the line varies with the load; e.g.,

$$\begin{aligned}P_a + jQ_a(R) &\rightarrow \text{voltage drop} = 21\% \\ P_a(R') &\rightarrow \text{voltage drop} = 6\%.\end{aligned}$$

In order to compensate for the voltage drop by keeping the absorbed active power  $P_a$  constant, it is necessary to ensure that the end of phasor  $E_p$  coincides with  $R''$ . In this configuration, the load has to be capacitive. We should therefore generate the reactive power  $Q = RR''$  at the end of the line. The fraction  $RR'$  is absorbed by the load, while the fraction  $R'R''$  is necessary to compensate for the reactive power absorbed by the line.

### Some Remarks on the Transmitted Active and Reactive Power

The absolute value of the complex power at the end of the line is (superscript \* for phasors denotes their conjugate)

$$\bar{S}_a = P_a + jQ_a = 3\bar{E}_a\bar{I}_a^* \quad (5.50)$$

Observing that

$$\begin{aligned}\bar{E}_p &= \bar{A}\bar{E}_a + \bar{B}\bar{I}_a \Rightarrow \bar{I}_a = \frac{\bar{E}_p - \bar{A}\bar{E}_a}{\bar{B}} \\ \Rightarrow \bar{S}_a &= 3\bar{E}_a \left( \frac{\bar{E}_p - \bar{A}\bar{E}_a}{\bar{B}^*} \right),\end{aligned}\quad (5.51)$$

assuming that  $\bar{E}_a$  is real, and introducing  $\theta$  as the phase difference between  $\bar{E}_p$  and  $\bar{E}_a$ , we obtain

$$\begin{aligned}\bar{S}_a &= P_a + jQ_a = 3 \frac{\bar{E}_a \bar{E}_p^*}{\bar{B}^*} - 3 \frac{\bar{E}_a \bar{E}_a \bar{A}^*}{\bar{B}^*} \\ &= 3 \frac{E_a E_p}{B} \frac{e^{-j\theta}}{e^{-j\beta_B}} - 3 \frac{E_a^2 A}{B} \frac{e^{-j\alpha_A}}{e^{-j\beta_B}} \\ &= 3 \frac{E_a E_p}{B} e^{j(\beta_B - \theta)} - 3 E_a^2 \frac{A}{B} e^{j(\beta_B - \alpha_A)} \\ &= \frac{3E_a E_p}{B} \cos(\beta_B - \theta) - 3E_a^2 \frac{A}{B} \cos(\beta_B - \alpha_A) \\ &\quad + j \left[ \frac{3E_a E_p}{B} \sin(\beta_B - \theta) - 3E_a^2 \frac{A}{B} \sin(\beta_B - \alpha_A) \right].\end{aligned}\quad (5.52)$$

Therefore,

$$P_a = \frac{3E_a E_p}{B} \cos(\beta_B - \theta) - 3E_a^2 \frac{A}{B} \cos(\beta_B - \alpha_A) \quad (5.53)$$

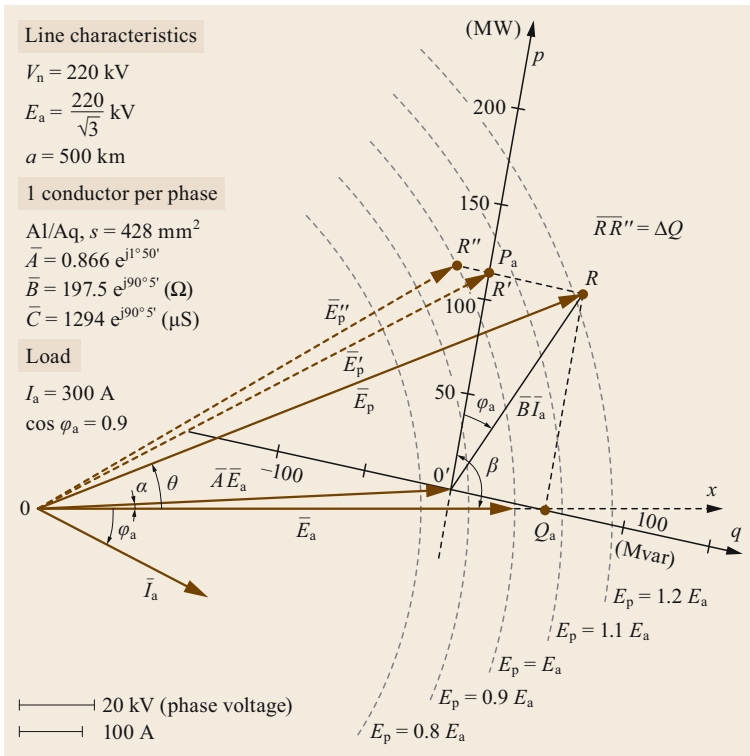

$$Q_a = \frac{3E_a E_p}{B} \sin(\beta_B - \theta) - 3E_a^2 \frac{A}{B} \sin(\beta_B - \alpha_A) \quad (5.54)$$

$$P_p = -\frac{3E_a E_p}{B} \cos(\beta_B + \theta) + 3E_p^2 \frac{A}{B} \cos(\beta_B - \alpha_A) \quad (5.55)$$

$$Q_p = -\frac{3E_a E_p}{B} \sin(\beta_B + \theta) + 3E_p^2 \frac{A}{B} \sin(\beta_B - \alpha_A). \quad (5.56)$$

If the line is lossless and transverse capacities are neglected ( $\alpha_A = 0$ ,  $A = 1$ ,  $\beta_B = \pi/2$ , and  $B = X$ ), the expressions assume the simplified forms

$$P_p = P_a = \frac{3E_p E_a}{X} \sin \theta \quad (5.57)$$

**Fig. 5.12** Perrine–Baum diagram (adapted from [5.3])

$$P_p = P_a = \frac{3E_p E_a}{X} \sin \theta \tag{5.58}$$

$$Q_a = \frac{3E_a}{X} (E_p \cos \theta - E_a) \tag{5.59}$$

$$Q_p = \frac{3E_p}{X} (E_p - E_a \cos \theta), \tag{5.60}$$

which leads us to conclude that:

- The active power flow  $P$  is proportional to the sine of the phase shift  $\theta$  (i.e., the difference between the voltage phases of the line terminals).
- The reactive power flow  $Q$  is proportional to the difference between the magnitudes of the voltages at the line terminals, and the sign of  $Q$  also depends on that difference. Note that the function  $\cos \theta$  does not vary much for small values of the argument (typically,  $\theta = 10\text{--}25^\circ$ ).

## 5.4 Load Flow

### 5.4.1 From the Real Network to the Admittance Matrix

A classical transmission network essentially comprises:

- *Buses*, which may be divided into *generation buses* (corresponding to the terminals of the alternators or, in general, the electric power sources), *reactive compensation buses* (corresponding to synchronous and static compensator terminals), *interconnection buses* (where many lines are connected to each other), and *load buses* (which supply the equivalent loads seen by the high-voltage network)
- *Capacitor banks*
- *Transformers*

- *Reactors*
- *Lines*; either overhead lines or cable lines that connect the various buses.

The study can be simplified by focusing only on the high-voltage part of the network and assuming that the parts at lower voltages, namely the distribution network, can be represented by their equivalent concentrated loads. Even so, the network is remarkably complex; for example, the Italian 380–220 kV network shown in Figs. 5.13 and 5.14 contains hundreds of buses, while the inclusion of the 132 kV network boosts this up to a thousand buses.

For the load flow study (also commonly denoted as power flow study) a number of assumptions are made.

**Fig. 5.13** Italian 380 kV network on 31.12.2018 (<https://www.terna.it>)

The three-phase symmetric and balanced network is in its steady state; the parameters and the configuration of the system as well as the load power request are considered to be constant. We also assume all the electric components are linear. All voltages, power flows, and impedances will be represented by their per-unit values. The active power injected by the generators at the buses is known.

Based on these assumptions, the load flow problem consists of determining the real and reactive power flowing in various components of the network (lines and transformers) under steady-state conditions. As the structure of the system and the values of the admittances of the network are known, the real and reactive power flow on each branch as well as the reactive power output of the generators can be determined analytically once the bus voltages are known. For this reason, the goal of a load-flow study is to determine voltage phase and magnitude values for each bus of a power system.

There are several reasons we need load-flow studies:

(a) To determine—on a daily basis, or more precisely every quarter of an hour—the network operating

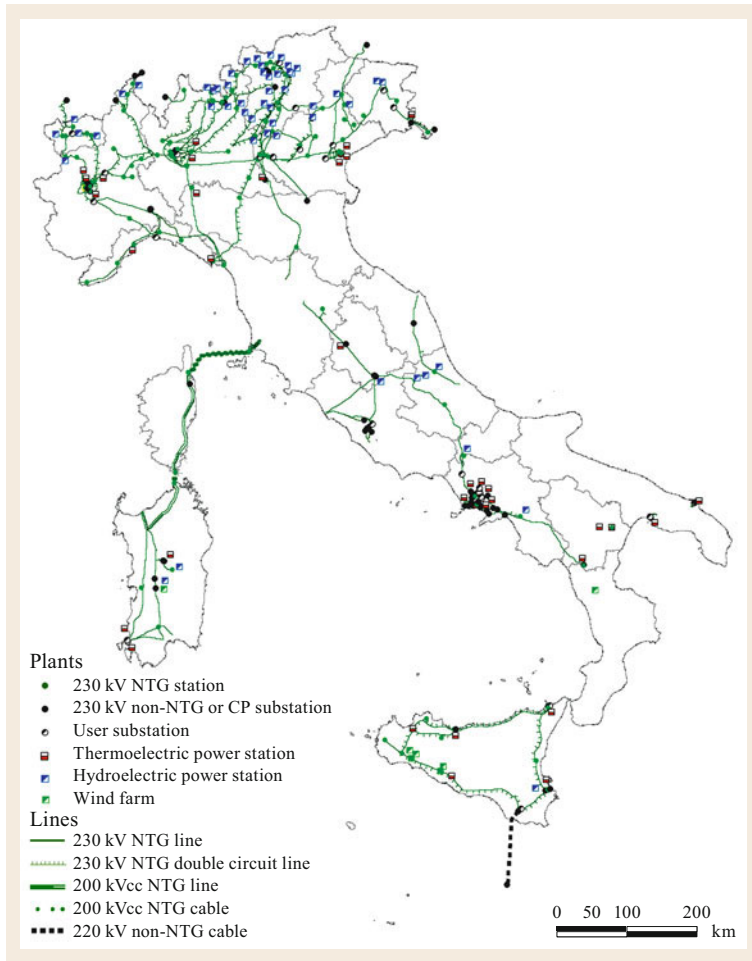

conditions that best satisfy the required load under secure conditions and with the minimum operational cost

- (b) To plan the expansion of a power system (either *long- or medium-term planning*, in which plans are made for 5–15 years into the future, or *short-term planning*, in which the plans are made for 1–3 years ahead)
- (c) To monitor and control the network in *real time*.

### Nodal Analysis of the Network

Nodal analysis of the network involves determining the voltages at the various nodes (buses) of the network in terms of the branch currents. It is important to bear in mind that each component of the network can be replaced by its  $n$ -port representation, as shown in Fig. 5.15.

Using the assumptions mentioned above, let us consider a generic bus of a network containing  $n + 1$  buses, including  $g$  generation buses and  $u$  load buses, as shown in Fig. 5.16. Conductor  $n + 1$  is the reference bus or *neutral*. Note that buses that are neither generation nor load buses (interconnection buses) can be seen as either

**Fig. 5.14** Italian 230 kV network on 31.12.2018 (<https://www.terna.it>)

generation or load buses with zero active and reactive power injected or absorbed, respectively. The total number of buses in the network,  $n + 1$ , is not necessarily equal to  $g + u + 1$ , as we need to have at least one bus that is not a generation or load bus. The network consists of  $m$  branches, each of which is characterized by a single linear admittance.

For the generic bus, or node  $i$ , we shall make use of the following notation:

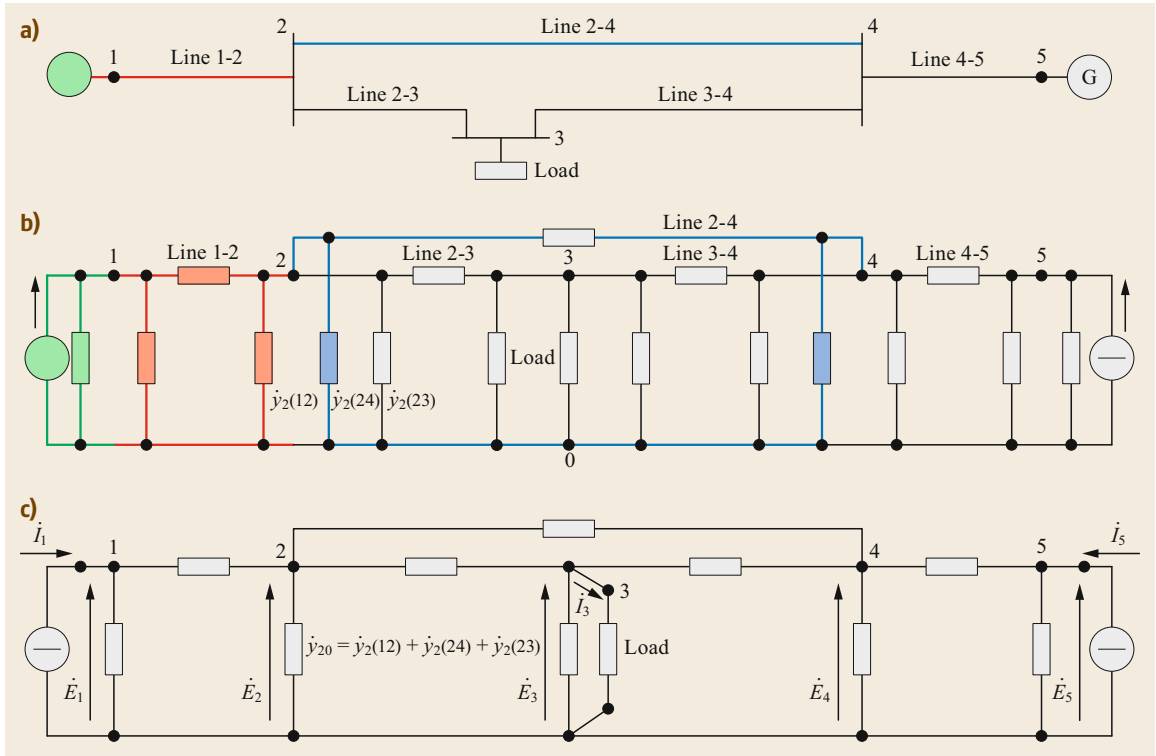

- $E_i$  is the bus voltage
- $I_i$  is the nodal current (i.e., the current supplied by the generator or absorbed by the load connected to the bus)
- $I_{ij}$  is the current flowing in the branch that connects node  $i$  to node  $j$
- $y_{ij}$  is the admittance between nodes  $i$  and  $j$
- $y_{i0}$  is the sum of all the admittances between the  $i$ th node and the neutral.

For the currents flowing in the branches connected to node  $i$ , we get

$$\begin{cases} \bar{I}_{i0} = \bar{y}_{i0} \bar{E}_i \\ \bar{I}_{i1} = \bar{y}_{i1} (\bar{E}_i - \bar{E}_1) \\ \vdots \\ \bar{I}_{in} = \bar{y}_{in} (\bar{E}_i - \bar{E}_n), \end{cases} \quad (5.61)$$

and by using the Kirchoff law, we obtain

$$\begin{aligned} \bar{I}_i &= \bar{y}_{i0} \bar{E}_i + \bar{y}_{i1} (\bar{E}_i - \bar{E}_1) + \cdots + \bar{y}_{in} (\bar{E}_i - \bar{E}_n) \\ &= (\bar{y}_{i0} + \bar{y}_{i1} + \cdots + \bar{y}_{in}) \bar{E}_i - \bar{y}_{i1} \bar{E}_1 - \cdots - \bar{y}_{in} \bar{E}_n \\ &= (\bar{y}_{i0} + \bar{y}_{i1} + \cdots + \bar{y}_{in}) \bar{E}_i - \sum_{\substack{h=1 \\ h \neq i}}^n \bar{y}_{ih} \bar{E}_h. \end{aligned} \quad (5.62)$$

**Fig. 5.15** (a) One-line diagram of a three-bus power network (buses 3, 4, and 5) with two generators (connected at buses 1 and 5) that supply one equivalent load impedance (connected at bus 3). (b) Relevant circuit representation where each generator is represented by its Norton equivalent one-port circuit and each line is represented by its two-port p equivalent circuit, and (c) simplified version of this circuit in which line admittances connected to the same bus have been added to each other. Voltage, current, and admittance symbols with dots are complex quantities (adapted from [5.2])

**Fig. 5.16** Network presentation used for nodal analysis

Setting

$$\begin{aligned} \bar{Y}_{ii} &= \bar{y}_{i0} + \bar{y}_{i1} + \dots + \bar{y}_{in} = \sum_{h=0}^n \bar{y}_{ih} \\ \bar{Y}_{i1} &= -\bar{y}_{i1} \\ &\vdots \\ \bar{Y}_{in} &= -\bar{y}_{in}, \end{aligned} \tag{5.63}$$

we get

$$\begin{aligned} \bar{I}_i &= \bar{Y}_{i1}\bar{E}_1 + \bar{Y}_{i2}\bar{E}_2 + \dots + \bar{Y}_{ii}\bar{E}_i + \dots + \bar{Y}_{in}\bar{E}_n \\ &= \sum_{h=1}^n \bar{Y}_{ih}\bar{E}_h \end{aligned} \tag{5.64}$$

and, analogously for the other buses,

$$\begin{cases} \bar{I}_1 = \bar{Y}_{11}\bar{E}_1 + \dots + \bar{Y}_{1h}\bar{E}_h + \dots + \bar{Y}_{1n}\bar{E}_n \\ \vdots \\ \bar{I}_h = \bar{Y}_{h1}\bar{E}_1 + \dots + \bar{Y}_{hh}\bar{E}_h + \dots + \bar{Y}_{hn}\bar{E}_n \\ \vdots \\ \bar{I}_n = \bar{Y}_{n1}\bar{E}_1 + \dots + \bar{Y}_{nh}\bar{E}_h + \dots + \bar{Y}_{nn}\bar{E}_n. \end{cases} \tag{5.65}$$

These equations can be conveniently written in matrix form as

$$\begin{bmatrix} \bar{I}_1 \\ \vdots \\ \bar{I}_h \\ \vdots \\ \bar{I}_n \end{bmatrix} = \begin{bmatrix} \bar{Y}_{11} & \dots & \bar{Y}_{1h} & \dots & \bar{Y}_{1n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \bar{Y}_{h1} & \dots & \bar{Y}_{hh} & \dots & \bar{Y}_{hn} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \bar{Y}_{n1} & \dots & \bar{Y}_{nh} & \dots & \bar{Y}_{nn} \end{bmatrix} \cdot \begin{bmatrix} \bar{E}_1 \\ \vdots \\ \bar{E}_h \\ \vdots \\ \bar{E}_n \end{bmatrix}. \quad (5.66)$$

Using a compact notation, we get

$$[\mathbf{I}] = [\mathbf{Y}] [\mathbf{E}], \quad (5.67)$$

where  $\bar{\mathbf{Y}}$  is the *admittance matrix* of the network.

The elements of  $\bar{\mathbf{Y}}$  satisfy a number of conditions (see also (5.63)), as follows.

The off-diagonal elements  $\bar{Y}_{ij}$  are called *mutual admittances* of the buses, and each equals the negative of the sum of all admittances connected directly between the buses  $i$  and  $j$ , i.e.,

$$\bar{Y}_{ij} = -\bar{y}_{ij} = \bar{I}_i \Big|_{\substack{\bar{E}_j=1 \\ \bar{E}_h=0 \ \forall h \neq j}}. \quad (5.68)$$

The diagonal elements  $\bar{Y}_{ii}$  are called *self-admittances* of the buses, and each equals the sum of all the admittances connected to the buses identified by double subscripts, i.e.,

$$\bar{Y}_{ii} = \bar{y}_{i0} + \sum \bar{y}_{ij} = \bar{I}_i \Big|_{\substack{\bar{E}_i=1 \\ \bar{E}_j=0 \ \forall j \neq i}}. \quad (5.69)$$

The calculation of the admittance matrix is demonstrated as an exercise in the supplementary material for this chapter.

### Admittance Matrix Update

The previous equations provide the relationship between the bus impedance and the admittance matrix. However, it is possible for the topology of the power system to change due to the connection or disconnection of a line, a transformer, etc. Below, we show that it is not necessary to redetermine the admittance matrix from scratch in this case. Before doing so, however, we examine the three basic changes that can occur to an  $n$ -bus network:

1. *The addition of bus  $n+1$ , which is connected to the generic bus  $k$  with an admittance  $\bar{y}_{n+1,k}$ .*

The updated matrix order is now  $n+1$ .

Bus  $k$  is the only bus adjacent to the new bus. Therefore, the only change in the matrix is the  $k$ th self-admittance.

By denoting the parameters of the updated matrix with a prime symbol, we get

$$\begin{aligned} \bar{Y}'_{k,k} &= \bar{Y}_{k,k} + \bar{y}_{n+1,k} \\ \bar{Y}'_{n+1,n+1} &= \bar{y}_{n+1,k} \\ \bar{Y}'_{n+1,k} &= \bar{Y}'_{k,n+1} = -\bar{y}_{n+1,k}. \end{aligned} \quad (5.70)$$

All the other elements of the  $(n+1)$ th row and column of matrix  $[\bar{\mathbf{Y}}']$  are equal to zero.

2. *The addition of an admittance  $\bar{y}^*_{k,0}$  from an existing bus  $k$  to the reference bus.*

In this case, the matrix order does not change. The only term that must be updated is the self-admittance of bus  $k$ , i.e.,

$$\bar{Y}'_{k,k} = \bar{Y}_{k,k} + \bar{y}^*_{k,0}. \quad (5.71)$$

3. *The addition of an admittance  $\bar{y}^*_{k,i}$  between two generic buses  $k$  and  $i$ .*

Again, the matrix order does not change; the only terms that need to be updated are the self-admittances of buses  $k$  and  $i$  and their relative mutual admittances such that

$$\begin{aligned} \bar{Y}'_{k,k} &= \bar{Y}_{k,k} + \bar{y}^*_{k,i} \\ \bar{Y}'_{i,i} &= \bar{Y}_{i,i} + \bar{y}^*_{k,i} \\ \bar{Y}'_{k,i} &= \bar{Y}'_{i,k} = \bar{Y}_{i,k} - \bar{y}^*_{k,i}. \end{aligned} \quad (5.72)$$

When appropriately combined and repeated, the three basic operations described above allow the admittance matrix to be updated for any physical modification of the network configuration.

Let us now consider a few typical cases:

- A line (represented by its  $\pi$ -equivalent two-port circuit) is added between two existing buses  $k$  and  $i$ . In this case, operation (2) is applied twice and operation (3) once.
- A new line (represented by its  $\pi$ -equivalent two-port circuit) is added that connects an existing bus  $k$  in the network with a new bus  $(n+1)$ . Here, operation (1) is applied once and operation (2) twice.
- A line between two buses is disconnected. Removing a branch is equivalent to adding admittances with opposite values to the admittances that are already present in the network. Hence, this case is analogous to the first one, but with opposite admittance values.

### 5.4.2 The Equations

In an  $n$ -bus system, the  $n$  voltages and the  $n$  complex currents are related by  $n$  equations with complex variables and coefficients. These relationships comprise the *internal or network constraints*. The  $2n$  complex voltages and currents are equivalent to  $4n$  real variables. On the other hand, the  $n$  equations with complex variables and coefficients are equivalent to  $2n$  linear equations with real variables and coefficients that can be obtained by separating the real and imaginary parts (or magnitudes and arguments). Thus, among the  $4n$  real variables,  $2n$  can be set arbitrarily, and the remaining  $2n$  can be calculated by solving the system of network equations.

When the solution to the system of equations has been evaluated and the bus voltages and currents have been determined, the active and reactive power absorbed and injected in the buses along with the power and current flows along the lines and the active and reactive power losses can be determined relatively simply. If the operating conditions of the network can be effectively represented by imposing only RMS values and phases of bus voltages and currents as external constraints, it follows from the above discussion that the power flows can be calculated by solving a system of linear equations.

In practice, the operating conditions imposed on the networks—the *external constraints*—are expressed by setting other quantities. This implies that the system of equations to be solved becomes nonlinear, as will be clarified shortly.

In particular:

- For *load buses*, the quantities that are generally set are the active and reactive power required at the buses:  $P_i^*$  and  $Q_i^*$ . It is worth noting that the use of constant admittances to represent loads is not generally appropriate. Consider, for instance, asynchronous motors, which absorb active power almost independently of the voltage (for voltage variations of  $\pm 10\%$ ), thus conflicting with the quadratic law that applies to impedances. Moreover, the dependence on the voltage is expressed by the general relations

$$P = P_0 \left( \frac{V}{V_0} \right)^{\alpha_p} \quad (5.73)$$

$$Q = Q_0 \left( \frac{V}{V_0} \right)^{\alpha_q}, \quad (5.74)$$

where the values of the exponentials depend on the nature of the load (they vary between 0 and 2).

- For *generation buses*, it is convenient to set the generated active power  $P_i^*$  and the RMS value of the voltage at their terminals  $E_i^*$ . The power  $P_i^*$  is assumed to be equal to the power that each generation unit must provide in accordance with the optimal repartition plan of the total grid demand among all production plants (namely the result of the *dispatching problem*, which will be briefly summarized at the end of this section). Setting the voltage  $E_i^*$  instead of the reactive power  $Q_i^*$  is convenient for various reasons. First, fixing the voltage value (at a value between  $E_n$  and  $1.1E_n$ , depending on the distance between the generation bus and the loads) leads to rapid convergence of the numerical procedure that is used to solve the nonlinear system of equations. Second, the reactive power of each generator can be varied by acting on the excitation system. Clearly, it will then be necessary to check that the upper and lower limits on  $Q$  imposed by the capability curves of each generator are not exceeded, and—more generally—that the maximum active and reactive power loadings can be supplied without exceeding the heating limits of each generator.

It is important to realize that it is not possible to fix the active power at an arbitrary value for each and every generation and load bus simultaneously. This would be equivalent to arbitrarily fixing the power losses of the network, which actually depend on the solution we are seeking. It is therefore possible to fix a maximum of  $(n-1)$  active power values. It is useful to fix the magnitude and the phase of the voltage for the  $n$ th bus, which is commonly termed the *slack bus*. The real power at this bus will be equal and opposite to the sum of all real load powers, all of the network losses, and all the real powers of the other generators. The slack bus is commonly considered to be a generation bus with a high capability for real power generation, and it is also the phase-reference bus ( $\arg(\bar{E}) = 0$ ).

Table 5.3 summarizes the types of buses that we have defined so far.

Because the operating conditions of the grids (external constraints) are expressed mainly by setting power

**Table 5.3** Types of buses used in a power network, and relevant electric quantities to be imposed and determined

Type of bus	Fixed quantities ( $2n$ )		Quantities to be determined ( $2n$ )	
Generation buses	$P_G$	$E_G$	$Q_G$	$\arg(E_G)$
Load buses	$P_L$	$Q_L$	$E_L$	$\arg(E_L)$
Slack bus	$E_n$	$\arg(E_n) = 0$	$P_n$	$Q_n$

values rather than currents, we can conclude from the above considerations that the equation system to be solved becomes nonlinear, as further clarified below.

### Cartesian Coordinates

The following notation will be used for the equations in Cartesian coordinates

$$\begin{aligned}\bar{E}_i &= E'_i + jE''_i && \text{voltage at bus } i \\ \bar{E}_h &= E'_h + jE''_h && \text{voltage at bus } h \\ \bar{Y}_{ih} &= G_{ih} + jB_{ih} && \text{element } ih \text{ of admittance matrix } [\bar{\mathbf{Y}}],\end{aligned}\quad (5.75)$$

where the meanings of the symbols are obvious.

The complex power injected or absorbed at each bus is

$$\bar{S}_i = P_i + jQ_i = \bar{E}_i \bar{I}_i. \quad (5.76)$$

Given that

$$\bar{I}_i = \sum_{h=1}^n \bar{Y}_{ih} \bar{E}_h \Rightarrow \bar{I}_i = \sum_{h=1}^n \underline{Y}_{ih} \underline{E}_h, \quad (5.77)$$

(5.76) becomes

$$\begin{aligned}\bar{S}_i &= \bar{E}_i \sum_{h=1}^n \underline{Y}_{ih} \underline{E}_h \\ &= (E'_i + jE''_i) \sum_{h=1}^n (G_{ih} - jB_{ih})(E'_h - jE''_h).\end{aligned}\quad (5.78)$$

The active and reactive powers of the  $i$ th node will therefore be expressed as

$$\begin{cases} P_i = E'_i \sum_{h=1}^n (G_{ih} E'_h - B_{ih} E''_h) \\ \quad + E''_i \sum_{h=1}^n (B_{ih} E'_h + G_{ih} E''_h) \\ Q_i = -E'_i \sum_{h=1}^n (B_{ih} E'_h + G_{ih} E''_h) \\ \quad + E''_i \sum_{h=1}^n (G_{ih} E'_h - B_{ih} E''_h). \end{cases}\quad (5.79)$$

Recall that  $g$  and  $u$  are used to indicate the number of generator nodes and users (loads), respectively. Since we also need to account for one slack bus, it follows that  $g + u = n - 1$ .

In Cartesian coordinates, the entire system of equations takes the form

$$\begin{cases} E''_i = 0 \\ i = n \text{ for slack bus only} \\ E_i^{*2} = E_i'^2 + E_i''^2 \\ i = 1, 2, \dots, g + i = n \text{ for } g \text{ generation buses} \\ \quad + \text{slack bus} \\ P_i^* = E'_i \sum_{h=1}^n (G_{ih} E'_h - B_{ih} E''_h) \\ \quad + E''_i \sum_{h=1}^n (B_{ih} E'_h + G_{ih} E''_h) \\ i = 1, 2, \dots, g + u \text{ for generation buses} \\ \quad + u \text{ load buses} \\ Q_i^* = -E'_i \sum_{h=1}^n (B_{ih} E'_h + G_{ih} E''_h) \\ \quad + E''_i \sum_{h=1}^n (G_{ih} E'_h - B_{ih} E''_h) \\ i = g + 1, \dots, g + u \text{ for load buses,} \end{cases}\quad (5.80)$$

where an asterisk indicates a quantity that is set (i.e., imposed by the transmission system operator). Thus, we eventually obtain  $1 + (g + 1) + (g + u) + u = 2(g + u + 1) = 2n$  equations.

### Polar Coordinates

The following notation will be used for the equations in polar coordinates, where  $\varphi_i$  and  $\theta_i$  are the arguments of the current and the voltage of the  $i$ th bus, respectively, and  $\gamma_{ih}$  is the argument of the admittance  $\bar{Y}_{ih}$ :

- $\bar{E}_i = E_i e^{j\theta_i}$  is the voltage of the  $i$ th bus
- $\bar{I}_i = I_i e^{j\varphi_i}$  is the current of the  $i$ th bus
- $\bar{Y}_{ih} = Y_{ih} e^{j\gamma_{ih}}$  is element  $ih$  of the admittance matrix.

The complex power injected or absorbed at each bus is

$$\bar{S}_i = P_i + jQ_i = \bar{E}_i \bar{I}_i. \quad (5.81)$$

Thus, using (5.67) for the current, we get

$$\begin{aligned}\bar{S}_i &= \bar{E}_i \sum_{h=1}^n \underline{Y}_{ih} \underline{E}_h = \sum_{h=1}^n \bar{E}_i \underline{Y}_{ih} \underline{E}_h \\ &= \sum_{h=1}^n E_i E_h Y_{ih} e^{j(\theta_i - \theta_h - \gamma_{ih})}.\end{aligned}\quad (5.82)$$

The real and reactive power at the  $i$ th bus are therefore

$$\begin{cases} P_i = \sum_{h=1}^n E_i E_h Y_{ih} \cos(\theta_i - \theta_h - \gamma_{ih}) \\ Q_i = \sum_{h=1}^n E_i E_h Y_{ih} \sin(\theta_i - \theta_h - \gamma_{ih}) \end{cases} \quad (5.83)$$

The entire system of equations in polar coordinates takes the form

$$\begin{cases} 0 = \theta_i \\ i = n \text{ for the slack bus only} \\ E_i^* = E_i \\ i = 1, 2, \dots, g \text{ and } i = n \\ \text{for the slack bus and the generation buses} \\ P_i^* = E_i \sum_{h=1}^n E_h Y_{ih} \cos(\theta_{ih} - \gamma_{ih}) \\ i = 1, 2, \dots, g + u \text{ for load and generation buses} \\ Q_i^* = E_i \sum_{h=1}^n E_h Y_{ih} \sin(\theta_{ih} - \gamma_{ih}) \\ i = g + 1, \dots, g + u \text{ for } u \text{ load buses,} \end{cases} \quad (5.84)$$

where, as before, an asterisk indicates a quantity that is set (imposed by the transmission system operator). Also, we again ultimately obtain  $1 + (g + 1) + (g + u) + u = 2n$  equations, of which  $g + 2$  are identities.

#### Power Flow

The power flowing from bus  $i$  to bus  $h$  is given by

$$\bar{S}_{ih} = P_{ih} + jQ_{ih} = \bar{E}_i (\underline{E}_i - \underline{E}_h) y_{ih} + E_i^2 y_{i(ih)} \quad (5.85)$$

In polar coordinates,

$$\begin{aligned} \bar{S}_{ih} &= \bar{E}_i (\underline{E}_i - \underline{E}_h) y_{ih} + E_i^2 y_{i(ih)} \\ &= E_i e^{j\theta_i} (E_i e^{-j\theta_i} - E_h e^{-j\theta_h}) y_{ih} e^{-j\gamma_{ih}} + E_i^2 y_{i(ih)} e^{-j\gamma_i} \\ &= E_i^2 y_{ih} e^{-j\gamma_{ih}} - E_i E_h y_{ih} e^{j(\theta_i - \theta_h - \gamma_{ih})} + E_i^2 y_{i(ih)} e^{-j\gamma_i}, \end{aligned} \quad (5.86)$$

where  $\gamma_i$  is the argument of the admittance  $y_{i(ih)}$ .

In Cartesian coordinates,

$$\begin{aligned} P_{ih} &= (g_{ih} + g_{i(ih)}) (E_i'^2 + E_h''^2) - g_{ih} (E_i' E_h' + E_i'' E_h'') \\ &\quad + b_{ih} (E_i' E_h'' - E_h' E_i'') \\ Q_{ih} &= -(b_{ih} + b_{i(ih)}) (E_i'^2 + E_h''^2) + g_{ih} (E_i' E_h'' - E_h' E_i'') \\ &\quad + b_{ih} (E_i' E_h' + E_i'' E_h''). \end{aligned} \quad (5.87)$$

Expressing the voltages in polar coordinates and the admittances in Cartesian coordinates, we obtain the useful relationship

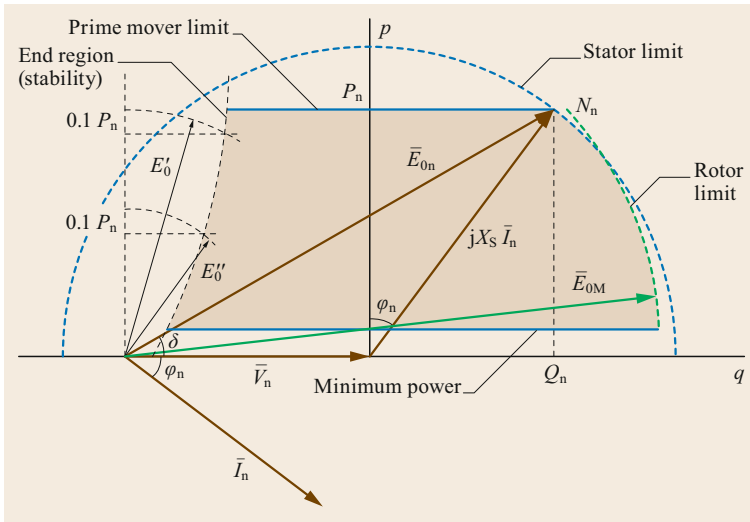

$$P_{ih} = E_i^2 (g_{ih} + g_{i(ih)}) - E_i E_h (g_{ih} \cos \theta_{ih} + b_{ih} \sin \theta_{ih}) \quad (5.88)$$

$$Q_{ih} = -E_i^2 (b_{ih} + b_{i(ih)}) - E_i E_h (g_{ih} \sin \theta_{ih} - b_{ih} \cos \theta_{ih}). \quad (5.89)$$

### 5.4.3 Capability Curves

In this section, we briefly review the concept of generator capability curves. The generator must be able to meet the active and reactive power demands within the limits of appropriate generator operation under both steady-state and transient conditions. Let us consider a round-rotor synchronous generator with a linear magnetic circuit. We can define the following operational limits, which are known as *capability limits* (see also Fig. 5.18):

- The *armature current limit*. The maximum allowable heating of the stator windings sets the maximum value of the phase current  $I_n$  for the machine. This is equivalent to setting the maximum apparent power of the generator.
- The *field current limit*. The maximum allowable heating of the rotor excitation windings sets the maximum field current  $I_F$  of the machine. This is equivalent to setting the maximum no-load emf  $E_{0M}$  for the machine. Note that  $E_{0M}$  is larger than  $E_{0n}$ .
- The *stability limit*. During underexcitation, the power angle must not exceed a certain value in order to maintain steady-state stability  $\delta < \delta_{\max}$ , therefore, the supplied active power should not exceed a certain threshold. A particular safety margin, e.g., 10% of the rated active power  $P_n$  power should be maintained for stability reasons.
- The *end region*. During underexcitation, the current leads the voltage by almost  $90^\circ$  and leakage flux is directed along the direct axis—a condition which can produce some local heating in the end regions of some machines.
- The *prime mover limit*. Limits on the mechanical input power from the prime mover impose constraints on the active power generated. The maximum and minimum active power generated ( $P_{\max}$  and  $P_{\min}$ , respectively) are determined directly from the characteristics of the prime mover. This is shown in Fig. 5.17.

**Fig. 5.17** Capability curve showing the mechanical, rotor, and stator limits

**Fig. 5.18** Graphical interpretation of Newton–Raphson’s method

### 5.4.4 Solution Methods

#### Newton–Raphson’s Method

Let us first briefly recall the basis for Newton–Raphson’s method for solving nonlinear equations and systems of nonlinear equations. Given a generic function  $f(x)$  that is derivable and nonlinear, we want to determine the value  $x^*$  of the unknown  $x$  such that  $f(x)$  assumes a fixed value  $y^*$ ; in other words,

$$f(x^*) = y^* . \tag{5.90}$$

Since  $x^{(0)}$  is close to  $x^*$ , we can define

$$\Delta x^{(0)} = x^* - x^{(0)} . \tag{5.91}$$

We now consider the Taylor expansion of  $f(x)$  in the neighborhood of  $x^{(0)}$ ,

$$\begin{aligned} f(x^*) &= f(x^{(0)} + \Delta x^{(0)}) \\ &= f(x^{(0)}) + \left(\frac{df}{dx}\right)^{(0)} \Delta x^{(0)} \\ &\quad + \left(\frac{d^2f}{dx^2}\right)^{(0)} \frac{(\Delta x^{(0)})^2}{2!} + \dots \end{aligned} \tag{5.92}$$

Provided that  $x^{(0)}$  is close enough to  $x^*$ , we can linearize and write

$$f(x^*) \cong f(x^{(0)}) + \left(\frac{df}{dx}\right)^{(0)} \Delta x^{(0)} . \tag{5.93}$$

Equation (5.90) can be rewritten as

$$f(x^{(0)}) + \left(\frac{df}{dx}\right)^{(0)} \Delta x^{(0)} = y^* . \tag{5.94}$$

Using (5.94), we can infer a value of  $\Delta x$  that will generally differ from that expressed by (5.91) because of the above approximation (the truncation of the Taylor expansion after the first term). We shall therefore denote this value  $\Delta x^{(1)}$ , where

$$\Delta x^{(1)} = \frac{y^* - f(x^{(0)})}{\left(\frac{df}{dx}\right)^{(0)}} = \frac{\Delta y^{(0)}}{\left(\frac{df}{dx}\right)^{(0)}} \tag{5.95}$$

and

$$\Delta y^{(0)} = y^* - f(x^{(0)}) . \tag{5.96}$$

If we now add the value of  $\Delta x^{(1)}$  to the value of the initial guess  $x^{(0)}$ , we get a new value of  $x$  that is closer to the initial solution. We shall call this new value  $x^{(1)}$ , and

$$x^{(1)} = x^{(0)} + \Delta x^{(1)} = \begin{cases} x^{(0)} + \frac{\Delta y^{(0)}}{\left(\frac{df}{dx}\right)^{(0)}} & \text{if } y^* \neq 0 \\ x^{(0)} - \frac{f(x^{(0)})}{\left(\frac{df}{dx}\right)^{(0)}} & \text{if } y^* = 0. \end{cases} \quad (5.97)$$

Generalizing, the  $(v + 1)$ th iteration yields

$$x^{(v+1)} = x^{(v)} + \Delta x^{(v+1)} = \begin{cases} x^{(v)} + \frac{\Delta y^{(v)}}{\left(\frac{df}{dx}\right)^{(v)}} & \text{if } y^* \neq 0 \\ x^{(v)} - \frac{f(x^{(v)})}{\left(\frac{df}{dx}\right)^{(v)}} & \text{if } y^* = 0, \end{cases} \quad (5.98)$$

where

$$\begin{aligned} \Delta x^{(v+1)} &= x^{(v+1)} - x^{(v)} \\ \Delta y^{(v)} &= y^* - f(x^{(v)}), \end{aligned}$$

so we obtain

$$\left(\frac{df}{dx}\right)^{(v)} \Delta x^{(v+1)} = \begin{cases} \Delta y^{(v)} & \text{if } y^* \neq 0 \\ -f(x^{(v)}) & \text{if } y^* = 0, \end{cases} \quad (5.99)$$

which is Newton–Raphson’s iterative formula. A graphical interpretation of this method is given in Fig. 5.18.

The iterative process performed in Newton–Raphson’s method stops when either

$$\Delta x^{(v+1)} < \varepsilon \quad (5.100)$$

or

$$\begin{cases} \Delta y^{(v+1)} < \varepsilon & \text{if } y^* \neq 0 \\ f(x^{(v+1)}) < \varepsilon & \text{if } y^* = 0, \end{cases} \quad (5.101)$$

where  $\varepsilon$  is defined as the *tolerance* and  $f(x^{(v+1)})$  or  $\Delta y^{(v+1)}$  is the *residual*.

If the function exhibits smooth behavior around  $x^{(0)}$  (i.e., its derivative does not change sign or vary too much), convergence can be attained after a reasonable (i.e., not excessive) number of iterations, even without recalculating the derivative at each iteration.

When there are  $n$  equations with  $n$  unknowns, the system

$$\begin{cases} f_1(x_1, x_2, \dots, x_n) = y_1^* \\ f_2(x_1, x_2, \dots, x_n) = y_2^* \\ \vdots \\ f_n(x_1, x_2, \dots, x_n) = y_n^* \end{cases} \quad (5.102)$$

is considered. Using a procedure similar to that followed for a single-variable function, the  $(v + 1)$ th iteration yields

$$\begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \dots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \dots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \dots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \\ \vdots \\ \Delta x_n \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta y_1 \\ \Delta y_2 \\ \vdots \\ \Delta y_n \end{bmatrix}^{(v)}, \quad (5.103)$$

which can be written in compact form as

$$[\mathbf{J}]^{(v)} \times [\Delta \mathbf{x}]^{(v+1)} = [\Delta \mathbf{y}]^{(v)}, \quad (5.104)$$

where

$$[\mathbf{J}]^{(v)} = \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \dots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \dots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \dots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}^{(v)} \quad (5.105)$$

$$\Delta x_i^{(v+1)} = x_i^{(v+1)} - x_i^{(v)} \quad (5.106)$$

and

$$\Delta y_i^{(v)} = y_i^* - f_i(x_1^{(v)}, x_2^{(v)}, \dots, x_n^{(v)}). \quad (5.107)$$

The solution is given by

$$\begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}^{(v+1)} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}^{(v)} + \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \\ \vdots \\ \Delta x_n \end{bmatrix}^{(v+1)}, \quad (5.108)$$

where

$$\begin{bmatrix} \Delta x_1 \\ \Delta x_2 \\ \vdots \\ \Delta x_n \end{bmatrix}^{(v+1)} = \left( \begin{bmatrix} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \dots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \dots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \dots & \frac{\partial f_n}{\partial x_n} \end{bmatrix}^{(v)} \right)^{-1} \times \begin{bmatrix} \Delta y_1 \\ \Delta y_2 \\ \vdots \\ \Delta y_n \end{bmatrix}^{(v)}. \quad (5.109)$$

In compact form,

$$[\mathbf{x}]^{(v+1)} = [\mathbf{x}]^{(v)} + [\Delta \mathbf{x}]^{(v+1)} \quad (5.110)$$

$$[\Delta \mathbf{x}]^{(v+1)} = ([\mathbf{J}]^{(v)})^{-1} \times [\Delta \mathbf{y}]^{(v)}. \quad (5.111)$$

To solve the system represented by (5.102), we make an initial guess of  $(x_1^{(0)}, x_2^{(0)}, \dots, x_n^{(0)})$  and then calculate  $\Delta y_i^{(0)} = y_i^* - f_i(x_1^{(0)}, x_2^{(0)}, \dots, x_n^{(0)})$ . It is reasonable to assume that  $\Delta y_i^{(1)}$  will not satisfy the condition  $\Delta y_i^{(1)} < \varepsilon_i$  at the first iteration, so we need to calculate the elements of the Jacobian using  $(x_1^{(0)}, x_2^{(0)}, \dots, x_n^{(0)})$  in order to obtain all terms  $\Delta x_i^{(1)}$ , which are then used to derive the values of  $x_i(1)$ . This process is repeated until the  $(n+1)$ th iteration, when condition  $\Delta y_i^{(n+1)} \leq \varepsilon_i$  or condition  $\Delta x_i^{(n+1)} \leq \varepsilon_i$  is satisfied.

Let us now apply this method to the load-flow problem [5.37–39].

For the  $u$  load buses, we have

$$\begin{bmatrix} \frac{\partial P}{\partial E} & \frac{\partial P}{\partial \vartheta} \\ \frac{\partial Q}{\partial E} & \frac{\partial Q}{\partial \vartheta} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \\ \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix}^{(v)}. \quad (5.112)$$

For the  $g$  generation buses, we have

$$\begin{bmatrix} \frac{\partial P}{\partial E} & \frac{\partial P}{\partial \vartheta} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \\ \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \end{bmatrix}^{(v)}. \quad (5.113)$$

Note that we have a total of  $g$  equations rather than the  $2g$  equations that would be obtained with the Cartesian formulation. This is because the remaining  $g$  ones, which correspond to the amplitudes of the voltages of the generator buses, are known quantities.

The overall compact formulation of the problem is

$$\begin{bmatrix} J_{PE} & J_{P\vartheta} \\ J_{QE} & J_{Q\vartheta} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \\ \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix}^{(v)}, \quad (5.114)$$

in which the elements of the Jacobian are expressed as

$$\begin{cases} \frac{\partial P_i}{\partial E_i} = Y_{ih} E_i \cos(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial P_i}{\partial E_i} = 2Y_{ii} E_i \cos \gamma_{ii} + \sum_{h=1, h \neq i}^n Y_{ih} E_h \cos(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial P_i}{\partial \vartheta_h} = Y_{ih} E_i E_h \sin(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial P_i}{\partial \vartheta_i} = -E_i \sum_{h=1, h \neq i}^n Y_{ih} E_h \sin(\vartheta_i - \vartheta_h - \gamma_{ih}) \end{cases} \quad (5.115)$$

and

$$\begin{cases} \frac{\partial Q_i}{\partial E_h} = Y_{ih} E_i \sin(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial Q_i}{\partial E_i} = -2Y_{ii} E_i \sin \gamma_{ii} + \sum_{h=1, h \neq i}^n Y_{ih} E_h \sin(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial Q_i}{\partial \vartheta_h} = -Y_{ih} E_i E_h \cos(\vartheta_i - \vartheta_h - \gamma_{ih}) \\ \frac{\partial Q_i}{\partial \vartheta_i} = E_i \sum_{h=1, h \neq i}^n Y_{ih} E_h \cos(\vartheta_i - \vartheta_h - \gamma_{ih}) \end{cases} \quad (5.116)$$

A load-flow calculation that uses the Newton–Raphson method and is performed with the EMTP-RV (electromagnetic transient program) code is included in the supplementary material for this chapter.

## 5.4.5 Approximations for Calculating the Load Flow

### Carpentier's Approximation

Before we dive any further into this section, it is important to note that the word *approximation* is not used in this section to describe the nature of the results (which are always approximate given that we utilize iterative solution methods), but to refer to the nature of the equations used to compute the load flow.

The first approximation that we introduce is Carpentier's approximation [5.40], which makes the assumption that the active powers injected in the nodes depend only on the phases of the voltages, whereas the reactive powers depend only on the magnitudes of the voltages. This allows us to decouple system (5.114). In other words, the elements of the submatrix  $[\partial P / \partial \vartheta]$  are normally much larger than those of the submatrix  $[\partial P / \partial E]$ , and the elements of  $[\partial Q / \partial E]$  are much larger than those of  $[\partial Q / \partial \vartheta]$ .

The new system of equations becomes

$$\begin{aligned} & \begin{bmatrix} \frac{\partial P}{\partial E} & \frac{\partial P}{\partial \vartheta} \\ \frac{\partial Q}{\partial E} & \frac{\partial Q}{\partial \vartheta} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \\ \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix}^{(v)} \\ \Rightarrow & \begin{bmatrix} 0 & \frac{\partial P}{\partial \vartheta} \\ \frac{\partial Q}{\partial E} & 0 \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \\ \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix}^{(v)}, \end{aligned} \quad (5.117)$$

which corresponds to the two subsystems

$$\begin{bmatrix} \frac{\partial P}{\partial \vartheta} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta \vartheta \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta P \end{bmatrix}^{(v)} \quad (5.118)$$

$$\begin{bmatrix} \frac{\partial Q}{\partial E} \end{bmatrix}^{(v)} \times \begin{bmatrix} \Delta E \end{bmatrix}^{(v+1)} = \begin{bmatrix} \Delta Q \end{bmatrix}^{(v)}. \quad (5.119)$$

What we have achieved here is known as *active and reactive power decoupling*.

It is useful to recall that, for a very short line (i.e., a line in which transversal admittance can be neglected), the expressions for the active and reactive power in absolute values (i.e., not in pu) at the terminations are

$$P_1 = P_2 = \frac{3E_1 E_2}{X} \sin \vartheta \quad (5.120)$$

$$Q_1 = \frac{3E_1}{X} (E_1 - E_2 \cos \vartheta) \quad (5.121)$$

$$Q_2 = \frac{3E_2}{X} (E_1 \cos \vartheta - E_2). \quad (5.122)$$

In general, especially when the line is short and not overloaded,  $\vartheta$  is a small angle. As a first approximation,

we can therefore state that the active power depends on the phase shift between the two voltages, while the reactive power depends on the voltage magnitudes.

The statements made above regarding a very short line are normally also valid for longer lines, and generally extend to the grids. Recall the equations for power transmission along a generic transmission line,

$$\begin{cases} P_{ih} = E_i^2(g_{ih} + g_{i(ih)}) - E_i E_h [g_{ih} \cos(\vartheta_i - \vartheta_h) \\ \quad + b_{ih} \sin(\vartheta_i - \vartheta_h)] \\ Q_{ih} = -E_i^2(b_{ih} + b_{i(ih)}) - E_i E_h [g_{ih} \sin(\vartheta_i - \vartheta_h) \\ \quad - b_{ih} \cos(\vartheta_i - \vartheta_h)]. \end{cases} \quad (5.123)$$

Differentiating with respect to the magnitudes and phases of the voltages, we obtain the real power derivatives

$$\begin{cases} \frac{\partial P_{ih}}{\partial E_i} = 2E_i(g_{ih} + g_{i(ih)}) \\ \quad - E_h [g_{ih} \cos(\vartheta_i - \vartheta_h) + b_{ih} \sin(\vartheta_i - \vartheta_h)] \\ \frac{\partial P_{ih}}{\partial E_h} = -E_i [g_{ih} \sin(\vartheta_i - \vartheta_h) + b_{ih} \cos(\vartheta_i - \vartheta_h)] \end{cases} \quad (5.124)$$

$$\begin{cases} \frac{\partial P_{ih}}{\partial \vartheta_i} = E_i E_h [g_{ih} \sin(\vartheta_i - \vartheta_h) - b_{ih} \cos(\vartheta_i - \vartheta_h)] \\ \frac{\partial P_{ih}}{\partial \vartheta_h} = -\frac{\partial P_{ih}}{\partial \vartheta_i} \end{cases} \quad (5.125)$$

and the reactive power derivatives

$$\begin{cases} \frac{\partial Q_{ih}}{\partial E_i} = -2E_i(b_{ih} + b_{i(ih)}) \\ \quad - E_h [g_{ih} \sin(\vartheta_i - \vartheta_h) - b_{ih} \cos(\vartheta_i - \vartheta_h)] \\ \frac{\partial Q_{ih}}{\partial E_h} = -E_i [g_{ih} \sin(\vartheta_i - \vartheta_h) - b_{ih} \cos(\vartheta_i - \vartheta_h)] \end{cases} \quad (5.126)$$

$$\begin{cases} \frac{\partial Q_{ih}}{\partial \vartheta_i} = -E_i E_h [g_{ih} \cos(\vartheta_i - \vartheta_h) + b_{ih} \sin(\vartheta_i - \vartheta_h)] \\ \frac{\partial Q_{ih}}{\partial \vartheta_h} = -\frac{\partial Q_{ih}}{\partial \vartheta_i} \end{cases} \quad (5.127)$$

The conductance  $g_{ij}$  and the angle  $\vartheta_{ih} = \vartheta_i - \vartheta_h$  are generally small. As a consequence, we can state that

$$\frac{\partial P_{ih}}{\partial E_i} \ll \frac{\partial P_{ih}}{\partial \vartheta_i}, \quad \frac{\partial Q_{ih}}{\partial \vartheta_i} \ll \frac{\partial Q_{ih}}{\partial E_i}. \quad (5.128)$$

As a result, small variations in the voltage magnitudes do not appreciably affect the active power transmission and, analogously, small phase variations do not substantially alter the reactive power flow. It follows that the active power transmission mainly depends on the voltage phase shifts, while the reactive power flow is mainly influenced by the difference in the voltage magnitudes at the line terminations.

### Stott's Approximation

This approximation is also known as fast decoupled load flow [5.41, 42]. As discussed earlier, the power injection at bus  $i$  can be written as

$$\bar{S}_i = \bar{E}_i \sum_{h=1}^n \underline{Y}_{ih} \bar{E}_h = \sum_{h=1}^n \bar{E}_i \underline{Y}_{ih} \bar{E}_h. \quad (5.129)$$

We know that

$$\begin{cases} \bar{E}_i = E_i e^{j\vartheta_i} = E_i (\cos \vartheta_i + j \sin \vartheta_i) \\ \bar{E}_h = E_h e^{-j\vartheta_h} = E_h [\cos(-\vartheta_h) + j \sin(-\vartheta_h)] \\ \underline{Y}_{ih} = G_{ih} - jB_{ih}, \end{cases} \quad (5.130)$$

so we can substitute (5.130) into (5.129), which yields

$$\begin{aligned} \bar{S}_i &= E_i \sum_{h=1}^n E_h (G_{ih} - jB_{ih}) [\cos(\vartheta_i - \vartheta_h) + j \sin(\vartheta_i - \vartheta_h)] \\ &= E_i \sum_{h=1}^n E_h (G_{ih} - jB_{ih}) [\cos \vartheta_{ih} + j \sin \vartheta_{ih}]. \end{aligned} \quad (5.131)$$

Using (5.131), it is possible to obtain the expressions for  $P$  and  $Q$  presented in the previous section, i.e.,

$$\begin{cases} P_i = E_i \sum_{h=1}^n E_h (G_{ih} \cos \vartheta_{ih} + B_{ih} \sin \vartheta_{ih}) \\ Q_i = E_i \sum_{h=1}^n E_h (G_{ih} \sin \vartheta_{ih} - B_{ih} \cos \vartheta_{ih}). \end{cases} \quad (5.132)$$

Extracting the term relevant to node  $i$  from the summation, we have

$$\begin{cases} P_i = G_{ii} E_i^2 + E_i \sum_{h \neq i}^n E_h (G_{ih} \cos \vartheta_{ih} + B_{ih} \sin \vartheta_{ih}) \\ Q_i = -B_{ii} E_i^2 + E_i \sum_{h \neq i}^n E_h (G_{ih} \sin \vartheta_{ih} - B_{ih} \cos \vartheta_{ih}). \end{cases} \quad (5.133)$$

Differentiating the active power with respect to  $\vartheta_i$  and the reactive power with respect to  $E_i$  leads to

$$\begin{aligned} \frac{\partial P_i}{\partial \vartheta_i} &= -E_i \sum_{\substack{h=1 \\ h \neq i}}^n E_h (G_{ih} \sin \vartheta_{ih} - B_{ih} \cos \vartheta_{ih}) \\ &= -B_{ii} E_i^2 - Q_i \\ \frac{\partial Q_i}{\partial E_i} &= -2B_{ii} E_i + \sum_{\substack{h=1 \\ h \neq i}}^n E_h (G_{ih} \sin \vartheta_{ih} - B_{ih} \cos \vartheta_{ih}) \\ &= -2B_{ii} E_i + \frac{Q_i + B_{ii} E_i^2}{E_i} = \frac{Q_i}{E_i} - B_{ii} E_i. \end{aligned} \quad (5.134)$$

We can make the following assumptions (known as Stott's assumptions) based on (5.134) [5.41]:

- $B_{ih} \cos \vartheta_{ih} \cong B_{ih}$ , given that the displacements  $\vartheta_{ih}$  at the ends of a single link are small (i.e.,  $Q_i \ll B_{ii}E_i^2$ )
- $G_{ih} \sin \vartheta_{ih} \ll B_{ih}$  as both the conductances and  $\vartheta_{ih}$  are small
- $Q_i \ll B_{ii}E_i^2$ , which is explained below.

Let us consider a generation node connected to the high-voltage grid by means of the corresponding elevator transformer, which has a reactance  $x$  of 0.1 pu (referred to its own rated power  $A_n$ ). Taking  $E_i$  to be equal to 1 pu, we obtain  $B_{ii}E_i^2 = 10$  pu. It is reasonable to assume that the reactive power produced or absorbed by a generator under normal operating conditions is 0.6–0.7 pu; furthermore, as the rated power of the elevator transformer is approximately equal to that of the generator, we can conclude that the assumption is acceptable ( $B_{ii}E_i^2 = 10 \gg Q_i \cong 0.7$ ).

Similar statements can be made for the load nodes. It can be observed that the longitudinal reactance of a line (in pu of the characteristic power) is about 0.1 pu for a 100 km overhead line. The reactive power absorbed by the loads is usually very small compared to the active one ( $\cos \varphi \cong 0.8$ – $0.9$ ), and two lines converge in every load bus on average.

In view of the discussion above, introducing Stott's assumptions into (5.134) leads us to

$$\begin{cases} \frac{\partial P_i}{\partial \vartheta_h} = -E_i E_h B_{ih} \\ \frac{\partial P_i}{\partial \vartheta_i} = -E_i^2 B_{ii} \end{cases} \quad h \neq i \Rightarrow \frac{\partial P_i}{\partial \vartheta_h} = -E_i E_h B_{ih} \quad \forall h \quad (5.135)$$

$$\begin{cases} \frac{\partial Q_i}{\partial E_h} = -E_i B_{ih} \\ \frac{\partial Q_i}{\partial E_i} = -E_i B_{ii} \end{cases} \quad h \neq i \Rightarrow \frac{\partial Q_i}{\partial E_h} = -E_i B_{ih} \quad \forall h. \quad (5.136)$$

Like Carpentier's method, Stott's method is based on the approximation that the active power and reactive power are related to the voltage angles and magnitudes, respectively, i.e., it is also based on active/reactive decoupling. If we consider the load-flow equations obtained using Carpentier's approximation,

$$\begin{cases} \Delta P_i^{(v)} = \sum_{h=1}^n \frac{\partial P_i^{(v)}}{\partial \vartheta_h} \Delta \vartheta_h^{(v+1)} \\ \Delta Q_i^{(v)} = \sum_{h=1}^n \frac{\partial Q_i^{(v)}}{\partial E_h} \Delta E_h^{(v+1)}, \end{cases} \quad (5.137)$$

replacing the partial derivatives with expressions (5.135) and (5.136) yields

$$\begin{cases} \frac{\Delta P_i^{(v)}}{E_i} = \sum_{h=1}^n -B_{ih} E_h^{(v)} \Delta \vartheta_h^{(v+1)} \\ \frac{\Delta Q_i^{(v)}}{E_i} = \sum_{h=1}^n -B_{ih} \Delta E_h^{(v+1)}. \end{cases} \quad (5.138)$$

The great advantage of Stott's method is that the partial derivatives of the Jacobian matrix are replaced with simple susceptances, so there is no need to update the Jacobian at each iteration.

### DC Approximation

The load-flow solution methods shown so far have been *AC methods* in the sense that the unknowns to be determined are the voltages (magnitude and phase) that affect the distributions of active and reactive power in the various branches of the network.

Considerable time is needed to perform these methods when dealing with large networks. On the other hand, in some situations it is sufficient to estimate only the active power flows in the various lines, which leads to a marked reduction in computational time. Such situations include the initial planning stage of a transmission network, short-term operational planning (daily and weekly programs implemented *off-line*), and even the *on-line* control of a transmission system that checks for the consequences of a possible sudden loss of a critical component (such as a line or large generator) every few minutes.

The *direct current* load-flow solution method [5.42] is based on the following simplifications:

- The conductor resistances are generally negligible compared to the series reactances of the lines and transformers. The ratio between the reactance and the resistance is about 10 for a distribution line, but can reach 50 for large interconnecting lines. Therefore, losses are neglected in this method.
- The transversal admittances of power components are neglected. The line capacitances generate reactive power that does not significantly affect the active power flow.
- The transversal conductances are neglected.
- Based on similar considerations, the shunt reactances and bank of capacitors can also be neglected.

Let us now consider a branch of the network characterized by a longitudinal reactance  $x_{ih}$ .  $\bar{E}_i$  and  $\bar{E}_h$  are the voltages at the ends of the line, with a phase shift  $\vartheta_{ih}$  between them.

The active power flow in the branch is

$$P_{ih} = \frac{3E_i E_h}{x_{ih}} \sin \vartheta_{ih}. \quad (5.139)$$

Let us also assume that the voltages are close to their nominal values, i.e.,

$$\bar{E}_i \cong \bar{E}_h. \quad (5.140)$$

Also, noting that the angle  $\vartheta_{ih} = \vartheta_i - \vartheta_h$  is generally small, the pu expression of (5.139) becomes

$$p_{ih} = \frac{1}{x_{ih}} \vartheta_{ih}. \quad (5.141)$$

This relationship is analogous to Ohm's law in a DC circuit with a current  $p_{ih}$  flowing through a resistor of value  $x_{ih}$ , causing a voltage drop  $\vartheta_{ih}$  across it.

As a consequence of this expression, the active power injection in the generic node  $i$  (in pu) is

$$p_i = \sum_{\substack{h=1 \\ h \neq i}}^n p_{ih} = \frac{\vartheta_{i1}}{x_{i1}} + \frac{\vartheta_{i2}}{x_{i2}} + \dots + \frac{\vartheta_{in}}{x_{in}}$$

$$\stackrel{\vartheta_{ih} = \vartheta_i - \vartheta_h}{\Rightarrow} \left( \frac{1}{x_{i1}} + \frac{1}{x_{i2}} + \dots + \frac{1}{x_{in}} \right) \vartheta_i - \sum_{\substack{h=1 \\ h \neq i}}^n \frac{1}{x_{ih}} \vartheta_h. \quad (5.142)$$

The terms in parentheses can be interpreted as self-admittances, while the terms in the summation can be considered transadmittances. Therefore, we define that

$$\sum_{\substack{h=1 \\ h \neq i}}^n \frac{1}{x_{ih}} = \frac{1}{X_{ii}} \quad ; \quad \frac{1}{x_{ih}} = \frac{1}{-X_{ih}}, \quad (5.143)$$

and the active power injection becomes

$$p_i = \sum_{h=1}^n \frac{1}{X_{ih}} \vartheta_h \Rightarrow p_i = \sum_{h=1}^n B_{ih} \vartheta_h. \quad (5.144)$$

Thus, the linear matrix equation

$$[\mathbf{p}] = [\mathbf{B}] \times [\boldsymbol{\vartheta}] \quad (5.145)$$

is obtained for the whole network, where  $[\mathbf{B}]$  is the susceptance matrix of the entire transmission network in pu. The diagonal terms  $B_{ii}$  of this matrix are the sum of the susceptances of all the lines that converge at the  $i$ th node, and are positive since the susceptances are inductive. The other terms are all negative and satisfy the condition  $B_{hk} = B_{kh} = -b_{hk} = -b_{kh}$ .

An exercise to calculate the load flow of a simple three-bus network using the current approximation is included in the supplementary material.

### 5.4.6 Concluding Remarks

The methods examined so far do not consider any constraints. In real applications, however, there can be many types of constraints:

- The voltages in the various nodes must not be too different from the nominal ones

- In the generation nodes, the reactive power injection resulting from the calculation must be compatible with the capability curves of the generators
- When the slack bus—which is also a generation node—is assumed to be concentrated in one bus and not distributed, it must have an active and reactive power output compatible with the above production of the generators.

The limits are therefore of the type

$$\begin{cases} Q_{i,\min} \leq Q_i \leq Q_{i,\max} \\ i = 1, 2, \dots, g \end{cases} \quad (5.146)$$

$$\begin{cases} E_{i,\min} \leq E_i \leq E_{i,\max} \\ i = 1, 2, \dots, g + u \end{cases} \quad (5.147)$$

$$P_{n,\min} \leq P_n \leq P_{n,\max}. \quad (5.148)$$

Load-flow calculations with constrained variables must be performed to account for these issues ([5.43], from which the following discussion is adapted).

Now suppose that constraints (5.146) are violated; in other words, the computation yields reactive powers that exceed the limit in some generation buses and are lower than the limit in others. In order to obtain a load-flow solution that is technically feasible, it is necessary to change the voltages in the various buses. These buses, originally of  $(P, E)$  type, can therefore be converted into  $(P, Q)$  ones by fixing their reactive power production (i.e.,  $Q_i \cong Q_{i,\max}$  or  $Q_i \cong Q_{i,\min}$ ), so the voltage magnitude  $E_i$  becomes unknown. Note that the effect of forcing a generator to decrease its reactive power production is that the reactive power generation of the other groups must increase, because the loads do not change.

If the violated constraints are of the type represented by (5.148) for the active power, it will be necessary to vary the power distribution among the other generators of the network. If, for instance, the upper limit is violated (i.e., if the active power to be produced in the slack bus is larger than the maximum allowed), it is necessary to increase the production of the other groups. This does not guarantee a priori that the constraints will be respected, as changing the active power production changes the phases of the voltages and therefore the currents in the branches. Consequently, the transmission losses change too. In other words, it will be necessary to verify that the new calculated active power respects constraints (5.148).

Modern computer software can automatically consider:

- The effects of generator speed control and shifting transformers, in order to determine their optimal set-ups
- The dependence of the loads on the voltage

- Primary and secondary frequency control and the frequency dependence of the loads
- Secondary voltage regulation.

These topics are discussed in the optimal load flow, more commonly known as optimal power flow, (OPF) chapters of several books [5.13, 43]. OPF is closely related to economic dispatch and unit commitment, and any attempt to realize OLF will need to take electricity market rules and constraints into consideration (see Chap. 18). We do not address these topics in this chapter, but we do delve into the essential elements of economic dispatching below.

### Some Basic Elements of Economic Dispatching

For simplicity's sake, suppose that we have a system, as depicted in Fig. 5.19, consisting of:

- $g$  thermal power stations
- one network
- $u$  users.

In a vertically integrated system, we wish to determine the power that the generators (the power plants) must provide in order to meet the power requirements of the users at minimum cost. Any technical constraints on the groups are disregarded for simplicity.

The plot presented in Fig. 5.20 shows the hourly cost curve of a power plant: the efficiency is constant regardless of the power produced. The curved line, on the other hand, shows a more realistic trend for the hourly

Fig. 5.19 Single-bus power system

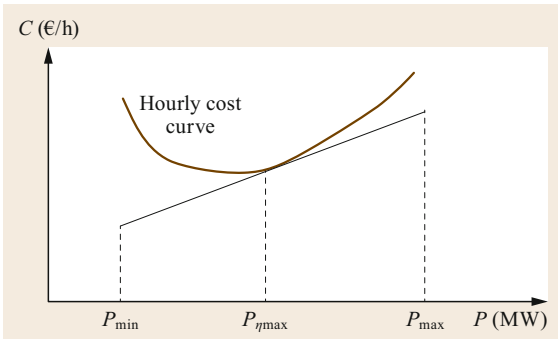

Fig. 5.20 Hourly cost curve for a thermal power plant as a function of the power produced

cost—there is a point on the curve at which the cost is minimized, and we would like to operate the plant at the power corresponding to this point.

Defining  $C$  as the overall cost, the function to be minimized is

$$C = C_1(P_1) + C_2(P_2) + \cdots + C_g(P_g). \quad (5.149)$$

In accordance with the constraint,

$$P_1 + P_2 + \cdots + P_g - (P_{U1} + P_{U2} + \cdots + P_{Uu}) - p = 0, \quad (5.150)$$

where  $p$  represents the losses of the system. It is worth noting that

$$p = p(P_1, P_2, \dots, P_g); \quad (5.151)$$

in other words, the losses are linked to the power produced, as expected.

To solve the problem, it is necessary to use the method of Lagrange multipliers. We define the Lagrangian as

$$\begin{aligned} L &= (\text{condition to be minimized}) - \lambda(\text{constraint}) \\ &= C(P_1, P_2, \dots, P_g) - \lambda \left( \sum_{i=1}^g P_i - \sum_{i=1}^u P_{Ui} - p \right). \end{aligned} \quad (5.152)$$

In order to solve it, we must calculate

$$\begin{cases} \frac{\partial L}{\partial P_i} = 0 \\ \frac{\partial L}{\partial \lambda} = 0 \end{cases} \Rightarrow P_1, P_2, \dots, P_g, \lambda, \quad (5.153)$$

which means that

$$\begin{cases} \frac{\partial C_1}{\partial P_1} - \lambda \left( 1 - \frac{\partial p}{\partial P_1} \right) = 0 \\ \frac{\partial C_2}{\partial P_2} - \lambda \left( 1 - \frac{\partial p}{\partial P_2} \right) = 0 \\ \vdots \\ \frac{\partial C_g}{\partial P_g} - \lambda \left( 1 - \frac{\partial p}{\partial P_g} \right) = 0 \\ P_1 + P_2 + \cdots + P_g \\ = P_{U1} + P_{U2} + \cdots + P_{Uu} + p \end{cases} \Rightarrow P_1, P_2, \dots, P_g, \lambda. \quad (5.154)$$

If the system losses  $p$  are negligible, it follows that  $p = 0$ . This is equivalent to neglecting the power losses along the lines, i.e.,

$$\frac{\partial p}{\partial P_1}, \frac{\partial p}{\partial P_2}, \dots, \frac{\partial p}{\partial P_g}, p = 0. \quad (5.155)$$

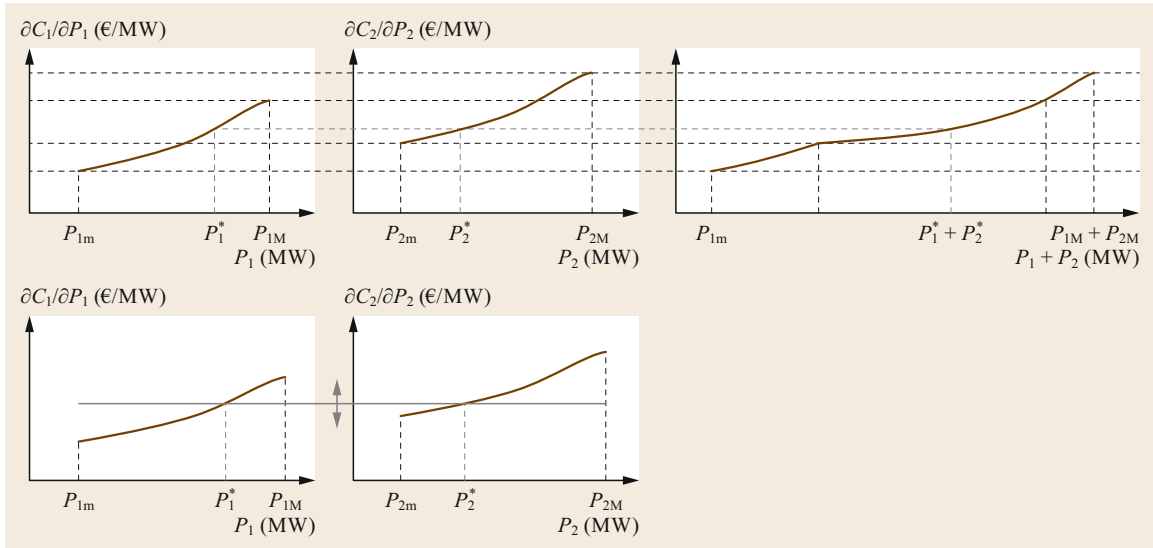

Fig. 5.21 Dispatched Power for two Power Stations 1 and 2 (adapted from [5.36])

In this case, the system is called a *single-bar system*, and the equations reduce to

$$\frac{\partial C_1}{\partial P_1} = \frac{\partial C_2}{\partial P_2} = \dots = \frac{\partial C_g}{\partial P_g} \quad (5.156)$$

Rewriting the partial derivatives as total derivatives yields

$$\frac{dC_1}{dP_1} = \frac{dC_2}{dP_2} = \dots = \frac{dC_g}{dP_g} = \lambda \quad (5.157)$$

Equality of marginal hourly costs is therefore the minimum condition sought.

The simplified assumptions of this section permit the problem to be solved in a simple way graphically using the known hourly cost curves for two power stations, as shown in Fig. 5.21. The incremental hourly cost is obtained by deriving the hourly costs with respect to the power variable. To determine the operating point, it is sufficient to draw a horizontal line that intercepts both curves such that the sum of the power on the first graph ( $P_1^*$ ) and that on the second graph ( $P_2^*$ ) equals the power required by the load.

## 5.5 Unsymmetrical Fault Analysis

A short circuit is the term given to the unintended flow of current along a low-impedance connection between two points at different potentials in an electric circuit (phase-to-phase or phase-to-ground) rather than along the intended path. The most common types of faults in power systems are single line-to-ground (or phase-to-ground), three-phase, line-to-line (or phase-to-phase), and double line-to-ground. Faults can occur for various reasons, such as insulation breakdown (due to overvoltage or aging) or direct contact with bare conductors.

### 5.5.1 Types of Faults in Electric Power Systems

The following fault phenomena can occur in electric power systems:

- (a) A sudden increase in conductor temperature  $\theta$  due to the Joule effect, as calculated via

$$\Delta\theta = KI^2\Delta t \quad (5.158)$$

As the temperature  $\theta$  increases, the extra heat alters the dielectric properties of the insulating materials. Heating also alters the mechanical properties of the conductor, and the disconnecter contacts deteriorate. For faults of this nature, it is clear that reducing the duration of the fault is of paramount importance.

- (b) Electrodynamical forces that are proportional to the square of the peak current amplitude, i.e.,

$$F = KI_p^2 \quad (5.159)$$

which deform or even disrupt conductors and insulation materials.

There are a range of relevant effects, including:

- Damage caused by an electric arc at the location of the fault is common, and often leads to fusion or erosion of the relevant parts (conductors, electrical machines, ferromagnetic plates), representing a fire risk.
- Voltage dips at the faulty bus and in the adjacent network portion, causing malfunctions, trips (of, e.g., synchronous motors and mercury-vapor lamps), disturbing users that are sensitive to voltage drops, and possibly leading to a loss of system stability.
- Dangerous step and touch voltages caused by the large short-circuit currents
- Electromotive force (EMF) induction in telecommunication circuits that are located parallel to power lines
- When present, homopolar sequence current circulation through cable sheaths, pipelines, or other underground structures leads to heating or electric arcs and metal fusion, pipeline punctures, and the potential for fire.

### 5.5.2 Protection Measures Against Faults

Although electric power systems are well designed, faults are relatively frequent phenomena in such systems, so relevant countermeasures must be taken, including:

- i. Installing circuit breakers and fuses with adequate short-circuit breaking capacities to withstand/open the short-circuit current
- ii. Ensuring that components are designed/selected to withstand thermal and electrodynamic stresses without incurring damage
- iii. Designing appropriate grounding systems that keep touch and step voltages within standard limits
- iv. Appropriate calibration/setting of protection relays. Note that setting these devices to open the maximum short-circuit current may result in the failure of the devices to open the lowest fault currents.

To realize the above measures, it is necessary to perform fault current calculations for the various types of possible faults at each network bus. Indeed, as already mentioned, ignoring the calculation of a modest fault current (corresponding to the minimum load operation of the network with different units out of service) during the calibration and validation of protection relays can be critical.

To determine the breaking capacity, it is convenient to calculate short circuits with null fault impedance ( $Z_g = 0$ ). Since this type of fault is rare, for complete-

ness, we shall extend the discussion to the more general case of a nonzero  $Z_g$ .

In fault analysis, the network is generally unbalanced, as most short circuits have this characteristic (e.g., single-line to ground, line-to-line, double line-to-ground).

### 5.5.3 Unbalanced Faults: Short-Circuit Calculation

To simplify the analysis of fault currents in networks, we follow the approach given in [5.3] and make the following simplifications:

- Transmission lines are represented by their series reactance
- Transformers are represented by their short-circuit reactance
- Synchronous machines are modeled as a Thévenin equivalent network consisting of an ideal generator and the direct-axis transient (or subtransient) reactance
- Induction motors are ignored or treated as synchronous machines
- Other (nonspinning) loads are ignored
- The voltage level of the neutral conductor is common to all the voltage levels of the network (i.e., there are no voltage levels with an isolated neutral).

We shall denote the phase voltages and currents by  $\bar{E}_a, \bar{E}_b, \bar{E}_c, \bar{I}_a, \bar{I}_b,$  and  $\bar{I}_c$ , respectively, and the direct (or positive), inverse (or negative), and homopolar (or zero) sequence symmetrical components of the voltages and currents by  $\bar{E}_d, \bar{E}_i, \bar{E}_0, \bar{I}_d, \bar{I}_i,$  and  $\bar{I}_0$ , respectively. Fortescue theory provides various phase voltage and current transformations,

$$\begin{cases} \bar{E}_d = \frac{1}{3}(\bar{E}_a + \alpha\bar{E}_b + \alpha^2\bar{E}_c) \\ \bar{E}_i = \frac{1}{3}(\bar{E}_a + \alpha^2\bar{E}_b + \alpha\bar{E}_c) \\ \bar{E}_0 = \frac{1}{3}(\bar{E}_a + \bar{E}_b + \bar{E}_c) \end{cases} \quad (5.160)$$

$$\begin{cases} \bar{I}_d = \frac{1}{3}(\bar{I}_a + \alpha\bar{I}_b + \alpha^2\bar{I}_c) \\ \bar{I}_i = \frac{1}{3}(\bar{I}_a + \alpha^2\bar{I}_b + \alpha\bar{I}_c) \\ \bar{I}_0 = \frac{1}{3}(\bar{I}_a + \bar{I}_b + \bar{I}_c) \end{cases} \quad (5.161)$$

$$\begin{cases} \bar{E}_a = \bar{E}_d + \bar{E}_i + \bar{E}_0 \\ \bar{E}_b = \alpha^2\bar{E}_d + \alpha\bar{E}_i + \bar{E}_0 \\ \bar{E}_c = \alpha\bar{E}_d + \alpha^2\bar{E}_i + \bar{E}_0 \end{cases} \quad (5.162)$$

$$\begin{cases} \bar{I}_a = \bar{I}_d + \bar{I}_i + \bar{I}_0 \\ \bar{I}_b = \alpha^2\bar{I}_d + \alpha\bar{I}_i + \bar{I}_0 \\ \bar{I}_c = \alpha\bar{I}_d + \alpha^2\bar{I}_i + \bar{I}_0, \end{cases} \quad (5.163)$$

where  $\alpha = e^{j2\pi/3}$ . Note that for simplicity  $\alpha$  has not been overlined.

**Fig. 5.22** Direct, inverse, and homopolar sequence components of the phase voltages. The amplitudes of  $E_d$ ,  $E_i$ , and  $E_0$  are not necessarily equal

A phasor diagram of the direct, inverse, and homopolar sequence components of the phase voltages is reported in Fig. 5.22.

Let us connect a system of nonsymmetrical (unbalanced) impedances to a point in the symmetrical three-phase network, as shown in Fig. 5.23.

After the relevant transient, the voltages  $\bar{E}'_a$ ,  $\bar{E}'_b$ , and  $\bar{E}'_c$  and the currents  $\bar{I}'_a$ ,  $\bar{I}'_b$ , and  $\bar{I}'_c$  are obtained (note that the relevant quantities are denoted by an apex). It is clear that these values depend on the impedances  $\bar{Z}_a$ ,  $\bar{Z}_b$ ,  $\bar{Z}_c$ , and  $\bar{Z}_n$  shown in Fig. 5.23, as well as the network parameters. In the postfault steady state, the system in Fig. 5.23 is equivalent to both of those presented in Fig. 5.24.

Note that if we connect the three voltage sources  $\bar{E}'_a$ ,  $\bar{E}'_b$ , and  $\bar{E}'_c$  at the fault point (Fig. 5.24a), the three currents in the considered section will actually be equal to the three currents  $\bar{I}'_a$ ,  $\bar{I}'_b$ , and  $\bar{I}'_c$  injected at the fault point by the three current sources shown in Fig. 5.24b.

**Fig. 5.23** Connection of unsymmetrical (unbalanced) impedances

Let us suppose that  $\bar{E}'_a$ ,  $\bar{E}'_b$ , and  $\bar{E}'_c$  are known quantities. According to the superposition principle and the Fortescue theorem, each of the three voltage sources can be decomposed into three series generators (as shown in Fig. 5.24b), and further decomposed into three different circuits (as presented in Fig. 5.26).

The asymmetrical network of Fig. 5.25 has now been decomposed into three symmetrical three-phase ones (Fig. 5.26). In the first network, only the positive (direct) sequence set of sources  $\bar{E}'_d$  is present, in addition to those impressed by the generators of the network. The second network only has the negative (inverse) sequence source  $\bar{E}'_i$ , whereas the third only has the zero (homopolar) sequence source  $\bar{E}'_0$ . It is worth noting that, because it is symmetrical, the starting network only has direct-sequence internal emfs.

The three networks of Fig. 5.26 are symmetrical (balanced), so they can be studied by means of three equivalent single-phase circuits, as shown in Fig. 5.27. Once all the quantities in the sequence networks have been determined, the starting network voltages and currents can be calculated using (5.162) and (5.163).

Note that the three sequence networks only differ from each other and the given network in the following ways:

- The set of three emfs that simulate the set of impedances  $\bar{Z}_a$ ,  $\bar{Z}_b$ ,  $\bar{Z}_c$ , and  $\bar{Z}_n$  differ for each of the three networks and differ from the emfs of the starting network
- In inverse and homopolar networks, there is no internal EMF (power system generators only provide direct emf).

In view of the above, we can now transform the three networks of Fig. 5.27 into their Thévenin equivalent networks, as represented in Fig. 5.28.

The parameters in these single-phase Thévenin equivalent networks are as follows:  $\bar{E}$  is the voltage present before nonsymmetrical impedance insertion (i.e., the prefault voltage) at the fault position;  $\bar{Z}_d$ ,  $\bar{Z}_i$ , and  $\bar{Z}_0$  are the equivalent sequence impedances of the network measured at the faulty bus. Voltage  $\bar{E}$  is known from the load-flow calculation. In the absence of further information, it can be assumed to be equal to the rated voltage  $E_n$ , or, conservatively, to the maximum permissible operating voltage, which is often  $1.1E_n$ . It is evident that this assumption leads to the largest short-circuit current values.

The six quantities  $\bar{E}'_d$ ,  $\bar{E}'_i$ ,  $\bar{E}'_0$ ,  $\bar{I}'_d$ ,  $\bar{I}'_i$ , and  $\bar{I}'_0$  can be determined once  $\bar{Z}_a$ ,  $\bar{Z}_b$ ,  $\bar{Z}_c$ , and  $\bar{Z}_n$  are known. Three vector equations are therefore needed (six scalars), in addition to the three expressed by the Thévenin circuits

**Fig. 5.24a,b** Equivalent circuits of the system shown in Fig. 5.23 after the fault in terms of equivalent ideal voltage sources (a) and ideal current sources (b)

**Fig. 5.25** Representation of the Fortescue transformation

**Fig. 5.26** Representation of the Fortescue transformation: superposition of the three different circuits

**Fig. 5.27** Single-phase equivalent networks of the systems represented in Fig. 5.26

**Fig. 5.28** Single-phase Thévenin equivalent networks

$(\bar{E} = \bar{Z}_d \bar{I}_d + \bar{E}_d; 0 = \bar{Z}_i \bar{I}_i + \bar{E}_i; 0 = \bar{Z}_0 \bar{I}_0 + \bar{E}_0)$ , which depend on the particular nature of the fault.

Note that different emf systems are applied in the three networks: direct, inverse, and homopolar, respectively. Therefore, the reduction to single-phase circuits described above leads to different parameters for the equivalent circuits of the various elements of the network.

### Three-Phase Fault

Let us consider the general case depicted in Fig. 5.29a. The system shown in Fig. 5.29a is obtained from Fig. 5.20 by setting  $\bar{Z}_a = \bar{Z}_b = \bar{Z}_c = \bar{Z}_a$ . Due to the symmetrical configuration of the system,  $\bar{E}'_n$  is equal to zero regardless of the value of  $\bar{Z}_n$ , so the circuits presented in Fig. 5.29a and b are equivalent.

In this symmetrical configuration, the only nonzero current is the positive-sequence one. In phase a, the cur-

rent is

$$\bar{I}'_a = \bar{I}'_d = \frac{\bar{E}'_d}{\bar{Z}} \quad (5.164)$$

The equivalent circuit for the three-phase fault is provided in Fig. 5.30, and consists of the positive-sequence Thévenin equivalent network for Fig. 5.25.

The fault current is therefore

$$\bar{I}'_a = \bar{I}'_d = \frac{\bar{E}}{\bar{Z}_d + \bar{Z}} \quad (5.165)$$

In the case of a bolted fault, this becomes

$$\bar{I}'_a = \bar{I}'_d = \frac{\bar{E}}{\bar{Z}_d} \quad (5.166)$$

**Fig. 5.29a,b** Three-phase balanced fault

**Fig. 5.30** Equivalent circuit at the positive sequence of a three-phase fault

$$\bar{E}'_d - \bar{E}'_i = 2\bar{Z}\bar{I}'_d, \text{ so}$$

$$\begin{cases} \bar{I}'_0 = 0 \\ \bar{I}'_1 = -\bar{I}'_d \\ \bar{E}'_d - \bar{E}'_i = -2\bar{Z}\bar{I}'_d \end{cases} \quad (5.168)$$

**Line-to-Line Fault**

Now consider the circuit presented in Fig. 5.31. In this case,  $\bar{Z}_a = \infty, \bar{Z}_b = \bar{Z}_c = \bar{Z}, \bar{Z}_n = \infty$ .

The system of equations

$$\begin{cases} \bar{I}'_a = 0 \\ \bar{I}'_b + \bar{I}'_c = 0 \\ \bar{E}'_b - \bar{Z}\bar{I}'_c = \bar{E}'_c - \bar{Z}\bar{I}'_b \end{cases} \quad (5.167)$$

are obtained from Fig. 5.31. Upon applying Fortescue's current transformations (5.161), we find that  $\bar{I}'_d = -\bar{I}'_i$  and  $\bar{I}'_0 = 0$ . Then, utilizing the second and third equations of (5.162) and (5.163), respectively, we obtain

**Fig. 5.31** Line-to-line fault

Using (5.168), it is possible to infer the equivalent circuit of the system, which is shown in Fig. 5.32. The zero sequence is not involved in the fault.

Employing the circuit shown in Fig. 5.32, we can derive the expressions

$$\begin{cases} \bar{E}'_0 = 0 \\ \bar{I}'_d = \frac{\bar{E}}{\bar{Z}_d + \bar{Z}_i + 2\bar{Z}} = -\bar{I}'_i \\ \bar{E}'_i = \frac{\bar{E}\bar{Z}_i}{\bar{Z}_d + \bar{Z}_i + 2\bar{Z}} \\ \bar{E}'_d = \frac{\bar{E}(\bar{Z}_i + 2\bar{Z})}{\bar{Z}_d + \bar{Z}_i + 2\bar{Z}} \end{cases} \quad (5.169)$$

Finally, by applying Fortescue's transformations, the line-to-line fault current is obtained as

$$\bar{I}'_b = \frac{-j\sqrt{3}\bar{E}}{\bar{Z}_d + \bar{Z}_i + 2\bar{Z}} \quad (5.170)$$

**Double Line-to-Ground Fault**

The circuit of interest here is that reported in Fig. 5.33, with  $\bar{Z}_a = \infty, \bar{Z}_b = \bar{Z}_c = 0, \bar{Z}_n = \bar{Z}$ .

From Fig. 5.33, we can infer that

$$\begin{cases} \bar{I}'_a = 0 \\ \bar{E}'_b = \bar{E}'_c \\ \bar{E}'_b = \bar{Z}(\bar{I}'_c + \bar{I}'_b) \end{cases} \quad (5.171)$$

If we employ the same procedure we adopted for the line-to-line fault, i.e., we apply Fortescue's transforma-

**Fig. 5.32** Equivalent circuit of the line-to-line fault

Fig. 5.33 Double line-to-ground fault

Fig. 5.35 Line-to-ground fault

tions to (5.171), we obtain the system

$$\begin{cases} \bar{I}'_d + \bar{I}'_i + \bar{I}'_0 = 0 \\ \bar{E}'_i = \bar{E}'_d \\ \bar{E}'_0 = \bar{E}'_d + 3\bar{Z}\bar{I}'_0 \end{cases} \quad (5.172)$$

Figure 5.34 presents the equivalent circuit resulting from (5.172); this equivalent circuit leads to the expressions

$$\begin{cases} \bar{I}'_d = \frac{\bar{E}}{\bar{Z}_d + [(\bar{Z}_0 + 3\bar{Z})\bar{Z}_i] / (\bar{Z}_i + \bar{Z}_0 + 3\bar{Z})} \\ \bar{I}'_i = -\bar{I}'_d \frac{\bar{Z}_0 + 3\bar{Z}}{\bar{Z}_i + \bar{Z}_0 + 3\bar{Z}} \\ \bar{E}'_d = \bar{E} - \bar{Z}_d \bar{I}'_d = \bar{E}'_i \\ \bar{E}'_0 = -\bar{Z}_0 \bar{I}'_0 \end{cases} \quad (5.173)$$

After some mathematical manipulation, we get

$$\bar{I}'_b = -j\sqrt{3}\bar{E} \frac{\bar{Z}_0 - \alpha\bar{Z}_i}{\bar{Z}_d\bar{Z}_i + \bar{Z}_d\bar{Z}_0 + \bar{Z}_i\bar{Z}_0} \quad (5.174)$$

for a bolted fault.

### Line-to-Ground Fault

We now investigate the circuit depicted in Fig. 5.35, with  $\bar{Z}_a = \bar{Z}$ ,  $\bar{Z}_b = \bar{Z}_c = \infty$ ,  $\bar{Z}_n = 0$ .

Figure 5.35 leads to the expressions

$$\begin{cases} \bar{E}'_a = \bar{Z}\bar{I}'_a \\ \bar{I}'_b = 0 \\ \bar{I}'_c = 0 \end{cases} \quad (5.175)$$

Applying Fortescue's transformations to (5.175) yields

$$\begin{cases} \bar{I}'_d = \bar{I}'_i = \bar{I}'_0 \\ \bar{E}'_d + \bar{E}'_i + \bar{E}'_0 = 3\bar{Z}\bar{I}'_0 \end{cases} \quad (5.176)$$

The equivalent circuit resulting from system (5.176) is shown in Fig. 5.36. Note that the impedance  $3\bar{Z}$  is in series with the direct, inverse, and homopolar circuit.

The expressions

$$\begin{cases} \bar{I}'_d = \bar{I}'_i = \bar{I}'_0 = \frac{\bar{E}}{\bar{Z}_d + \bar{Z}_i + \bar{Z}_0 + 3\bar{Z}} \\ \bar{E}'_d = \bar{E} - \bar{Z}_d \bar{I}'_d \\ \bar{E}'_i = -\bar{Z}_i \bar{I}'_i \\ \bar{E}'_0 = -\bar{Z}_0 \bar{I}'_0 \end{cases} \quad (5.177)$$

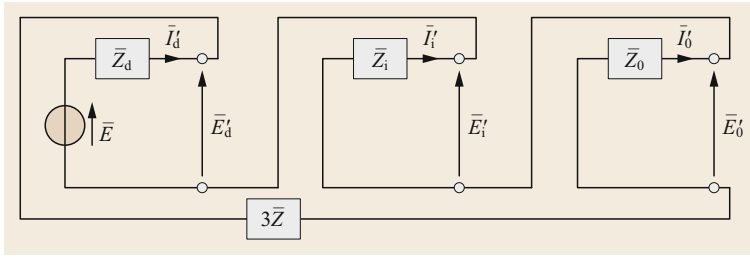

Fig. 5.34 Equivalent circuit of the double line-to-ground fault

**Fig. 5.36** Equivalent circuit of the line-to-ground fault

are readily obtained from the circuit shown in Fig. 5.36. Finally, the fault current for the line-to-ground fault is

$$\bar{I}'_a = \frac{3\bar{E}}{\bar{Z}_d + \bar{Z}_i + \bar{Z}_o + 3\bar{Z}} \quad (5.178)$$

### 5.5.4 Direct, Inverse, and Homopolar Sequence Impedances

This section provides the main guidelines for determining the direct, inverse, and homopolar sequence impedances of the main power system elements. The following simplifying assumptions are made:

- Transversal parameters are negligible
- The equations are written using the per unit (pu) method.

The pu values of the component parameters (e.g., the reactance  $\dot{x}$  of a generator or transformer, etc.), which are provided by the manufacturer based on the rated voltage  $V_b$  and the rated apparent power of the equipment  $S_b$ , need to be converted to suitable base values of power, voltage  $V'_b$ , and apparent power  $S'_b$  for the various parts of the system according to

$$\dot{x}' = \dot{x} \left( \frac{V_b}{V'_b} \right)^2 \frac{S'_b}{S_b} \quad (5.179)$$

For *generators*, the equivalent circuits for direct, inverse, and homopolar sequences are shown in Fig. 5.37. Note that:

- To a good approximation,  $z_d$  can be represented by  $x''_d$ , the direct-axis subtransient reactance (which is

**Fig. 5.37** Equivalent circuit of a generator: direct, inverse, and homopolar sequences

provided by the manufacturer and is typically in the range 0.1–0.3 pu).

- The inverse sequence  $z_i \approx x''_d$  does not produce an effective armature reaction.
- $z_0$  is given by the manufacturer. Any impedance that is connected between the neutral point and the earth is multiplied by 3 and inserted into the equivalent circuit in series with  $Z_0$ .

For *power transformers*, the inverse sequence is equal to the direct sequence and—as shown in Fig. 5.38—can be assumed to be equal to the short-circuit impedance in pu, i.e.,

$$z_{cc} = 0.01 v_{cc}\% \quad (5.180)$$

In the case of a three-winding transformer, the impedance of a particular winding can be calculated on the basis of the short-circuit test measurements

$$z_1 + z_2 = v_{cc,p-s}\% \times 0.01 \quad (5.181)$$

$$z_1 + z_3 = v_{cc,p-t}\% \times 0.01 \quad (5.182)$$

$$z_2 + z_3 = v_{cc,s-t}\% \times 0.01 \quad (5.183)$$

$$z_1 = 0.5(v_{cc,p-s}\% + v_{cc,p-t}\% - v_{cc,s-t}\%) \times 0.01 \quad (5.184)$$

$$z_2 = 0.5(v_{cc,p-s}\% + v_{cc,s-t}\% - v_{cc,p-t}\%) \times 0.01 \quad (5.185)$$

$$z_3 = 0.5(v_{cc,s-t}\% + v_{cc,p-t}\% - v_{cc,p-s}\%) \times 0.01 \quad (5.186)$$

where  $v_{cc,p-s}\%$ ,  $v_{cc,s-t}\%$ , and  $v_{cc,p-t}\%$  are the short-circuit impedances measured in three cases: when winding 1 is supplied, 2 is short-circuited, and 3 is open; when winding 2 is supplied, 3 is short-circuited, and 1 is open; and

**Fig. 5.38a,b** Equivalent circuit of a transformer at the direct (a) and inverse sequences (b)

**Fig. 5.39** Equivalent circuit of a three-winding transformer at the direct (a) and inverse sequences (b)

when 2 is supplied, 3 is short-circuited, and 1 is open, respectively. The equivalent circuit of a three-winding transformer at the direct and inverse sequences is represented in Fig. 5.39b.

Finally, Figs. 5.40 and 5.41 show the homopolar sequence impedances of the transformer and the three-winding transformer for different groups and connections of windings.

Any impedance connected between the neutral point and the earth is multiplied by 3 and introduced into the equivalent circuit in series to  $Z_0$  (or, for the three-winding transformer, in series to  $Z_p$  or  $Z_s$ ).

The equivalent circuits of a *transmission line* can be approximated as shown in Fig. 5.42. The positive and negative-sequence impedances  $Z_d$  and  $Z_i$  are equal. The

zero-sequence impedance  $Z_0$  is typically 3 to 4 times larger than  $Z_d$ .

For three-phase and single-phase faults in a *generic network with given short-circuit power* (Fig. 5.43), the equivalent impedances are given by

$$z_d = \frac{E_{nom}}{I_{cc,3}} \tag{5.187}$$

$$z_d = z_i \tag{5.188}$$

$$z_0 = 3 \frac{E_{nom}}{I_{cc,1}} - 2z_d, \tag{5.189}$$

where  $I_{cc,3}$  and  $I_{cc,1}$  are the values for balanced and line-to-ground faults, respectively.

The short-circuit power for a three-phase fault is calculated via

$$P_{cc,3f} = E_{nom} I_{cc,3f}, \tag{5.190}$$

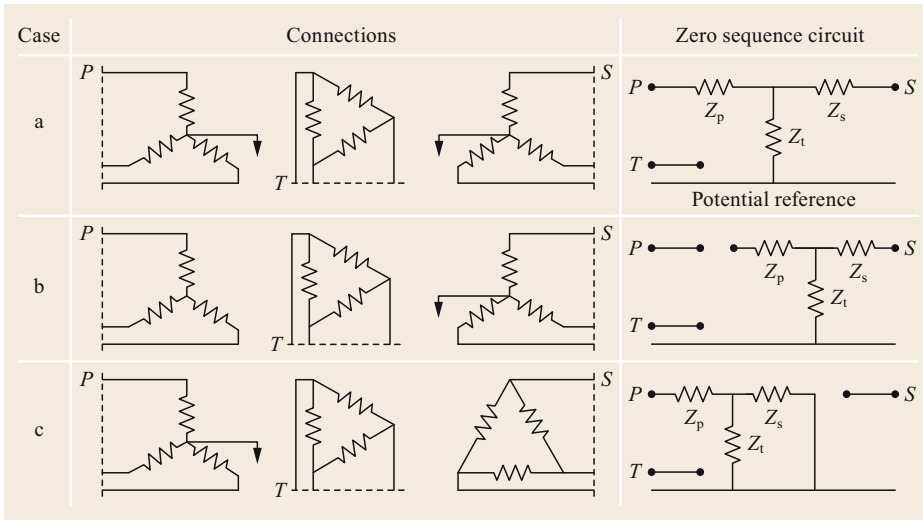

while the short-circuit power for a single-phase fault is obtained using

$$P_{cc,1f} = E_{nom} I_{cc,1f}. \tag{5.191}$$

An *infinite power bus* can be assumed to be equivalent to the bus of a network with infinite short-circuit cur-

rent (for single-phase and three-phase faults). Also, we can assume that a bus without generators is equivalent to the bus of a network with null short-circuit current (for single-phase and three-phase faults). Loads, unless otherwise indicated, are neglected in the calculations.

### 5.5.5 Fault at Any Point in the Network

Consider the network depicted in Fig. 5.44. A symmetrical fault occurs at bus 3. We shall refer to the equivalent single-phase network, neglecting the presence of loads (no current is absorbed).

According to Thévenin’s theorem, the linear part of the network can be replaced with an ideal indepen-

**Fig. 5.44** The network considered; there is a fault at bus 3 (adapted from [5.12])

dent generator with an emf  $E$  (*no-load* emf) and an impedance  $Z_{th}$  (the equivalent impedance with all emfs short-circuited) in series, as shown in Fig. 5.45.

In the presence of loads, the voltage prior to the fault is given by the steady-state solution. Otherwise, it is approximated by the maximum permissible operating voltage of the transmission network, 1.1 pu.

By neglecting the loads and the transversal parameters of the network components,  $Z_{th}$  can be obtained by calculating the equivalent series and parallel impedances and by star-delta transformations ( $Z_{33}$  in Fig. 5.45, which is equal to  $j0.34$ , was obtained in this way).

The equivalent impedance  $Z_{th}$  can also be determined by inverting the nodal admittance matrix of the network to obtain the impedance matrix;  $Z_{th}$  is the element of the main diagonal of the impedance matrix that corresponds to the fault node.

**Fig. 5.45** The network following the application of Thévenin's theorem; there is a fault at bus 3 (adapted from [5.12])

**Fig. 5.46** Power system consisting of  $n$  buses; there is a fault at bus  $k$  (adapted from [5.12])

Let us consider the bus of a power system consisting of  $n$  buses, as shown in Fig. 5.46.

We now assume a symmetrical fault at bus  $k$  such that the fault impedance is  $Z_f$ .

The nodal voltages before the fault can be obtained by calculating the load flow, and are represented by the vector

$$\mathbf{E}(0) = \begin{bmatrix} E_1(0) \\ \vdots \\ E_k(0) \\ \vdots \\ E_n(0) \end{bmatrix}. \quad (5.192)$$

The voltage variations caused by the fault with impedance  $Z_f$  are equivalent to those caused by the voltage  $E_k(0)$  when all the other generators are short-circuited.

The Thévenin equivalent circuit, as shown in Fig. 5.47, can be obtained by short-circuiting all of the generators and representing all of the loads and network components by their respective impedances.

Although we have ignored loads so far (since the steady-state currents are much lower than the short-circuit ones), the loads at the various buses can be accounted for by introducing a constant impedance. The

**Fig. 5.47** Thévenin equivalent network of a power system consisting of  $n$  buses; there is a fault at bus  $k$  (adapted from [5.12])

value of this impedance can be obtained by

$$Z_{iL} = \frac{|E_i(0)|^2}{S_L}, \quad (5.193)$$

$S_L$  being the power absorbed by the load before the fault. Let us denote the fault-induced nodal voltage variations by the vector

$$\Delta \mathbf{E} = \begin{bmatrix} \Delta E_1 \\ \vdots \\ \Delta E_k \\ \vdots \\ \Delta E_n \end{bmatrix}. \quad (5.194)$$

The nodal voltages during the fault are therefore given by the sum of the voltages before the fault and the variations due to the fault current, i.e.,

$$\begin{bmatrix} E_1(F) \\ \vdots \\ E_k(F) \\ \vdots \\ E_n(F) \end{bmatrix} = \begin{bmatrix} E_1(0) \\ \vdots \\ E_k(0) \\ \vdots \\ E_n(0) \end{bmatrix} + \begin{bmatrix} \Delta E_1 \\ \vdots \\ \Delta E_k \\ \vdots \\ \Delta E_n \end{bmatrix}. \quad (5.195)$$

In compact form,

$$\mathbf{E}(F) = \mathbf{E}(0) + \Delta \mathbf{E}. \quad (5.196)$$

The voltages at the nodes are related to the current by the expression

$$\mathbf{I} = \mathbf{Y} \cdot \mathbf{E}. \quad (5.197)$$

In the Thévenin circuit shown in Fig. 5.47, the incoming current at each node is zero except at node  $k$ , where it is

considered positive if injected (so we consider it to be negative).

Therefore, we get

$$\begin{bmatrix} 0 \\ \vdots \\ -I_k(F) \\ \vdots \\ 0 \end{bmatrix} = \begin{bmatrix} Y_{11} & \dots & Y_{1k} & \dots & Y_{1n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ Y_{k1} & \dots & Y_{kk} & \dots & Y_{kn} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ Y_{n1} & \dots & Y_{nk} & \dots & Y_{nn} \end{bmatrix} \begin{bmatrix} \Delta E_1 \\ \vdots \\ \Delta E_k \\ \vdots \\ \Delta E_n \end{bmatrix}, \quad (5.198)$$

which can be rewritten in compact form as

$$\mathbf{I}(F) = \mathbf{Y} \cdot \Delta \mathbf{E}, \quad (5.199)$$

leading to

$$\Delta \mathbf{E} = \mathbf{Z} \cdot \mathbf{I}(F), \quad (5.200)$$

where

$$\mathbf{Z} = \mathbf{Y}^{-1}, \quad (5.201)$$

which is known as the impedance matrix.

Therefore, from (5.196),

$$\mathbf{E}(F) = \mathbf{E}(0) + \mathbf{Z} \cdot \mathbf{I}(F). \quad (5.202)$$

In matrix form,

$$\begin{bmatrix} E_1(F) \\ \vdots \\ E_k(F) \\ \vdots \\ E_n(F) \end{bmatrix} = \begin{bmatrix} E_1(0) \\ \vdots \\ E_k(0) \\ \vdots \\ E(0)_n \end{bmatrix} + \begin{bmatrix} Z_{11} & \dots & Z_{1k} & \dots & Z_{1n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ Z_{k1} & \dots & Z_{kk} & \dots & Z_{kn} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ Z_{n1} & \dots & Z_{nk} & \dots & Z_{nn} \end{bmatrix} \begin{bmatrix} 0 \\ \vdots \\ -I_k(F) \\ \vdots \\ 0 \end{bmatrix}. \quad (5.203)$$

This leads to

$$E_k(F) = E_k(0) - Z_{kk} I_k(F). \quad (5.204)$$

We also know from Fig. 5.47 that

$$E_k(F) = Z_f I_k(F), \quad (5.205)$$

and that  $E_k(F) = 0$  for a solid balanced fault (i.e.,  $Z_f = 0$ ). Therefore,

$$I_k(F) = \frac{E_k(0)}{Z_{kk} + Z_f}. \quad (5.206)$$

Hence, for a fault at bus  $k$ , we only need the element  $Z_{kk}$ , which is the Thévenin equivalent impedance of the network viewed from the fault location.

We also have that

$$E_k(F) = Z_f I_k(F). \quad (5.207)$$

Substituting the previous expression for  $I_k$  into this equation yields

$$E_i(F) = E_i(0) - \frac{Z_{ik}}{Z_{kk} + Z_f} E_k(0). \quad (5.208)$$

The knowledge of the nodal voltages during the fault allows the fault current to be calculated for all of the lines. The short-circuit current in the line that connects buses  $i$  and  $j$  (where the current is defined to be positive in the  $i \rightarrow j$  direction) through impedance  $z_{ij}$  is given by

$$I_{ij}(F) = \frac{E_i(F) - E_j(F)}{z_{ij}}. \quad (5.209)$$

Note that the knowledge of the impedance matrix allows the fault current and the node voltage during the fault to be readily evaluated for every node of the network.

This method is simple and practical: all the calculations relevant to a specific fault are formulated with respect to the fault bus using the impedance matrix  $\mathbf{Z}$  which can be calculated by inverting  $\mathbf{Y}$ , although this inversion is computationally prohibitive for large power systems with many nodes. A more efficient method of determining  $\mathbf{Z}$  is to construct it by adding one element of the network at a time.

### 5.5.6 Three-Phase Short Circuit at a Synchronous Generator's Terminals

A synchronous machine operating as a generator can be studied by considering it as an active two-port network. It is also linear when the working conditions are far from saturation, as is usual during faults. The following considerations are made for a round rotor machine, but they can easily be extended to the case of a salient pole machine.

The equivalent two-port equation of the alternator is

$$\bar{E} - \bar{Z}_s \bar{I} = \bar{V}, \quad (5.210)$$

where:

- $\bar{E}$  is the emf generated in the alternator by the excitation current  $I_f$  (the voltage measured at the machine's terminal under no-load conditions)
- $\bar{V}$  is the voltage measured at the machine's terminal when the machine supplies current  $\bar{I}$
- $\bar{Z}_s$  is the internal impedance of the machine, commonly termed the synchronous impedance, which is the sum of two components: (i) the impedance of the stator's windings and (ii) the armature's reaction.

For a given value of the excitation current and a given current  $\bar{I}$  flowing in the stator's windings, the voltage  $\bar{V}$  at the machine's terminals is different from the no-load emf  $\bar{E}$ . The difference

$$\bar{Z}_s \bar{I} = \bar{E} - \bar{V} \quad (5.211)$$

is the voltage drop due to the current  $\bar{I}$  and its shift with respect to  $\bar{V}$ . This voltage drop is given by the two components mentioned above:

- The drop in the impedance of the stator's windings  $(R_1 + jX_1)\bar{I}$ , where  $R_1$  and  $X_1$  are the resistance of the stator's windings and the leakage reactance, respectively
- The armature's reaction, which is equal to  $jX_r\bar{I}$  for a round rotor machine.

Therefore, it holds that

$$\bar{Z}_s = R_1 + j(X_1 + X_r) \quad (5.212)$$

The quantity

$$X_s = X_1 + X_r \quad (5.213)$$

is the synchronous reactance of the machine.

Let us assume that a synchronous generator is supplying an inductive load. In this case, we assume that  $I$  lags  $E$  and  $V$  by  $90^\circ$  (ignoring the circuit resistance): the flux produced by the stator (the armature flux) has the opposite polarity to the main flux  $\Phi$ , thus reducing the main flux. Consequently, the total emf induced in the stator decreases. This phenomenon is called the demagnetizing effect and it is represented in Figs. 5.48 and 5.49.

Let us assume that the synchronous generator is supplying a capacitive load. In this case, we assume that  $I$  leads  $E$  and  $V$  by  $90^\circ$  (the excitation current is kept the same as in the previous case): the flux produced by the stator (armature flux) is in phase with the main flux  $\Phi$ , thus increasing the main flux. Consequently, the total emf induced in the stator increases. This phenomenon is known as the magnetizing effect and it is represented in Figs. 5.50 and 5.51.

In order to simulate the alternator under transient conditions, we make use of the EMTP-RV model pre-

**Fig. 5.48** Armature reaction: the current  $I$  lags the voltage by  $90^\circ$ . Waveform (a) shows the main flux  $\Phi$ , while waveform (b) shows the armature flux (adapted from [5.1])

**Fig. 5.49** Phasor diagram of the alternator for an inductive load

**Fig. 5.50a,b** Armature reaction: current  $I$  leads the voltage by  $90^\circ$ . Waveform (a) shows the main flux  $\Phi$ , while waveform (b) shows the armature flux (adapted from [5.1])

sented in [5.8, 45]. Park's transformation is initially used with saturation neglected to obtain linear relations and apply superposition.

The magnetic circuits of the rotor windings are assumed to be symmetric with respect to the direct axis, which is the axis of the field created by the rotor. The quadrature axis lags the direct one by  $90^\circ$ .

A current in any winding produces a sinusoidal magnetic field in the air gap. This field can be decomposed along the direct and quadrature axes. The effects of harmonics in the field distribution are negligible for a correctly dimensioned machine. The effects of hysteresis are neglected. Eddy currents are negli-

**Fig. 5.51** Phasor diagram of the alternator for a capacitive load

**Fig. 5.52** Schematic representation of the machine showing the d-axis and q-axis (adapted from EMTP-RV help)

ble, except in the case of a solid rotor (cylindrical rotor) machine, where they can be represented by a q-axis winding.

The synchronous machine model consists of nine windings:

- Three for the stator (one for each phase); these are denoted by the indices a, b, and c, respectively.
- Six for the rotor. Along the axis of the rotor field (the direct axis), we have the excitation winding  $f$  and a maximum of two damper windings:  $d_1$  and  $d_2$ . There are also a maximum of three damper windings, denoted  $q_1$ ,  $q_2$ , and  $q_3$ , along the quadrature axis.

This machine is represented in Fig. 5.52.

### Short-Circuit Currents with the Generator Initially at No Load

Let us consider a three-phase synchronous generator with the following parameters:

- Rated power: 1000 MVA
- Nominal frequency: 50 Hz
- Rated voltage (RMSLL (RMS line-to-line)): 20 kV
- Winding (armature) resistance: 0.002 pu
- Armature leakage reactance: 0.188 pu
- Direct-axis synchronous reactance:  $x_d = 2$  pu
- Quadrature-axis synchronous reactance:  $x_q = 2$  pu
- Direct-axis transient reactance:  $x'_d = 0.4$  pu
- Quadrature-axis transient reactance:  $x'_q = 0.4$  pu
- Direct-axis short-circuit transient constant:  $T'_d = 1$  s
- Quadrature-axis short-circuit transient constant:  $T'_q = 1$  s.

It is initially assumed that the d-axis and q-axis sub-transient reactances are negligible. As a consequence, if we refer to the equivalent model in Fig. 5.52, only the field winding is relevant along the d-axis, while only one damper is considered along the q-axis (winding  $q_1$ ).

Let us assume that no-load steady-state conditions apply. A three-phase short circuit occurs at the machine's terminals at  $t = 200$  ms. At  $t_{\text{fault}} = 200$  ms, a three-phase bolted short circuit occurs at the machine's terminals. Figure 5.53 shows the currents in the three stator windings during the fault. The subtransient reactance is neglected. If the winding resistances are neglected, the stator current lags the voltage by  $90^\circ$ , as the machine's reactances are equivalent to a purely inductive load. Therefore, at the instant that the short circuit occurs, the current in phase a is at its natural zero crossing, so this current has no unidirectional component—only the symmetrical component. Initially, the current reaches a peak value of approximately 100 kA, before decreasing exponentially to reach its steady-state value. The current in phase b reaches its maximum and the current in phase c reaches its minimum at the instant that the short circuit occurs, meaning that those currents have unidirectional components, as shown in Fig. 5.53.

The envelope for the current in phase a is shown in Fig. 5.54, and is given by

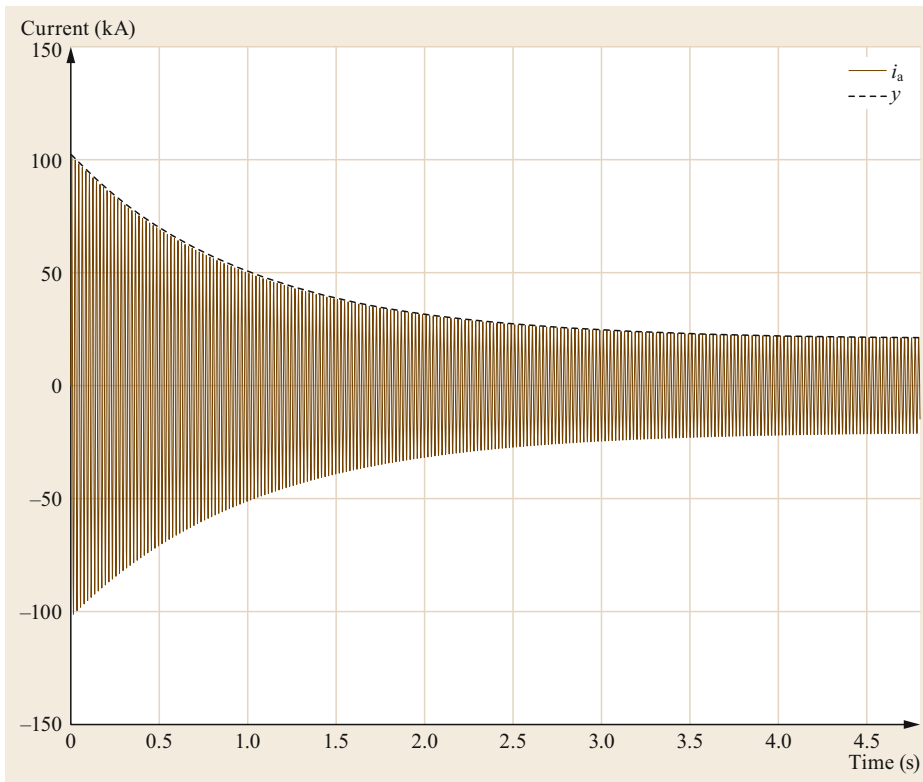

$$y(t) = \sqrt{2} \left[ \left( \frac{1}{x'_d} - \frac{1}{x_d} \right) e^{-\frac{t}{T'_d}} + \frac{1}{x_d} \right] I_{\text{base}}, \quad (5.214)$$

where

$$I_{\text{base}} = \frac{A_n}{\sqrt{3}V_n} = 28.9 \text{ kA}. \quad (5.215)$$

**Fig. 5.53** Phase currents: three-phase fault at 200 ms (subtransient state neglected)

**Fig. 5.54** The current and the current envelope in phase a (subtransient state neglected); 200 ms time shift

**Fig. 5.55a,b** Flux linkages along (a) the d-axis and (b) the q-axis (subtransient state neglected)

The envelope of the symmetrical component of the short circuit current  $y(t)$ , in pu, is initially equal to

$$y(t = t_{\text{fault}}) = \frac{1}{x'_d} \quad (5.216)$$

In the first few moments, the armature reaction is weakened by the rapid variation of the total flux linkage. At the beginning of the electromagnetic transient, therefore, the armature reactance is not equal to the synchronous reactance of the machine but to the transient one (ignoring the subtransient state).

The steady-state value of the symmetrical component (in pu) is given by

$$y(t \rightarrow \infty) = \frac{1}{x_d} \quad (5.217)$$

Upon substituting the values of the reactances into (5.214), it becomes apparent that the peak value of  $y(t)$  for the configuration of interest is initially equal to 102 kA, and it reaches 20.4 kA in the steady state.

The flux linkages along the d-axis and the q-axis are shown in Fig. 5.55. Prior to short-circuit inception, the flux along the d-axis is at a constant value dictated by

the excitation winding current. During the transient, it decreases exponentially until it attains a low constant value in the steady state. This is due to the demagnetizing effect of the short-circuit current, in agreement with the phasor diagram of Fig. 5.49. Since the machine operates under no-load conditions before the fault, the total flux is equal to the d-axis flux, while the flux linkage along the q-axis is null. The sudden variation in the armature current leads to rapid variation of the q-axis flux, which quickly reaches its peak value before decreasing exponentially to zero again.

It is worth noting that, besides the exponential decay, the flux along each axis shows an oscillatory component. This component oscillates at a frequency of 50 Hz with respect to the d-q frame because it is induced by the unidirectional components of the currents in phases b and c. These components generate a magnetic field that is stationary with respect to the stator but appears to be a magnetic field rotating at 50 Hz in the d-q frame. This is confirmed by the detail shown in Fig. 5.56. The amplitude of the oscillatory component along the q-axis decays with the same time constant as the unidirectional component of the stator winding current. Similar considerations apply for the current flowing in the q-axis damper winding  $i_{q1}$ , as shown in

**Fig. 5.56a,b** Flux linkages along (a) the d-axis and (b) the q-axis shown in detail (the subtransient state is neglected)

**Fig. 5.57a,b** Currents in the field winding (a) and the first q-axis damper winding (b)

**Fig. 5.58** Phase currents with the subtransient state considered

Fig. 5.57. According to the Faraday–Neumann–Lenz law, the magnetic field generated by the current flowing in the damper windings during the transient opposes the initial changing magnetic field. The current  $i_f$  that flows in the rotor field winding is also reported in Fig. 5.57. Before the fault,  $i_f$  is set to 2494 A. The sudden variation in the current in the stator windings induces an emf in the rotor field winding, which causes an increase of the currents in both the field and damper windings, as shown in Fig. 5.57. Just as for the damper windings, the magnetic field created by the current induced in the field winding opposes the initial changing magnetic field. Similar to the flux linkage and  $i_{q1}$ , the oscillatory component of  $i_f$  is generated by the unidirectional component of the stator winding current. In the steady state, as the flux linkage is constant with respect to the rotor frame of reference, the value of the rotor current  $i_f$  returns to its previous value, 2494 A.

Let us now consider the effects of the damper windings on the direct axis and a second damper on the q-axis. The d-axis and q-axis subtransient reactances are  $x_d'' = x_q'' = 0.3$  pu, and the short-circuit subtransient constant is  $T_d'' = 0.03$  s.

Figure 5.58 shows the currents in the three stator windings during the fault. The current waveforms in the three stator windings are similar to those in the previous case in which the subtransient state was neglected, but the initial current peaks are larger.

The envelope of the current in phase a is shown in Fig. 5.59 and is given by the expression

$$y_s(t) = \sqrt{2} \left[ \left( \frac{1}{x_d''} - \frac{1}{x_d'} \right) e^{-\frac{t}{T_d''}} + \left( \frac{1}{x_d'} - \frac{1}{x_d} \right) e^{-\frac{t}{T_d}} + \frac{1}{x_d} \right] I_{\text{base}} \quad (5.218)$$

The armature reaction during the subtransient state is lower than those in the transient and steady states. As a consequence, the initial value of the current is higher than that given by (5.214).

#### Short-Circuit Currents in the Loaded Generator

In this final comparison, we consider the case in which the generator is supplying a load before the fault occurs. Figure 5.60 shows the current in phase a when the machine is under no-load and on-load conditions. In the latter case, the current is not null before the fault. The peak value is similar to that calculated for the machine under no-load conditions, but the final steady-state current amplitude is slightly larger.

It is interesting to observe the variation in the flux linkage—particularly that along the q-axis (see Fig. 5.61)—during the transient. Unlike the case shown in Fig. 5.55, the flux is not null before fault inception, but the steady-state value after the fault is zero due to the demagnetizing effect of the short-circuit current.

**Fig. 5.59** The current and the current envelope in phase a with the subtransient state considered; 200 ms time shift

**Fig. 5.61a,b** Flux linkages along (a) the d-axis and (b) the q-axis under on-load conditions

## 5.6 Stability

A wide variety of dynamic phenomena occur in electric power systems. These phenomena are often called transients. Transients have various physical origins and timescales. Ignoring small variations in the operating conditions (which are always present), a transient corresponds to a significant perturbation of the steady state of a system. During the transient, several other perturbations may occur due to control and protective actions.

### 5.6.1 Transient Phenomena

Listed in order of the fastest to the slowest, transients in power systems are usually categorized into:

- Propagating electromagnetic transients that affect lines, transformers, and other connected components. These transients are caused by lightning or switching maneuvers, and have typical time horizons of between  $10^{-7}$  and  $10^{-3}$  s (corresponding to frequencies ranging from 10 MHz to kHz).
- Electromagnetic transients in rotating machine windings that are caused by disturbances, switch-

ing maneuvers, or interactions between machines (time horizon:  $10^{-3}$ – $10^{-1}$  s; frequency: a few kHz to 10 Hz).

- Electromechanical transients, namely rotor swings in synchronous machines and motors. These originate in the same way as for the two types of transients defined above, as well as from voltage and frequency control (0.1–10 s; 10–0.1 Hz).
- Non-electrodynamic transients, including mechanical phenomena, thermodynamic phenomena, and their interactions with the control systems of power plants ( $10$ – $10^4$  s, 0.1 Hz–0.1 mHz).

Obviously, real events can be very complex and often involve dynamics associated with all four groups listed above. For example, when lightning strikes a power line, it produces traveling surges that propagate along the line. The overvoltage may cause a fault, which may cause transients in the synchronous machines, leading to interventions by relays. Also, protective operations can cause frequency transients that may require interventions from power-plant governors and control systems.

### 5.6.2 Definition of Stability

For given operating conditions, the power system stability is the ability of the system to regain the state of operating equilibrium after being subjected to a disturbance, with most system variables bounded such that practically the entire system remains intact. As a power system is a nonlinear system, its behavior after any disturbance depends on the type and magnitude of the disturbance, its consequences, and the initial operating point. Even though the system does not reach the same steady-state operating equilibrium as that prior to the disturbance, the system is considered stable if the final operating equilibrium after the perturbation is an acceptable steady state, meaning that further intervention through protective or control actions can be avoided.

To introduce this analysis, it is useful to first provide a brief overview of the different operating states of power systems as well as a classification of power-system stability studies.

### 5.6.3 States of Operation

There are typically considered to be five possible states of operation, as shown in Fig. 5.62.

This classification refers to three sets of equations that describe the dynamic phenomena: one differential and two algebraic (generally nonlinear) equations corresponding to equality constraints, which represent the balance between the generation and the load demand; and inequality constraints, which represent the operating limits.

The normal secure state is a system operating condition that is able to satisfy both the equality and inequality constraints with adequate reserve margins for both transmission and generation taking into account the reasonable stresses to which the system may be sub-

jected. For example, the N-1 security criterion implies that a system in its normal state can withstand a single contingency (i.e., the loss of a line, a transformer, or a generator) and that the new steady state still satisfies all the equality and inequality constraints.

The alert state characterizes a system operating condition that satisfies both the equality and inequality constraints but the security level is considered to be insufficient. This implies that the system is vulnerable; in other words, some of the inequality constraints will be violated in the event of some reasonable contingencies. To bring the system to a normal state, some preventive control actions should be taken.

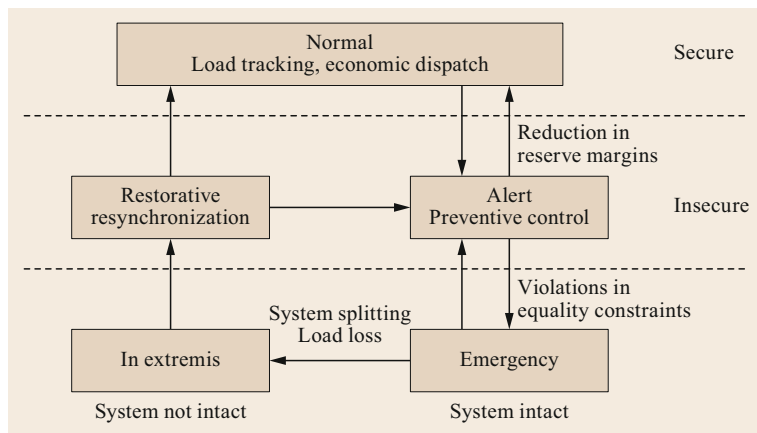

The emergency state characterizes a system operating condition in which at least one of the inequality constraints is violated but the system is still intact (i.e., all the equality constraints are met). Emergency corrective actions should be initiated to restore the system to the alert state. If these measures are not taken in time or are ineffective, the system will break down and reach the in extremis state in which both equality and inequality constraints are violated. The in extremis state corresponds to a system failure characterized by a loss of system integrity involving uncontrolled islanding and the uncontrolled loss of large blocks of loads.

The restorative state describes a system that is separated into areas that may or may not be energized, and in which restorative actions are carried out to bring the system to either an alert or a normal state.

### 5.6.4 Classification of Power System Stability

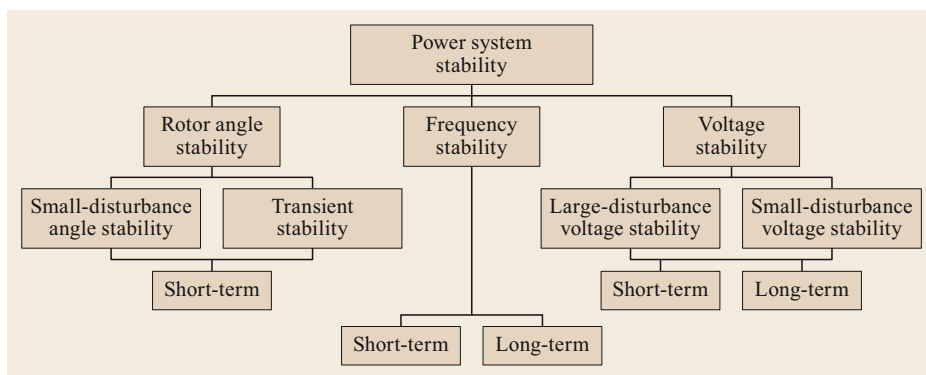

The traditional classification of power system stability is summarized in Fig. 5.63.

A common cause of instability phenomena is an excessive imbalance of active and reactive power in the system, either locally or globally.

**Fig. 5.62** Classification of power system states (adapted from [5.46, 47])

**Fig. 5.63**  
Classification of power system stability (adapted from [5.48])

### Rotor Angle Stability

Rotor angle stability refers to the balance of the torques in the rotors of the synchronous generators. This balance is achieved when the mechanical power provided by the prime mover (e.g., the hydro and steam turbines) meets the load fed by the alternator. If there is an imbalance, the rotors of the generators will act as an energy buffer and the kinetic energy stored in them will decrease or increase. Rotor angle stability refers to the ability of a synchronous machine in the power system to maintain synchronism after a disturbance and regain a steady-state condition characterized by a constant speed without long-lasting oscillations. If the disturbance is local and substantial, such as a fault in a line close to a generator, the generator can fall out of step, as it is accelerated during the fault. A protection will promptly trip the generator in order to avoid machine damage. This kind of dynamic phenomenon is called transient instability, and typically develops within a couple of seconds. On the other hand, small-disturbance (or small-signal) stability instead refers to the ability of the power system to maintain synchronism and regain a steady-state condition after disturbances so small that linearization of the system equations is acceptable for the analysis. Transient instability is associated with insufficient synchronizing torque, whilst small-disturbance problems are associated with insufficient damping of oscillations.

### Frequency Stability

Frequency stability issues are associated with global power imbalances due to the difference between the total power fed into the system by the prime movers and the power consumed by the loads, including losses. The imbalance is compensated for by the kinetic energy stored in the rotors of the machines, resulting in a frequency deviation. If the imbalance is limited, the frequency is controlled by the governors of the prime movers. If the imbalance is too large, the amplitude of the frequency deviation can prompt interventions from

protections that disconnect loads and generators. The time horizon of frequency stability issues ranges from a few seconds (short-term instability) up to several minutes (long-term instability).

### Voltage Stability

Voltage stability refers to the ability of a power system to maintain steady voltages at all buses after a small or large disturbance. Voltage problems are often local and caused by the dynamic responses of loads to disturbance. They are called voltage instabilities, voltage collapses, and load instabilities. Depending on the timescale, voltage stability issues are classified as either short-term (a couple of seconds) or long-term (tens of seconds to minutes). Short-term phenomena are associated with the dynamic responses of fast-acting components (such as induction motors, electronically controlled loads, and HVDC converters) to perturbations. Long-term phenomena are due to the actions of slow-acting equipment, such as step-changing transformers, thermostatically controlled loads, and generator current limiters. As explained above, generators (i.e., synchronous machines) are strongly linked to angular instabilities, and it is sometimes said that they are the driving force for this instability.

### 5.6.5 $P$ - $\delta$ Curves of Synchronous Machines

Before discussing how to study rotor angle stability, we first recall some concepts relating to the operation of a synchronous machine under steady-state and transient conditions.

#### Selection of the Machine Model

Let us ignore the presence of automatic voltage regulators (AVRs). When the stator current varies for any reason (e.g., a sudden load variation or short circuit), the excitation and damper circuits tend to oppose the consequent variation in the flux. Specifically, some currents start to circulate in these circuits, producing a flux

**Table 5.4** Typical parameter values for large generators (adapted from [5.11])

Parameter	Round rotor			Salient pole rotor	
	200 MVA	600 MVA	1500 MVA	150 MVA	230 MVA
$X_d$	1.65	2.00	2.20	0.91	0.93
$X_q$	1.59	1.85	2.10	0.66	0.69
$X'_d$	0.23	0.39	0.44	0.3	0.3
$X'_q$	0.38	0.52	0.64	–	–
$X''_d$	0.17	0.28	0.28	0.24	0.25
$X''_q$	0.17	0.32	0.32	0.27	0.27
$T'_d$	0.83	0.85	1.21	1.10	3.30
$T'_q$	0.42	0.58	0.47	–	–
$T''_d$	0.023	0.028	0.030	0.05	0.02
$T''_q$	0.023	0.058	0.049	0.06	0.02

that instantaneously opposes the mentioned flux variation. It is possible to distinguish two different states: the subtransient state, which persists until all of the currents in the damper windings have been extinguished, and the subsequent transient state, which ends when the current in the excitation circuit eventually vanishes. The durations of these subtransient and transient states are related to the time constants of the damper and excitation windings, respectively. Accordingly, it is possible to identify the subtransient and transient reactances as they are the reactances of the machine during these two different states. Although the detailed illustration of the synchronous machine model provided by Park is beyond the scope of this chapter, it is worth mentioning that each of these two reactances—subtransient and transient—can be split into two components along the d-axis and the q-axis.

A comparison of typical values of the time constants of alternators (Table 5.4) with the period of the oscillations (0.5–1 s) suggests that the transient model of a synchronous machine should be assumed (the flux is kept constant by the currents induced in the rotor circuits—mainly in the excitation winding—since the currents induced in the damping circuits cease in the subtransient state).

At this point, we feel that it would be helpful to remind the reader of several important points.

In the steady state:

- In a salient pole generator, the large air gap along the q-axis causes the q-axis reactance  $X_q$  to be lower than the d-axis reactance  $X_d$ ; i.e.,  $X_q < X_d$
- In a round-rotor generator,  $X_q \approx X_d$ .

During a transient state:

- In a salient pole generator, once the subtransient state has ended, there are no induced currents along the q-axis. Thus, the flux adopts its rated value, so the transient q-axis reactance  $X'_q = X_q$ . Also,  $X'_q =$

$X_q$  is larger than the transient d-axis reactance  $X'_d$ ; i.e.,  $X_q > X'_d$ .

- In a round-rotor generator (where currents can be induced in the rotor's iron as well as in the damping circuits during transients), once the subtransient state has ended, the currents induced in the excitation circuit along the d-axis have an appreciable effect, meaning that  $X'_q > X'_d$ .

#### Salient Pole Synchronous Machines: Vector Diagram and $P$ - $\delta$ Curves in Steady-State and Transient Conditions

The vector diagrams of a salient pole synchronous machine in steady-state and transient conditions are presented in Table 5.5, which also lists the relevant equations for convenience. These equations can be used to infer the expressions for the  $P$ - $\delta$  curves. It follows from the vector diagrams and the equations reported in Table 5.5 that the expression for the active power as a function of the rotor electrical angle for a three-phase machine in the steady state is

$$P = 3VI \cos \varphi = 3 \frac{EV}{X_d} \sin \delta + \frac{3}{2} \frac{X_d - X_q}{X_d X_q} V^2 \sin 2\delta, \quad (5.219)$$

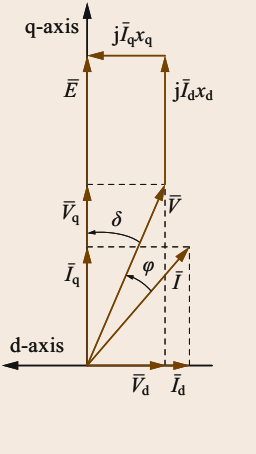

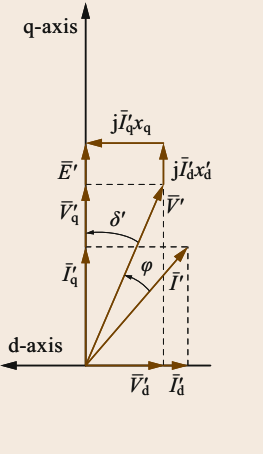

while the expression for a salient rotor machine in a transient state is

$$P' = 3V'I' \cos \varphi' = 3 \frac{E'V'}{X'_d} \sin \delta' + \frac{3}{2} \frac{X'_d - X_q}{X'_d X_q} V'^2 \sin 2\delta'. \quad (5.220)$$

To reinforce these ideas, we now present a quantitative example of a round-rotor synchronous generator that is characterized by the following reactance values:

- $x_d = 1.2$  pu
- $x'_d = 0.25$  pu
- $x'_q = x_q = 0.7$  pu.

**Table 5.5** Vector diagrams of a salient pole synchronous machine in steady-state and transient conditions (adapted from [5.11])

Steady state		Transient	
	$x_q < x_d$ $\frac{V}{\sqrt{3}} + jX_d \bar{I}_d + jX_q \bar{I}_q = \bar{E}$ $\text{Re}(\bar{V} \bar{I}) = V_d I_d + V_q I_q$ $X_q I_q = V_d = V \sin \delta$ $X_d I_d = E - V_q = E - V \cos \delta$ $VI \cos \varphi = V_d I_d + V_q I_q$ $= V \sin \delta \frac{E - V \cos \delta}{X_d} + V \cos \delta \frac{V \sin \delta}{X_q}$ $= \frac{EV}{X_d} \sin \delta + V^2 \left( \frac{1}{X_q} - \frac{1}{X_d} \right) \sin \delta \cos \delta$ $= \frac{EV}{X_d} \sin \delta + \frac{V^2}{2} \frac{X_d - X_q}{X_d X_q} \sin 2\delta$		$x_q > x'_d$ $\frac{V'}{\sqrt{3}} + jX'_d \bar{I}'_d + jX'_q \bar{I}'_q = \bar{E}'$
<p>For a three-phase machine, we have</p> $P = 3VI \cos \varphi = 3 \frac{EV}{X_d} \sin \delta + \frac{3}{2} \frac{X_d - X_q}{X_d X_q} V^2 \sin 2\delta$		<p>For a three-phase machine, we have</p> $P' = 3V'I' \cos \varphi = 3 \frac{E'V'}{X'_d} \sin \delta' + \frac{3}{2} \frac{X'_d - X'_q}{X'_d X'_q} V'^2 \sin 2\delta'$	

Let us assume that the generator is connected to an infinite power bus with a voltage  $v = 1$  pu, and that it is supplying an active power  $p = 0.8$  pu and a reactive power  $q = 0.2$  pu through an external reactance of  $x = 0.2$  pu.

$$p = \frac{ev}{x_d + x} \sin \delta + \frac{(x_d + x) - (x_q + x)}{2(x_d + x)(x_q + x)} v^2 \sin 2\delta$$

$$= 1.2 \sin \delta + 0.2 \sin 2\delta$$

$$p' = \frac{e'v}{x_d + x} \sin \delta + \frac{(x'_d + x) - (x_q + x)}{2(x'_d + x)(x_q + x)} v^2 \sin 2\delta$$

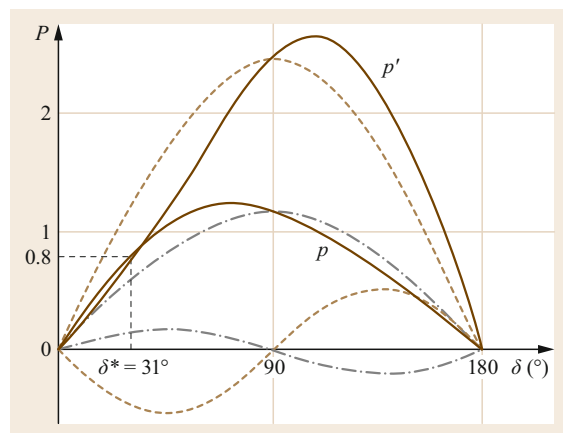

$$= 2.5 \sin \delta - 0.55 \sin 2\delta$$

The two curves are shown in Fig. 5.64. Changing the active and reactive power initially supplied to the infinite power bus from the values  $p = 0.8$  pu and  $q = 0.2$  pu, respectively, results in the same steady-state  $P$ - $\delta$  curve as that shown in the figure but a different transient  $P$ - $\delta$  curve. We shall come back to this observation later.

**Round-Rotor Synchronous Machines: Vector Diagram and  $P$ - $\delta$  Curves in Steady-State and Transient Conditions**

The vector diagrams for a round-rotor synchronous machine in steady-state and transient conditions are presented in Table 5.6, along with the relevant equations for convenience. These equations can be used to infer the expressions for the  $P$ - $\delta$  curves.

It follows from the vector diagrams and the equations reported in Table 5.5 that the expression for the

**Fig. 5.64**  $P$ - $\delta$  curves for a salient pole synchronous machine in steady-state and transient conditions (adapted from [5.11])

active power as a function of the rotor electrical angle for a three-phase round-rotor machine in the steady state is

$$P = 3 \frac{EV}{X} \sin \delta, \tag{5.221}$$

while the expression for a round-rotor machine in the transient state is

$$P' = 3 \frac{E'_q V'}{X'_d} \sin \delta - 3 \frac{E'_d V'}{X'_d} \cos \delta + \frac{3}{2} \frac{X'_d - X'_q}{X'_d X'_q} V'^2 \sin 2\delta. \tag{5.222}$$

**Table 5.6** Vector diagrams of round-rotor synchronous machines in steady-state and transient conditions (adapted from [5.11])

Steady state	Transient
$\frac{x_q \approx x_d}{\bar{V} + jX\bar{I} = \bar{E}}$	$\begin{aligned} \frac{x'_q > x'_d}{\bar{V}' + jX'_d \bar{I}'_d + jX'_q \bar{I}'_q = \bar{E}'} \\ X'_q I'_q = V'_d - E'_d = V' \sin \delta - E'_d \\ X'_d I'_d = E'_q - V'_q = E'_q - V' \cos \delta \\ X'_q = X_q \rightarrow E'_d = 0 \\ V' I' \cos \varphi = V'_d I'_d + V'_q I'_q \\ = V' \sin \delta \frac{E'_q - V' \cos \delta}{X'_d} + \\ V' \cos \delta \frac{V' \sin \delta - E'_d}{X'_q} \\ = \frac{E'_q V'}{X'_d} \sin \delta - \frac{E'_d V'}{X'_q} \cos \delta + \\ V^2 \left( \frac{1}{X'_q} - \frac{1}{X'_d} \right) \sin \delta \cos \delta \end{aligned}$
<p>For a three-phase machine, we have</p> $P = 3 \frac{EV}{X} \sin \delta$	<p>For a three-phase machine, we have</p> $P' = 3 \frac{E'_q V'}{X'_d} \sin \delta - 3 \frac{E'_d V'}{X'_q} \cos \delta + \frac{3}{2} \frac{X'_d - X'_q}{X'_d X'_q} V'^2 \sin 2\delta$

Section 5.6

**Fig. 5.65**  $P$ - $\delta$  curves for a round-rotor synchronous machine in steady-state and transient conditions

To demonstrate these ideas, we now present a quantitative example of a round-rotor synchronous generator that is characterized by the following reactance values:

- $x_d = x_q = 1.2$  pu
- $x'_d = 0.25$  pu
- $x'_q = 0.3$  pu.

Also, let us assume that the generator is connected to an infinite power bus with a voltage  $v = 1$  pu, and that it supplies an active power  $p = 0.8$  pu and a reactive power  $q = 0.2$  pu through an external reactance of

$x = 0.2$  pu. The transient and static characteristics, illustrated in Fig. 5.65, are

$$\begin{aligned} p &= \frac{ev}{x_d + x} \sin \delta = 1.2 \sin \delta \\ p' &= \frac{e'_q v}{x_d + x} \sin \delta - \frac{e'_d v}{x_d + x} \cos \delta \\ &\quad + \frac{(x'_d + x) - (x'_q + x)}{2(x'_d + x)(x'_q + x)} v^2 \sin 2\delta \\ &= 2.35 \sin \delta - 0.85 \cos \delta - 0.11 \sin 2\delta . \end{aligned}$$

We can get various curves for this machine depending on the assumptions made. For instance, if we assume that  $x'_q = x_q$ , the transient characteristics becomes (Fig. 5.66)

$$\begin{aligned} p' &= \frac{e'_q v}{x_d + x} \sin \delta + \frac{(x'_d + x) - (x_q + x)}{2(x'_d + x)(x_q + x)} v^2 \sin 2\delta \\ &= 2.35 \sin \delta - 0.75 \sin 2\delta . \end{aligned}$$

On the other hand, if we assume that  $x'_q = x'_d$  (i.e., isotropy), the transient characteristics becomes (Fig. 5.67)

$$\begin{aligned} p' &= \frac{e'_q v'}{x'_d} \sin \delta - \frac{e'_d v'}{x'_d} \cos \delta \\ e'_d &= e' \cos \alpha \\ e'_q &= e' \sin \alpha \\ p' &= \frac{e' v'}{x'_d} \sin(\delta - \alpha) \\ p' &= 2.35 \sin \delta - \cos \delta = 2.6 \sin(\delta - 22.9^\circ) . \end{aligned}$$

**Fig. 5.66**  $P$ - $\delta$  curves for a round-rotor synchronous machine in steady-state and transient conditions assuming  $x'_q = x_q$

For illustrative purposes, Fig. 5.68 presents the three  $P$ - $\delta$  curves obtained in transient conditions based on the assumptions specified above.

Note that all of the  $P$ - $\delta$  characteristics presented in this section were obtained using a MATLAB file that can be found in the chapter's supplementary material.

#### Salient Pole Synchronous Machines: Effect of Varying the Initial Steady-State Operating Conditions on the ( $P$ - $\delta$ ) Curves Obtained in Steady-State and Transient Conditions

Let us consider a generator with the following reactances:

- $x_d = 1.2$  pu
- $x'_d = 0.25$  pu
- $x_q = x'_q = 0.7$  pu.

The generator has a no-load excitation emf  $e = 1.7$  pu that is connected to an infinite power bus with a voltage  $v = 1$  pu through a reactance  $x = 0.2$  pu.

Let us consider three initial conditions:

- $\delta = 20^\circ \rightarrow p = 0.5, q = 0.4$
- $\delta = 40^\circ \rightarrow p = 1.0, q = 0.1$
- $\delta = 60^\circ \rightarrow p = 1.2, q = -0.4$ .

In pu, the expressions for active and reactive power are

$$p = \frac{ev}{x_d + x} \sin \delta + \frac{v^2}{2} \frac{x_d - x_q}{x_d + x_d + 2x} \sin 2\delta$$

$$q = \frac{ev}{x_d + x} \cos \delta - v^2 \left( \frac{\sin^2 \delta}{x_q + x} + \frac{\cos^2 \delta}{x_d + x} \right).$$

**Fig. 5.67**  $P$ - $\delta$  curves obtained in steady-state and transient conditions for a round-rotor synchronous machine assuming  $x'_q = x'_d$  (i.e., isotropy)

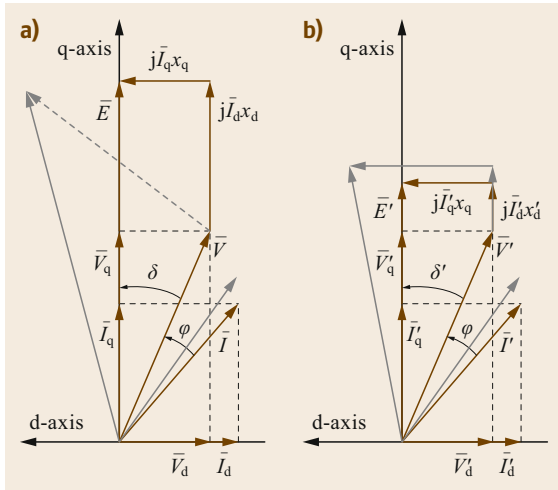

**Fig. 5.68** Comparison of the  $P$ - $\delta$  curves obtained in transient conditions for a round-rotor synchronous machine assuming that  $x'_q = 0.3$ ,  $x'_q = x_q$ , or  $x'_q = x'_d$  (i.e., isotropy)

In the steady state, the magnitude of  $E$  remains constant, as do  $V$  and all of the reactances. Therefore, applying a different initial active power  $P$ , and thus a different  $\delta$ , does not change the steady-state  $P$ - $\delta$  curve. Apart from  $\delta$ , the quantities that differ in the new initial state are the current and its power factor; however, changes to these quantities do not alter the steady-state curve. However, the vector diagram does change if we start from new steady-state operating conditions, as  $\delta$ ,  $I$ , and  $E$  (which simply rotates) change.

**Fig. 5.69**  $P$ - $\delta$  curves obtained in steady-state and transient conditions for a salient pole synchronous machine with three different initial steady-state operating conditions

**Fig. 5.70** (a) Steady-state and (b) transient vector diagrams for different initial operating conditions, marked in gray (adapted from [5.11])

In the transient state, changing the initial values of the current and the power factor alters the voltage drops at the transient reactances and changes the transient emf, meaning that the  $P$ - $\delta$  characteristic in the transient state varies depending on the initial operating conditions. Thus, three different initial steady-state operating conditions yield three different transient curves, as shown in Fig. 5.69. The relevant vector diagrams are shown in Fig. 5.70.

### Round-Rotor Synchronous Machines: Effect of Varying the Initial Steady-State Operating Conditions on the ( $P$ - $\delta$ ) Curves Obtained in Steady-State and Transient Conditions

Let us consider a generator with the following reactances:

- $x_d = 1.2$  pu
- $x'_d = x'_q = 0.25$  pu.

This generator has a no-load excitation emf  $e = 1.7$  pu, which is connected to an infinite power bus with a voltage  $v = 1$  through a reactance  $x = 0.2$  pu.

Let us consider three initial conditions:

- $\delta = 20^\circ \rightarrow p = 0.5$  pu,  $q = 0.4$  pu
- $\delta = 40^\circ \rightarrow p = 1.0$  pu,  $q = 0.1$  pu
- $\delta = 60^\circ \rightarrow p = 1.2$  pu,  $q = -0.4$  pu.

In pu, the expressions for the active and reactive power are

$$p = \frac{ev}{x_d + x} \sin \delta$$

$$q = \frac{ev}{x_d + x} \cos \delta - \frac{v^2}{x_d + x} .$$

The same considerations that were relevant to the salient pole machine also apply to a round-rotor machine, so again three different initial steady-state operating conditions yield just one steady-state curve but three different transient curves, as shown in Fig. 5.71.

**Fig. 5.71**  $P$ - $\delta$  curves obtained in steady-state and transient conditions for a round-rotor synchronous machine with three different initial steady-state operating conditions

**Fig. 5.72** Synchronous machine connected to an infinite power bus

## 5.6.6 Rotor Angle Stability

### Classical Methods

We now review the classical method of analyzing a simple system consisting of a synchronous machine connected to an infinite power bus, as shown in Fig. 5.72.

The following simplifications are made [5.49]:

- The synchronous machine is modeled as a constant emf  $\vec{E}$  behind the transient reactance  $x'$ , and the angle  $\delta$  of the emf is assumed to coincide with the difference between the rotor electrical angle and  $\omega_0 t$  as illustrated in Fig. 5.73
- The resistances of lines, transformers, and the synchronous machine are ignored
- Voltage and currents are assumed to be symmetrical (i.e., positive sequence)
- The angular velocity is close to nominal
- Static models are used for lines
- The mechanical power  $P_m$  (the power from the prime mover) is constant during the transient studied.

### Swing Equation

In the following, a subscript m denotes a mechanical quantity while a subscript e denotes an electrical quantity.

The differential equation that describes the rotor dynamics is

$$J \frac{d^2 \theta_m}{dt^2} = T_m - T_e, \quad (5.223)$$

where:

- $J$  = total moment of inertia (kg m<sup>2</sup>)
- $\theta_m$  = mechanical angle of the rotor (rad)
- $T_m$  = mechanical torque from turbine (N m)
- $T_e$  = electrical torque on the rotor (N m).

Multiplying (5.223) by the mechanical angular speed  $\omega_m$  yields

$$J \omega_m \frac{d^2 \theta_m}{dt^2} = P_m - P_e, \quad (5.224)$$

where:

$$P_m = T_m \omega_m = \text{mechanical power acting on the rotor (W)}$$

$$P_e = T_e \omega_m = \text{electrical power acting on the rotor (W)}.$$

We can express the angular acceleration via the electrical angle instead by inserting  $\theta_m = (\theta_e)/p - \theta_{e0}/p$  (where  $p$  is the number of pairs of poles on the machine) into (5.224), which gives

$$\frac{1}{p} \omega_m J \frac{d^2 \theta_e}{dt^2} = P_m - P_e. \quad (5.225)$$

It is now convenient to introduce the inertia constant  $H$  (in s), defined as

$$H = \frac{\frac{1}{2} J \omega_{m0}^2}{S}, \quad (5.226)$$

where  $\omega_{m0}$  is the rated mechanical angular speed and  $S$  is the MVA rating of the machine.

Using (5.226), and noting that  $d^2 \theta_e / dt^2 = d^2 \delta / dt^2$  (where  $\delta = \theta_e - \omega_0 t - \theta_{e0}$ ), (5.225) becomes

$$\frac{2H}{\omega_0} \frac{d^2 \delta}{dt^2} = P_m^{\text{pu}} - P_e^{\text{pu}}, \quad (5.227)$$

where  $\omega_0$  indicates the rated electrical angular speed ( $\omega_0 = p \omega_{m0}$ )<sup>2</sup>, and a superscript pu indicates that the electrical power and mechanical power are expressed in pu with respect to the rating of the synchronous machine. In the case of a synchronous machine connected to an infinite power bus, we can write (omitting the superscript pu for simplicity)

$$P_e = P_e(\delta, \dot{\delta}) = P_s(\delta) + P_d(\dot{\delta}), \quad (5.228)$$

where  $P_s$  is the synchronizing power, i.e., making reference to Fig. 5.74,

$$P_s(\delta) = \frac{E' V_n}{x' + x_e} \sin(\delta), \quad (5.229)$$

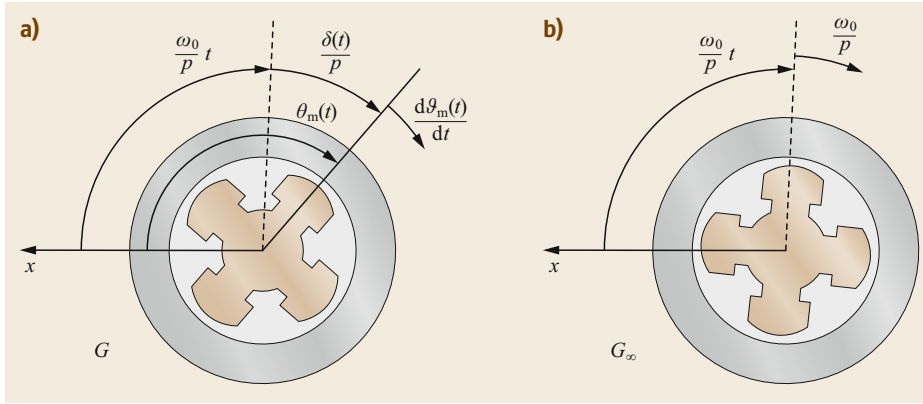

and  $P_d$  is the damping power, with

$$P_d(\dot{\delta}) = D \dot{\delta}. \quad (5.230)$$

$P_d$  is due to the currents in the rotor circuits, and tends to damp out the oscillations.

Taking  $x_1 = \delta$  and  $x_2 = d\delta/dt$  to be the state variables, (5.227) can be expressed in the state form as

$$\begin{cases} \dot{x}_1 = x_2 \\ \dot{x}_2 = \frac{\omega_0}{2H} (P_m^{\text{pu}} - P_e^{\text{pu}}) \end{cases} \quad (5.231)$$

**Fig. 5.73a,b** Definitions of the quantities used to derive the swing equations. The alternator of interest is shown in (a), while the infinite power machine is depicted in (b)

**Fig. 5.74** Simple circuit representation of a generator in the transient state

The vector  $x = [x_1, x_2]^T$  is the state vector of the system; the equilibrium points (EPs) for the system of equations are given by  $\dot{x} = 0$ , i.e.,

$$\begin{aligned} x_1 &= \arcsin\left(\frac{P_m}{P_{\max}}\right) \\ x_2 &= 0, \end{aligned} \tag{5.232}$$

where  $P_{\max} = E' V_n / (x' + x_c)$ .

For the power angle curve shown in Fig. 5.75, there are two values of  $\delta$  for each value of  $P_m$  (when  $P_m < P_{\max}$ ), i.e., two EPs:  $\delta_s$  and  $\delta_u$ .

After linearizing (5.231) and introducing a small deviation ( $\Delta x_1, \Delta x_2$ ) from an EP, we can write

$$\begin{bmatrix} \Delta \dot{x}_1 \\ \Delta \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\frac{\omega_0}{H} k & -\frac{\omega_0}{H} D \end{bmatrix} \cdot \begin{bmatrix} \Delta x_1 \\ \Delta x_2 \end{bmatrix}, \tag{5.233}$$

where  $k = P_{\max} \cos(\delta_e)$  and  $\delta_e$  is the angle at equilibrium ( $\delta_s$  or  $\delta_u$ ).

The eigenvalues of the linearized system are given by

$$\lambda = -\frac{1}{2} \frac{\omega_0}{2H} D \pm \sqrt{\frac{\omega_0^2 D^2}{16H^2} - \frac{\omega_0}{2H} k}. \tag{5.234}$$

If  $k$  is positive, both eigenvalues have negative real parts. If  $k$  is negative, one of the eigenvalues is positive

**Fig. 5.75** Power angle curve; note that there are two values of  $\delta$  for each value of  $P_m$

real. Therefore,  $\delta_s$  is a stable EP and  $\delta_u$  is an unstable EP. The criterion for stability is algebraic and given by

$$\frac{dP_s}{d\delta} > 0. \tag{5.235}$$

If  $D$  is small and  $k > 0$ , the eigenvalues are complex and are obtained via

$$\lambda = -\sigma \pm j\omega_p, \tag{5.236}$$

where

$$\sigma = \frac{1}{2} \frac{\omega_0}{2H} \times D \quad \text{and} \quad \omega_p = \sqrt{\frac{\omega_0}{2H} \times k - \frac{\omega_0^2 D^2}{16H^2}}.$$

The two EPs ( $\delta_s$  and  $\delta_u$ ) become closer to each other as  $P_m$  increases. The maximum power supplied by the generator is equal to  $P_{\max}$  and occurs at  $\delta^* = \pi/2$ .

**Fig. 5.76a,b** Loci of eigenvalues in the  $s$  plane (a) at the SEP and (b) at the UEP

The condition for stability can also be stated as

$$\delta_s < \delta^* . \quad (5.237)$$

The loci of eigenvalues in the  $s$  plane as  $P_m$  is varied are shown in Fig. 5.76.

At the SEP (state equilibrium point), the eigenvalues are initially complex and split into two real values. One of them reaches origin as  $P_m$  is increased to  $P_{\max}$  (when  $k = 0$ ), while the other eigenvalue approaches  $-D\omega_0/(2H)$ .

At the UEP (unstable equilibrium point), both eigenvalues are real. As  $P_m$  increases, both move towards the origin. At  $P_m = P_{\max}$ , one of the values is 0 while the other is  $-D\omega_0/(2H)$ .

There is no equilibrium when  $P_m > P_{\max}$ .

### Equal Area Criterion

Quite often, we are not interested in the exact behavior of the solution to (5.227), only whether the system is stable after a given contingency. By applying the equal area criterion described below, it is possible to investigate the stability of the system in Fig. 5.76 following various disturbances using simple calculations. As our interest is focused on the dynamics during the first swing, the damping can be neglected, i.e.,  $D = 0$ . A necessary but not sufficient condition for stability is that there is a moment in time  $t_m$  during this swing when  $\dot{\delta}(t_m) = 0$ . The corresponding angle is  $\delta_m$ .

The stability criterion is obtained by manipulating (5.227) and applying the condition  $\dot{\delta}(t_m) = 0$ . Multiplying (5.227) by  $\dot{\delta}$  on both sides yields

$$\dot{\delta} \frac{d^2\delta}{dt^2} = \frac{\omega_0}{2H} P_a \dot{\delta} , \quad (5.238)$$

which can be written as

$$\delta \frac{1}{2} \frac{d}{dt} \left( \frac{d\delta}{dt} \right)^2 = \frac{d}{dt} \left( \frac{\omega_0}{2H} \int_{\delta_i}^{\delta} P_a d\delta \right) , \quad (5.239)$$

where  $P_a = P_m - P_e$ .

Equation (5.239) can be integrated to give

$$\frac{d\delta}{dt} = \sqrt{\frac{\omega_0}{H} \int_{\delta_i}^{\delta} P_a d\delta + c} , \quad (5.240)$$

where  $c$  is an integration constant with a value of 0 since  $\dot{\delta} = 0$  when  $\delta = \delta_i$  ( $\delta_i$  is the pre-disturbance rotor angle).

Thus, a necessary condition for stability is that there is an angle  $\delta_m$  such that

$$\int_{\delta_i}^{\delta} P_a d\delta = 0 , \quad (5.241)$$

i.e., there is an angle  $\delta_m$  such that the area below the accelerating power  $P_a$  in the  $\delta$ - $P$  diagram between  $\delta_i$  and  $\delta_m$  vanishes. In other words,

$$\int_{\delta_0}^{\delta^*} P_a d\delta = \int_{\delta_0}^{\delta^*} (P_m - P_e) d\delta = 0 . \quad (5.242)$$

A graphical interpretation of this formula is shown in Fig. 5.77. This is the *equal area criterion*. The two areas represent the *fictitious* kinetic energies absorbed/released and then released/absorbed by the rotor.

### Heffron–Phillips Model of a Generator Connected to an Infinite Power Bus

The Heffron–Phillips model is a linear model that takes into account the actions of the voltage control and the exciter [5.50]. This model justifies and illustrates the use of power system stabilizers (PSS).

The rotor angle dynamics in pu can be written as

$$\frac{d\delta}{dt} = \omega_0(\omega_{pu} - 1) \quad (5.243)$$

$$2H \frac{d\omega_{pu}}{dt} = T_m - T_s - D\omega_{pu} , \quad (5.244)$$

where  $\omega_{pu} = \omega/\omega_0$ ,  $D$  is the damping coefficient, and  $T_m$  and  $T_s$  are the mechanical and the synchronizing

**Fig. 5.77** Graphical interpretation of the equal area criterion

torques, respectively. Assuming that  $\omega_{pu} \approx 1$  pu, we can write

$$T_s = \frac{|E'| |V_\infty|}{x' + x_e} \sin \delta, \quad (5.245)$$

where  $E'$  is the transient internal voltage,  $V_\infty$  is the voltage at the infinite power bus (the bus of the network to which many generators are connected),  $x'$  is the transient reactance of the alternator, and  $x_e$  is the reactance of the link between the alternator and the infinite power bus. For small variations, the linearized approximation of (5.245) is

$$\Delta T_s = k_1 \Delta \delta + k_2 \Delta |E'|, \quad (5.246)$$

where

$$k_1 = \left( \frac{\partial T_s}{\partial \delta} \right)_0 = \frac{|E'_0| |V_\infty|}{x' + x_e} \cos \delta_0 \quad (5.247)$$

$$k_2 = \left( \frac{\partial T_s}{\partial |E'|} \right)_0 = \frac{|V_\infty|}{x' + x_e} \sin \delta_0. \quad (5.248)$$

In order to account for the variation of  $|E'|$  with respect to both  $\Delta E_f$  (which is proportional to the variation of the excitation voltage) and to  $\Delta \delta$ , the equation relevant to the flux decay of the excitation winding is included as

$$v_f = r_f i_f + \frac{d\lambda_f}{dt}, \quad (5.249)$$

where  $v_f$  is the excitation voltage,  $i_f$  is the excitation current, and  $\lambda_f$  is the flux linkage. Equation (5.249) can be written at the stator side as

$$|E_f| = |E| + T'_0 \frac{d|E'|}{dt}. \quad (5.250)$$

Here,  $T'_0 = L_f / r_f$ , where  $r_f$  is the resistance and  $L_f$  is the self-inductance of the excitation winding.

As a first approximation, we can write

$$\frac{|E| - |V_\infty| \cos \delta}{|E'| - |V_\infty| \cos \delta} \approx \frac{\tilde{x}}{\tilde{x}'}, \quad (5.251)$$

where  $\tilde{x}' = x' + x_e$  and  $\tilde{x} = x_s + x_e$  ( $x_s$  is the synchronous reactance).

From (5.251),

$$|E| = \frac{1}{k_3} |E'| + \left( 1 - \frac{1}{k_3} \right) |V_\infty| \cos \delta, \quad (5.252)$$

where

$$k_3 = \frac{\tilde{x}'}{\tilde{x}}. \quad (5.253)$$

Inserting (5.252) into (5.250) gives

$$k_3 T'_0 \frac{d|E'|}{dt} + |E'| = k_3 |E_f| + (1 - k_3) |V_\infty| \cos \delta. \quad (5.254)$$

Introducing the Laplace transform for small variations leads to

$$(sk_3 T'_0 + 1) \Delta |E'| = k_3 \Delta |E_f| - k_4 k_3 \Delta \delta, \quad (5.255)$$

where

$$k_4 = \left( \frac{1}{k_3} - 1 \right) |V_\infty| \sin \delta. \quad (5.256)$$

The relevant block diagram is shown in Fig. 5.78.

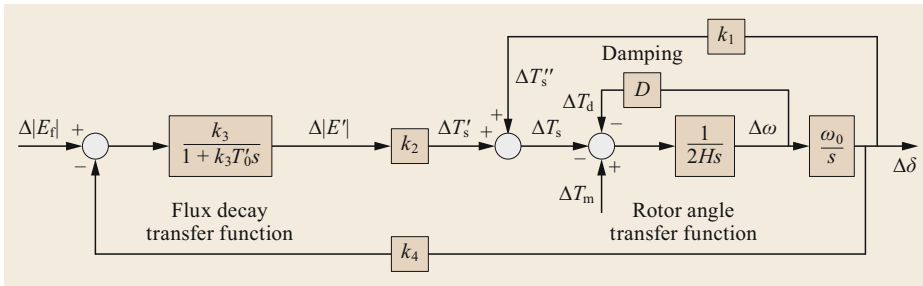

As shown in Fig. 5.78, the feedback loop arises because of the link between  $\Delta |E'|$  and  $\Delta \delta$ . When the exciter and voltage regulator are included,  $\Delta |E_f|$  depends on the output voltage at the generator terminals  $|V_t|$  through the excitation system.

When the excitation voltage is constant ( $\Delta |E_f| = 0$ ), the field flux variations  $\Delta |E'|$  are only caused by the feedback of  $\Delta \delta$  through the coefficient  $k_4$ . This represents the demagnetizing effect of the armature reaction.

The change in air-gap torque due to the field flux variations caused by rotor angle changes (indicated as  $\Delta T'_s$  in the block diagram) is given by

$$\left. \frac{\Delta T'_s}{\Delta \delta} \right|_{\Delta |E_f|=0} = \frac{k_2 k_3 k_4}{1 + sk_3 T'_0}, \quad (5.257)$$

where the constants  $k_2$ ,  $k_3$ , and  $k_4$  are usually positive. The contributions of  $\Delta |E'|$  to the synchronizing torque  $\Delta T'_s$  and the damping torque  $\Delta T_d$  depend on the oscillating frequency as follows:

**Fig. 5.78** Block diagram of an alternator with damping and flux decay accounted for

- (1) In the steady state and at very low oscillating frequencies (i.e.,  $s = j\omega \rightarrow 0$ ),

$$\Delta T'_s = -k_2 k_3 k_4 \Delta \delta. \tag{5.258}$$

The variation in the field flux due to  $\Delta \delta$  feedback introduces a negative synchronizing torque component. The system becomes monotonically unstable when this exceeds  $k_1 \Delta \delta$  (i.e.,  $T'_s$ ). The steady-state stability limit is reached when

$$k_2 k_3 k_4 = k_1. \tag{5.259}$$

- (2) At oscillating frequencies  $\gg 1/(k_3 T'_0)$ ,

$$\Delta T'_s = \frac{-k_2 k_3 k_4 \Delta \delta}{j\omega k_3 T'_0}. \tag{5.260}$$

Equation (5.260) can be written as

$$\Delta T'_s = j \frac{k_2 k_4 \Delta \delta}{\omega T'_0}. \tag{5.261}$$

Thus, the component of the air-gap torque due to  $\Delta |E'|$  leads  $\Delta \delta$  by  $90^\circ$ , or is in phase with  $\Delta \omega$ . Hence,  $\Delta |E'|$  results in a positive damping component that is added to  $\Delta T_d$ .

- (3) At a typical machine oscillating frequency of about 1 Hz,  $\Delta |E'|$  results in a positive damping torque component and a negative synchronizing torque component. The net effect is to slightly reduce the synchronizing torque component and increase the damping torque component.

$k_4$  is generally positive, although there are a few cases in which it may be negative, such as for a hydraulic generator without damper windings that is operating with a light load and is connected by a line with a relatively high resistance to reactance ratio to a larger system.

A simple model of the voltage control system and exciter is shown in Fig. 5.79.

For small variations, we can write

$$\Delta |V_t| = k_s \Delta \delta + k_6 \Delta |E'|, \tag{5.262}$$

where  $k_s = |\partial |V_t| / \partial \delta|_0$  and  $k_6 = |\partial |V_t| / \partial |E'|_0$ .

**Fig. 5.79** Simple model of the voltage control system and exciter

$k_6$  is positive whereas  $k_5$  can be positive or negative (it is negative under heavy loading conditions and with high external impedance).

The block scheme of Fig. 5.80 is obtained by including the block scheme of Fig. 5.79 in that of Fig. 5.78.

The stability criterion is given by

$$k_5 k_E + k_4 > 0, \tag{5.263}$$

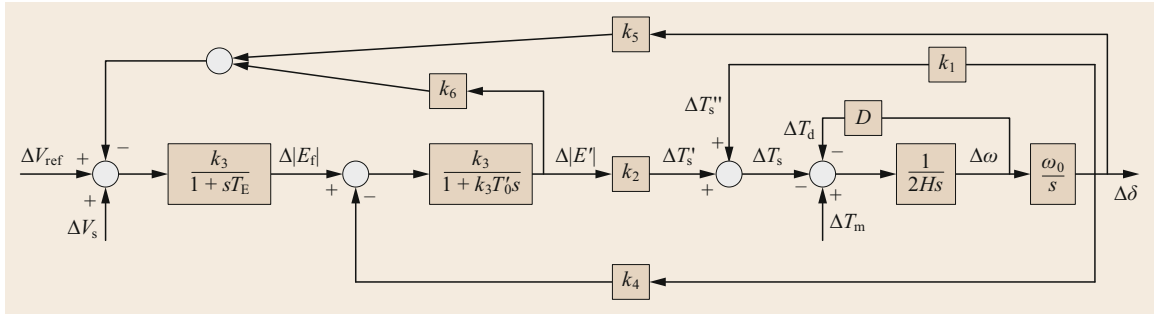

so when  $k_5 < 0$ , (5.263) limits the value of  $k_E$ . In order to maintain a high value of  $k_E$  in the steady state, a PSS is adopted.

A simple PSS scheme is shown in Fig. 5.81.

### Multi-Machine Stability Studies

The equal area criterion cannot be used directly in systems with three or more machines. When a multi-machine system operates under electromechanical transient conditions, machine oscillations occur in the transmission system connecting the machines. In this case, we introduce the following assumptions to formulate the so-called classical model:

1. The mechanical power input of each machine remains constant throughout the swing computation
2. The damping power is negligible
3. Each machine can be represented by a constant transient reactance in series with a constant transient internal voltage
4. The mechanical rotor angle of each machine coincides with  $\delta$ , the electrical phase angle of the internal voltage
5. All loads can be considered shunt impedances to ground, with values that are governed by the prevailing conditions immediately prior to the transient condition.

**Fig. 5.80** Block diagram of an alternator with the damping, flux decay, voltage control system, and exciter considered

**Fig. 5.81** Simple PSS scheme, where  $K_{PSS}$  is the gain,  $T_w$  is the washout time constant, and the other time constants ( $T_1$ ,  $T_2$ ,  $T_3$ , and  $T_4$ ) are those of the two stage lead-lag block for phase compensation

The system conditions before the fault and the network configuration both during and after the fault must be known in any transient stability study. Consequently, in the multi-machine case, two preliminary steps are performed:

- The steady-state pre-fault conditions for the system are calculated using a power flow code
- The pre-fault network representation is determined and then modified to account for the fault and post-fault conditions.

We know the active power, reactive power, and voltage values at each generator terminal and load bus for the preliminary steps. The transient internal voltage of each generator is then calculated using

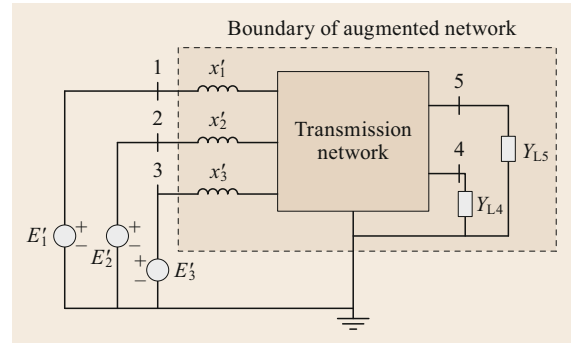

$$\vec{E}' = \vec{V}_t + jx'\vec{I}, \tag{5.264}$$

where  $\vec{V}_t$  is the corresponding terminal voltage and  $\vec{I}$  is the output current. Each load is converted into a constant admittance to ground and its bus using

$$Y_L = \frac{P_L - jQ_L}{V_L^2}, \tag{5.265}$$

where  $P_L + jQ_L$  is the load and  $\vec{V}_L$  is the magnitude of the corresponding bus voltage.

The bus admittance matrix used for the pre-fault power flow calculation is now augmented to include the transient reactance of each generator and the shunt admittance of each load, as illustrated in Fig. 5.82.

**Fig. 5.82** Model of augmented network nodal analysis

The injected currents are zero at all buses except for the internal buses of the generators. In the second preliminary step, the bus admittance matrix is modified to correspond to the faulted and post-fault conditions. Since only the internal buses of the generator have injections, all other buses can be eliminated by Kron reduction. The power injected into the network from each generator is calculated using the corresponding power angle equation. For example, in Fig. 5.82, the power supplied by generator 1 is given by

$$P_{1l} = E_1'^2 G_{11} + E_1' E_2' Y_{12} \cos(\delta_{12} - \vartheta_{12}) + E_1' E_3' Y_{13} \cos(\delta_{13} - \vartheta_{13}), \tag{5.266}$$

where  $\delta_{12} = \delta_1 - \delta_2$ ,  $\bar{Y}_{12} = Y_{12} e^{j\vartheta_{12}}$ , and  $\bar{Y}_{13} = Y_{13} e^{j\vartheta_{13}}$ .

Similar equations can be written for  $P_{l2}$  and  $P_{l3}$  using the  $Y_{ij}$  elements of the  $3 \times 3$  bus admittance matrix.

The  $P_{li}$  expressions are used in the swing equations

$$\frac{2H_i}{\omega_0} \frac{\partial^2 \delta_i}{\partial t^2} = P_{mi} - P_{ei} \quad i = 1, 2, 3, \tag{5.267}$$

which represent the motion of each rotor during and after the fault. The solution depends on the location and the duration of the fault and the  $Y_{bus}$  that results from the removal of the faulted line.

**Fig. 5.83** Scheme of a load connected to an infinite bus through a line

### 5.6.7 Voltage Stability

Just as the single machine to infinite bus system is used to describe some basic properties of angular stability, some fundamental aspects of voltage stability can be described by referring to the simple system shown in Fig. 5.83, where a load with active power  $P$  and reactive power  $Q$  is supplied through a line with longitudinal impedance  $z$  (shunt capacitance is neglected) from a bus with constant voltage  $v_0$  (infinite bus).

In steady-state and balanced conditions, this simple system is expressed by

$$\bar{i} = \frac{\bar{v}_0 - \bar{v}}{\bar{z}} \quad (5.268)$$

$$P - jQ = \bar{v}^* \bar{i}, \quad (5.269)$$

where  $\bar{v}^*$  indicates the conjugate of the voltage phasor.

Replacing  $i$  in (5.269) with (5.268) yields the equation

$$P - jQ = \frac{v^* v_0 - v^2}{z}, \quad (5.270)$$

which can be rearranged by introducing the line resistance  $r$ , the reactance  $x$ , and the angle  $\theta$  (the difference between the angles of  $v_0$  and  $v$ ),

$$(r + jx)(P - jQ) + v^2 = vv_0(\cos \vartheta + j \sin \vartheta). \quad (5.271)$$

Equating the real and imaginary parts leads to

$$\begin{aligned} rP + xQ + v^2 &= vv_0 \cos \vartheta \\ xP - rQ &= vv_0 \sin \vartheta. \end{aligned} \quad (5.272)$$

The angle  $\theta$  can be eliminated by squaring both sides and adding the two equations, to give

$$v^4 + (r^2 + x^2)(P^2 + Q^2) + 2(rP + xQ)v^2 = v^2 v_0^2. \quad (5.273)$$

Dividing by  $|v|^2$  results in the typical equation used in the Distflow method [5.51] to calculate the steady-state operating conditions in a radial distribution network,

$$v^2 = v_0^2 - (r^2 + x^2)i^2 - 2(rP + xQ). \quad (5.274)$$

By neglecting the effects of voltage variations on both  $P$  and  $Q$ , (5.273) can be written as a quadratic equation in the variable  $u = v^2$ ,

$$u^2 - [v_0^2 - 2(rP + xQ)u + (r^2 + x^2)(P^2 + Q^2)] = 0. \quad (5.275)$$

Equation (5.275) only has feasible solutions (i.e., solutions that are real numbers) if the discriminant is larger than or equal to 0, i.e.,

$$v_0^4 - 4(rP + xQ)v_0^2 - 4(xP - rQ)^2 \geq 0, \quad (5.276)$$

which can also be used as a stability index.

If  $r$  can be ignored, (5.275) can be rewritten as

$$\hat{u}^2 + (2\hat{Q} - 1)\hat{u} + \hat{P}^2 + \hat{Q}^2 = 0, \quad (5.277)$$

where  $\hat{u} = u/v_0^2$ ,  $\hat{P} = xP/v_0^2$ , and  $\hat{Q} = xQ/v_0^2$ .

The solutions to (5.277) are

$$\hat{u} = \frac{1}{2} - \hat{Q} \pm \sqrt{\left(\frac{1}{2} - \hat{Q}\right)^2 - \hat{P}^2 - \hat{Q}^2}, \quad (5.278)$$

**Fig. 5.84** Feasibility condition when the resistance is ignored

**Fig. 5.85** Nose curves for different values of the power factor PF

with the feasibility condition

$$\hat{P}^2 + \hat{Q} \leq \frac{1}{4}. \quad (5.279)$$

The feasibility condition is depicted in Fig. 5.84. Below the curve there are two real solutions; on the curve there is a single solution; and above the curve there are no real solutions.

In the case of a constant power factor (i.e.,  $\hat{Q} = \hat{P} \tan \varphi$  with  $\tan \varphi$  constant), the feasibility condition (5.279) becomes

$$\hat{P}^2 + \hat{P} \tan \varphi - \frac{1}{4} \leq 0. \quad (5.280)$$

**Fig. 5.86** QV curve for  $\hat{P} = 0.1$

When  $\hat{P} \geq 0$  (load consumption), the critical conditions are  $\hat{P}_{\max} = \cos \varphi / [2(1 + \sin \varphi)]$ ,  $\hat{Q}_{\max} = \sin \varphi / [2(1 + \sin \varphi)]$ , and  $\hat{u}_{\text{cr}} = 1 / [2(1 + \sin \varphi)]$ .

For constant power factor values, the curves presented in Fig. 5.85 are obtained. These show the variation of  $v/v_0$  as a function of  $\hat{P} \geq 0$  based on (5.278). Such curves are often called nose curves or power voltage (PV) curves. Just as for the case considered in Fig. 5.84, three cases can be distinguished regarding the number of possible operating points: (a) there are two solutions when  $\hat{P}$  is less than the tip of the nose; (b) there is one solution at the tip of the nose; and (c) there are no solutions for larger values of  $\hat{P}$ .

In case (a), the upper solution corresponds to high voltage and low current while the lower one corresponds to low voltage and high current. The upper solution is obviously of particular interest since it reduces the power loss.

The power factor has a significant influence on the nose curve (as shown in Fig. 5.85), and therefore on the voltage stability limit.  $\hat{P}_{\max}$  decreases as the reactive power drawn by the load increases.

If  $\hat{P}$  is assumed to be constant, applying (5.277) yields the QV curve, which shows the amount of reactive power that must be provided to the network with a given load to obtain a predefined voltage level. Figure 5.86 shows this curve for  $\hat{P} = 0.1$ . The voltage sensitivity factor  $dv/dQ$  can be used as a stability criterion. Since we usually expect the voltage to increase when the adsorption of reactive power from the bus decreases, stability is obtained when  $dv/dQ$  is negative. This condition is met for voltages higher than 0.6 pu in Fig. 5.86.

In three dimensions, (5.277) defines an infinite paraboloid, as illustrated by Fig. 5.87.

The relationship between the load power and voltage variations depends on the timescale considered. At short timescales of a few seconds, the physical processes associated with the load device determine the characteristics, whereas various control actions must be considered at longer timescales.

**Fig. 5.87a–c** Surfaces illustrating the relationship between voltage, active power, and reactive power; (a) and (b) show lateral views whereas (c) depicts the top view

One generic model often used for short timescales is the exponential

$$P_L = P_{L0} \left( \frac{V}{V_0} \right)^{k_p}, \quad (5.281)$$

where  $P_{L0}$  is the active power absorbed when the voltage is equal to the rated value  $V_0$ . A similar expression, albeit usually with a different exponent value, can be used for the reactive power.

At longer timescales, the control actions that are applied to keep the load power constant are typically those of the thermostatically controlled load and those of the variable tap changers of distribution transformers.

Figure 5.88 shows the load characteristic (with  $k_p = 1.75$ ) plotted together with two different nose curves. The solid one is the unity power factor curve of Fig. 5.85; the dotted nose curve refers to the case in which the reactance doubles due to a fault.

Load control is achieved by increasing the load admittance in order to increase the load power. Indeed, one of the definitions of voltage stability is that an increase in load admittance results in an increase in load power.

At point A in Fig. 5.88, an increase in load admittance shifts the load curve to the right and then increases the load power. Thus, the system is voltage stable according to the definition above. If a disturbance occurs, the equivalent network impedance increases dramatically and the nose curve shifts to the dotted one. The new operating point will be point B. The load controller will try to restore the load power to the previous value

**Fig. 5.88** The load characteristic crosses the nose curve at point A before and at point B after a network fault that doubles the equivalent reactance

represented by crossing point A. The controller will increase the load admittance, decreasing the voltage and shifting the operating point to the tip of the nose. The power cannot be restored to the original value since the tip of the nose curve is to the left of the vertical curve.

With the operating point at the tip of the nose, increasing the load admittance further causes a decrease in power because the voltage drop is larger than the in-

crease in current. This situation is clearly unstable and the system will collapse. Note that this description does not consider the actions of undervoltage protections.

## 5.7 Power System Control

In this section, we largely focus on frequency control. We will refer to the basic scheme shown in Fig. 5.89, which comprises a generating unit equipped with a turbine-alternator group connected to the grid. However, this scheme is becoming less common in real power systems due to the increasing utilization of renewable energy from solar (mainly photovoltaics) and wind technologies, as these types of generators are usually connected to the network and make use of inverters.

Frequency control is performed due to power quality considerations and requirements (some loads and components of power plants such as induction motors, steam, gas, and hydro turbines may be significantly affected by frequency deviations of a few Hz) and to maintain the global equilibrium in the network between the power produced by the power stations and the power consumed by the loads. The disconnection of a generating unit, a line trip, or an increased load decrease the frequency, while the disconnection of a load or a sudden increase in the power produced increases the frequency. Within this context, each mismatch is initially compensated for mainly by the kinetic energy stored in the rotors of the synchronous generators and induction motors. However, this kinetic energy is limited, so frequency deviations need to be promptly compensated through appropriate frequency control actions.

In the scheme shown in Fig. 5.89, a load increase (decrease) corresponds to a decrease (increase) in the alternator angular velocity that needs to be compensated for through appropriate action of the speed governor (Reg), which opens (closes) the turbine valve. The speed governor control system may require some other input signals (b) in addition to the angular velocity.

The frequency regulation and the available reserve of a system are designed such that the frequency does not shift outside predefined limits even when the largest

disturbances that can be reasonably expected occur (e.g., the largest generator in the system trips).

### 5.7.1 Generation Reserve

As the energy stored in the rotating masses is fairly small, a power reserve must always be available to ensure that the balance between the power provided by the turbines and the power requested by the electrical system is maintained. In this respect, during the system planning stage, it is useful to distinguish between *normal operation* and a *disturbance* as reasons for utilizing the reserve. Power imbalances due to incorrect load forecasts and random load variations are both compensated for using the normal operation reserve. On the other hand, typical disturbances are plant outages or line trips.

The reserves are categorized according to the time needed to activate them:

- The *spinning reserve* is provided by the margins between the current power output and the maximum and minimum limits of a generating unit. This reserve can be activated in a few seconds, and is used during primary frequency control.
- The *supplementary reserve* is employed to restore the spinning reserve when it has been used in the event of a large perturbation, and it is often activated by automatic generation control (AGC) after tens of seconds. Thus, it is significantly slower to activate than primary frequency control; indeed, it is designed not to interact with it. This phase is known as secondary frequency control.
- The *back-up reserve* is a slow reserve that can be activated within a couple of hours to restore a faster reserve when it has been used. This phase is known as tertiary frequency control.

Fig. 5.89 Basic scheme of a speed governor

Figure 5.90 illustrates the concepts of primary, secondary, and tertiary frequency control using an example of a large perturbation in the network of continental Europe. The entire system is involved during primary control; secondary control action is expected to be limited to the affected area only; whilst the rescheduling associated with tertiary control is applied to just a few power stations.

**Fig. 5.90a,b** Primary, secondary, and tertiary frequency control: (a) general scheme and (b) example showing the activation of each control phase after a large perturbation in the European network [5.52]

### 5.7.2 Dynamics of the Generators

After a disturbance in a large power system, the frequency varies across the system. For typical disturbances, however, the frequencies of the different machines can be regarded as being close to an average *system frequency* defined by a *center of inertia* (COI). A model that is valid for reasonable frequency deviations is described below.

We start with the swing equation (torque version) in pu,

$$\dot{\omega}_i = \frac{1}{2H_i}(T_{mi} - T_{ei}) \tag{5.282}$$

The initial condition for (5.282) is the pre-disturbance frequency, which is assumed equal to the rated frequency  $\omega_i(t_0) = \omega_0$ . The angular frequency deviation

$\Delta\omega_i$  is given by

$$\Delta\omega_i = \omega_i - \omega_0, \tag{5.283}$$

which, in SI units, yields

$$\frac{2H_i S_{ni}}{\omega_0} \Delta\dot{\omega}_i = \frac{\omega_0}{\omega_i} (P_{mi} - P_{ei}), \tag{5.284}$$

where, for each unit  $i$ ,  $S_n$  is the rated power,  $H$  is the constant of inertia, and  $P_m$  and  $P_e$  are the mechanical and electrical power, respectively. If we assume that it is a highly meshed system, all generating units can be assumed to be connected to the same bus. The COI frequency can be defined as

$$\omega = \frac{\sum_i H_i S_{ni} \omega_i}{\sum_i H_i S_{ni}} \tag{5.285}$$

**Fig. 5.91** Block diagram representing the inertia of the system

All generating units can be considered to be aggregated into a single unit

$$\Delta \dot{\omega} = \frac{\omega_0^2}{2HS_n} (P_m - P_e), \quad (5.286)$$

where:

$S_n = \sum_i S_{ni}$  is the total rating, i.e., the sum of the power ratings of the generators

$H = \sum_i H_i S_{ni} / \sum_i S_{ni}$  is the total constant of inertia

$P_m = \sum_i P_{mi}$  is the total mechanical power

$P_e = \sum_i P_{ei}$  is the total electrical power.

By assuming that  $\omega = \omega_0$  on the right-hand side, a linear approximation of (5.286),

$$\Delta \dot{\omega} = \frac{\omega_0}{2HS_n} (P_m - P_e), \quad (5.287)$$

can be obtained. Equation (5.284) can also be expressed in terms of frequency as

$$\Delta \dot{f} = \frac{f_0}{2HS_n} (P_m - P_e). \quad (5.288)$$

After a disturbance, we can write

$$\Delta \dot{f} = \frac{f_0}{2HS_n} (\Delta P_m - \Delta P_{load}), \quad (5.289)$$

where  $\Delta P_m$  and  $\Delta P_{load}$  denote the variations in the total mechanical and electrical power outputs (taking into account the variations in the system power losses) with respect to the respective steady-state values before the perturbation.

Equation (5.289) can be represented by the block diagram shown in Fig. 5.91, where  $s$  is the Laplace variable.

### 5.7.3 Frequency Dependence of the Load

The aggregated system load is clearly frequency dependent. This has a stabilizing effect on the system frequency  $f$ . In addition to a component that depends on  $f$ , large rotating motors provide a contribution that depends on the time derivative  $\dot{f}$  (known as the rate of change of the frequency, ROCOF) due to the change in

**Fig. 5.92** Model used for the frequency-dependent behavior of the aggregated load

the kinetic energy stored in the rotating masses of the motor. Both of these frequency dependences are incorporated into the load model

$$\Delta P_{load}^f = D_L \Delta f + g(\Delta \dot{f}). \quad (5.290)$$

The function  $g(\Delta \dot{f})$  can be derived by observing that the kinetic energy of rotating masses can be expressed by

$$W(f) = \frac{1}{2} J (2\pi f)^2 \quad (5.291)$$

and that  $\Delta W$  can be approximated by

$$\Delta W = \frac{2W_0}{f_0} \Delta f, \quad (5.292)$$

where  $W_0 = J/2(2\pi f_0)^2$ . Hence,

$$g(\Delta \dot{f}) = \frac{2W_0}{f_0} \Delta \dot{f}. \quad (5.293)$$

The values of  $W_0$  and  $D_L$  are highly dependent on the composition of the load and can vary over time. Typical values of the constant  $D_L$  are such that the load variation is between 0 and 2% of the frequency variation.

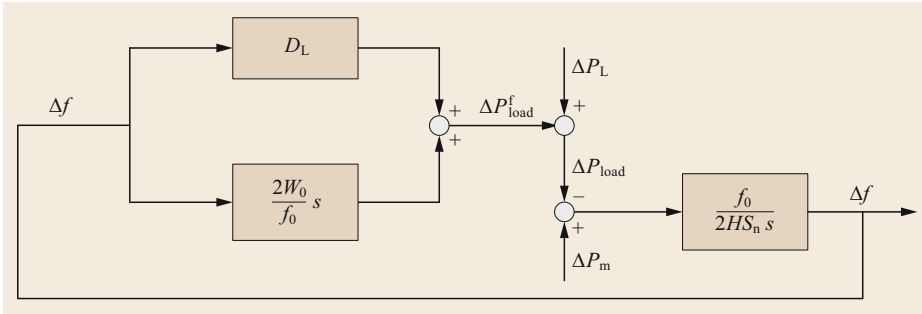

A model of the loads is provided in Fig. 5.92.

### 5.7.4 Dynamic Response of an Uncontrolled Power System

The model generated by combining the models used for the system inertia and the load is shown in Fig. 5.93.

Figure 5.94 shows the typical stable response of the frequency over time following an increasing or decreasing disturbance  $\Delta P_L$ .

The stabilizing effect of the frequency dependence of the load is generally too small to maintain the frequency within reasonable bounds.

**Fig. 5.93** Model of an uncontrolled system

**Fig. 5.94** Typical behavior of the frequency in the system shown in Fig. 5.93 after a perturbation

frequency control, the goal is to quickly return the frequency to acceptable values. However, even after primary control has acted, some of the frequency error will remain. Moreover, all of the generators must contribute to primary control, irrespective of the location of the disturbance.

In secondary frequency control (also called AGC or load frequency control), the power set points of the generators are adjusted in order to compensate for the frequency error remaining after the primary control has acted. Moreover, for large systems consisting of several control areas, the secondary control returns the power flows in the tie lines between the areas to the scheduled value.

Underfrequency load shedding is a form of system protection that acts on timescales of less than a second. As this scheme is only applicable when there is a loss of load across entire regions, it must only be activated when necessary to save the system from a blackout.

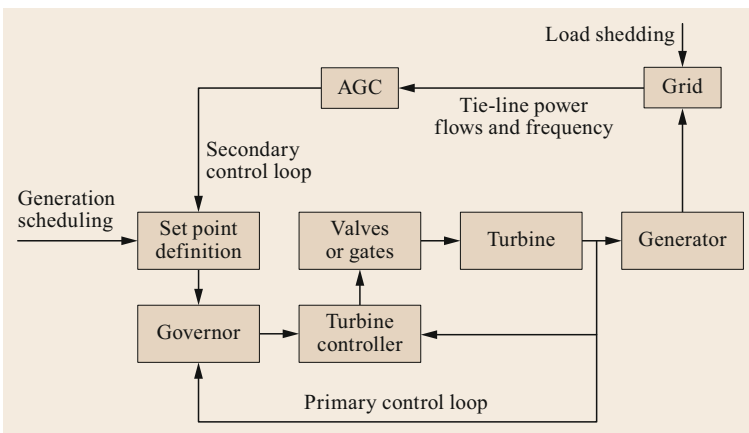

### 5.7.5 Control Structure for Frequency Control

The automatic control system consists of two main parts: primary control and secondary control, as shown in Fig. 5.95. Primary control refers to control actions that are performed locally (at the power plant) based on the set points for frequency and power. In primary

#### Dynamic Characteristics of Primary Control

The action of the governor for the generic unit  $i$  can be described by

$$(f_0 - f) \frac{1}{R_i} + (P_{m0,i}^{\text{set}} - P_{m,i}^{\text{set}}) = 0, \quad (5.294)$$

**Fig. 5.95** Structure of the frequency control system

**Fig. 5.96** Scheme of the turbine control loop

where  $R_i$  is the speed droop (in Hz/MW), which typically ranges from 4% to 8%.

Assuming an integral turbine power controller, we obtain the scheme depicted in Fig. 5.96.

If the dynamics of the turbine are neglected, we get

$$\Delta P_{m,i}(s) = \frac{1}{1 + T_i s} [\Delta P_{m0,i}^{set}(s) + \Delta P_{m,i}^{set}(s)], \quad (5.295)$$

where the time constant  $T_i = 1/K_i$  is small compared to the frequency dynamics of the system.

By defining

$$\frac{1}{R} = \sum_i \frac{1}{R_i}, \quad (5.296)$$

we get

$$\Delta P_{m,i}^{set} = -\frac{1}{R} \Delta f, \quad (5.297)$$

where  $\Delta P_m^{set} = \sum_i \Delta P_{m,i}^{set}$  and  $\Delta f$  is the frequency variation of the COI.

The models for the turbine control and the governor can be inserted into the model derived in the previous section, as shown in Fig. 5.97.

**Fig. 5.98** Typical response of the system with primary control

We now analyze the effect of a disturbance in the system above. Both a loss of generation and a loss of load can be simulated by imposing a positive or negative step input on the variable  $\Delta P_L$ . For obvious reasons, a change in the set value of the system frequency  $f_0$  is not considered here.

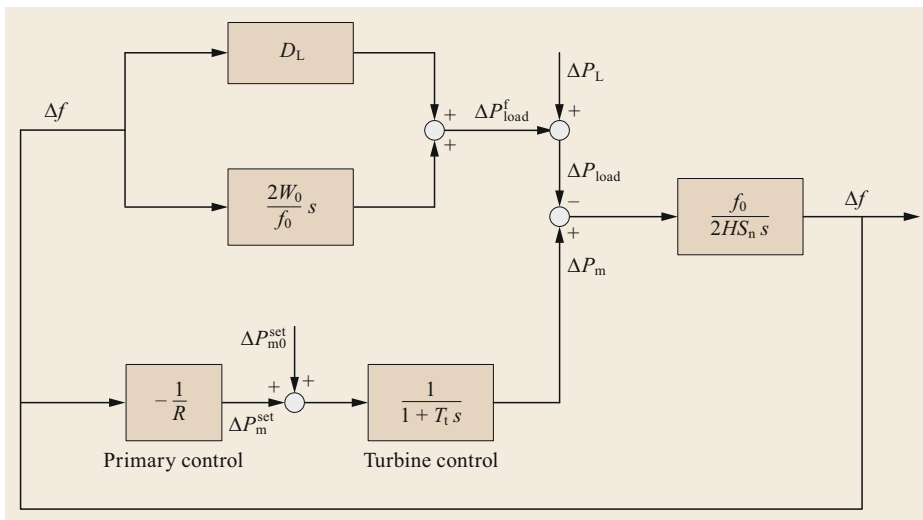

From the block diagram shown in Fig. 5.100, the transfer function between  $\Delta P_L$  and  $\Delta f$  ( $\Delta P_m^{set} = 0$ ) is

$$\Delta f(s) = -\frac{1 + sT_t}{\left[ \frac{1}{R} + D_L(1 + sT_t) + \left( \frac{2W_0}{S_n} + 2H \right) \frac{S_n}{f_0} s(1 + sT_t) \right]} \Delta P_L(s). \quad (5.298)$$

The step response for  $\Delta P_L(s) = \Delta P_L/s$  is illustrated in Fig. 5.98.

The frequency deviation in the steady state is

$$\Delta f_\infty = \lim_{s \rightarrow 0} (s \Delta f_s) = -\frac{\Delta P_L}{\frac{1}{R} + D_L}. \quad (5.299)$$

**Fig. 5.97** Model of the system with primary control

Fig. 5.99 Scheme for a two-area system

In real systems, the turbine controller time constant  $T_t$  is much smaller than the time constant of the frequency dynamics  $T_M$  presented in Fig. 5.94, so

$$T_M = \frac{2W_0}{S_n} + 2H. \quad (5.300)$$

Transfer function (5.298) can be approximated as

$$\Delta f(s) = -\frac{1}{1 + \frac{S_n}{f_0} T_M \frac{1}{R + D_L} s} \frac{\Delta P_{L,1}(s)}{\frac{1}{R} + D_L}. \quad (5.301)$$

The equivalent time constant for a step response is

$$T_{eq} = T_M \frac{S_n}{f_0} \frac{1}{\frac{1}{R} + D_L}. \quad (5.302)$$

#### Dynamic Model of a Two-Area System

In practice, a large interconnected power system is always divided into various control blocks or areas. For a simplified analysis, a system with two areas can be represented by two single bus systems with a tie-line between them, as shown in Fig. 5.99.

If we assume that  $|V_1|$  and  $|V_2|$  are constant and ignore the power loss in the tie-line, the power exchange  $P_{12}$  over the tie-line is

$$P_{12} = \frac{|V_1||V_2|}{x} \sin(\theta_1 - \theta_2), \quad (5.303)$$

where  $x$  is the equivalent reactance of the tie line and  $\theta_1$  and  $\theta_2$  are the voltage angles.

For small deviations, we obtain

$$\begin{aligned} \Delta P_{12} &= \left. \frac{\partial P_{12}}{\partial \theta_1} \right|_0 \Delta \theta_1 + \left. \frac{\partial P_{12}}{\partial \theta_2} \right|_0 \Delta \theta_2 \\ &= \frac{|V_1||V_2|}{x} \cos(\theta_1^0 - \theta_2^0) (\Delta \theta_1 - \Delta \theta_2) \end{aligned} \quad (5.304)$$

or

$$\Delta P_{12} = P_T (\Delta \theta_1 - \Delta \theta_2) \quad (5.305)$$

with

$$P_T = \frac{|V_1||V_2|}{x} \cos(\theta_1^0 - \theta_2^0). \quad (5.306)$$

Using this model, the block diagram of the power system can be extended as shown in Fig. 5.100.

We now study the behavior after a load change in area 1, where area 1 is considered to be much smaller than area 2, which can be regarded as an infinite bus. As  $\Delta f_2 = 0$ ,  $\Delta \theta_2 = 0$ , so

$$\Delta P_{12} = 2\pi P_T \int \Delta f_1 dt. \quad (5.307)$$

Without any generator setpoint changes (i.e.,  $\Delta P_{m0,1}^{\text{set}} = 0$ ), the transfer functions for a change of  $\Delta P_{L,1}(s)$  are

$$\Delta f_1(s) = -\frac{s}{\left[ 2\pi P_T + \left( D_{L1} \frac{1}{R_1(1+sT_{t1})} \right) s + \left( \frac{T_{M1} S_{n1}}{f_0} \right) s^2 \right]} \Delta P_{L,1}(s) \quad (5.308)$$

$$\Delta T_{12} = \frac{2\pi P_T}{s} \Delta f_1(s) \quad (5.309)$$

$$\Delta T_{12}(s) = -\frac{2\pi P_T}{\left[ 2\pi P_T + \left( D_{L1} \frac{1}{R_1(1+sT_{t1})} \right) s + \left( \frac{T_{M1} S_{n1}}{f_0} \right) s^2 \right]} \Delta P_{L,2}(s). \quad (5.310)$$

The step response for  $\Delta P_{L,1}(s) = \Delta P_{L,1}/s$  is shown in Fig. 5.101.

The steady-state frequency deviation is

$$\Delta f_\infty = \lim_{s \rightarrow 0} s \Delta f_1(s) = 0, \quad (5.311)$$

and the steady-state deviation of the tie-line power is

$$\Delta P_{12\infty} = \lim_{s \rightarrow 0} s \Delta P_{12}(s) = \Delta P_{L,1}. \quad (5.312)$$

The infinite bus brings the frequency deviation  $\Delta f_1$  back to 0. This is achieved by increasing  $P_{21}$  such that the load variation  $\Delta P_{L,1}$  is fully compensated for.

While this is beneficial for the system frequency in area 1, unscheduled and persistent energy exchange has arisen between the two areas.

#### Automatic Generation Control

Following the application of primary frequency control after a disturbance, a static frequency error will generally persist unless additional control actions are taken.

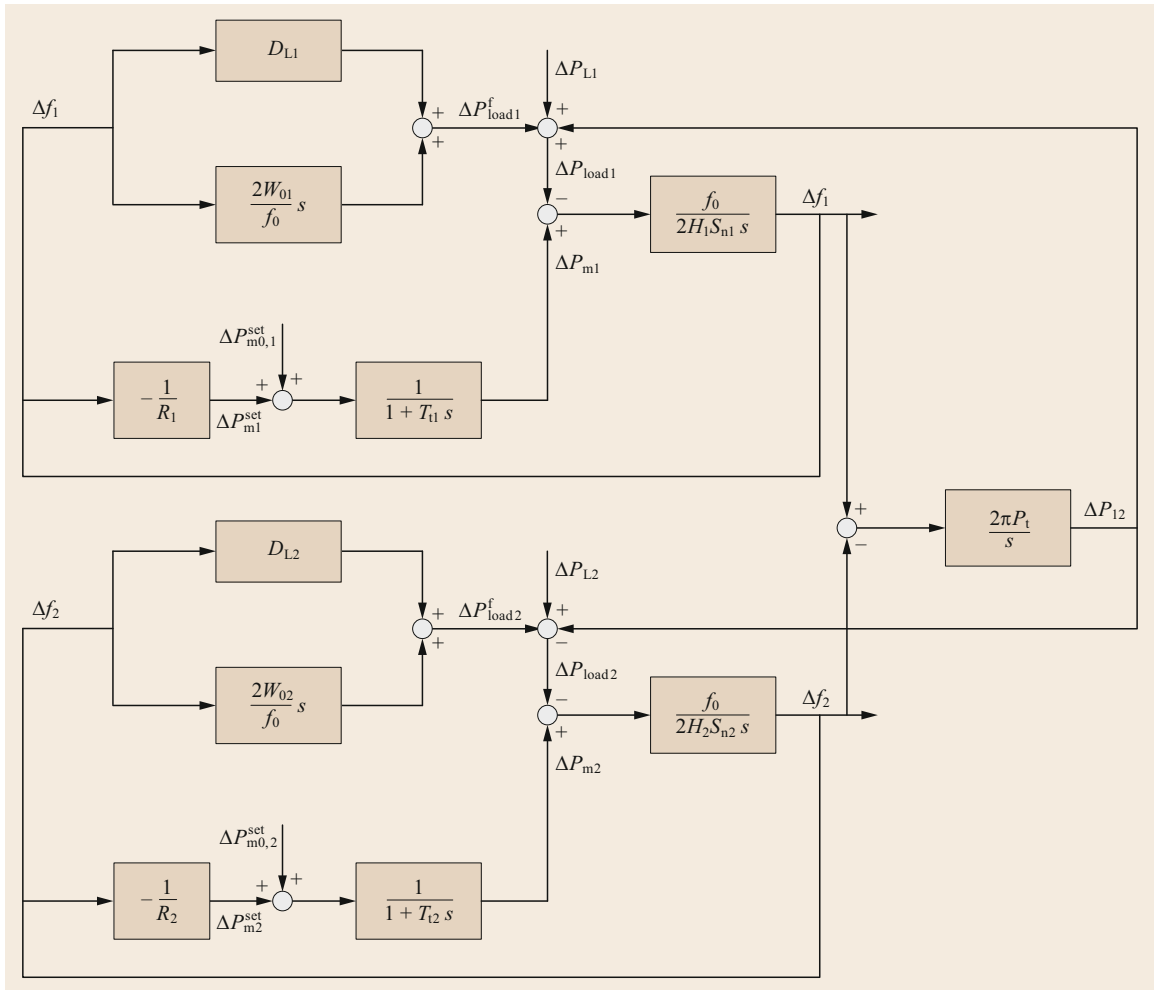

Fig. 5.100 Dynamic model of a two-area system

Fig. 5.101 Step response of the two-area system model

Furthermore, primary frequency control may change the scheduled interchanges between different areas in an interconnected system. The restoration of both the

frequency and the power interchanges to their pre-disturbance values is accomplished through the AGC.

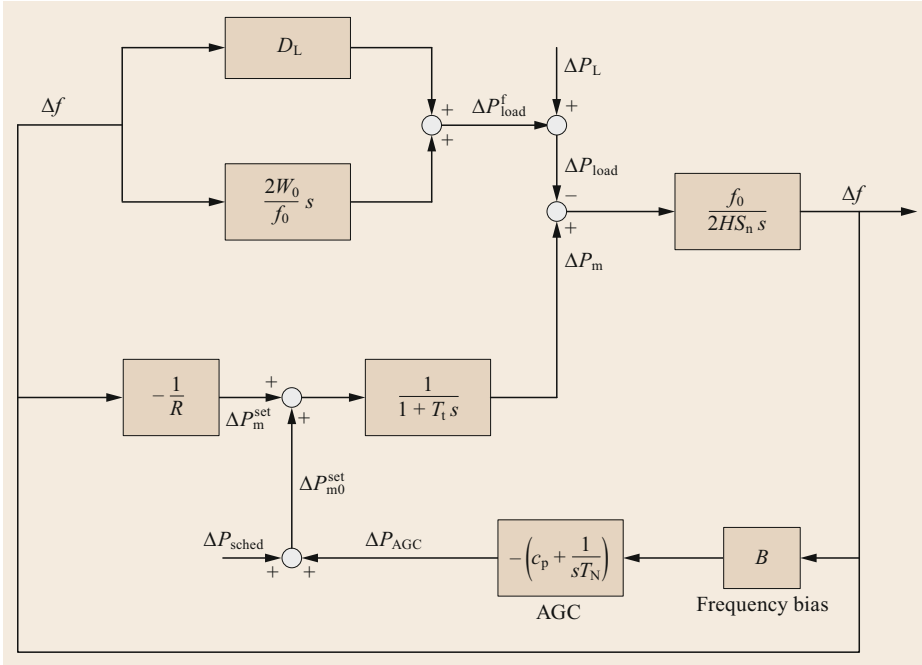

In an  $N$ -area system, there are  $N$   $AGC_i$  controllers, one for each area  $i$ . Each implements a proportional-integral (PI) controller, i.e.,

$$\Delta P_{AGC_i} = - \left( C_{P_i} + \frac{1}{s T_{N_i}} \right) \Delta e_i, \quad (5.313)$$

with  $C_{P_i}$  typically ranging between 0.1 and 1 and  $T_{N_i}$  between 30 and 200 s, implying that AGC reacts much more slowly than primary frequency control.

The error  $\Delta e_i$  is termed the area control error (ACE) for area  $i$ , and

$$ACE_i = \sum_{j \in \Omega_i} (P_{ij} - P_{ij}^0) + B_i (f_i - f_0), \quad (5.314)$$

**Fig. 5.102** Model of a single-area system with AGC

**Fig. 5.103** Step response of a single-area system with AGC

where  $P_{ij}$  is the power transfer from area  $i$  to area  $j$  and  $P_{ij}^0$  is the corresponding scheduled value. Defining

$$\Delta P_i = \sum_{j \in \Omega_i} (P_{ij} - P_{ij}^0), \tag{5.315}$$

where the summation includes all of the areas  $j$  directly connected to area  $i$ ,  $ACE_i$  can be written as

$$ACE_i = \Delta P_i + B_i(f_i - f_0). \tag{5.316}$$

The constant  $B_i$  is called the frequency bias factor (MW/Hz). It is assumed that the frequency references are the same in all areas. The goal is to bring all  $ACE_i$  values to 0.

The variables are thus  $\Delta P_i$  and  $f$ , i.e., there are  $N + 1$  variables in total, which are uniquely defined by  $N$

linear equations ( $ACE_i = 0$ ) and

$$\sum_i \Delta P_i = 0. \tag{5.317}$$

### Selection of Frequency Bias Factors

Let us consider a two-area system. The load is increased by  $\Delta P_L$  in area 2. If the power in the tie-line is to be kept constant, the generation in area 2 must be increased by  $\Delta P_L$  after the AGC has reacted. Before the AGC has reacted, we have a frequency deviation of  $\Delta f$  in both areas, which means that for area 1,

$$\Delta f = -R_1 \Delta P_{12}, \tag{5.318}$$

and for area 2,

$$\Delta f = -R_2(\Delta P_L - \Delta P_{12}), \tag{5.319}$$

and  $\Delta P_{12} = \Delta P_{21}$ . The two ACEs can now be written as

$$\begin{aligned} ACE_1 &= \Delta P_{12} + B_1 \Delta f = \Delta P_{12} + B_1(-R_1 \Delta T_{12}) \\ &= \Delta P_{12}(1 - B_1 R_1) \end{aligned} \tag{5.320}$$

and

$$\begin{aligned} ACE_2 &= \Delta P_{21} + B_2 \Delta f \\ &= \Delta P_{21} + B_2[-R_2(\Delta P_L - \Delta P_{12})] \\ &= \Delta P_{12}(1 - B_2 R_2) - B_2 R_2 \Delta P_L \end{aligned} \tag{5.321}$$

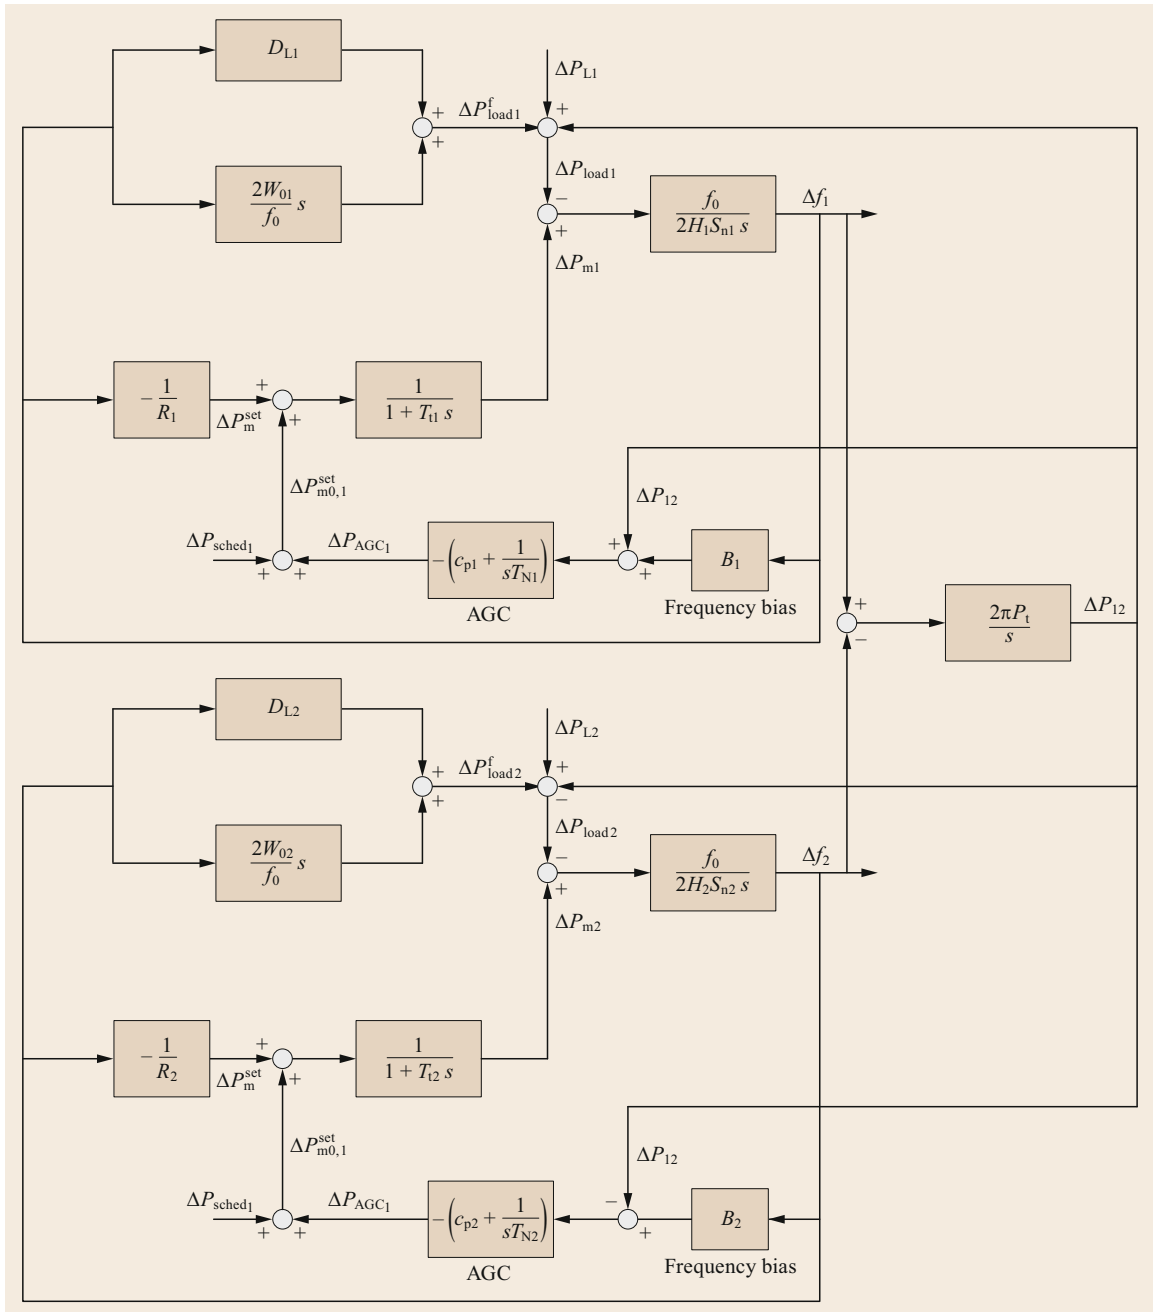

Fig. 5.104 Model of a two-area system with AGC

In this case, it is desirable that the AGC controller for area 1 should not react. If we set  $B_1 = 1/R_1$ , we can see from (5.320) that  $ACE_1 = 0$ . If  $B_2 = 1/R_2$  is chosen, the ACE in area 2 becomes

$$ACE_2 = -\Delta P_L. \tag{5.322}$$

This means that only controller 2 reacts to a load perturbation  $\Delta P_L$  in the same area.

In the multi-area case, this corresponds to selecting  $B_i = 1/R_i$  for all areas, which is known as noninteractive control. However, for the controller described by (5.313), all positive values of  $B_i$  will guarantee that all

**Fig. 5.105** Step response of a two-area system model with AGC ▶

the  $ACE_i$  tend to 0. The application of noninteractive control results in reduced control effort and costs.

#### Dynamic Characteristics of AGC

We now include the AGC control in both the single-area and two-area models.

#### Single-Area System

AGC only acts to restore the nominal system frequency, as illustrated in Fig. 5.102, where  $P_{\text{sched}}$  indicates the scheduled value of the power output of the generators. Figure 5.103 shows how the system frequency response is brought back to the rated value after a load increase.

#### Two-Area System

A model of a two-area system with AGC is shown in Fig. 5.104.

If area 1 is assumed to be much smaller than area 2, the step response of the system for a load increase

of  $\Delta P_{L,1}$  is shown in Fig. 5.105. Due to the action of AGC, the perturbation in area 1 is fully compensated for by the generators in the same area (area 1) after the transients have decayed.

## 5.8 Propagation of Electromagnetic Transients Along Transmission Lines

In *steady-state* operating conditions, the wavelength of the sinusoidal currents and voltages is large compared with the physical dimensions of the network. Therefore, for steady-state analysis, a *lumped* element representation of transmission lines is generally adequate. However, for transient analysis, this is no longer the case, and the travel time of the electromagnetic waves must be taken into account.

For example, in the case of insulation coordination analysis against overvoltages (particularly those due to lightning), we need to account for the fact that voltages and currents induced by lightning strikes have non-negligible frequency contents above 1 MHz. If the travel time of the electromagnetic field within the boundaries of the region of interest cannot be neglected with respect to the period over which electromagnetic quantities vary, then the lumped element model must be replaced in order to accurately represent electromagnetic field propagation along the line. Although the electric field cannot be expressed as the gradient of a scalar potential in our analysis of the electromagnetic field along lossless transmission lines, we can assume a transverse electromagnetic mode (TEM) of propagation (i.e., no component of the electric field or the magnetic field in the direction of propagation), so the rotor of the electric field is null in each plane orthog-

onal to the direction of propagation. This means that the integrals of the electric field in these planes can be expressed as potential differences. For lossy lines, and assuming a quasi-transverse electromagnetic mode of propagation, we can still apply the useful concepts of phase-to-ground and line-to-line voltages. In the quasi-TEM approximation, it is assumed that the electric and magnetic field components along the line are non-null but small enough to make the rotor of the electric field practically null in the plane orthogonal to the line.

Research into electromagnetic transients along transmission lines and relevant phenomena has developed impressively since the introduction of the Electromagnetic Transients Program [5.8] developed by *Herman Dommel* in the 1970s, and there have been various textbooks devoted to this subject [5.27, 28, 53, 54]. In this section, we limit our discussion to a brief summary of the basic concepts.

### 5.8.1 Traveling Waves in a Lossless Line

In order to introduce the equations describing the response of a transmission line to a transient, we consider a single line conductor that has ground return and is at a constant height above the ground (Fig. 5.106). The developments that follow are somewhat inspired

**Fig. 5.106** A single line-conductor section and the path of integration of the electric field that passes through the line

by [5.55], except that we consider a voltage source at one of the line terminations rather than an overhead line excited by an external electromagnetic field. The following approach can also be applied to a line consisting of two straight conductors that are parallel to each other.

Let us assume a triplet of Cartesian orthogonal axes  $x$ ,  $y$ , and  $z$ , where the  $x$ -axis is parallel to the axis of the line conductor that lies in the  $x$ - $z$  plane. The line height is  $z = h$ . The current in the line conductor is assumed to be positive if it is directed along the positive  $x$ -axis. Let us consider a closed path  $\Gamma$  that passes through the line and the ground (which lies in the  $x$ - $y$  plane), with vertical sections perpendicular to the ground. Let the path  $\Gamma$  be oriented according to the  $y$ -axis and the right-hand rule. The integral of the electric field along  $\Gamma$  is given by

$$\oint_{\Gamma} \bar{E} d\bar{l} = \int_0^h E_z(x_1, 0, z, t) dz + \int_{x_1}^{x_2} E_x(x, 0, h, t) dx - \int_0^h E_z(x_2, 0, z, t) dz - \int_{x_1}^{x_2} E_x(x, 0, 0, t) dx \quad (5.323)$$

If the conductors are ideal (i.e., both the line and the ground have infinite conductivity), the electric field components along  $x$  are null, so

$$\oint_{\Gamma} \bar{E} d\bar{l} = \int_0^h E_z(x_1, 0, z, t) dz - \int_0^h E_z(x_2, 0, z, t) dz \quad (5.324)$$

Assuming TEM propagation, the integrals of the electric field in the  $y$ - $z$  plane can be expressed as differences in scalar potentials. Therefore, assuming that the potential is zero at the ground, the integral of  $E$  along  $\Gamma$  can

be written as

$$\oint_{\Gamma} \bar{E} d\bar{l} = u(x_2, t) - u(x_1, t) \quad (5.325)$$

The law of electromagnetic induction

$$\oint_{\Gamma} \bar{E} d\bar{l} = -\frac{\partial}{\partial t} \int_{S_{\Gamma}} \bar{B} d\bar{S} \quad (5.326)$$

where  $B$  is the magnetic flux density and  $S_{\Gamma}$  is any surface with  $\Gamma$  as a contour, gives

$$u(x_2, t) - u(x_1, t) = -\frac{\partial}{\partial t} \int_{x_1}^{x_2} \int_0^h B_y(x, 0, z, t) dx dz \quad (5.327)$$

By taking  $x_2 = x_1 + \Delta x$ , where  $\Delta x$  is small, we can write

$$\int_{x_1}^{x_2} \int_0^h B_y(x, 0, z, t) dx dz = \int_0^h B_y(x_1, 0, z, t) dz \Delta x \quad (5.328)$$

where

$$\int_0^h B_y(x_1, 0, z, t) dz = L' i(x_1, t) \quad (5.329)$$

in which  $L'$  is the line inductance pu length.

We can then write

$$u(x_1 + \Delta x, t) - u(x_1, t) = -\frac{\partial}{\partial t} [L' i(x_1, t) \Delta x] \quad (5.330)$$

Dividing by  $\Delta x$  and assuming that the line is nondeformable, we get

$$\frac{u(x_1 + \Delta x, t) - u(x_1, t)}{\Delta x} = -L' \frac{\partial i(x_1, t)}{\partial t} \quad (5.331)$$

By taking the limit as  $\Delta x$  approaches zero, we obtain the first telegrapher's equation,

$$\frac{\partial u(x_1, t)}{\partial x} = -L' \frac{\partial i(x_1, t)}{\partial t} \quad (5.332)$$

Let us now consider a cylindrical surface surrounding the  $\Delta x$  section of the line conductor (Fig. 5.107). We denote the base surfaces orthogonal to the plane  $y$ - $z$  at  $x_1$  and  $x_2$  as  $S_1$  and  $S_2$ , respectively, and label the lateral surface as  $S_l$ .

The flux of the current density through the cylindrical surface has three components, i.e.,

$$\oint \bar{J} d\bar{S} = -\int_{S_1} J_x dS + \int_{S_l} \bar{J} d\bar{S} + \int_{S_2} J_x dS \quad (5.333)$$

**Fig. 5.107** A single line-conductor section and the surface of integration of the current density

If the insulating medium surrounding the conductor is ideal (i.e., it has null conductivity), the radial component of the current density is null, so

$$\oint \bar{J} d\bar{S} = - \int_{S_1} J_x dS + \int_{S_2} J_x dS. \quad (5.334)$$

The fluxes of the current density through  $S_1$  and  $S_2$  are the line currents at  $x_1$  and  $x_2$ ; therefore,

$$\oint \bar{J} d\bar{S} = i(x_2, t) - i(x_1, t). \quad (5.335)$$

The law of charge conservation

$$\oint_S \bar{J} d\bar{S} = - \frac{\partial}{\partial t} \int_{\tau_S} \rho d\tau, \quad (5.336)$$

where  $\rho$  is the charge density and  $\tau_S$  is the volume with  $S$  as a boundary, gives

$$i(x_2, t) - i(x_1, t) = - \frac{\partial}{\partial t} [C' u(x_1, t) \Delta x], \quad (5.337)$$

where  $C'$  is the line capacitance pu length. By taking  $x_2 = x_1 + \Delta x$ , where  $\Delta x$  is small, we can write

$$\frac{i(x_1 + \Delta x, t) - i(x_1, t)}{\Delta x} = -C' \frac{\partial u(x_1, t)}{\partial t}. \quad (5.338)$$

Taking the limit as  $\Delta x$  approaches zero, we obtain the second telegrapher's equation

$$\frac{\partial i(x_1, t)}{\partial x} = -C' \frac{\partial u(x_1, t)}{\partial t}. \quad (5.339)$$

Rewriting the two telegrapher's equations with reference to a generic abscissa  $x$  yields

$$\frac{\partial u(x, t)}{\partial x} + L' \frac{\partial i(x, t)}{\partial t} = 0 \quad (5.340)$$

$$\frac{\partial i(x, t)}{\partial x} + C' \frac{\partial u(x, t)}{\partial t} = 0. \quad (5.341)$$

By differentiating the first wave equation with respect to  $x$  and the second with respect to  $t$  and using substitution, we obtain

$$\frac{\partial^2 u(x, t)}{\partial x^2} = L' C' \frac{\partial^2 i(x, t)}{\partial t^2}. \quad (5.342)$$

Differentiating the first wave equation with respect to  $t$  and the second with respect to  $x$  and using substitution, we get an analogous equation for the current,

$$\frac{\partial^2 i(x, t)}{\partial x^2} = L' C' \frac{\partial^2 u(x, t)}{\partial t^2}. \quad (5.343)$$

Both of these equations have the form of the 1-D (one-dimensional) wave equation

$$\frac{\partial^2 f(x, t)}{\partial x^2} = \frac{1}{v^2} \frac{\partial^2 f(x, t)}{\partial t^2}, \quad (5.344)$$

where  $v$  is the speed of the wave in the direction of propagation.

Therefore, the telegrapher's equations describe the propagation of the voltage and the current along a transmission line. It is worth noting that the propagation speed, given by

$$v = \frac{1}{\sqrt{L' C'}}, \quad (5.345)$$

for a lossless line is practically equal to the speed of light. In fact, for a single line conductor of radius  $R$  and height  $h$  above the perfectly conducting ground,

$$L' = \frac{\mu_0}{2\pi} \ln \left( \frac{2h}{R} \right) \quad (5.346)$$

$$C' \approx \frac{2\pi\epsilon_0}{\ln(2h/R)}. \quad (5.347)$$

Inserting this into (5.345) gives

$$v = \frac{1}{\sqrt{\mu_0 \epsilon_0}}. \quad (5.348)$$

According to D'Alembert, the solution to the 1-D wave equation is

$$f(x, t) = f_1(x - vt) + f_2(x + vt), \quad (5.349)$$

where  $f_1$  is a forward-traveling wave (i.e., a wave traveling in the positive  $x$  direction) while  $f_2$  is a backward-traveling wave (i.e., a wave traveling in the negative  $x$  direction).

It is easy to verify that (5.349) is a solution of (5.344) by observing that

$$\begin{aligned}\frac{\partial f_1(x-vt)}{\partial t} &= -v \frac{\partial f_1(x-vt)}{\partial x} \\ \frac{\partial f_2(x+vt)}{\partial t} &= v \frac{\partial f_2(x+vt)}{\partial x}.\end{aligned}\quad (5.350)$$

We then find that the solution of the wave equation for the voltage takes the form

$$u(x, t) = u_1(x - vt) + u_2(x + vt), \quad (5.351)$$

and that there is an analogous equation for the current,

$$i(x, t) = i_1(x - vt) + i_2(x + vt). \quad (5.352)$$

These two solutions are not independent; in fact, the relationship between forward and backward voltage and current waves can be shown (via substitution and differentiation) to be

$$\begin{aligned}i_1(x) &= \frac{u_1(x)}{Z_0} \\ i_2(x) &= -\frac{u_2(x)}{Z_0},\end{aligned}\quad (5.353)$$

where  $Z_0$  is the surge impedance of the line, given by

$$Z_0 = \sqrt{\frac{L'}{C'}}. \quad (5.354)$$

Substituting (5.346) and (5.347) into (5.354) yields

$$Z_0 = 60 \ln \left( \frac{2h}{R} \right) \quad (5.355)$$

for a single lossless line conductor.

It is worth noting that  $u_1(\xi)$  with  $\xi = x - vt$  represents a forward-traveling wave, because  $\xi$  assumes the same value at  $x_0$  and time  $t_0$  as it does at  $x_0 + v\Delta t$  and time  $t_0 + \Delta t$ , and that an observer traveling forward at speed  $v$  would see the same voltage value.

A forward-traveling voltage wave is shown schematically in Fig. 5.108.

The same approach can be adopted for backward-traveling waves.

Note that it is changes in charge density that travel at the propagation speed  $v$ , not the charges themselves.

Fig. 5.108 Schematic of a forward-traveling voltage wave (adapted from [5.36])

In the absence of an external electromagnetic field coupled with the transmission lines, the traveling voltage and current waves depend on the boundary conditions at the line terminations (i.e., energizations, surge impedance discontinuities, loads, etc.).

Figure 5.109 presents four simple cases involving traveling waves: forward-traveling waves at the top and backward-traveling waves at the bottom with different polarities. According to (5.353), forward-traveling voltage and current waves have the same polarity, while backward-traveling voltage and current waves have opposite polarities.

## 5.8.2 Reflection and Transmission Coefficients

We now consider a discontinuity in the surge impedance of the line. Such a discontinuity may occur where there is a change in geometric size or a junction of a cable line with an overhead line that has bare conductors, or where there is a busbar with several lines connected, or where lumped devices are connected (e.g., a load or a transformer or a surge-protection device). When the traveling waves reach such a discontinuity, reflection and transmission (or refraction) processes occur due to the principle of energy conservation, and new voltage and current waves start to travel away from that point.

If the point of discontinuity  $M$  connects two lines  $L_1$  and  $L_2$  with different surge impedances  $Z_1$  and  $Z_2$ , a pair of incident voltage and current waves  $v_i$  and  $i_i$  from  $L_1$  give rise to a pair of transmitted waves  $v_t$  and  $i_t$  that travel forward along  $L_2$  as well as a pair of reflected waves  $v_r$  and  $i_r$  that travel backward along  $L_1$ .

The voltage and the current at the point of discontinuity must obey the equations (see also Fig. 5.110)

$$u_i + u_r = u_t \quad (5.356)$$

$$i_i + i_r = i_t. \quad (5.357)$$

If we define the transmission coefficient  $\tau_v$  as the ratio of  $v_t$  to  $v_i$  and the reflection coefficient  $\rho_v$  as the

**Fig. 5.109a-d** Schematic of four combinations of forward- and backward-traveling voltage and current waves: (a) positive forward-traveling waves, (b) negative forward-traveling waves, (c) negative backward-traveling current wave, (d) positive backward-traveling current wave (adapted from [5.28])

**Fig. 5.110** Voltage waves reflected and transmitted at a point of discontinuity in the surge impedance (adapted from [5.36])

ratio of  $v_r$  to  $v_i$ , (5.356) yields

$$1 + \rho_v = \tau_v \tag{5.358}$$

Analogously, we can define the transmission coefficient  $\tau_i$  as the ratio of  $i_t$  to  $i_i$  and the reflection coefficient  $\rho_i$  as the ratio of  $i_r$  to  $i_i$ .

Inserting (5.353) into (5.357) gives

$$\frac{u_i}{Z_1} - \frac{u_r}{Z_1} = \frac{u_t}{Z_2} \tag{5.359}$$

By adding and subtracting each member of (5.356) and (5.359), we obtain

$$u_t = \frac{2Z_2}{Z_1 + Z_2} u_i \tag{5.360}$$

$$u_r = \frac{Z_2 - Z_1}{Z_2 + Z_1} u_i \tag{5.361}$$

Therefore, the transmission coefficient  $\tau_v$  is

$$\tau_v = \frac{2Z_2}{Z_1 + Z_2} \tag{5.362}$$

while the reflection coefficient  $\rho_v$  is

$$\rho_v = \frac{Z_2 - Z_1}{Z_1 + Z_2} \tag{5.363}$$

Analogously, the transmission coefficient  $\tau_i$  is

$$\tau_i = \frac{2Z_1}{Z_1 + Z_2} \tag{5.364}$$

and the reflection coefficient  $\rho_i$  is

$$\rho_i = \frac{Z_1 - Z_2}{Z_2 + Z_1} \tag{5.365}$$

Line terminations are line discontinuities that give rise to surge wave reflections. For an ideal lossless line that is terminated on a resistive lumped device, these reflections can easily be explained using reflection and transmission coefficients, as they are constant and scalar in this case. The reflections at a short-circuited end and at an open end can be considered a particular case of resistive termination, as illustrated below.

The surge response at a generic line termination can be calculated via Thévenin's theorem so long as reflections at the far termination of a line of finite length do not influence phenomena at the termination of interest within the considered observation time.

The system corresponding to (5.356), (5.357), and (5.353), i.e.,

$$\begin{cases} u_i + u_r = u_t \\ i_i + i_r = i_t \\ u_t = Z_2 i_t \\ u_r = -Z_1 i_r \end{cases} \tag{5.366}$$

yields

$$2v_i - Z_1 i_t = u_t \tag{5.367}$$

which is the equation of a Thévenin equivalent circuit with a no-load voltage of  $2v_i$  and an equivalent impedance of  $Z_1$ .

Analogously, system (5.366) can also be solved for the incident current,

$$2i_i - \frac{u_t}{Z_1} = i_t. \tag{5.368}$$

This corresponds to a Norton equivalent circuit with a short-circuit current of  $2i_i$  and an equivalent conductance of  $1/Z_1$ .

### Reflections at an Open Termination

An incident voltage wave undergoes complete reflection at an open termination. Superposition of the incident wave on a reflected wave of the same amplitude and polarity produces voltage doubling at the line termination. On the other hand, the incident current wave is canceled out by a reflected wave of equal and opposite amplitude, thereby resulting in a null current overall at the open end. The amplitudes and polarities of the reflected voltage and current waves can be deduced by considering the boundary conditions and the energy balance at the line termination. Voltage doubling can be viewed as a consequence of the increase in electric energy associated with the cancellation of the current at the line termination, as well as the associated magnetic energy. The same results can be deduced by noting that an open end can be considered a termination on a device with a very large equivalent resistance. The surge impedance seen by the surge waves is therefore very large. By taking the limits of (5.361) and (5.365) as  $Z_2$  approaches infinity, we obtain  $\rho_v = 1$  and  $\rho_i = -1$ . Ultimately, we have  $v_t = 2v_i$ ,  $v_r = v_i$ ,  $i_t = 0$ , and  $i_r = -i_i$  at an open end. The effect of incident and reflected wave superposition at an open line end in the case of stepwise incident voltage and current waves is presented schematically in Fig. 5.111.

For a surge waveform of limited duration, superposition of the incident and reflected voltage waves only occurs close to the open end, and the ultimate effect of the reflection is a voltage with a mirrored waveform that propagates in the opposite direction. The case of a tri-

**Fig. 5.111a,b** Incident and reflected voltage waves (a) and current waves (b) at the open end of a transmission line (adapted from [5.36])

**Fig. 5.112a-c** A triangular voltage (a) before, (b) during, and (c) after reflection at the open end of a line (adapted from [5.36])

angular wave is presented in Fig. 5.112, which shows the diagram of the incident wave (ABC, propagating to the right) in Fig. 5.112a, the superposition of the diagram of the incident wave (ADM) on the wave  $C'B'DM$  (the mirror image of the wave  $CBDM$  with respect to the straight line  $m$ ), which gives rise to wave  $AFG$  in Fig. 5.112b, and the mirrored wave  $C'B'A'$  propagating to the left in Fig. 5.112c.

### Reflections at a Short-Circuited End

Another extreme case is a short-circuited end. An identical approach to that used for an open end can be applied for a short-circuited end, but with the behavior of the voltage and current waves swapped. An incident voltage wave undergoes complete but negative reflection, resulting in a null voltage overall at the short-circuited end, while the current amplitude doubles. The amplitudes and polarities of the reflected voltage and current waves can be deduced by considering the boundary conditions and the energy balance at the line termination, as well as by noting that a short-circuited end can be considered a termination on a device with very low resistance. Thus, by taking the limits of (5.361) and (5.365) as  $Z_2$  approaches zero, we obtain  $\rho_v = -1$  and  $\rho_i = 1$ . Ultimately, we have  $v_t = 0$ ,  $v_r = -v_i$ ,  $i_t = 2i_i$ , and  $i_r = 0$  at the short-circuited end. The effect of superposing the incident and reflected waves at a short-circuited line end in the case of stepwise incident voltage and current waves is presented schematically in Fig. 5.113.

**Fig. 5.113a,b** Incident and reflected voltage waves (a) and current waves (b) at the short-circuited end of a transmission line (adapted from [5.36])

**Reflections at an Inductive Termination**

Reflection at an inductive termination is similar to that at an open circuit immediately after the arrival of the incident wave, but ultimately resembles reflection at a short circuit. The voltages (in pu with respect to the amplitude of the voltage source) at three points along a 60 km line with a step voltage source at  $x = 0$  and a 25 mH inductance at  $x = 60$  km are depicted in Fig. 5.114. Figure 5.115 reports the voltage profiles along the line at three different times. The results presented in this and subsequent sections are obtained using a finite-difference time-domain solution of the telegrapher’s equations, and using Bergeron’s lines to solve the boundary conditions.

The waveform of the inductive terminal voltage can be justified by substituting the Laplace transform of the inductor constitutive equation

$$u_t(s) = Ls i_t(s) \tag{5.369}$$

into the Laplace transformation of (5.367), with

$$u(s) = \frac{E}{s} \tag{5.370}$$

**Fig. 5.114** Voltage waveforms along a 60 km line in the case of an inductive termination

**Fig. 5.115** Voltage profiles along a 60 km line at different times in the case of an inductive termination

This leads to

$$u_t(s) = E \frac{2T}{1 + Ts} \tag{5.371}$$

$$i_t(s) = \frac{E}{Z_1} \frac{2}{s(1 + Ts)} \tag{5.372}$$

where

$$T = \frac{L}{Z_1} \tag{5.373}$$

which correspond to

$$u_t(t) = 2Ee^{-\frac{t}{T}} \tag{5.374}$$

$$i_t(t) = \frac{2E}{Z_1} (1 - e^{-\frac{t}{T}}) \tag{5.375}$$

**Reflections at a Capacitive Termination**

Reflection at a capacitive termination is similar to that at a short circuit immediately after the arrival of the incident wave, but ultimately resembles reflection at an open circuit. The voltages (in pu with respect to the amplitude of the voltage source) at three points along a 60 km line with a step voltage source at  $x = 0$  and a 100 nF capacitance at  $x = 60$  km are presented in Fig. 5.116. Figure 5.117 shows the voltage profiles along the line at three different times.

The waveform of the capacitive terminal voltage can be justified by substituting the Laplace transform of the capacitor constitutive equation

$$u_t(s) = \frac{1}{Cs} i_t(s) \tag{5.376}$$

**Fig. 5.116** Voltage profiles along a 60 km line at different times in the case of a capacitive termination

**Fig. 5.117** Voltage waveforms along a 60 km line in the case of a capacitive termination

into the Laplace transformation of (5.367) and using (5.370), thus obtaining

$$u_t(s) = E \frac{2}{s(1 + Ts)} \tag{5.377}$$

$$i_t(s) = E \frac{2C}{1 + Ts} \tag{5.378}$$

where

$$T = CZ_1 \tag{5.379}$$

Finally, antitransforming these equations yields

$$u_t(t) = 2E \left( 1 - e^{-\frac{t}{T}} \right) \tag{5.380}$$

$$i_t(t) = \frac{2E}{T} e^{-\frac{t}{T}} \tag{5.381}$$

### 5.8.3 Multiple Reflections in a Line of Finite Length

In a line of finite length, the voltage and the current at a point along the line are obtained by superposing the waves traveling in both directions—the incident wave and the waves that have been reflected at the line ends. If one of the terminations is connected to an ideal voltage source, the voltage at that terminal will always be equal to the voltage impressed by the generator, meaning that any reflected wave that moves backward from the opposite end will be canceled out by the new reflection at the generator. In other words, the reflection coefficient at the generator side is equal to  $-1$ . In this section, we consider multiple reflections along the line in the extreme cases of open and short-circuited ends, as well as two cases of multiple reflection along a line with a resistive termination.

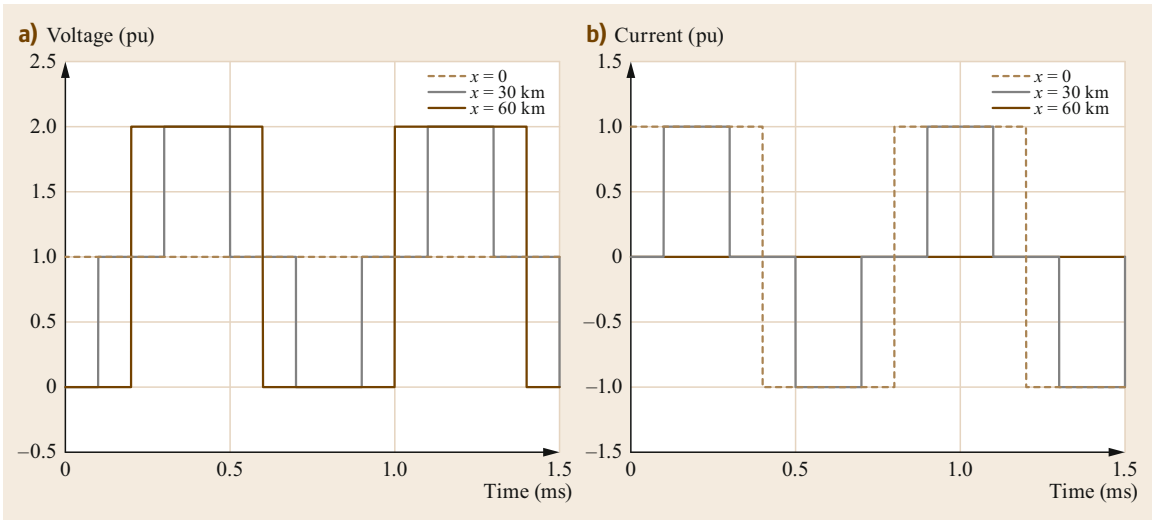

#### Open End

Figure 5.118 presents the case of a single conductor line of finite length  $d$  with one termination (A) connected to a DC voltage source and the other termination (M) kept open. The voltage reflection coefficients are 1 at A and  $-1$  at M. Therefore, the voltage is doubled at the open end and restored to the impressed voltage value  $E$  at the source. Due to the backward voltage wave reflected by the open end, the voltage along the line is  $2E$  so long as the doubling effect is canceled out by the

**Fig. 5.118** (a) The schematic depicts a single line conductor of finite length  $d$  with a DC voltage source at the left end (A) and an open right end (M), while the schematic in (b) shows the effect of multiple reflections on the voltage at the point a distance  $kd$  along the line from the powered end (adapted from [5.36])

**Fig. 5.119** (a) Voltages and (b) currents at different points along a 60 km line with a step voltage source at  $x = 0$  and an open end at  $x = 60$  km. Voltage/current values are in pu with respect to the incident voltage/current wave amplitude

forward voltage wave from the source, as illustrated in Fig. 5.119 for the terminal ends and the middle point of a 60 km line. The figure also shows the currents at the same points along the line; the waveform can be justified by observing that the current reflection coefficients are  $-1$  at the open end and  $1$  at the receiving end. The voltage and current waveforms along the line present oscillatory components that persist due to the assumed absence of dissipative elements along the line and at the line ends.

**Short-Circuited End**

Figure 5.120 presents the case of a single line conductor of finite length  $d$  with one termination (A) connected to a DC voltage source and the other termination (M) short-circuited. The voltage reflection coefficients are  $-1$  at both ends. Therefore, the voltage is canceled at

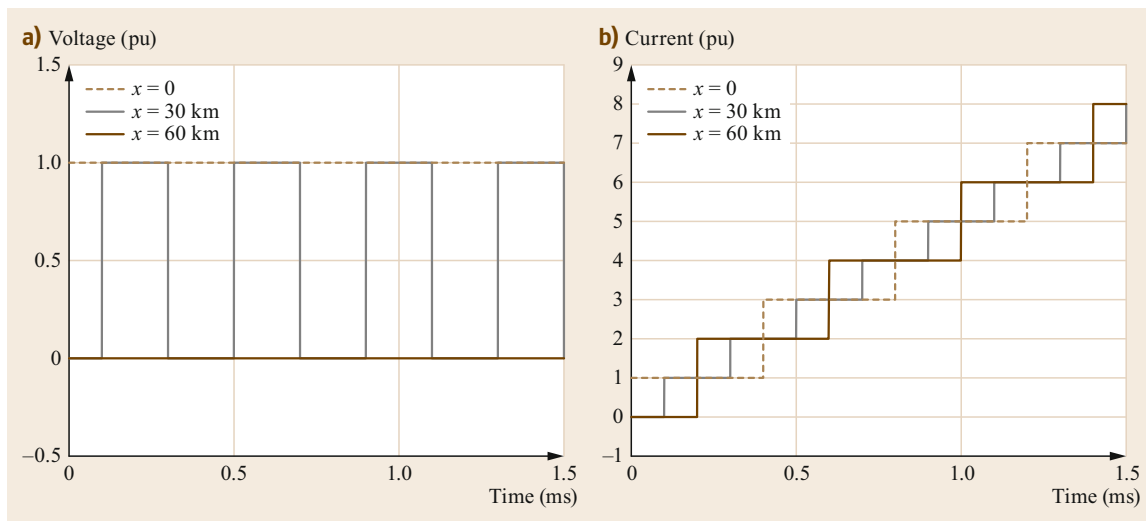

the short-circuited end and restored to the impressed voltage value  $E$  at the source. The voltage along the line is  $E$  so long as it is not canceled out by the backward voltage wave reflected at the short-circuited end, as illustrated in Fig. 5.121 for the terminal ends and the middle point of a 60 km line. The figure also shows the current at the same points; the waveform can be justified by observing that the current reflection coefficient is  $1$  at both ends.

**Resistive End**

Figure 5.122 presents the case of a single line conductor with one termination (A) connected to a DC voltage source and the other termination (M) feeding a resistance  $R$ . The diagram showing the reflected voltage waves refers to the case where  $R$  is equal to  $3Z$  ( $Z$  is the surge impedance of the line), which—according

**Fig. 5.120** (a) The schematic depicts a single line conductor of finite length  $d$  with a DC voltage source at the left end (A) and a short-circuited right end (M), while the schematic in (b) shows the effect of multiple reflections on the voltage at a point a distance  $kd$  along the line from the powered end (adapted from [5.36])

**Fig. 5.121** (a) Voltages and (b) currents at different points along a 60 km line with a step voltage source at  $x = 0$  and a short-circuited end at  $x = 60$  km. Voltage/current values are in pu with respect to the incident voltage/current wave amplitude

**Fig. 5.122** (a) The schematic depicts a single line conductor of finite length  $d$  with a DC voltage source at the left end (A) and a resistance  $R$  (which is three times larger than the surge impedance of the line,  $Z$ ) at the right end (M), while the schematic in (b) shows the effect of multiple reflections of the voltage at a point along the line (adapted from [5.36])

to (5.363)—gives a voltage reflection coefficient of 0.5 at M. The voltage coefficient is  $-1$  at A, just as in the previous cases. The backward-traveling voltage waves increase the voltages along the line, whereas the forward-traveling ones reflected by the source reduce them. The voltages along the line, and in particular the voltage at M (see Fig. 5.123), show an oscillatory trend with an overshoot with respect to the steady-state value. It is worth noting that the oscillations are not persistent as they are damped by the energy dissipation in  $R$ .

Figure 5.124 presents a case study that is similar to the previous one but with  $R$  equal to one-third of the surge impedance of the line  $Z$ , which gives—according to (5.363)—a voltage reflection coefficient of  $-0.5$  at M. In this case, the backward-traveling voltage

waves reduce the voltages along the line, whereas the forward-traveling ones reflected by the source increase them (due to the voltage reflection coefficient of  $-1$  at A). The voltages along the line, and in particular the voltage at M (see Fig. 5.125), show an increasing aperiodic trend towards the steady-state value.

### Sinusoidal Source

We now consider the case of a transmission line energized by an ideal 50 Hz sinusoidal voltage source. The voltages in the figures presented in this section are expressed in pu with respect to the amplitude of the voltage source, while the currents are given with respect to the amplitude of the incident current wave (i.e., the ratio of the voltage source amplitude to the surge impedance of the line).

**Fig. 5.123** (a) Voltages and (b) currents at different points along a 60 km line with a step voltage source at  $x = 0$  and a resistance that is three times the surge impedance at  $x = 60$  km. Voltage/current values are in pu with respect to the incident voltage/current wave amplitude

**Fig. 5.124** (a) The schematic depicts a single line conductor of finite length  $d$  with a DC voltage source at the left end (A) and a resistance  $R$  that is one-third the surge impedance of the line ( $Z$ ) at the right end (M), while the schematic in (b) shows the effect of multiple reflections of the voltage at a point along the line (adapted from [5.36])

Figures 5.126 and 5.127 present the voltage profiles along a 6000 km transmission line 1 ms before and 1 ms after the incident voltage wave reaches the non-energized termination. Different resistive terminations are considered; in particular, the receiving end is assumed to be connected to a resistance  $R$  that is equal to the surge impedance  $Z_0$ , three times  $Z_0$ , or one-third of  $Z_0$ . The voltage profiles before the arrival of the wave at the receiving end are the same, but they differ after the wave has been reflected. It is worth noting that the incident voltage amplitude varies sinusoidally along the line length with a period of 6000 km, which is the wavelength of a signal at 50 Hz traveling at the speed of light.

Figures 5.128 and 5.129 show the same comparison as Fig. 5.127, but they present the results obtained for

lines 600 and 60 km long, respectively. Note that the incident voltage wave amplitude still varies sinusoidally in these two figures, but that the variation is less prominent.

Figure 5.130 compares the above three cases with different line lengths in terms of the voltage and current waveforms obtained at the two ends of the line. The resistive termination is assumed to have a resistance equal to the surge impedance of the line. Under these conditions, neither voltage nor current reflection takes place, and the line is often said to be *matched*. The voltage and current waves (in pu) coincide. When the line length is equal to the wavelength, the voltage waveforms at the line ends coincide, except for the delay with which the receiving end is energized. For shorter lines, a displacement between the waveforms can be observed.

**Fig. 5.125** (a) Voltages and (b) currents at different points along a 60 km line with a step voltage source at  $x = 0$  and a resistance that is one-third of the surge impedance at  $x = 60$  km. Voltage/current values are in pu with respect to the incident voltage/current wave amplitude

**Fig. 5.126** Voltage profile along a 6000 km line 19 ms after energization by a 50 Hz sinusoidal voltage source connected at  $x = 0$ . Voltage values are given in pu with respect to the source voltage amplitude

A comparison between the voltage waveforms obtained at the receiving end when different resistive terminations are present is provided in Fig. 5.131. It can be observed that the speed of the transition between the transient and the steady-state responses of the line increases as the line shortens and the termination resistance increases.

Comparisons between the current waveforms obtained at the sending and receiving line terminations when different resistive terminations are present are re-

**Fig. 5.127** Voltage profile along a 6000 km line 21 ms after energization by a 50 Hz sinusoidal voltage source connected at  $x = 0$ . The other termination at  $x = 6000$  km is resistive; cases where this resistance  $R$  is equal to, larger than, or lower than the surge impedance  $Z_0$  of the line are considered. Voltage values are given in pu with respect to the source voltage amplitude

ported in Figs. 5.132 and 5.133, respectively. In contrast to the voltage waveform, which only changes at the receiving end depending on the resistance of the resistive termination, it should be noted that the current at the sending end can vary too. In particular, for line lengths of 600 and 60 km, the current waveform is modified by the backward-reflected current waves.

**Fig. 5.128** Voltage profile along a 600 km line 2.1 ms after energization by a 50 Hz sinusoidal voltage source connected at  $x = 0$ . The other termination at  $x = 600$  km is resistive; cases where this resistance  $R$  is equal to, larger than, or lower than the surge impedance  $Z_0$  of the line are considered. Voltage values are given in pu with respect to the source voltage amplitude

**Fig. 5.129** Voltage profile along a 60 km line 0.21 ms after energization by a 50 Hz sinusoidal voltage source connected at  $x = 0$ . The other termination at  $x = 60$  km is resistive; cases where this resistance  $R$  is equal to, larger than, or lower than the surge impedance  $Z_0$  of the line are considered. Voltage values are given in pu with respect to the source voltage amplitude

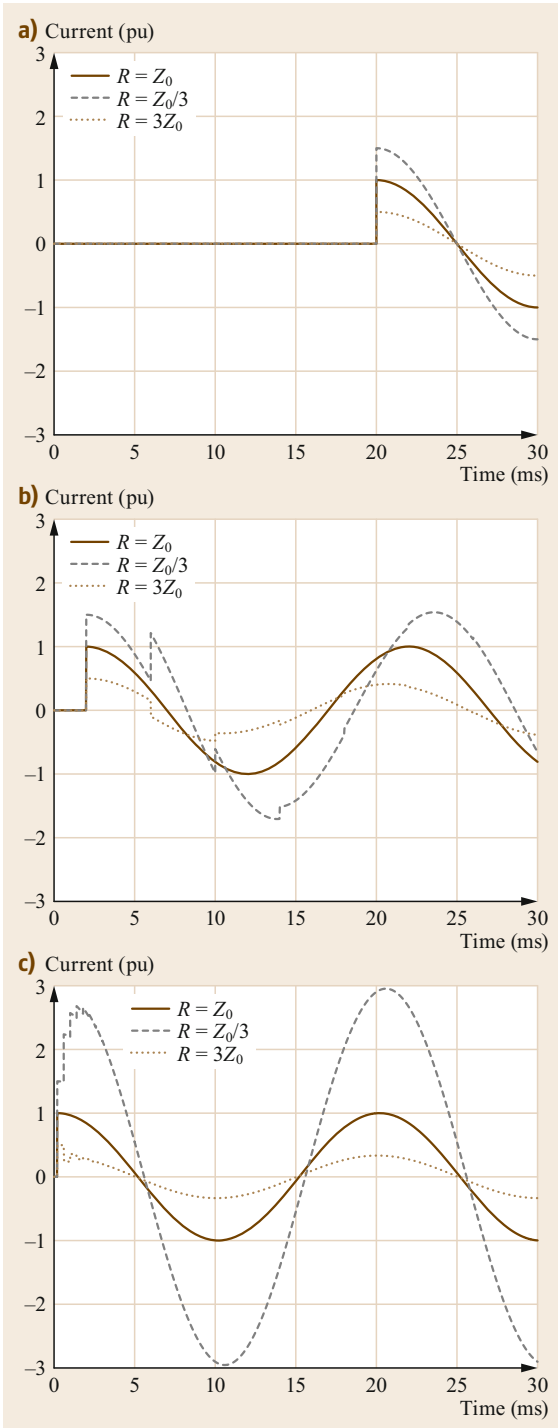

**Fig. 5.130a–c** Voltage and current waveforms at the sending and receiving ends of a transmission line, where the sending end is connected to a 50 Hz sinusoidal voltage source and the receiving end is connected to a resistance  $R$  that is equal to the surge impedance  $Z_0$  of the line. Values are given in pu with respect to the source voltage amplitude  $E$  and  $E/Z_0$ . Line lengths: (a) 6000 km, (b) 600 km, (c) 60 km

**Fig. 5.131a–c** Voltage waveforms at the receiving end of a transmission line, where the sending end is connected to a 50 Hz sinusoidal voltage source and the receiving end is connected to a resistance  $R$  that is equal to, larger than, or lower than the surge impedance  $Z_0$  of the line. ## 5.9 Electric Power Systems of the Future: Smart Grids

Electric power systems are continually evolving. Drivers of this evolution over the last few decades include the liberalization and development of competitive electricity markets, the increasingly widespread use of HVDC links to improve transmission capabilities and enhance interconnection, the growth in renewable energy sources (RESs), and the integration of distributed generation (DG). In the future, the expected large-scale adoption of electric vehicles and electric transportation technologies will lead to further power system development. Such development may include the implementation of a global power grid [5.56].

### 5.9.1 Evolution of Power Systems Towards Increased Deployment of Renewable Energy Resources

In this section, we focus on DG. There are many reasons for using DG in power systems, but the two main motivations are the introduction of the open electricity market and environmental requirements [5.57].

In Italy, the amount of power generated by RESs has increased considerably since the mid-2000s. Figure 5.134 shows how the power produced by each type of electric power plant has evolved in Italy since 1963. This graph is largely representative of those of many other countries in Europe too. From 2004 to 2013, the share of the total power generated in Italy that is contributed by RES plants increased from 26% to 39%, and this share reached 45% in 2017 (Fig. 5.135).

Since many RES technologies (photovoltaic units and several types of wind turbines in particular) are used in conjunction with power electronic convert-

ers [5.58, 59], the characteristics and fast dynamics of these devices tend to modify the behavior of the power system, especially during large perturbances.

The trends expected for Italy over the next decade are also expected to occur for Europe in general. Figure 5.136 shows the European targets for 2030 in relation to the transition to a zero-carbon economy, as well as the ambitions for 2050. This framework was adopted by the European Council in October 2014, and the targets for renewables and energy efficiency were revised in 2018.

The key targets for 2030 are:

- Cuts of at least 40% in greenhouse gas emissions with respect to 1990 levels
- A renewable energy share of at least 32%
- An improvement in energy efficiency of at least 32.5%.

The compositions of power systems in the future will also be influenced by the actions of transmission system operators (TSOs). Both Terna and ENTSO-E (the Italian TSO and the European network of TSOs, respectively) have set out possible future scenarios for the evolution of power systems up to 2040 [5.52, 61]. ENTSO-E forecasts that by 2040, between 65% and 81% of the electricity demand in the European Union (EU) will be met by renewable energy sources. Ensuring that this scenario is feasible and guaranteeing the economic sustainability and reliability of the electricity supply will require the implementation of technical solutions for storage system development and the strengthening of interconnections between states. Such measures should make it possible to exploit up to

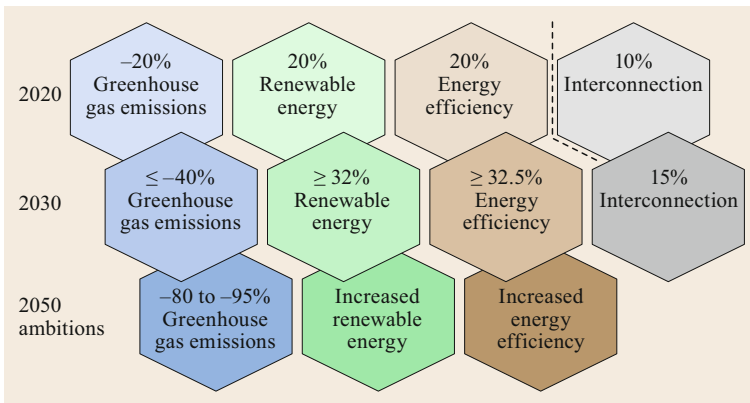

**Fig. 5.134**

Evolution of the contributions of various types of electric power plants to the total power produced in Italy since 1963 (from [www.terna.it](http://www.terna.it))

**Fig. 5.135** Italian power generation mix in 2004, 2013, and 2017. The pie charts and tables for 2004 and 2013 provide data on the power generation mix in Italy, including the types of power plants that contribute power, the number of plants of each type, the power contributed by each type, and the percentage contribution of each type to the total power generated in Italy. The pie chart for 2017 only presents the percentage contributions of renewables and thermal plants to the total power (from [www.terna.it](http://www.terna.it))

**Fig. 5.136** European targets for 2030 in relation to the transition to a zero-carbon economy (adapted from [5.60])

150 TWh of energy produced from nonprogrammable sources that would otherwise remain unused. In this regard, the EU has announced a thousand billion euro investment plan that aims to convert all conventional generation units to renewables ones by 2050 [5.62]. Unity across borders will be crucial to achieving clean energy production [5.63]. The European electric grid is the largest synchronous grid in the world, and the level of interconnectivity among European countries is expected to grow significantly over the next few decades in order to improve cross-border energy exchange.

The intermittent nature of the output from renewable energy sources (e.g., wind and solar) necessitates sufficient backup generation to meet the demand for electricity [5.64]. This is even more important if wind and solar generate 100% of the required energy on average. The need for backup generation can, however, be reduced through the utilization of storage systems and/or grid extensions. Interconnections can improve grid stability

and reduce energy prices, so huge investments aimed at strengthening transmission line capabilities in order to create a European supergrid are expected. The EU has set an interconnection target of at least 10% by 2020 in order to encourage EU countries to link their installed electricity production capacities [5.63]. This means that each nation should have sufficient transmission lines to allow at least 10% of the electricity produced by its power plants to be transported across its borders to neighboring countries at any time. The level of interconnection is also expected to rise to 15% by 2030 [5.65].

### 5.9.2 Power System Structure: Why We Need Smart(er) Grids

We discussed the structure of a power system in Sect. 5.1. Historically, generators were connected directly at the transmission level, and power flows were unidirectional from the transmission level towards the

loads connected at lower voltage levels. However, power systems have changed in structure over the last few decades to allow the deployment of a large number of RESs. The increasing penetration of RESs and DG into power systems has totally changed the power flows in these systems, as many generating units are now connected directly at the subtransmission and distribution levels, meaning that distribution grids have been transformed from passive to active networks.

The impact of renewable generation on electric power systems presents a challenge to transmission and distribution systems operators [5.66], and has resulted in a need for *smarter* grids for the reasons listed below.

#### High Variability in the Amount of Power Produced by RESs

This characteristic of RESs requires:

- Smarter management of the grid
- Extensive information and communications technology (ICT) deployment (e.g., metering, cosimulation tools, . . .)
- Deployment of storage systems.

#### Penetration of RESs

The increasingly widespread adoption of RESs poses problems:

- Generators are often used in conjunction with power electronic converters, which degrades system stability due to a lack of inertia
- Power quality issues arise.

#### Integration of Electric Vehicles

The expected increase in electric vehicle utilization implies that:

- Network transformers must be upgraded in terms of size and capability
- The possibility of supporting the network with vehicle-to-grid (V2G) applications should be explored.

#### Inverted Power Flows

The inverted power flows that result from the inclusion of RESs in power systems are problematic because:

- The lines were not designed for bidirectional flows
- Voltage profiles along the distribution feeders are altered
- Protection failures may occur.

### 5.9.3 The Definition of a Smart Grid

The reasons mentioned above have led to the introduction of the concept of a *smart grid*. There are various definitions of a smart grid; we report a few of them below:

1. *European Technology Platform on SmartGrids*: “A SmartGrid is an electricity network that can intelligently integrate the actions of all users connected to it—generators, consumers and those that do both—in order to efficiently deliver sustainable, economic and secure electricity supplies.”
2. *US Department of Energy*: “A smart grid uses digital technology to improve reliability, security, and efficiency (both economic and energy) of the electric system from large generation, through the delivery systems to electricity consumers and a growing number of distributed-generation and storage resources.”
3. *Department of Energy and Climate Change, UK*: “A smart grid uses sensing, embedded processing and digital communications to enable the electricity grid to be observable (able to be measured and visualized), controllable (able to be manipulated and optimized), automated (able to adapt and self-heal), fully integrated (fully interoperable with existing systems and with the capacity to incorporate a diverse set of energy sources).”
4. *Electric Power Research Institute, USA*. This institute is developing the IntelliGrid<sup>SM</sup> initiative, which is laying the technical foundations for smart grids. According to the Electric Power Research Institute, a smart grid is a “power system made up of numerous automated transmission and distribution systems, all operating in a coordinated, efficient and reliable manner;” “a power system that handles emergency conditions with *self-healing* actions and is responsive to energy-market and utility business-enterprise needs;” and “a power system that serves millions of customers and has an intelligent communications infrastructure enabling the timely, secure and adaptable information flow needed to provide reliable and economic power to the evolving digital economy.”
5. *Eurelectric*: “A smart grid is an electricity network that can intelligently integrate the behavior and actions of all users connected to it—generators, consumers and those that do both—in order to efficiently ensure sustainable, economic and secure electricity supply. As such, a smart grid, involving a combination of software and hardware allowing more efficient power routing and enabling consumers to manage their demand, is an important part of the solution for the future.”

### 5.9.4 Growth in the Utilization of ICT in Power Systems

The increasing use of ICT is an important characteristic of the development of power systems, as illustrated in Fig. 5.137. In transmission and distribution networks, the adoption of DG, together with electricity market procedures and the expected sudden growth in elec-

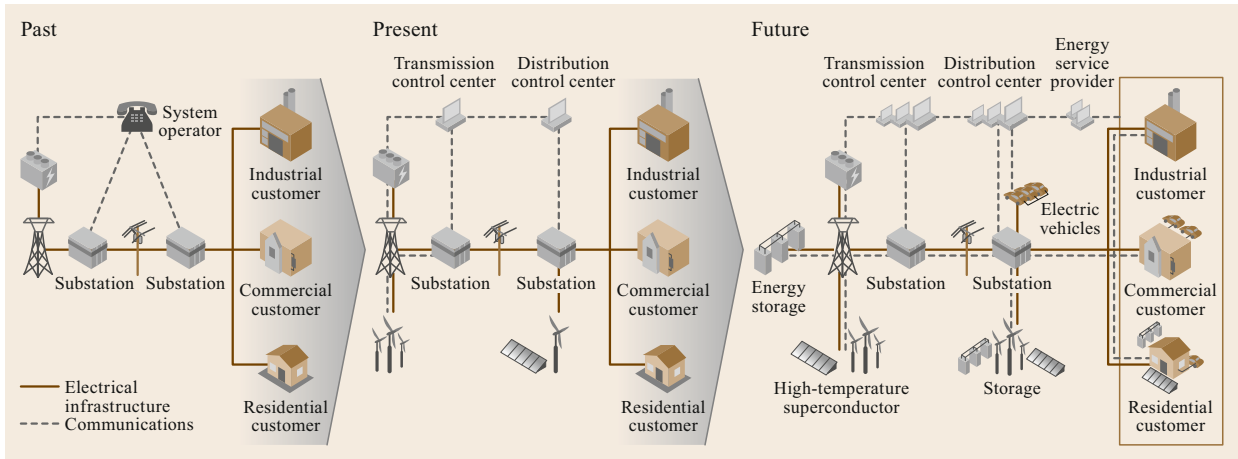

Fig. 5.137 Evolution of the utilization of ICT in power systems (from IEA, International Energy Agency)

tric vehicle deployment, is leading or will lead to more complex interactions among system components. Thus, in the future, it will be necessary to apply the most advanced ICT solutions to power system operation to ensure that reliability and performance targets are met. Enhancing MV and LV distribution network observability using both direct (smart metering) and indirect (state estimation [5.67], pseudomeasures [5.68], and load and production forecasts) methods can lay the groundwork for the development of new services and value-added functionalities [5.69].

The development of new tools that can be used to model the dynamic behavior of power systems and communications networks should facilitate the increased application of new ICT-based monitoring, control, and protection approaches in electric power grids [5.70, 71]. The expected key requirements of a ITC–power system cosimulation platform are easy configuration, good operating system compatibility, an ability to interconnect with external third-party programs/systems, a hardware-in-the-loop (HIL) capability, time synchronization, the ability to adjust the level of detail of the model (in both power and communications modeling), the interoperability needed to import models, and scalability.

### 5.9.5 Microgrids

The implementation of active distribution network technologies is leading to the formulation of new system concepts. The microgrid paradigm is perhaps the most promising novel network type [5.64]. A microgrid consists of a group of interconnected distributed energy resources such as microturbines, fuel cells, and photovoltaic arrays together with storage devices (i.e., flywheels, energy capacitors, and batteries) and controllable loads. Such systems offer considerable scope

for control and autonomous operation. They are interconnected to the distribution network but have the ability to voluntarily perform connection and disconnection maneuvers, meaning that they can smoothly and reliably switch between grid-connected and island modes (Fig. 5.138).

### 5.9.6 Energy Communities

Mechanisms enabling energy transactions between neighbors are becoming feasible in several countries. These mechanisms provide an incentive to install DG units (especially those based on RESs), which will encourage power generation that exceeds the local load, thus allowing the power demands of users connected nearby to the same distribution network to be exploited. As an example, on December 2018, the European Union approved the first part of a comprehensive legislative package entitled *Clean Energy for All Europeans* (CEP) [5.74]. This EU directive establishes appropriate legal frameworks for energy communities. A local energy community (LEC) can be defined as a set of end-users with local generation and storage units that cooperate to achieve common goals, in particular the minimum energy procurement costs and the efficient use of renewable resources [5.75].

Figure 5.139 illustrates the concepts of self-consumption, collective self-consumption, and the LEC [5.73]. Collective self-consumption, which builds on the well-established idea of self-consumption, involves cooperation between renewable energy self-consumers located in the same building or apartment block. In the figure, the LEC consists of a set of residential or small industrial sites, each acting as a prosumer, and it generally includes generation and battery energy storage units as well as loads. The LEC operates on an internal LV distribution network connected to the

Fig. 5.138 Schematic of a microgrid (adapted from [5.72])

Fig. 5.139 From self-consumption to LEC (adapted from [5.73])

external utility grid, and the prosumers use the available energy resources cooperatively. Specific scheduling procedures are generally needed to fully exploit the available resources and the flexibility of the system (see, for example, [5.76] and references therein). Technologies such as demand response appear to be more easily applicable in LECs than by the utility. Local en-

ergy communities may also incorporate aggregators for electric vehicles [5.77].

#### Additional Information and Exercises

Additional information and supplementary exercises relating to this chapter can be found at [https://go.sn.pub/SHb\\_PowerSystems\\_Nucci\\_PowerSystemsAnalysis](https://go.sn.pub/SHb_PowerSystems_Nucci_PowerSystemsAnalysis).

### Carlo Alberto Nucci

Department of Electrical, Electronic and Information Engineering  
University of Bologna  
Bologna, Italy  
carloalberto.nucci@unibo.it

Carlo Alberto Nucci graduated in Electrical Engineering in 1982 from the University of Bologna, where he is Professor of Electrical Power Systems since 2000. He has received fellowships from IEEE and CIGRÉ, an HC degree from University Politecnica di Bucharest, the CIGRE TC award, and the ICLP SC Golde Award. He is Editor-in-Chief of the journal *Electric Power Systems Research* and a Member of the Academy of Science of the Institute of Bologna.

### Alberto Borghetti

Department of Electrical, Electronic and Information Engineering  
University of Bologna  
Bologna, Italy  
alberto.borghetti@unibo.it

Alberto Borghetti (IEEE M'97–SM'03–F'15) graduated in electrical engineering from the University of Bologna in 1992, and is now Professor of Electrical Power Systems at the same institution. He received ICLP SC and CIGRÉ TC awards in 2016 and 2018, respectively. He is currently serving as an Editor on the journal *IEEE Transactions on Power Systems* and as Editor-in-Chief of the journal *Electrical Engineering*.

### Fabio Napolitano

Department of Electrical, Electronic and Information Engineering  
University of Bologna  
Bologna, Italy  
fabio.napolitano@unibo.it

Fabio Napolitano received his MS and PhD (Hons.) in electrical engineering from the University of Bologna in 2003 and 2009, respectively. He subsequently became an Assistant Professor (in 2010) and an Associate Professor (in 2020). His research interests include power system transients—particularly those due to indirect lightning strikes—and lightning protection systems.

### Fabio Tossani

Department of Electrical, Electronic and Information Engineering  
University of Bologna  
Bologna, Italy  
fabio.tossani@unibo.it

Fabio Tossani received his BS (Hons.), MS (Hons.), and PhD in electrical engineering from the University of Bologna in 2010, 2012, and 2016, respectively. He is currently a junior Assistant Professor in the Power Systems Laboratory of the Department of Electrical, Electronic and Information Engineering “Guglielmo Marconi,” University of Bologna.

# Rotating Elec

## 6. Rotating Electrical Machines

Erli F. Figueiredo

One of the most striking features in the development of rotating electrical machines has been the steady increase in their output. This marked increase was made possible by a combination of several factors, of which the most important include improvements in the magnetic properties of the sheet steel used for core material, as well as the development of insulating materials capable of withstanding relatively high temperatures, and better provision for cooling. This chapter is divided into two parts: Synchronous Machines and Induction Motors. For both types of machines considerations about insulating materials, cooling and construction are presented with a focus on the main aspects involved, as well as about their performance under different conditions of operation. Special emphasis was given to international standards. The effect of machine dimensions on the rating of synchronous and induction machines is included, as well as other design parameters. The application of variable frequency drives on induction motor speed control is highlighted. Some advanced technologies in synchronous generators and motors such as: superconducting generators and motors; permanent magnet motors; switched reluctance motors and line start permanent magnet motors, as well as those related to die cast copper and linear induction motors are presented.

## 6.1 Synchronous Machines

A synchronous machine may be constructed with a stationary armature and a rotating field, or a rotating armature and a stationary field. The former has been widely used because the armature winding is more complex than the field winding, and it is constructed more easily in a fixed structure. Besides that, the armature winding handles the load power of the machine, while the field winding consumes a small percentage (0.5–2%) of the rated load power. Thus, if the synchronous machine was constructed with a rotating armature, it would require slip rings and brushes to deliver energy to the load. This would cause a fast wear of the brushes and sparking on the slip rings, that could cause short-circuits. This type of construction may be found in small machines.

### 6.1.1 Construction Features

When synchronous generators are driven by steam/gas turbines they are referred to as a turbogenerator, and when they are driven by water turbines as a hydro-generator. Steam/gas turbines are high-speed units and these turbogenerators are built as cylindrical-rotor (also called round-rotor or nonsalient-pole rotor or turbine generators) machines. On the other hand, hydrogenerators are salient-pole machines, since hydraulic turbines run at low/medium speeds. When synchronous motors are required for high-speed operation, they are designed, similar to turbogenerators, as nonsalient-pole machines.

The armature core of both cylindrical-rotor and salient-pole machines is made of insulated steel laminations, in order to minimize eddy current and hysteresis losses. The core is mounted onto the frame through spring bars. The core is slotted and the coils/bars making the winding are placed in the slots around the periphery of the stator to provide better heat dissipation. The chief characteristics of the AC windings are defined by such features as: the number of circuits in parallel per phase, which may be one or more; the connections between phases, usually in star formation for generators and in delta formation for motors; the number of coil layers per slot, that may be either one or two, but with the two-layer type predominating; the angular spread of conductors belonging to a given phase belt; the pitch factor of the coils comprising the winding and the arrangement of the end connections. For the field winding a series connection is regularly used.

The field winding is arranged to produce as many pairs of poles as may be needed. The number of poles will depend upon the speed at which the machine should operate, which in turn depends upon the driven

machine or prime mover, and the desired frequency of the system to be supplied, in the case of generators. The field winding is fed by direct current by an exciter through a pair of brushes and slip-rings, except for the case of turbogenerators, that usually have a brushless exciter, i.e., an exciter without brushes and slip-rings.

When the number of poles is small, such as two, four, or sometimes six, as in the case of cylindrical-rotor machines, the generator is typically driven by steam or gas-turbine prime movers. The field winding is distributed in slots cut in the round surface of the rotor and retained, against large centrifugal forces, in the slots by wedges and in the end connections by retaining rings. Normally two thirds of the rotor periphery is slotted to accommodate the field winding and the remaining one third unslotted portion acts as poles. Rotors of cylindrical machines are constructed of solid steel forgings or of thick steel disks suitably bolted together. Figure 6.1 shows the rotor magnetic flux linking rotor and stator across the airgap of the cylindrical-rotor machine.

When the number of poles is larger, each pole is separate and distinct, forming a salient-pole structure, attached to the rotor. The winding on each pole is a concentrated coil wound closely around the pole. The field winding is then made up of a number of concentrated coils. The flux distribution is controlled by shaping the face of the pole, so that the airgap is a minimum at the pole center and increases toward the tips, thus helping to produce the desired sinusoidal flux distribution. Successive poles are wound in opposite directions so that the poles are alternately magnetically north and south. The terminals of the field winding are brought to

**Fig. 6.1** Cylindrical machine: Rotor magnetic flux linking the rotor and stator

**Fig. 6.2** Cross-sectional view of a salient-pole synchronous machine

two collector rings attached to, but insulated from the shaft.

The rotor of salient-pole machines consists of a steel spider to which poles of laminated steel, carrying the field winding, are keyed or bolted. Generally rectangular or round pole constructions are used for such type of alternators. Generators driven by water wheel turbines are of either horizontal or vertical shaft type. Generators of lower power ratings with fairly higher speeds are built with a horizontal shaft and the generators of higher power ratings and lower speeds are built with a vertical shaft design. Three types of construction are used for vertical shaft generators:

- (i) Umbrella type where the thrust bearing and a single guide bearing are mounted below the rotor.
- (ii) Semi-Umbrella type, similar to the Umbrella type, but with an additional guide bearing mounted above the rotor.
- (iii) Suspended type with a thrust and one guide bearing mounted above the rotor and another guide bearing mounted below the rotor.

Most salient-pole machines have an additional winding in the rotor, called the damper-winding (also known as an amortisseur), made of copper bars embedded in the head of the pole, and short-circuited at both ends by short-circuiting rings similar to end rings as in the case of squirrel cage rotors. In case of synchronous motors and compensators its purpose is to start the motor or compensator as an induction motor, and take it unloaded to almost synchronous speed, when the rotor is pulled in synchronism by the synchronous torque.

This structure, usually, includes all synchronous hydrogenerators. A cross-sectional view of a salient-pole machine is shown in Fig. 6.2.

Bearings are used to prevent friction between parts during relative movement. They fall into two primary categories: anti-friction or rolling element bearings and hydrodynamic journal (fluid film) bearings. There are applications where rolling bearings are the best choice. Smaller generators and motors commonly use rolling bearings.

In the case of large rotating machines the machine's shaft is most commonly isolated from the stationary equipment through the use of journal bearings, that are filled with lubricant in order to maintain low friction and as a consequence minimize wear of the surfaces. To inspect the journal bearings, that are generally split, rotor removal is not required. Journal bearing fatigue damage is usually visible at an early stage and allows for better diagnostics of failure modes so that corrective action can be taken to prevent recurrence. For these reasons, special care must be taken when selecting and implementing a lubrication system and special vibration monitoring techniques must be applied. The most important aspects of the health and longevity of a journal bearing are proper selection, proper installation, proper lubrication, and the alternating hydrodynamic loads imposed on the bearing surface by relative shaft-to-bearing vibration. While split rolling element bearings are also available they are costly and not common in large machines.

The proper alignment of turbo-units and hydro-units is critical to trouble free operation. A misalignment cannot only cause the premature failure of bearings, but

through excessive vibration, can cause wear and stress on other machine components as well. Unscheduled outages caused by misalignment can be avoided if the machinery is initially aligned correctly.

## 6.1.2 Cooling and Insulation

### Cooling

Losses in electrical machines appear in the form of heat. Heat is transferred from one machine part to another and to the surrounding medium by conduction, radiation and convection. Since the losses are produced mainly in the active parts of the machine, i.e., in the iron that carries the flux and in the conductors which carry the currents, the heat appears mainly in these machine parts. The result is an increase in temperature of the iron and copper above that of the surroundings. Cooling of the machine is necessary in order to keep the temperature rises of the iron and copper within the prescribed limits (Table 6.1).

The cooling system may be of two types: indirect and direct. In the indirect cooling system the windings are not in direct contact with the cooling medium, that is blown along the airgap, through ducts in the core and over the surface of the windings. In the direct cooling system the coolant in a closed circuit passes directly in contact with the windings. IEC and National Electrical Manufacturers Association standards describe the cooling systems in detail [6.1, 2].

### a) Cylindrical (Round)–Rotor Machines.

**a.1) Indirect Cooling.** The indirect cooling system may be of two types: open-circuit and closed-circuit. In an open-circuit cooling system a machine is cooled by the in-take of cold air, which passes through the machine and is expelled into the atmosphere. To prevent clogging of the machine with dust, that the air always contains, a filter is mounted at the air in-take. The closed-circuit cooling system is one in which the air or hydrogen passes through the machine becomes heated, then it passes through a cooler returning to the machine. In the indirect cooling system the windings are not in direct contact with the cooling medium (air or hydrogen), which is, usually, fed into the generator by fans at both sides of the rotor, i.e., the windings are cooled by flowing air or hydrogen over their surfaces and through the core.

The output equation of a generator in MVA (apparent power) is  $S = CD^2Ln$  (Sect. 6.1.20, *Apparent Nominal Power: Output Equation*), where  $C$  is the output coefficient in MVA s/m<sup>3</sup>;  $D$  is the inner stator diameter in meters;  $L$  is the axial length of the core in meters and  $n$  is the speed in rps (rotation per second). In

the case of cylindrical-rotor machines the effect of the high speed  $n$  is to reduce the amount of active material, i.e., the generator size ( $D^2L$ ), much below that required in a slow speed machine of the same capacity, thereby greatly reducing the area available for direct radiation.

If the rotating speed  $n$  is constant, an increase of generator capacity can be attained by increasing the output coefficient  $C$  or the generator size or both. A larger stator and consequently rotor diameter, and active length greatly increase the windage losses. For instance, the surface friction loss, that represents a significant portion of the windage losses, rises as the fourth power of the diameter, and linearly with an increasing active length. Thus to reduce windage losses the most important parameter to consider is a reduction in the rotor diameter. Besides that, the diameter must be kept as small enough as possible to keep the peripheral speed  $v$  of the rotor within safe limits ( $v = \pi D_r n$ ), where  $D_r$  is the rotor diameter in meters,  $n$  is the rotating speed in rps, and  $v$  is in m/s, so that for large capacity machines the axial length must be considerable. This adds to the difficulty of cooling the central portion of the core with air, that is too far from the end of the rotor where fans are installed. Indirect air-cooled generators have been built up to 400 MVA.

All of these considerations point to the necessity of completely enclosing the machine in order to permit the use of hydrogen instead of air to carry away the heat, for larger size machines than those which use air cooling. The hydrogen density is about 1/14 that of air, for the same pressure and temperature, thus reducing windage loss and noise; its heat conductivity is around 6.7 times greater than that of air, that implies in a heat transfer coefficient of 1.5 times that of air, so more readily taking up and giving up heat. The hydrogen is maintained at a pressure above atmospheric in order to avoid the penetration of air and forming an explosive mixture inside the machine, which is totally closed. At 3.45 kPa its rating can be increased by about 30% above its air-cooled rating. An additional pressure increase from 3.45 to 103.5 kPa and a further increase to 207 kPa allows the machine rating to be increased additionally by 15 and 25% for the same temperature rise, respectively. The gas coolers are located inside the generator casing. Indirect hydrogen-cooled generators (Fig. 6.3) have been built up to 600 MVA.

**a.2) Direct Cooling.** To further increase the capacity of cylindrical-rotor machines, in relation to those obtained using indirect hydrogen-cooling, it is necessary to use an effective direct winding cooling system in which the stator and rotors windings are designed with internal ducts for the circulation of the coolant directly in contact with the windings. Direct cooling permits a specific electric load (Sect. 6.1.20, *Apparent Nominal Power:*

**Fig. 6.3**  
Simplified section  
of an indirect  
hydrogen-cooled  
generator [6.3]

*Output Equation*), i.e., and the armature current to be increased, while maintaining the limits of temperature rise. Hydrogen has been used, by some manufacturers, for rotor and stator winding cooling.

Figure 6.4 shows the cross-section of a rotor slot in a direct cooled cylindrical-rotor machine, where hydrogen enters the subslot in an axial direction, bringing it in direct contact with the copper conductors, thus reducing the thermal drop through the insulation.

However, for machines larger than 800 MW, in general, the volume of hydrogen required to cool the

**Fig. 6.4** Rotor slot  
in a direct hydrogen  
cooled cylindrical  
machine

machine may be so large that its use results in a great increase in machine cost. Thus, due to its excellent heat conductivity being about 60 times that of air and 40 times of that of hydrogen for the same pressure, highly purified water has been used for direct stator winding cooling, allowing a further increase in machine capacity, and lower costs when compared with direct stator hydrogen-cooled machines. Besides that, the duct area for water is smaller than for hydrogen, allowing more space for the conductors in the slot, giving a greater conductor cross section and as consequence a decrease in its resistance and lower losses, for the same armature current. Water may also be used for cooling the rotor winding, instead of hydrogen, to increase the output available from the same frame size. In this latter case the water-pipes have to be designed to support the centrifugal force and the internal pressure.

To take advantage of the good performance of water and hydrogen as a cooling medium, a 1350 MW round-rotor generator was constructed with the stator and rotor windings cooled by water and the steel sheet core cooled by hydrogen.

**b) Salient-Pole Machines.** These are characterized by low speed, large diameter and small axial length compared to cylindrical-rotor machines. In addition to the large areas available for direct radiation, there is the fanning action of the rotor. Even so, it is still necessary to subdivide the core by providing ventilating ducts to allow the flow of cooling radially through the core. In general, hydrogenerators are air-cooled where the air circulates through a heat exchanger in a closed circuit. Direct water cooling of hydrogenerators stator windings, where water is passed through the stator conductors has been applied to machines larger than 500 MW, while the rotor may be cooled by air.

#### Insulation

Electrical insulation is a combination of materials designed to perform the functions needed in electric equipment. They can be divided into two main categories: groundwall and conductor insulation [6.4].

**Table 6.1** Thermal classes of insulating materials

Numerical classification (°C)	Previous designation (class)	Hottest spot permitted (°C)	Permitted average winding temperature <sup>a</sup> (°C)
90	Y	90	NA
105	A	105	NA
130	B	130	120
155	F	155	140
180	H	180	165

<sup>a</sup> Temperature determined by resistance measurement (NA = not available)

A groundwall insulation separates those components that may not be in contact with each other, i.e., separation of the coil from the grounded stator core of the machine. Conductor insulation separates the wires and turns of a coil. Organizations like ANSI/IEEE (American National Standards Institute/Institute of Electrical and Electronic Engineers) and IEC have produced thermal classifications of materials for rotating electrical machines. A table adapted from IEC 60034-1 [6.5] and IEC 60085 [6.6] is shown in Table 6.1. A brief description of materials for each insulating class is presented in Table 6.2.

**Table 6.2** Description of material for each insulating class

Numerical classification (°C)	Material description
90	Materials or combinations of materials such as cotton, silk, paper, cellulose, and similar materials when neither impregnated nor immersed in a liquid electrical insulating material
105	Materials or combinations of materials such as cotton, silk, paper, and similar materials when either impregnated or coated or when immersed in a liquid electrical insulating material
130	Materials or combinations of materials such as mica, asbestos, fiberglass, used as suitable binding substances
155	Materials or combinations of materials such as mica, asbestos, fiberglass, and similar inorganic materials suitably bonded with organic (varnishes or resins) or synthetic inorganic thermo-setting resins of two types: epoxy mica and polyester mica
180	Materials or combinations of materials such as mica, asbestos, fiberglass, and similar inorganic materials in built-up form with binding substances composed of silicone resins, or materials with equivalent properties

**Fig. 6.5** Cross section showing the stator winding insulation components

*a) Stator Winding Insulation.* The basic stator winding insulation components are shown in Fig. 6.5, with:

- Strand insulation—to reduce the skin effect of copper strands
- Turn insulation—to prevent electrical shorts between turns
- Groundwall insulation—to prevent ground faults from high potential and
- Semiconductive coating—to prevent partial discharge of the coil or bar surface.

These insulation components together ensure that an electrical short does not occur, that the heat from the conductor losses are transmitted to a heat sink, and that the conductor does not vibrate in spite of the magnetic force.

Besides the insulation components above, on the coil or bar surface there is a special coat made of silicon carbide having a voltage dependent resistance. This coat is applied to the parts of the coil or bar that come out from the slots. In such a way, a uniform spread of electric potential is obtained thus avoiding partial discharges at exits from the slots.

*b) Rotor Winding Insulation.* Turn insulation (in both cylindrical-rotor and salient-pole machines) and groundwall insulation (in cylindrical-rotor machines) in a rotor can be relatively thin since the voltage in a rotor is much lower than in a stator.

For salient-pole machines rated at less than a few megawatts a magnetic wire, instead of a copper wire, is wrapped around the pole. A magnet wire is technically just an insulated copper wire which is coated

with an enamel insulation. This feature makes it ideal for winding coils where every millimeter is considered important. Thin insulated material helps to make more turns in a small area in machines. Common copper wire is insulated with thicker material which can require more area for more turns. Insulating washers and strips are placed between the magnetic wire and the field pole laminations to act as the ground insulation.

*c) Life Expectancy of Electric Equipment.* Apart from accidental electrical and mechanical failures, the life expectancy of an electrical apparatus is limited by the temperature of its insulation: The higher the temperature, the shorter its life. A rule of thumb (based upon the Arrhenius equation of chemical reaction time versus temperature) adapted to approximate the relationship between insulation life and operating temperature states that if the operating temperature is raised by  $10^{\circ}\text{C}$ , the thermal life expectancy of the insulation system is reduced by one half, and conversely if the operating temperature is reduced by  $10^{\circ}\text{C}$ , the thermal life of the insulation system is approximately doubled. Thus if a machine has a normal life expectancy of thirty years at a constant temperature of  $105^{\circ}\text{C}$ , it will have a service life of only seven and a half years at  $125^{\circ}\text{C}$ . This explains why sometimes a machine is specified for class F insulation, but operates as class B.

The factors that contribute most to the deterioration of insulators are (1) heat, (2) humidity, (3) vibration, (4) acidity, (5) oxidation, and (6) time. Because of these factors, the state of the insulation changes gradually; it slowly begins to crystallize and the transformation takes place more rapidly as the temperature rises.

In crystallizing, organic insulators become hard and brittle. Eventually, the slightest shock or mechanical vibration will cause them to break. Under normal conditions of operation, most organic insulators have a life expectancy of 8–10 years provided that their temperature does not exceed  $100^{\circ}\text{C}$ . On the other hand, some synthetic polymers can withstand temperatures as high as  $200^{\circ}\text{C}$  for the same length of time.

Low temperatures are just as harmful as high temperatures are, because the insulation tends to freeze and crack. Special synthetic organic insulators have been developed, which retain their flexibility at temperatures as low as  $-60^{\circ}\text{C}$ .

### 6.1.3 Armature Windings

This section summarizes single and double-layer, as well as integral and fractional slot armature windings. More extensive information can be found in references [6.4, 7, 8].

Armature windings comprise a set of coils/bars embedded in slots, uniformly spaced round the armature periphery. The main characteristics of alternating current windings are: the types of coils; the number of phases; the connections between phases; the number of coil layers per slot; the pitch of the individual coils comprising the winding; the number of circuits in parallel; and the arrangement of the end connections.

The types of stator coils include random-wound coils, form-wound coils and form-wound bars (called Roebel bars):

- a) Random-wound coils consist of round, insulated copper conductors that are wound continuously through slots in the stator core to form a coil. A cross-section of the coil shows that turns are randomly distributed and can be in close proximity to a number of other turns. Throughout the axial length of the coil, wires can migrate during manufacturing and take new positions with respect to other coils. Random windings are typically used for machines less than 1500 kW, where the size of the stator and the minimum wire thickness usually do not allow form-wound coils.
- b) Form-wound multiterm coils are preformed coils consisting of a continuous loop of magnetic wire shaped into a coil. Individual turns are arranged in precise locations with respect to each other. That is, turn one is always next to turn two, turn two is always next to turn three, and so on. The coils are shaped in a forming machine to the final configuration that they will occupy in the stator. They are used in generators rated up to 50–100 MVA and in most large motors.
- c) Form-wound Roebel bars are used in large generators as the form-wound multiterm coil is large enough so that there are difficulties in inserting both legs of the coil in the narrow slots in the stator core without risking mechanical damage to the coil during the insertion process. Thus, most large generators are not made from multi-turn coils, but rather from half-turn coils, often referred to as Roebel bars. With a Roebel bar construction, only one half of a coil is inserted into the slot at a time, which is considerably easier than inserting two sides of a coil in two slots simultaneously.

The EMFs are induced in armature coils/bars due to relative motion between them and the flux density wave in the airgap established by the field windings. In a three-phase AC machine the armature coils/bars are symmetrically connected to form a set of three balanced phases (equal EMF magnitudes with a relative phase

**Fig. 6.6a,b** Double-layer winding: (a) two coil sides per slot (b) eight coil sides per slot

displacement of  $2\pi/3$  rad). When the armature winding carries current, it establishes the same number of alternating (north-south) poles for which it is wound.

The active coil-side length in which the EMF is induced equals the armature length (over which the flux density is established). The pitch of a coil is the space angle (electrical) between its two sides and must equal an integral number of slots. The coil pitch may be full (equal to one pole pitch or  $180^\circ$  E) or short-pitch (chorded) coils may be used. The pitch of a coil could be expressed in terms of its angular span or in terms of slots. The slots/pole must be an integral number for a full-pitch coil.

Practically there are two types of windings, viz. single-layer and two-layer (or double-layer). In a single-layer winding each coil side of a coil occupies the whole slot, thus the number of coils is half the number of slots. In a double-layer winding one coil side of a coil occupies the upper position in one slot and the second coil side occupies the lower position in a slot displaced from the first coil-side by the coil-span. In a double-layer winding each slot is occupied by two coil-sides, one placed on top of the other, referred to as top and bottom coil sides. The number of coils is equal to the number of slots.

(Nomenclature:  $m$  = number of phases;  $p$  = number of poles;  $Q$  = number of slots (must be divisible by 3 in a three-phase AC machine);  $Q/p$  = slots per pole, i.e., pole pitch in terms of slots (is noninteger for fractional-slot winding);  $\gamma = (180p)/Q$  ° E = angle between midpoint of adjacent slots or slot pitch;  $q = Q/(mp)$  = number of slots per phase and pole and  $\sigma = q\gamma$  = phase belt or phase spread angle in ° E.)

### Single-layer Windings

Single-layer windings for a three-phase machine requires an overhang designated to allow the end connections to be placed in separate plans. They may be

classified into two main categories, i.e., unbifurcated (or half-coiled) and bifurcated (whole-coiled). In the former type the coils comprising a phase group in adjacent pole pitches are concentric. The individual coils may have a span greater or less than a pole pitch but the average coil-span equals one pole-pitch. This kind of arrangement is provided to avoid crossing of two coils under one phase-group. In a bifurcated winding, each coil group is split into two sets of concentric coils and the return coil-sides are shared with those of another group. This kind of arrangement is only possible when  $q$  is even.

For accommodating the windings for all the three-phases, the overhang must be arranged in two or three planes. The jointing of individual conductors to form the finished coil is usually done by electrical resistance welding and each turn must after joining be suitably insulated over the butt joint. This procedure is expensive which accounts for the decline in the use of single-layer in favour of double-layer windings. Single-layer windings are, therefore, rarely used in modern machine practice except in small sizes. Machines are of course still found in use with single-layer windings.

### Double-layer Windings

Double-layer windings usually lead to simpler end connections and to a machine which is more economical to manufacture and are found in all machines except small motors below 10 hp in size. The number of coils is the same as the number of slots. They fall into two main classes depending upon the value of  $q$ : integral slot winding when  $q$  is an integer and fractional-slot winding, when  $q$  is a fractional number. To meet the requirement of symmetry among phases, the number of slots/phase ( $Q/m$ ) must be a whole number. In Fig. 6.6a there are two coil sides per slot while in Fig. 6.6b there are eight coil sides per slot. For placing double-layer windings, usually open slots are used.

**Fig. 6.7** Detailed double-layer lap winding diagram for phase A for 3-phase armature having 24 slots, 4 poles, phase spread  $60^\circ$

**a) Integral-Slot Winding.** Here  $q$  is an integer. The winding arrangement is further illustrated through an example. Let  $q = 2$ ,  $p = 4$ ,  $Q/p = 6$ ,  $\sigma = 60^\circ$  E, full-pitch coils, double-layer, lap winding.

The winding diagram for one phase is shown in Fig. 6.7. The first set of phase-group coils (coil-group 1) lying under one pole-pair NS (North and South) are connected in series (finish end of the first coil is connected to the start of the next coil lying to the right of the first). The second coil-group of the phase lies under S-N poles and must therefore be connected in reverse to the first coil-group for additive EMF. Note that alternate coil-groups are reverse connected and that the winding appears like a bifurcated one. Observe that coil-sides lying in any given slots pertain to the same phase. All the coil-groups of the phase could be connected in series or in series-parallel.

In practice, however, it is common to use chorded or short-pitched coils. This type of arrangement offers certain inherent advantages such as reduction in the amount of copper needed for end connections. Furthermore, certain harmonics present in the EMF wave are greatly suppressed. The effect of coil chording on the EMF generated is shown in Sect. 6.1.4.

**b) Fractional-Slot Winding.** These windings have fractional values for the slots per pole ( $Q/p$ ) and number of slots per phase and pole ( $q$ ). Advantages of fractional-slot windings when compared with integral slot windings are:

- Great freedom of choice with respect to the number of slots.
- Possibility to reach a suitable magnetic flux density with the given dimensions.
- Multiple alternatives for short-pitching.
- If the number of slots is predetermined, the fractional-slot winding can be applied to a wider

range of numbers of poles than the integral slot winding.

- The segment structures of large machines are better controlled by using fractional-slot windings.
- Reduction of high-frequency slot harmonics, and as consequence this winding reduces the high-frequency harmonics in the EMF and MMF waveforms.

Fractional-slotting is practicable only with double-layer windings. While  $q$  is a noninteger in a fractional-slot winding,  $mQ'$ , i.e., the total number of slots, must be divisible by 3, i.e., the total slots per phase must be an integer in order to obtain a symmetrical 3-phase winding. The pole pitch,  $mQ'/p$ , is also fractional, so that the coil-span cannot be of full-pitch. The coil-span chosen is less than the full-pitch because of the inherent advantages of chording.

A winding constituting a basic unit under a pole-pair (N and S) is repeated for any number of pole pairs when  $q$  is integral. In order to obtain the *basic unit* for fractional-slot winding,  $q = Q/(mp)$  is reduced to the irreducible fraction, as shown

$$q = \frac{Q}{mp} = \frac{Q'}{p'} = a + \frac{b}{p'}. \quad (6.1)$$

For a fractional-slot winding:

- The basic unit of the winding has  $p'$  poles.
- Each phase has within  $p'$  poles  $Q' = qp'$  slots.
- All phases have within  $p'$  poles,  $mQ'$  slots.
- Each phase has within  $p'$  poles  $p' - b$  coil groups with  $a$  coils and  $b$  coil groups with  $a + 1$  coils.
- The maximum possible number of parallel circuits is  $p/p'$ .

In a double-layer winding, the phase-grouping of coil-sides for the top layer is repeated in the bottom layer

**Fig. 6.8** Layout of three-phase double-layer fractional-slot winding

with corresponding coil-sides being located one coil-span away. Therefore, all that is needed is to establish the phase-grouping of the top layer of coil-sides. An example of a fractional-slot winding for a three-phase, 10 pole machine with 108 slots is as follows

$$q = \frac{108}{3 \times 10} = \frac{18}{5} = 3 + \frac{3}{5}.$$

Then,  $p' = 5$  makes the basic unit of this winding. Each phase has in the 5 poles  $Q' = 18$  slots. All three-phases have in the 5 poles  $mQ' = 3 \times 18 = 54$  slots. Each phase has in the 5 poles  $p' - b = 5 - 3 = 2$  coil groups with  $a = 3$  coils and  $b = 3$  coil groups with  $a + 1 = 4$  coils. The groupings could be 4,4,3,4,3 coils and the basic unit would cover 5 pole-pitches. This allows one circuit with both units in series or two parallel circuits only.

The angle between two consecutive slots of the stator is

$$\gamma = \frac{180 \times 10}{108} \circ \text{E} = 16 \frac{2}{3} \circ \text{E}.$$

Figure 6.8 shows the layout of the winding for the basic unit of five poles (note that this need not be even). The sequence of slot groups (4,4,3,4,3) is determined to give the greatest symmetry in the winding.

Though the fractional-slot winding may appear to be somewhat complicated, it can be easily manufactured. The number of armature slots chosen is not an integral multiple of the number of poles. Consequently one may choose a particular number of slots for which the notching gear is available. This results in savings on machine tools. This flexibility can be effectively used where the number of poles (machine speed) varies over a wide range as in the case of synchronous machines.

As already said the high-frequency harmonics caused by slotting are considerably reduced by the use of fractional-slot winding. As the poles move past a slotted armature, the flux/pole fluctuates (does not move) as the slot-teeth pattern facing a pole repeats. This causes induction (static) of EMF harmonics of high frequency. If  $Q/p$  (slots per pole) is integral, the disposition of armature slots relative to pole simultaneously repeats (in time phase) at every pole so that the harmonics in phase-groups of a given phase are in

phase. Nonintegral  $Q/p$  causes the harmonics in phase-group to become out-of-phase thereby reducing their strength in the phase voltage.

### 6.1.4 Basic Concepts

The frequency  $f$  can be expressed in terms of revolutions per minute of the rotor and the number of poles.

#### Frequency, Speed and Angle Relations

In one complete revolution of the rotor, the EMF induced in the coil has one complete cycle. If the rotor rotates at  $n$  revolutions per minute, the EMF frequency in cycles per second will be  $f = n/60$ , that is the number of revolutions per second. This applies to a 2 pole machine. If the number of poles is  $p$  instead of 2, it still holds that the EMF goes through a complete cycle when the coil passes two poles of the machine and therefore the frequency is

$$f = \frac{p}{2} \frac{n}{60} = \frac{pn}{120} \text{ Hz}. \quad (6.2)$$

Hydraulic turbines operate at a relatively low speed and a great number of poles are necessary for obtaining a frequency of 50 or 60 Hz. Therefore, hydrogenerators have salient-poles. On the other hand, gas, oil, and nuclear turbines operate at high speeds and it is only necessary to have 2 or 4 poles for obtaining a frequency of 50 or 60 Hz. Therefore, these machines have nonsalient-poles. Multiplying  $f$  by  $2\pi$ ,

$$\omega = 2\pi f = \frac{p}{2} 2\pi \frac{n}{60} = \frac{p}{2} \omega_m. \quad (6.3)$$

Where  $\omega$  specifies angular velocity in terms of frequency, and this velocity is called the electrical angular speed, while  $\omega_m$  is the mechanical angular velocity. When a machine has more than two poles it is convenient to focus the analysis of the machine on a unique pair of poles because the electric, magnetic and mechanic conditions associated with another pair of poles are repetitions of those that occur on the pair of poles under consideration. For this reason it is convenient to express angles in electrical degrees (or radians electri-

**Fig. 6.9** Cylindrical-rotor synchronous machine

cal) instead of using mechanical units. Thus,

$$\theta_c = \frac{p}{2} \theta_m, \quad (6.4)$$

where  $\theta_c$  is the angle in electrical units and  $\theta_m$  is the angle in mechanical units.

#### Electromotive Force of a Concentrated Full-Pitch Armature Coil

The cross-sectional view of a 2 pole cylindrical-rotor AC synchronous machine is shown in Fig. 6.9.

The distribution of the field MMF and flux density in the airgap of Fig. 6.9, for nonsalient and salient-pole machines, is not sinusoidal, but is periodic, symmetrical in successive half loops. Single-value functions that do not include infinite discontinuities, in accordance with Fourier's theorem, can be resolved into a fundamental sine wave and a series of odd harmonics.

The field winding on the rotor is assumed, for the time being, to produce a sinusoidal space wave of flux density  $B_f$  at the stator surface, given by

$$B_f = B_p \sin \theta, \quad (6.5)$$

where  $B_p$  is peak flux density at the rotor pole center and  $\theta$  is measured in electrical radians from the rotor pole axis. The airgap field flux per pole is the integral of the field flux density over the pole area, where  $L$  is the active coil-side length (axial stator length) and  $r$  is the inner radius of the armature at the airgap; thus for a two pole machine

$$\phi_f = \int_{\alpha}^{\pi+\alpha} B_p \sin \theta L r d\theta = 2B_p L r \cos \alpha. \quad (6.6)$$

Because the pole area is  $2/P$  times that of a two pole machine of the same length and diameter, for a  $P$  pole

machine

$$\phi_f = \frac{2}{p} 2B_p L r \cos \alpha = \Phi_f \cos \omega t. \quad (6.7)$$

As the pole pitch is  $\tau = \pi D/P$ , where  $D$  is the inner stator diameter, the amplitude of the flux is given by

$$\Phi_f = \frac{2}{\pi} \tau L B_p \quad (6.8)$$

and the instantaneous EMF induced in the coil  $aa'$  of  $N$  turns is given by Faraday's law,

$$e = -\frac{d\lambda}{dt} = \omega N \Phi_f \sin \omega t - N \frac{d\Phi_f}{dt} \cos \omega t. \quad (6.9)$$

In steady state conditions the value of  $\Phi_f$  is constant, and the second term is zero. Thus, the only EMF induced in the coil is due to the first term, called the speed voltage.

#### Electromotive Force of a Full-Pitch Distributed Armature Winding

The winding of phase a in the machine of Fig. 6.10 has three coils ( $11'$ ,  $22'$  and  $33'$ ), that are placed in three slot-pairs distributed in space with an angular separation of  $\gamma$  electrical degree. The phase belt or phase band may be defined as the group of adjacent slots belonging to one phase under one pole, and the angle  $\sigma = q\gamma$  ( $^\circ$  E) occupied by each phase winding along the armature periphery per pole is the phase belt angle and  $q$  is the number of slots per pole and per phase, i.e.,  $q = Q/(mp)$  (Sect. 6.1.3). Such a winding is referred to as a distributed winding. As the machine is always wound with identical coils, the rms (root mean square) value ( $E$ ) of the sinusoidal EMFs induced in coils  $11'$ ,  $22'$  and  $33'$  are equal, but the EMFs have a progressive time phase difference  $\gamma$  because the coils are uniformly distributed in space.

**Fig. 6.10** Synchronous machine with distributed winding

The coils, in Fig. 6.10, are series connected to yield the resultant phase voltage  $E_a$ , which is the phasor sum of the coil EMFs. The number of EMF phasors  $n$  is equal to the number of slots where the coils of one phase are distributed divided by two, i.e., equal to  $q$ . Because of distribution, the rms resultant phase voltage is less than the arithmetic sum of the rms coil voltages. This reduction ratio called the distribution factor (also breadth factor), where the index 1 is for the fundamental frequency, and is given by

$$k_{d1} = \frac{\sin \frac{q\gamma}{2}}{q \sin \frac{\gamma}{2}} \quad (6.10)$$

The rms value  $E$  of the armature fundamental EMF induced per phase with  $N$  turns in series per phase of a three-phase winding is given by

$$E_1 = 4.44fNk_{d1}\Phi_{f1} \text{ V} \quad (6.11)$$

The amplitude of the fundamental flux per pole is

$$\Phi_{f1} = \frac{2}{\pi} B_1 \tau L \quad (6.12)$$

The windings of each phase are a combination of coils connected in series, forming a number of coil groups, that are distributed in parallel paths. For instance, if there are four coil groups connected in series, where  $N_c$  is the number of turns of each coil, the total number

of turns in (6.11) is  $N = 4N_c$ , but if the four coil groups are connected in two parallel paths  $N = 2N_c$ .

The distribution of the field MMF and field flux density in the airgap are not sinusoidal, being in the case of cylindrical-rotor machines represented approximately by a single trapezoidal section, in which the field MMF has a constant maximum value in the central region of the pole and decreases linearly in the slotted region at each side to zero at the position  $+\pi/2$  and  $-\pi/2$  electrical radians, while in the case of salient-pole machines the MMF distribution is rectangular. Because of symmetry the MMF and flux density waves, in both machines, are symmetrical about the direct-axis. As these waves are periodic, symmetrical in successive half loops, single-value functions that do not include infinite discontinuities and in accordance with Fourier's theorem, they can be resolved into a fundamental sine wave and a series of odd harmonics. The angle of displacement between two adjacent slots for a field harmonic of the  $h$  order is equal to  $h\gamma$ , and the distribution factor for the  $h$ -th harmonic becomes

$$k_{dh} = \frac{\sin \frac{qh\gamma}{2}}{q \sin \frac{h\gamma}{2}} \quad (6.13)$$

For the  $h$ -th harmonic, the rms value  $E_h$  for the EMF is

$$E_h = 4.44hfNk_{dh}\Phi_h \text{ V} \quad (6.14)$$

and the amplitude of the flux per pole for the  $h$ -th harmonic is

$$\Phi_h = \frac{2}{\pi} B_h \frac{\tau}{h} L \quad (6.15)$$

### Electromotive Force of a Short-Pitch Armature Winding

The assumption that the coil pitch is equal to the pole pitch ( $180^\circ$  E) is seldom true for an AC winding. Normally the coil pitch is smaller than the pole pitch, i.e., normally AC windings, besides being distributed over the surface of the machine, are short-pitched or chorded. If the coil pitch is called  $\rho$ , the coil is referred to as fractional-pitched. In this coil, there will be a phase difference between induced EMFs in two coil-sides of less than  $180^\circ$ . Hence, the resultant terminal voltage of the coil is the phasor sum of these two EMFs and it is less than that of a full-pitched coil of a distributed winding. Pitch factor is a measure of the resultant EMF ( $E_R$ ) of a short-pitched coil in comparison with resultant EMF of a full-pitched coil ( $2E$ ) and is given by

$$\begin{aligned} k_{p1} &= \frac{\text{EMF induced in a short pitch coil}}{\text{EMF induced in a full pitch coil}} \\ &= \frac{2E \cos \frac{\pi-\rho}{2}}{2E} = \cos \frac{\pi-\rho}{2} \end{aligned} \quad (6.16)$$

The fundamental frequency EMF of a phase consisting of  $n$  coils, in which the number of turns in series is  $N$ , can be written as

$$E_1 = 4.44fNk_{p1}\Phi_{f1} \text{ V.} \quad (6.17)$$

It should be noted that the coil span is rarely made less than  $2/3$  pole pitch =  $120^\circ$  E, because additional turns become necessary that offset the saving of overhang copper.

A  $h$ -th harmonic component of the flux wave may be imagined as being produced by  $h$  fictitious poles as compared to one pole for the fundamental component. Thus, the angle of displacement between two adjacent slots for a field harmonic of the  $h$  order is equal to  $h$  times the chording angle for the fundamental component and the pitch factor for the  $h$ -th harmonic is given by,

$$k_{ph} = \cos h \left( \frac{180 - \rho}{2} \right). \quad (6.18)$$

For the  $h$ -th harmonic, the rms value  $E_h$  for the EMF is

$$E_h = 4.44hfNk_{ph}\Phi_{fh} \text{ V.} \quad (6.19)$$

With an appropriated choice of the pitch factor an elimination of certain harmonics of the EMF is possible, by making  $h(180 - \rho)/2$  equal to  $90^\circ$  E, i.e., if the pole pitch  $\rho = 120^\circ$  E, that is equivalent to a coil (winding) pitch of  $120/180 = 2/3$ ; the 3rd harmonic of per phase EMF and the odd harmonics multiples of the 3rd, i.e., 9th, 15th, 21st, 27th, etc. . . . , are also eliminated. However, there will be a reduction in the fundamental component of the EMF as its pitch factor will be  $k_{p1} = 0.866$ .

### Winding Factor

Both distribution and pitch factors apply for a phase winding of  $N$  turns in series. Their product ( $k_d k_p$ ) is the winding factor  $k_w$ . Thus, for the fundamental and the  $h$ -th harmonic the expressions for the per phase EMFs are for the fundamental frequency,

$$E_1 = 4.44fNk_{w1}\Phi_{f1} \text{ V,} \quad (6.20)$$

for the  $h$ -th harmonic,

$$E_h = 4.44hfNk_{wh}\Phi_{fh} \text{ V,} \quad (6.21)$$

where

$$k_{wh} = k_{dh}k_{ph}, \quad \text{for the } h\text{-th harmonic.} \quad (6.22)$$

The quantity  $Nk_w$  can be considered as the number of effective turns per phase. It is smaller than the actual number of turns per phase  $N$ , owing to the distribution of the winding over several slots under each pole and to the chording of the coils.

In studying electrical machines the windings of each phase are represented by a full-pitch coil, taking into account the fact that in an actual machine the windings are distributed and have fractional-pitches by means of the winding factor that multiplies the resultant EMFs and MMFs.

### General Expression for the Electromotive Force of AC Machines Armature Windings Including Harmonics

The instantaneous value for the EMF of phase a can be written as

$$\begin{aligned} e_a &= \sqrt{2} \sum_{h=1,3,5,\text{etc.}} E_{fh} \sin h\omega t \\ &= \sqrt{2} (E_{f1} \sin \omega t + E_{f3} \sin 3\omega t \\ &\quad + E_{f5} \sin 5\omega t + \dots) \end{aligned} \quad (6.23)$$

and the rms EMF per phase will be

$$E_r = \sqrt{E_{f1}^2 + E_{f3}^2 + E_{f5}^2 + E_{f7}^2 + \dots} \quad (6.24)$$

The triple harmonic voltage components do not appear in the line to line terminal voltages, whether the machine is connected as star or delta. However, this should not be taken to mean that unbalanced triple harmonics voltages resulting from unbalanced loads or other causes may not occur.

### The Magnetomotive Force (MMF) of a Distributed and Short-Pitch One-Phase Armature Winding

Consider a basic 2-pole structure with a round rotor, with  $q = 5$  slots/pole/phase and a two-layer winding as shown, for phase a, in Fig. 6.11. Note that  $q$  is also equal to the number of full-pitch coils. The two-layer winding simplifies the geometrical problem of getting the end turns of the individual coils past each other. The corresponding developed diagram is shown in Fig. 6.12 along with the MMF diagram that is a stepped wave—much closer to a sine wave than the rectangular MMF wave of a single coil. At each slot the MMF wave has a step jump of  $2Ni$  ampere-turns, where  $N =$  coil turns and  $i =$  coil current. The resultant field produced by the armature MMF has the same of poles as that produced by the field MMF [6.9].

The fundamental frequency MMF of a full pitch coil of  $N$  turns at each airgap, for a two pole machine, by

**Fig. 6.11** A two-layer winding (phase a) of a 3-phase round rotor machine

Fourier's series, is

$$F_1 = \frac{4 Ni}{\pi} \tag{6.25}$$

and for the  $h$ -th harmonic

$$F_h = \frac{4}{\pi} \frac{1}{h} \frac{Ni}{2} \tag{6.26}$$

In the case of  $q$  full-pitch coils with  $N$  turns per coil in a single layer winding there are  $q$  MMFs, when all

the coils are connected in series. Thus in each airgap the MMF due to  $q$  coils is equal to  $qF_1$ . In the case of a distributed and short-pitch double layer winding, the instantaneous amplitude of the fundamental MMF of all coils (in a phase)  $F_{\text{phase1}}$  is

$$F_{\text{phase1}} = 2qF_1 k_{d1} k_{p1} = 2qF_1 k_{w1} \tag{6.27}$$

where the distribution and short-pitch factors are given by the same equations derived for the expression of an EMF (see Sects. 6.1.4, *Electromotive Force of a Full-Pitch Distributed Armature Winding* and *Electromotive Force of a Short-Pitch Armature Winding*).

Using (6.25) in (6.27),

$$F_{\text{phase1}} = 2q \frac{4}{\pi} \frac{Ni}{2} k_{w1} = \frac{4}{\pi} qNk_{w1}i \tag{6.28}$$

Similarly, for the  $h$ -th harmonic

$$F_{\text{phase } h} = \frac{4}{\pi} \frac{1}{h} qNk_{wh}i, \quad \text{where } k_{wh} = k_{dh}k_{ph} \tag{6.29}$$

A machine with 2 poles was considered above. With more than 2 poles and an integral number of slots per pole and phase, the MMF will be similar to that in the above machine over each pole pair arc. When all the coil groups of the double layer winding are connected in series the number of turns per phase will be

$$N_{\text{ph}} = qNp, \quad \text{where } p = \text{number of poles} \tag{6.30}$$

and the coil current

$$i = \sqrt{2}I \sin \omega t \tag{6.31}$$

**Fig. 6.12** (a) Developed diagram and (b) MMF wave of Fig. 6.11

Upon introducing these relations into (6.28) and (6.29), the MMFs amplitudes are

$$F_{\text{phase } 1} = \frac{4\sqrt{2} N_{\text{ph}}}{\pi p} k_{w1} I, \quad (6.32)$$

$$F_{\text{phase } h} = \frac{4\sqrt{2} 1}{\pi h} \frac{N_{\text{ph}}}{p} k_{wh} I. \quad (6.33)$$

The expressions (6.32) and (6.33) are also valid for a winding (phase) with parallel branches if  $N_{\text{ph}}$  is the number of series connected turns per path and  $I$  is the total winding (one phase) current. The expression for the total MMF of the winding (one phase) can be written as

$$F_t = F_{\text{phase } 1} \sin \omega t \cos \theta + F_{\text{phase } 3} \sin \omega t \cos 3\theta + \dots + F_{\text{phase } h} \sin \omega t \cos h\theta, \quad (6.34)$$

where the angle  $\theta$  is counted from the winding (phase) axis.

### The Magnetomotive Force of a Distributed and Short-Pitch Three-Phase Armature Winding

In a three-phase machine the armature windings are  $120^\circ$  E apart and the expressions for the currents in phases a, b and c are

$$i_a = \sqrt{2} I \sin \omega t, \quad (6.35)$$

$$i_b = \sqrt{2} I \sin \left( \omega t - \frac{2\pi}{3} \right), \quad (6.36)$$

$$i_c = \sqrt{2} I \sin \left( \omega t - \frac{4\pi}{3} \right) \quad (6.37)$$

where  $\omega = 2\pi f_1$  is the synchronous angular frequency.

For a certain time instant the three-phases contribute for the armature MMF at a point on the armature surface represented by the angle  $\theta$ . The equations for the MMFs of each phase are

$$F_a = [F_{\text{phase } 1} \cos \theta + F_{\text{phase } 3} \cos 3\theta + \dots + F_{\text{phase } h} \cos h\theta] \sin \omega t,$$

$$F_b = \left[ F_{\text{phase } 1} \cos \left( \theta - \frac{2\pi}{3} \right) + F_{\text{phase } 3} \cos 3 \left( \theta - \frac{2\pi}{3} \right) + \dots + F_{\text{phase } h} \cos h \left( \theta - \frac{2\pi}{3} \right) \right] \sin \left( \omega t - \frac{2\pi}{3} \right),$$

$$F_c = \left[ F_{\text{phase } 1} \cos \left( \theta - \frac{4\pi}{3} \right) + F_{\text{phase } 3} \cos 3 \left( \theta - \frac{4\pi}{3} \right) + \dots + F_{\text{phase } h} \cos h \left( \theta - \frac{4\pi}{3} \right) \right] \sin \left( \omega t - \frac{4\pi}{3} \right). \quad (6.38)$$

The fundamental space component the resultant MMF of the three-phase winding is

$$\begin{aligned} F_1 &= \frac{3}{2} F_{\text{phase } 1} \sin(\omega t - \theta) \\ &= \frac{6\sqrt{2} N_{\text{ph}}}{\pi p} K_{w1} I \sin(\omega t - \theta) \\ &= 2.7 \frac{N_{\text{ph}}}{p} K_{w1} I \sin(\omega t - \theta) = A_1 \sin(\omega t - \theta). \end{aligned} \quad (6.39)$$

Hence it follows that the fundamental space harmonic of the resultant MMF in a three-phase machine is no longer a wave pulsating in space as in a single phase winding, but a wave traveling to the right around the stator periphery.

For the  $h$ -th harmonic, the MMF is

$$F_{h1} = 2.7 \frac{N_{\text{ph}}}{\text{HP}} K_{wh} I \sin(\omega t \pm h\theta) = A_h \sin(\omega t \pm h\theta), \quad (6.40)$$

where for phases b and c,  $\theta = \theta - 120^\circ$  and  $\theta = \theta - 240^\circ$ , respectively.

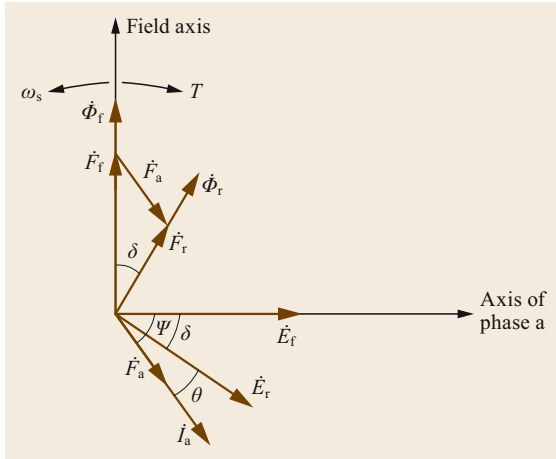

The resultant MMF  $F_r$  of all three-phases including harmonics is

$$\begin{aligned} F_r &= A_1 \sin(\omega t - \theta) + A_5 \sin(\omega t + 5\theta) \\ &\quad + A_7 \sin(\omega t - 7\theta) + \dots + A_h \sin(\omega t \pm h\theta). \end{aligned} \quad (6.41)$$

The resultant MMF is the sum of the MMFs due to:

- Harmonics of order  $h = 6k + 1$ , i.e.,  $h = 1, 7, 13, \dots$ , that produce a magnetic field rotating to the right, in the same direction of the fundamental MMF field and rotor, with a speed equal to  $\omega/h$ .
- Harmonics of order  $h = 6k - 1$ , i.e.,  $h = 5, 11, 17, \dots$ , that produce a magnetic field rotating to the left, opposite to the direction of the fundamental MMF field and the rotor, with a speed equal to  $\omega/h$ .
- The harmonics of order  $h = 3k$ , multiples of 3, i.e., 3, 6, 9,  $\dots$ , do not produce MMFs at the airgap.

The fifth and seventh harmonics create in the rotor a frequency of  $6f_1$ , the 11th and the 13th a frequency of  $12f_1$ , and so on, where  $f_1$  is the synchronous frequency of the armature currents. The fluxes due to these MMFs harmonics give rise not only to eddy currents losses in the rotor, which reduce the efficiency of the machine, but also to pulsating torques in the shaft at the frequencies  $6f_1, 12f_1$ , etc.  $\dots$

**Fig. 6.13** Synchronous generator supplying an inductive load

### 6.1.5 Armature Reaction and Phasor Diagrams

#### Cylindrical (Round) Rotor Machines

The winding of phase a is represented by a single concentrated coil  $aa'$ . The armature MMF, called the armature-reaction MMF  $F_a$ , depends on the amplitude of armature current  $I_a$  and its effect over the field MMF  $F_f$  depends on the type of load that is connected to a generator or motor, which establishes the angle  $\psi$  between the voltage  $E_f$  induced in the armature by the field magnetic flux  $F_f$  and the armature current  $I_a$ . The following conditions are considered.

**a) Operation as a Generator.** 1) When the generator supplies an inductive load,  $0 < \psi \leq -90^\circ$ . In this case  $I_a$  lags  $E_f$  by an angle  $\psi$ , the positive current maximum in coil  $aa'$  will occur at an angle  $\psi^\circ$  later;  $F_f$  lies  $(90^\circ + \psi)$  ahead of  $F_a$  as shown in the phasor diagram of Fig. 6.13. The output apparent power is

$$S = E_r I_a \exp(j(\theta)) = P + jQ, \quad (6.42)$$

where it can be concluded that the generator will supply reactive power to the load, when the power factor is inductive.

From Fig. 6.13 it is observed that the component  $F_a \sin \psi$  of  $F_a$  is directly opposite to the field MMF. Thus, when the current in a phase lags its excitation voltage a demagnetizing effect appears on the field axis, which will decrease the resulting EMF  $E_r$ , unless the DC field current increases, increasing  $F_f$  and maintaining  $E_r$  constant.

2) When the generator supplies a capacitive load ( $0 < \psi \leq 90^\circ$ ). In this case the armature current  $I_a$  is

ahead of EMF  $E_f$  and a magnetizing effect appears and to keep the resulting EMF constant  $E_r$  the DC field current must decrease. The output apparent power is

$$S = E_r I_a \exp(j(-\theta)) = P - jQ, \quad (6.43)$$

where it can be concluded that the generator will absorb reactive power when the power factor is capacitive.

3) When the generator supplies a resistive load  $\psi = 0$ . In this case the armature current  $I_a$  is in phase with EMF  $E_f$ , and neglecting saturation there will be no effect of MMF  $F_a$  over the field MMF  $F_f$ . The output apparent power is

$$S = E_r I_a \exp(j(0)) = P + j0, \quad (6.44)$$

where it can be concluded that the generator will supply no reactive power to a resistive load.

The effects of  $F_a$  on the field MMF  $F_f$  are called the direct-axis armature reaction for generating action.

**a.1) Additional Considerations.** It is seen from Fig. 6.13 that the field poles lie an angle  $\delta$  ahead of the resultant MMF (or resultant flux) wave. The electromagnetic torque developed in the machine tries to align the field poles with the resultant field and is, therefore, opposite to the mechanical torque of the turbine, i.e., against rotation, and this is true for every other operating condition of the generator. The magnitude of the torque in a cylindrical (round) rotor synchronous machine is given by

$$T = \frac{\pi}{2} \left( \frac{P}{2} \right)^2 \Phi_r F_f \sin \delta = KE_r E_f \sin \delta. \quad (6.45)$$

When  $\Phi_r$  and  $F_f$  are held constant in magnitude, the machine meets the changing requirements of the load by adjustment of the angle  $\delta$ , which is known as the torque (power) angle.

**b) Operation as a Motor.** In motoring action two conventions can be used for the armature current. The first considers the current flowing in the same sense as that of a generator, i.e., out of the machine, and the second considers the current with an opposite sense as that of a generator, i.e., current into the machine. In the latter one, the current is considered negative in the equations to be derived.

Figure 6.14 shows a phasor diagram with both conventions when a motor is connected to an inductive source, where it can be seen that there is a component of  $F_a$ , which acts over the field excitation, and is called the magnetizing component of the armature-reaction MMF. This component will increase the resulting EMF

**Fig. 6.14** Synchronous motor connected to an inductive source

$E_r$ , unless the DC field current decreases  $F_f$  in order to maintain the resultant EMF  $E_r$  constant. The motor input apparent power is given by

$$\begin{aligned} S &= E_r I_a \exp(j(\theta - 180)) = -E_r I_a \exp(j(\theta)) \\ &= -P - jQ, \end{aligned} \quad (6.46)$$

where it can be concluded that the motor receives active and reactive power from the source.

#### Phasor Diagrams and Equations for Cylindrical (Round) Rotor Machines

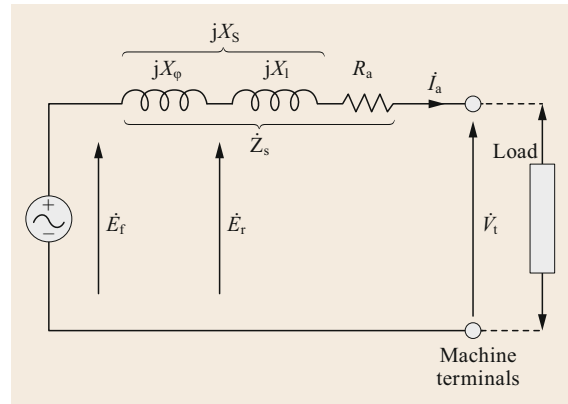

**a) Operation as a Generator.** The resultant flux is the phasor sum of the fluxes generated by the field and armature MMFs. These fluxes induce the EMFs  $\dot{E}_f$  and  $\dot{E}_a$  in the armature, respectively. The resultant EMF is

$$\dot{E}_r = \dot{E}_f + \dot{E}_a. \quad (6.47)$$

The EMF  $E_a$  is proportional to the armature current  $I_a$  and lags it by  $90^\circ$  as the EMF induced in an inductive reactance, so the effect of armature reaction is exactly as if the stator had a reactance  $X_\varphi$ , called the magnetizing or armature reaction reactance, thus

$$\dot{E}_a = -j\dot{I}_a X_\varphi \quad \text{and} \quad \dot{E}_r = \dot{E}_f - j\dot{I}_a X_\varphi. \quad (6.48)$$

The flux produced by the armature currents consists of two parts, the mutual flux that links the field winding (whose effect is represented by the EMF  $E_a$ ) and the leakage flux that only links the armature windings. The leakage flux includes the flux across the armature slots linking part or all of the coils in the slots, the end flux at the ends of the armature that links the loops or *end turns* of the armature coils where they emerge from the slots to cross over and complete the paths of the coils from slot to slot, and the tooth-top flux which is the flux between the tooth tops in the airgap without going through

**Fig. 6.15** Equivalent circuit for a cylindrical-rotor generator

the iron of the armature. The effect of the leakage flux is represented by a voltage drop in an armature leakage reactance  $X_l$  due to armature current.

The EMF resultant differs from the terminal voltage by the voltage drops in the armature resistance  $R_a$  and leakage reactance  $X_\lambda$  due to armature current  $I_a$ . Thus

$$\begin{aligned} \dot{V}_t &= \dot{E}_r = \dot{I}_a (R_a + jX_l) \\ \Rightarrow \dot{V}_t &= \dot{E}_f - j\dot{I}_a X_\varphi - (\dot{I}_a R_a + jX_l \dot{I}_a) \\ \Rightarrow \dot{E}_f &= \dot{V}_t + j\dot{I}_a (X_\varphi + X_\lambda) + \dot{I}_a R_a \\ \Rightarrow \dot{E}_f &= \dot{V}_t + \dot{I}_a R_a + j\dot{I}_a X_s, \end{aligned} \quad (6.49)$$

where  $X_s = X_\varphi + X_\lambda$  is the synchronous reactance and considers the effect of all the fluxes due to armature current  $I_a$ , while the excitation EMF  $E_f$  considers the flux due to the DC field current.

The synchronous impedance is denoted by

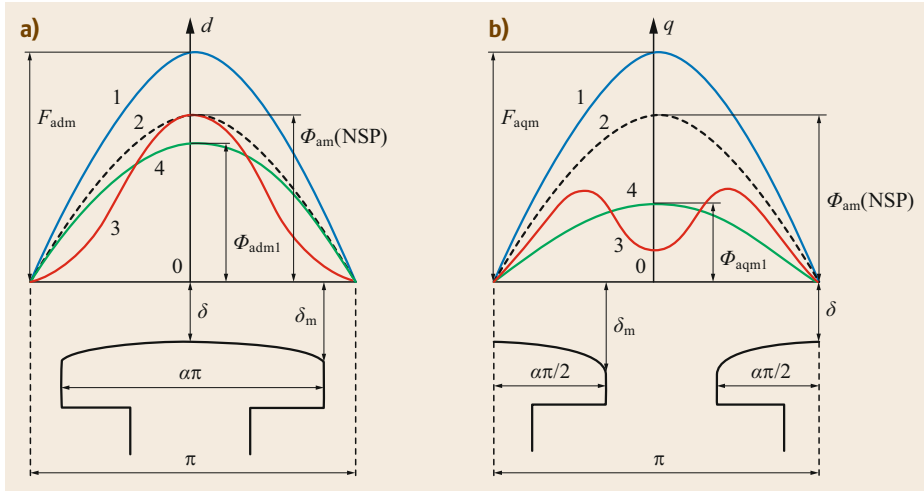

$$Z_s = R_a + jX_s. \quad (6.50)$$

According with (6.48)–(6.50) the equivalent circuit of a cylindrical generator can be represented by Fig. 6.15.

Typical values of resistance, leakage reactance and synchronous reactance for large machines, in per-unit, are

$$R_a = 0.01 \text{ p.u.}; \quad X_l = 0.15 \text{ p.u.}; \quad X_s = 1.10 \text{ p.u.}$$

In large machines the armature resistance is usually neglected except insofar as its effect on losses and heating is concerned. The per-unit armature resistance increases and the synchronous reactance decreases with decreasing size of the machine. In very small machines the armature resistance may be in the vicinity of 0.05 p.u. and the synchronous reactance in the vicinity of 0.5 p.u.

**Fig. 6.16a,b** Armature MMF and flux waves components in the (a) direct and (b) quadrature-axis. The index  $m$  means maximum values and  $\alpha\pi$  is the pole arc

**b) Operation as a Motor.** If in the equations for synchronous cylindrical generators the armature current is considered with a negative signal, i.e., current with an opposite sense as that of a generator, i.e., current into the machine, the equations for a synchronous motor are obtained, as

$$\dot{E}_t = \dot{E}_f + j\dot{I}_a X_\varphi \quad \text{and} \quad \dot{V}_t = \dot{E}_f + j\dot{I}_a X_s + \dot{I}_a R_a. \quad (6.51)$$

#### Armature Reaction in Salient-Pole Rotor Machines

**a) Operation as a Generator.** In the case of salient-pole machines the airgap reluctance varies from a low value when the armature MMF axis coincides with the direct (field) axis—which is the case when  $\psi = \pm 90^\circ$ —up to a high value when the armature MMF axis coincides with the quadrature-axis, which is the case when  $\psi = 0^\circ$ . It is relatively simple to determine the effect of the armature MMF reaction for these positions because the direct and quadrature-axis are both axis of symmetry for the rotor, but it is not so easy to determine the effect which the armature MMF has in intermediate positions. This difficulty was overcome by the use of Blondé's two-reaction theory.

This theory consists essentially of the replacement of the sinusoidal armature MMF of amplitude  $F_a$  by two sinusoidal waves, one of which has its amplitude coinciding with the direct-axis, and the other has its amplitude coinciding with the quadrature-axis. Thus the fundamental components amplitudes of armature MMF are

$$F_{ad} = F_a \sin \psi = 1.35 \frac{N_{ph}}{p} K_{w1} I_d, \quad \text{where} \quad I_d = I_a \sin \psi, \quad (6.52)$$

$$F_{aq} = F_a \cos \psi = 1.35 \frac{N_{ph}}{p} K_{w1} I_q, \quad \text{where} \quad I_q = I_a \cos \psi, \quad (6.53)$$

where

$$F_a = 1.35 \frac{N_{ph}}{p} K_{w1} I_a, \quad I_a = \text{rms armature current}. \quad (6.54)$$

In Fig. 6.16 the direct and quadrature-axis components of the armature MMF  $F_a$  are shown. Curves 1 represent the fundamental frequency components of direct ( $F_{ad}$ ) and quadrature-axis ( $F_{aq}$ ) armature MMFs; curves 2 show, just for comparison, the fundamental frequency component of armature flux for cylindrical machines, considering a uniform airgap (NSP = nonsalient-pole); curves 3 represent the actual armature fluxes in the direct ( $\phi_{ad}$ ) and quadrature-axis ( $\phi_{aq}$ ) for salient-pole machines, and curves 4 depict the fundamental frequency components of armature fluxes in the direct ( $\phi_{adm}$ ) and quadrature-axis ( $\phi_{aqm}$ ) for salient-pole machines. The slots and teeth effects were neglected.

**a.1) The Generator Supplies a Resistive Load ( $\psi = 0$ ).** Considering the current in phase a with its maximum value, the currents in phases b and c will have half of their maximum values. The current in phase a is in phase with the generated EMF  $E_f$  ( $\psi = 0$ ), there is no armature reaction demagnetizing or magnetizing effect, because the armature MMF has its symmetry axis coincident with the quadrature (interpolar)-axis and the resultant magnetic flux is distorted. The field flux has an increase under the trailing pole tips and a decrease, by the same amount (neglecting the effect of saturation), under the leading pole tips. This is called the cross-

magnetizing effect as the armature flux crosses the field flux perpendicularly. However, due to magnetic saturation the resultant flux decreases and the resultant EMF  $E_r$  is less than the excitation voltage  $E_f$ .

a.2) **The Generator Supplies a Pure Inductive/Capacitive Load ( $\psi = \pm 90^\circ$ ).** In this case the current differs in phase from  $E_f$  by  $\psi = \pm 90^\circ$ , the cross-magnetizing effect vanishes, and the entire armature MMF is demagnetizing if  $\psi$  is an angle of lag, i.e., the armature flux weakens the field flux and has only a direct-axis component; or the entire armature MMF is magnetizing if  $\psi$  is an angle of lead, i.e., the armature flux reinforces the field flux and has also a direct-axis component.

b) **Operation as a Motor.** In motoring action, for salient-pole motors the same conclusions as seen in the case of cylindrical-rotor synchronous motors apply for salient-pole rotor synchronous motors, i.e., when the current in a phase lags its excitation voltage a magnetizing effect appears on the field axis, which will increase the resulting voltage, unless the DC field current decreases, decreasing  $F_f$  and maintaining  $\bar{E}_r$  constant. Reciprocally, when the current in a phase is ahead of  $\bar{E}_r$  a demagnetizing effect appears and to maintain constant  $\bar{E}_r$  the DC field current must decrease. These effects are called the direct-axis armature reaction for motoring action. In both of these situations there will be a component of the armature MMF  $F_a$  that is perpendicular to the field axis MMF  $F_f$  and causes distortion and reduction (because of saturation effect) in the resultant magnetic field. This is called the cross-magnetizing effect of the armature reaction. However, if the angle between the armature current and the excitation voltage  $\psi = \pm 90^\circ$  there will be no cross-magnetizing effect of the armature reaction.

#### Phasor Diagrams and Equations for Salient-Pole Rotor Machines

a) **Operation as a Generator.** A method for obtaining the phasor diagram of a salient-pole machine was developed from the Blondel diagram by Doherty and Nickle, and consists of representing, in the same diagram, the EMFs due to each flux in the machine, as shown in Fig. 6.17.

With respect to Fig. 6.17 the following equations can be written

$$\begin{aligned} \dot{E}_f + \dot{E}_{aq} + E_{ad} - \dot{E}_r &= 0 \Rightarrow \dot{E}_{aq} = -j\dot{I}_q X_{\varphi q} \\ \Rightarrow \dot{E}_{ad} &= -j\dot{I}_d X_{\varphi d}, \end{aligned} \quad (6.55)$$

where  $X_{\varphi q}$  and  $X_{\varphi d}$  are called the direct and quadrature-axis magnetizing or armature reaction reactance's, re-

Fig. 6.17 Modified phasor diagram showing fluxes and EMFs of a salient-pole generator supplying an inductive load

spectively. They take into account the inductive effects of the direct ( $\phi_{ad}$ ) and quadrature-axis ( $\phi_{aq}$ ) fluxes. Thus

$$\begin{aligned} \dot{E}_f &= \dot{E}_r + j\dot{I}_q X_{\varphi q} + j\dot{I}_d X_{\varphi d} \\ \text{and } \dot{E}_r &= R_a \dot{I}_a + jX_1 \dot{I}_a + \dot{V}_t. \end{aligned} \quad (6.56)$$

As

$$\begin{aligned} \dot{I}_a &= \dot{I}_d + \dot{I}_q \\ \Rightarrow \dot{E}_f &= \dot{V}_t + \dot{I}_a R_a + j\dot{I}_d (X_{\varphi d} + X_1) + j\dot{I}_q (X_{\varphi q} + X_1). \end{aligned} \quad (6.57)$$

Defining:

$X_d = X_{\varphi d} + X_\lambda$  (direct-axis synchronous reactance)  
 $X_q = X_{\varphi q} + X_\lambda$  (quadrature-axis synchronous reactance),

$$\dot{E}_f = \dot{V}_t + \dot{I}_a R_a + j\dot{I}_d X_d + j\dot{I}_q X_q. \quad (6.58)$$

In machines larger than 100–200 kW, the resistance is usually small enough to be neglected. In salient-pole machines the reactance  $X_q$  is less than the reactance  $X_d$  because of the greater reluctance of the airgap in the quadrature-axis. Usually  $X_q = 0.6\text{--}0.7$  of  $X_d$ .

In turbogenerators a small salient-pole effect is present, even though they are cylindrical-rotor machines, because of the effect of the rotor slots in the quadrature-axis reluctance, which causes a slightly longer average airgap in this axis than in the direct-axis, and as a consequence the permeance in the quadrature-axis will be lower than in the direct-axis, and  $X_q$  is slightly smaller than  $X_d$ . However, in most problems involving cylindrical-rotor machines,  $X_d$  and  $X_q$  may be assumed equal with negligible error.

**Fig. 6.18** Phasor diagram of a salient-pole synchronous motor—lagging current

**b) Operation as a Motor.** For a motor the procedure is similar to obtaining the phasor diagram for a generator, but adopting the convention of an armature current entering into the machine. Thus, in the equations for the operation as a generator the armature current must be considered negative. In this case the excitation voltage is given by

$$\dot{E}_f = \dot{V}_t - \dot{I}_a R_a - j\dot{I}_d X_d - j\dot{I}_q X_q. \quad (6.59)$$

The phasor diagram for a lagging current is shown in Fig. 6.18, where it can be noted that  $V_t$  is ahead of  $E_f$  and the angle  $\delta$  is negative.

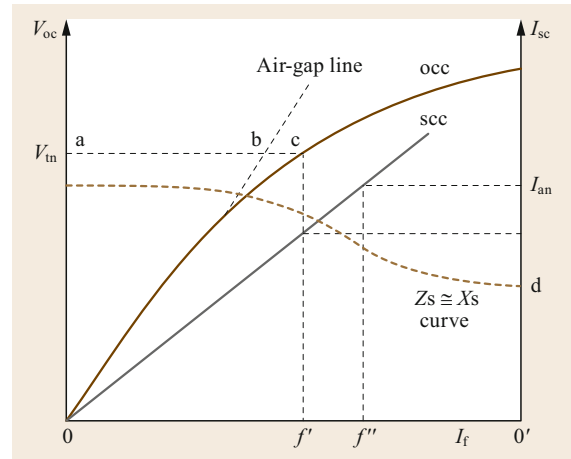

### 6.1.6 Open and Short-Circuit Characteristics

The synchronous impedance/direct-axis reactance's, for cylindrical-rotor and salient-pole rotor machines, can be obtained by the open and short-circuit characteristics. In addition, machine losses are obtained, that makes it possible to calculate its efficiency.

#### Open-Circuit Characteristic and No-Load Rotational Losses

The open-circuit characteristic (OCC) is obtained, with the machine rotating at synchronous speed, and with the armature terminals open, by reading the values of the terminal armature voltage as ordinate, and the field current as abscissa. The general shape of the OCC is the same in all synchronous machines, but the slope of the air-gap line and the rate at which the OCC bends over will differ in machines of different design. The air-gap line is the extended straight line part of the OCC. This characteristic is shown in Fig. 6.19, together with the short-circuit characteristic and the synchronous impedance reactance curve.

At low values of field excitation the OCC is a straight line because the MMF required for the iron parts of the magnetic path is negligible in comparison with the MMF needed to maintain the flux in the airgap

**Fig. 6.19** Open and short-circuit characteristics, with air-gap line and the synchronous impedance curve

between the rotor and stator. The field excitation necessary to induce rated (nominal) terminal voltage  $V_{tn}$  in the stator winding is equal to ac. The ab part corresponds to the excitation MMF necessary to drive the flux through the airgap, and the bc part is necessary to drive the flux through the iron parts of the magnetic path.

If the mechanical power is measured during the open-circuit test [6.10], the open-circuit or no-load rotational losses ( $P_{rot}$ ) can be determined. No-load rotational losses comprise the sum of the no-load core losses ( $P_c$ ) with the mechanical losses.

The no-load core losses consist of hysteresis and eddy current losses due to excitation flux, which induces in the armature the open-circuit voltage, and are confined largely to the armature iron, although the flux pulsations arising from slot openings will cause losses on the pole surfaces, as well as on an iron surface in salient-pole machines and on the surface of the solid rotor in cylindrical-rotor machines.

Mechanical losses are the sum of losses due to friction in the bearings and brushes ( $P_a$ ), with the loss due to windage ( $P_w$ ), i.e., the machine loss due to the resistance offered by air (salient-pole machines) or hydrogen (cylindrical-rotor machines) to the rotation of the shaft. The losses due to friction and windage are constant at synchronous speed. Bearing friction losses depend on the first power of shaft speed, bearing type, properties of the lubricant and the load on the bearing. Windage losses depend on the density of the coolant (air/hydrogen) surrounding the rotor, machine geometry, surface roughness, torque coefficient, and increases with the cube of rotor speed. Due to the cubic relationship with speed, windage is an important loss to manage in the design of high speed machines. The use

of hydrogen instead of air as a cooling medium reduces the windage losses to about 10% of those which appear with air. Thus

$$P_{\text{rot}} = P_a + P_w + P_c. \quad (6.60)$$

With zero excitation,  $P_c = 0$  and the no-load rotational losses are the sum of  $P_a$  and  $P_w$ . With nonzero excitation the  $P_c$  can be obtained from the difference between the mechanical power and the sum of  $P_a$  and  $P_w$ . The no-load core loss  $P_c$  may be plotted as a function of armature voltage.

### Short-Circuit Characteristic and Short-Circuit Load Losses

If the armature terminals of a synchronous machine that is operating as a synchronous speed generator are short-circuited and armature current  $I_a$  and excitation current  $I_f$  readings are obtained, the losses caused by the armature current are obtained.

The mechanical power ( $P_m$ ) supplied by the machine during the short-circuit test is equal to the sum of the losses due to friction in the bearings and brushes ( $P_a$ ), the losses due to windage ( $P_w$ ) and the losses caused by the armature current ( $P_{\text{la}}$ ) (also referred to as short-circuit load losses). Thus

$$P_{\text{la}} = P_m - (P_a + P_w). \quad (6.61)$$

The short-circuit load losses due to  $I_a$  are in turn the sum of the losses in the copper in the armature windings considering the value of the DC armature resistance and the additional losses, also called stray-load losses.

The stray-load losses are equal to the sum of the losses in the core of the armature due to the leakage flux, the losses in the core of the armature and rotor due to the resulting flux and the increase of the losses in the copper due to nonuniform distribution of the current in the conductors, i.e., the difference between the copper losses of the armature due to alternating current and direct current. As seen in short-circuit the resulting flux is very small and the losses in the core due to it are usually neglected.

Copper losses of the armature due to direct current (DC) resistance can be calculated if this resistance is known for a certain temperature  $t$  by measuring the average winding temperature of the armature  $T$  during the test by the formula

$$\frac{R_T}{R_t} = \frac{K + T}{K + t}, \quad (6.62)$$

where  $K = 234.5^\circ\text{C}$  for copper conductors.

Thus, by subtracting from the short-circuit losses, the losses in the DC resistance of the armature, we obtain the stray-load losses due to  $I_a$  ( $P_{\text{ad}}$ ). As in any equipment, the effective resistance of the armature is equal to the losses attributed to the current of the armature divided by the square of the current. Generally, the rated value is used for  $I_a$ , and

$$R_a(\text{effective}) = \frac{\text{short-circuit load loss}}{I_a^2}. \quad (6.63)$$

### Determination of Synchronous Impedance/Reactances and Short-Circuit Relation

*a) Determination of Synchronous Impedance/Reactances.* For a cylindrical-rotor machine on short-circuit the excitation voltage is  $\dot{E}_f = (R_a + jX_s)\dot{I}_a$ , where  $\dot{I}_a$  is the armature current. Its amplitude is  $|\dot{E}_f| = Z_s |\dot{I}_a|$ , where  $Z_s = \sqrt{R_a^2 + X_s^2}$  is the synchronous impedance.

For a salient-pole machine on short-circuit, also from Sect. 6.1.6,

$$\begin{aligned} \dot{E}_f &= \dot{I}_a R_a + j\dot{I}_d X_d + j\dot{I}_q X_q \\ &= \dot{I}_a R_a + j\dot{I}_a X_d \quad \text{as } \dot{I}_q = 0. \end{aligned}$$

$$\text{Then, } \dot{I}_d = \dot{I}_a. \quad (6.64)$$

If the value of the voltage from the no-load characteristic is divided by the value of the current obtained from the short-circuit characteristic for the same value of field excitation, the synchronous impedance  $Z_s$  is obtained. Considering other points for the field excitation, and assuming the same open-circuit characteristic for a cylindrical-rotor and a salient-pole machine, the synchronous impedance curve may be found, where

$$Z_s = \sqrt{R_a^2 + X_s^2}$$

for a cylindrical-rotor machine

$$\text{and } Z_s = \sqrt{R_a^2 + X_d^2}$$

for a salient-pole machine. (6.65)

The  $Z_s$  curve is constant only in the unsaturated part of the open-circuit characteristic, and decreases with increasing excitation.

Considering  $R_a$  neglected in relation to synchronous reactance

$$X_s \quad \text{or} \quad X_d = \frac{|\dot{E}_f|}{|\dot{I}_a|}. \quad (6.66)$$

Thus, the saturated values of the synchronous reactance  $X_s$  for cylindrical-rotor machines and of the direct-axis

synchronous reactance  $X_d$  for salient-pole machines are obtained. To find the unsaturated values for these reactances, the voltage on open-circuit, before the short-circuit, should be taken from the airgap line, instead of the open-circuit characteristic. The unsaturated values for these reactances are always greater than their saturated values.

**b) Determination of Short-Circuit Ratio (SCR).** The SCR of a synchronous generator is defined in the IEC 60034-4 [6.11] standard as “The ratio of the field current for rated armature voltage on open-circuit (OC) to the field current for rated armature current on sustained symmetrical short-circuit, both with the machine running at rated speed”. The short-circuit ratio is the inverse of the saturated value of the synchronous reactance in p.u. From Fig. 6.20

$$\text{SCR} = \frac{\text{OF}_O}{\text{OF}_S} = \frac{\text{CF}_O}{\text{BF}_S} = \text{CF}_O \quad \text{in p.u.}, \quad (6.67)$$

where:

$\text{OF}_O$  = p.u. field current required to develop rated voltage on the open-circuit characteristic (OCC)

$\text{OF}_S$  = p.u. field current required to develop rated current on the short-circuit characteristic (SCC)

$\text{CF}_O$  = p.u. sc armature current, also herein designated as  $I'_a$

$\text{BF}_S$  = p.u. rated armature voltage on open-circuit (OC).

The armature resistance is very small when compared with the synchronous reactance, so for a short-circuit at the machine terminal the short-circuit current may be considered totally inductive and the impedance seen by the machine is  $X_s$  for a nonsalient-pole machine

Fig. 6.20 Determination of short-circuit ratio (SCR)

(NSPM – round rotor) or  $X_d$  for a salient-pole machine (SPM).

For operation near or at the rated voltage the machine may be considered as equivalent to a nonsaturated machine whose magnetizing curve is a straight line passing through the points O and A. According to this approximation and supposing the same graphic for nonsalient and salient-pole machines,

$$\begin{aligned} X_s \text{ (p.u.)} &= X_d \text{ (p.u.)} = (V_{tn}/V_{tn})/(I'_a/I_{an}) = I_{an}/I'_a \\ &= I'_a \text{ in p.u.}, \end{aligned}$$

where  $I'_a$  in p.u. =  $\text{CF}_O$  in p.u. Therefore, the SCR is equal to the inverse of the synchronous reactance in p.u.

$$\begin{aligned} \text{SCR} &= \frac{1}{X_s \text{ p.u. (sat)}} \quad (\text{NSPM}) \\ &= \frac{1}{X_d \text{ p.u. (sat)}} \quad (\text{SPM}). \end{aligned} \quad (6.68)$$

Note that these values of reactances are saturated values.

### 6.1.7 Efficiency

The efficiency is equal to the ratio of output power to machine-supplied power. In small machines, such as those used in laboratories, these powers are obtained by measurement. On larger machines where mechanical power cannot be measured accurately, the efficiency is calculated on the basis of the losses obtained in the tests performed to obtain the characteristics of open-circuit and of short-circuit. The following losses are considered:

- Friction and windage loss
- Core losses due to the resulting (voltage) flux
- Stray-load loss
- Joule losses of armature winding, using the direct current resistance
- Resistive losses of field winding
- Ventilation and cooling losses.

It should be noted that only losses in the field winding are computed. The rheostat loss (if the excitation is provided by a rotary exciter) and the thyristor bridge loss (if the excitation is provided by a static exciter), that controls the field current, and all losses in external sources that supply excitation to the machine are not considered in the determination of machine efficiency. These losses are charged against the plant.

The values of  $I_a$  and  $I_f$  to be used in calculating copper losses are those for the operating conditions of the

machines in which it is desired to calculate their efficiency, in general, for the nominal operating condition. If the temperature values of field windings and armature are not obtained, a conventional value of 75 °C should be used.

For a synchronous machine the efficiency  $\eta$ , in percentage, is calculated by the expression

$$\eta(\%) = \left( 1 - \frac{\sum \text{losses}}{\text{output power} + \sum \text{losses}} \right) \times 100. \quad (6.69)$$

The core loss is obtained from the loss curve with the machine on open-circuit (Sect. 6.1.6), using the resulting voltage in the armature due to the resulting flux, for the operating conditions of the machine on which the efficiency is to be calculated. For generators,

$$\dot{E}_r = \dot{V}_t + \dot{I}_a R_a + j\dot{I}_a X_l. \quad (6.70)$$

As the stray-load loss already takes into account the core loss due to the leakage flux, the term  $j\dot{I}_a X_l$  is neglected in (6.70), therefore the voltage  $\dot{E}_r = \dot{V}_t + \dot{I}_a R_a$  is used to calculate the core loss. For the case of motors the resulting voltage to be considered in the core loss calculation is

$$\dot{E}_r = \dot{V}_t - \dot{I}_a R_a. \quad (6.71)$$

The ventilating and cooling loss includes any power required to circulate the cooling medium through the machine (if used) by fans or pumps that are driven by external means (such as a separate motor), so that their power requirements are not included in the friction and windage loss.

## 6.1.8 Reactances and Time Constants

### Reactances

The choice of base field current as the current required to produce rated voltage at rated speed on the airgap line is convenient for constructing phasor diagrams, but not for including the effects of currents in rotor circuits additional to the field circuit. This can best be done by defining base currents for each rotor winding so that the mutual inductances in per-unit between stator and rotor in the direct-axis are equal and the mutual inductances in per-unit between stator and quadrature-axis are also equal.

For the stator the base quantities are maintained, i.e., rated apparent power, rated voltage and rated frequency, from which other base quantities like impedance, current and flux linkage are derived. For a comprehensive

treatment of the per-unit system and equivalent circuits of synchronous machines see [6.12–14].

Unbalanced operation and faults conditions are usually analyzed by the method of symmetrical components by defining expressions for the reactances according to each sequence component of the method, which are presented hereafter.

**a) Positive-Sequence Reactances.** If positive-sequence currents of rated frequency are applied to the armature, a fundamental space wave of magnetomotive force (MMF) is produced that rotates forward in synchronism with the rotor. The airgap permeance offered to this MMF wave depends upon its position relative to the poles and whether the armature currents are suddenly applied or are sustained, and, if suddenly applied, whether the machine has a damper winding.

**a.1) Direct-Axis Synchronous Reactance  $X_d$  and Quadrature-Axis Synchronous Reactance  $X_q$ .** Designating the magnetizing reactance in the direct-axis  $X_{qd} = X_{ad}$  and the magnetizing reactance in the quadrature-axis  $X_{qq} = X_{aq}$  (Sect. 6.1.5),

$$X_d = X_{ad} + X_l \quad \text{and} \quad X_q = X_{aq} + X_l. \quad (6.72)$$

These two-reactances take into account the inductive effects of the fluxes due to the armature current.

**a.2) Direct-Axis Transient Reactance  $X'_d$  and Subtransient Reactance  $X''_d$ .** If field currents are expressed in the reciprocal per-unit system,  $X'_d$  may be determined from the per-unit reciprocal equivalent circuit of Fig. 6.21a, where  $X_{fl}$  is the field leakage reactance,  $X_{ff}$  is the total field reactance,  $X_l$  is the armature leakage reactance, and  $X_{ad}$  is the mutual reactance between armature and field. Direct-axis transient reactance  $X'_d$ , which is a reactance viewed from the armature terminals is given by

$$\begin{aligned} X'_d &= X_l + \frac{X_{ad} X_{fl}}{X_{ad} + X_{fl}} = X_l + \frac{X_{ad} (X_{ff} - X_{ad})}{X_{ff}} \\ &= X_d - \frac{X_{ad}^2}{X_{ff}}. \end{aligned} \quad (6.73)$$

It should be noted that direct-axis synchronous reactance  $X_d$  is obtained by opening the field leakage reactance branch  $X_{fl}$  of Fig. 6.21a.

Direct-axis subtransient reactance  $X''_d$  may be determined from the equivalent circuit of Fig. 6.21b, in which the damper winding in the direct-axis is represented as an equivalent single winding having a leakage reactance  $X_{1d}$ . This circuit, based on the assumption that the mutual reactances between armature and field, between armature and damper, and between damper and

**Fig. 6.21 (a-c)** Reciprocal per-unit equivalent circuits for armature and rotor circuits for determining  $X'_d$ ,  $X''_d$  and  $X'_q$ , respectively

field are all equal to  $X_{ad}$ . The direct-axis subtransient reactance  $X''_d$  is given by

$$X''_d = X_l + \frac{X_{ad}X_{fl}X_{ld}}{X_{ad}X_{fl} + X_{ad}X_{ld}X_{fl}X_{ld}} \quad (6.74)$$

**a.3) Quadrature-Axis Transient Reactance  $X'_q$  and Subtransient Reactance  $X''_q$ .** Consider a salient-pole machine without a damper winding. With the rotor rotated at synchronous speed, let the positive-sequence quadrature-axis currents of rated frequency be suddenly applied. The voltages induced in one-half of the field winding balance those induced in the other half, so that no currents are induced in the rotor circuit. The flux paths under this condition are the same as those for sustained conditions, i.e., there will be no linkage with the field winding. Thus, the quadrature-axis subtransient, transient and synchronous reactances are equal, i.e.,

$$X'_q = X''_q = X_q = X_l + X_{aq} \quad (6.75)$$

where  $X_l$  is the leakage reactance and  $X_{aq}$  is the quadrature-axis magnetizing or quadrature-axis armature reaction reactance.

In the case of a salient-pole machine with a damper winding, quadrature-axis subtransient reactance  $X''_q$  may be determined from the equivalent circuit of Fig. 6.21c, in which the  $X_{aq}$  is the mutual reactance between the armature and rotor circuit in the quadrature-axis and  $X_{lq}$  represents the leakage reactance of the damper winding of a salient-pole machine or the analogous effect in a cylindrical-rotor machine. Viewed from the armature terminals,

$$X''_q = X_l + \frac{X_{aq}X_{lq}}{X_{aq} + X_{lq}} \quad (6.76)$$

In a salient-pole-machine a representation with one damper winding on each axis has been considered satisfactory.

For cylindrical-rotor (turbogenerator) machines the eddy current paths in the iron can be considered as a squirrel cage having an infinite number of bars, and

require an infinite number of damper coils for their representation. Thus, the representation of Fig. 6.21c is an approximation. However, if data is available, a second damper winding with reactance  $X_{2q}$  in parallel to  $X_{lq}$  can be represented in Fig. 6.21c, so that transient and subtransient effects can be both considered. In this case  $X'_q > X''_q$ .

**b) Negative-Sequence Reactance.** The rotating space wave of MMF produced by rated-frequency armature currents of negative-sequence order differ from those due to positive-sequence phase order in their direction of rotation, i.e., it rotates backward at twice the synchronous speed with respect to the rotor. As this MMF wave passes rapidly over each axis of the poles, the permeance presented varies rapidly from that in the direct and quadrature-axis, the reactance corresponding alternately to direct and quadrature-axis subtransient reactances. Thus, the negative-sequence reactance  $X_2$  is given by

$$X_2 = \frac{X''_d + X''_q}{2} \quad (6.77)$$

**c) Zero-Sequence Reactance.** If zero-sequence currents of fundamental frequency are applied to a three-phase machine, the MMF waves in all phases pulsate in phase and produce a stationary field that alternates at the fundamental frequency. When the equations for each phase are added the fundamental and all harmonic space MMF waves, that pulsate at the fundamental frequency disappear, except the third harmonic MMF and multiples of the third. At other than full pitch, the coil sides in some of the slots carry currents in opposite directions and the slot, airgap, and end-leakage fluxes are all small. The zero-sequence reactance may vary greatly, depending upon the coil pitch, but it is never greater than positive-sequence armature leakage reactance and may be less than half of it.

**d) Effect of Saturation on Machine Reactances.** Both the saturated synchronous reactance  $X_s$  of a cylindrical-rotor machine and the saturated direct-axis syn-

chronous reactance  $X_d$  of a salient-pole machine may be obtained according to Sect. 6.1.6, as well their unsaturated reactances. Concerning the quadrature-axis synchronous reactance  $X_q$  the usual assumption is that it is not affected by saturation. This assumption is suitable especially where external impedance is associated with the machine. Nevertheless, its saturated value may be obtained by testing.

The direct-axis transient and subtransient reactances  $X'_d$  and  $X''_d$  are predominantly determined by armature leakage and field or damper-winding leakage, although magnetizing or mutual reactances also enter. They are therefore influenced by saturation to a lesser extent than is  $X_d$ . Usually two values of each reactance are available. One, called the rated-voltage, or saturated value, is determined from short-circuit tests in which the field current is adjusted to give a pre-fault terminal voltage at or near the rated machine voltage. The other, called the rated-current value or unsaturated value is also found from short-circuit tests in which the field current is reduced so that the initial symmetrical transient or subtransient current is equal to the rated current. The rated-voltage value of these reactances is usually 10–15% lower than the rated-current value. The choice between them depends on the specific application. For studies involving circuit-interruption duties, protective relay settings, and short-circuit stresses, the rated-voltage value ordinarily is used. For stability studies, the rated-current value is usually employed because it leads to conservative synchronizing powers and torques.

The saturated value and unsaturated value of  $X'_q$  may be obtained by test, while specifically for cylindrical-rotor machines the saturated value of  $X'_q$  is around 87% of its unsaturated value.

### Time Constants

In a synchronous machine, because the coupling between armature and rotor circuits differ in the direct and quadrature-axis, there are direct-axis and quadrature-axis time constants. Subtransient time constants apply to rapidly decreasing components and transient time constants to slowly decreasing components of current or voltage. There is also the time constant of the armature winding which applies to DC armature current and to the alternating current induced in the field winding. It should be noted that when defining time constants, resistances are added in Fig. 6.21, in series with the respective leakage winding reactances, as:  $R_f$ , in series with  $X_{fl}$ ,  $R_{1d}$  in series with  $X_{1d}$  and  $R_{1q}$  in series with  $X_{1q}$ , being  $\omega = 2\pi f$  and armature resistance neglected, except when determining the armature time constant.

### a) Open-Circuit Time Constants.

a.1) Direct-Axis Transient Open-Circuit Time Constant  $T'_{d0}$ . The change of field current in response to sudden application, removal, or change of EMF in the field circuit, with the armature open-circuit, is governed by the field open-circuit time constant, or direct-axis transient open-circuit time constant, given by

$$T'_{d0} = \frac{X_{ff}}{\omega R_f} . \quad (6.78)$$

a.2) Direct-Axis Subtransient Open-Circuit Time Constant  $T''_{d0}$ . This determines the decrement curve of the rapidly decreasing component of the quadrature-axis fundamental frequency armature voltage, after the sudden removal of a three-phase short-circuit, with the machine running at synchronous speed. It is given by

$$T''_{d0} = \frac{X_{1d} + X_{fl}X_{ad}/(X_{fl} + X_{ad})}{\omega R_{1d}} . \quad (6.79)$$

a.3) Quadrature-Axis Transient and Subtransient Open-Circuit Time Constants  $T'_{q0}$  and  $T''_{q0}$ . These time constants are analogous to  $T'_{d0}$  and  $T''_{d0}$  the difference being that they are defined in terms of components of voltage in the direct-axis instead of in the quadrature-axis. The quadrature-axis transient open-circuit time constant  $T'_{q0}$  has no significance in a salient-pole machine, as there is no low resistance winding in the quadrature-axis which corresponds to the field winding in the direct-axis. In the case of a cylindrical-rotor machine represented as two damper windings in the quadrature-axis, both constants  $T'_{q0}$  and  $T''_{q0}$  may be defined, however with the consideration of just one damper winding in the quadrature-axis the induced currents are of a subtransient nature, and the subtransient time constant  $T''_{q0}$  is

$$T''_{q0} = \frac{X_{1q} + X_{aq}}{\omega R_{1q}} . \quad (6.80)$$

### b) Short-Circuit Time Constants.

b.1) Direct-Axis Transient and Subtransient. The time constant  $T'_d$  governs the slowly decreasing component of the AC armature current under a suddenly applied symmetrical three-phase short-circuit at the armature terminals, while the time constant  $T''_d$  applies to the rapidly decreasing component. They are given by

$$T'_d = \frac{X_{fl} + X_l X_{ad}/(X_l + X_{ad})}{\omega R_f} = T'_{d0} \frac{X'_d}{X_d} , \quad (6.81)$$

$$T_d'' = \frac{X_{1d} + X_l X_{fl} X_{ad} / (X_{ad} X_l + X_{ad} X_{fl} + X_l X_{fl})}{\omega R_{1d}}$$

$$= T_{d0}'' \frac{X_d''}{X_d'} \quad (6.82)$$

### b.2) Quadrature-Axis Transient and Subtransient.

If a synchronous machine is operated under load, there will be flux mutual to the armature and rotor current in the quadrature-axis; therefore, if a three-phase short-circuit is suddenly applied under load there will be quadrature-axis AC components of current which decrease rapidly in accordance with the quadrature-axis subtransient short-circuit time constant  $T_q''$ , and then less rapidly in accordance with the quadrature-axis transient short-circuit time constant  $T_q'$ .  $T_q'$  and  $T_q''$  are analogous to  $T_d'$  and  $T_d''$ , respectively, except that they apply to components of current in the quadrature-axis of the AC component of armature current.  $T_q'$  is applied only for a cylindrical-rotor machine with two damper circuits represented. For the representation of Fig. 6.21c, then

$$T_q'' = \frac{X_{1q} + X_{aq} X_l / (X_{aq} + X_l)}{\omega R_{1q}} = T_{q0}'' \frac{X_q''}{X_q'} \quad (6.83)$$

c) *Armature Short-Circuit Time Constant  $T_a$ .* The time constant  $T_d'$  governs the decay of the DC armature current and the alternating currents induced by it in the field and damper windings, under a suddenly applied symmetrical three-phase short-circuit at the armature terminals. It depends on the DC armature resistance and the inductive coupling between armature, field and damper circuits. As the rotor revolves the DC stationary MMF created by the armature currents passes by the direct and quadrature-axis rotor circuits, so that the equivalent reactance seen by the MMF wave, on an intuitive basis, may be considered as an arithmetic mean of  $X_d''$  and  $X_q''$ . Thus,

$$T_a = \frac{X_d'' + X_q''}{2\omega R_a} \quad (6.84)$$

d) *Relations Between Time Constants.* From the previous values of time constants the followings relations can be derived

$$T_d' = T_{d0}' \frac{X_d'}{X_d}, \quad T_d'' = T_{d0}'' \frac{X_d''}{X_d'}, \quad T_q'' = T_{q0}'' \frac{X_q''}{X_q'} \quad (6.85)$$

### Poitier Reactance

The armature leakage reactance can not be obtained by testing. It is determined from geometric and physical details usually only available to the designer, while

the manufacture can provide its value. However, from the Poitier diagram it is possible to obtain a reactance called Poitier reactance, that is an approximate value for the leakage reactance. For this it is necessary to have the open-circuit (OCC) and the zero-power factor characteristics (ZPFC). This latter characteristic may be obtained from testing with the generator connected to a reactor whose reactance may be varied or to an idle synchronous motor, so that the current in the machine is maintained constant and equal to the rated value  $I_{an}$ , while the field current is adjusted to give various values of terminal voltage, including nominal voltage  $V_{tn}$ . In the case of a large machine tested in a power station, the desired test to obtain the Poitier diagram, may be done with its active power loading close to zero, by redistribution of its reactive power loading among other machines on the same bus or system, without removing them from service. The armature MMF under nominal current can be obtained from this test.

### Additional Considerations

Testing for reactances and time constants is performed by applying a three-phase fault on the machine terminals with the machine unloaded and on open-circuit. Values obtained from such tests are direct-axis values. Quadrature-axis transient and subtransient values can be calculated, but can not be tested by tests from open-circuit pre-fault conditions. IEC 60034-4 [6.11] describes unconfirmed tests for determining transient and subtransient quadrature-axis synchronous machine characteristic values.

In recent years standstill frequency response testing based on impedance measurements has been developed to obtain parameter values for the elements of the direct and quadrature-axis equivalent circuits. These tests are made with the rotor held stationary and by appropriate alignment of the rotor, the armature is excited with variable frequency currents ranging from as low as 0.001 to around 100 Hz, and the corresponding impedance is measured. These impedances correspond to the input impedances of direct and quadrature-axis equivalents such as those of Fig. 6.21. Experience has shown that for certain types of analysis, models based on frequency measurements may exhibit increased accuracy over analysis based on parameters obtained by the traditional methods. Difficulties with such tests include the fact that measurements are made at low excitation levels and the fact that contact resistances of the rotor elements such as slot wedges and retaining rings are different when the rotor is stationary from when the rotor is rotating and centrifugal forces are acting on them. Many discussions of modeling are found in the growing literature on synchronous machines.

**Table 6.3** Synchronous machine reactances and resistances in per unit based on rating

Reactance/resistance	Turbogenerators		Salient-pole generators (with dampers)	
	Nonsaturated	Saturated	Nonsaturated	Saturated
$X_d$	1.49–1.87	1.35–1.65	0.70–1.50	0.60–0.95
$X_q$	1.45–1.83	1.32–1.60	0.52–1.00	0.45–0.85

$R_a$ (dc)	0.0020–0.0070		0.0030–0.0180	
$R_2$	0.0280–0.0430		0.0100–0.1800	

**Table 6.4** Synchronous machine time constants

Time constant	$T'_{d0}$	$T''_{d0}$	$T'_d$	$T''_d$	$T''_{q0}$	$T''_q$	$T_a$
Turbogenerators	4–12	0.02–0.06	1–2	0.02–0.05	0.02–0.06	0.02–0.05	0.04–0.36
Salient-pole generators (with dampers)	3–8	0.01–0.06	1.5–3	0.01–0.05	0.01–0.09	0.01–0.05	0.03–0.25

Tables 6.3 and 6.4 show the range of typical values of reactances, resistances and time constants. It is to be noted that these values indicate usual values of parameters, although exceptions may be found depending on individual machine design.

For salient-pole machines without damper windings  $X''_q = X'_q = X_q$  and  $X_2 = (X'_d + X_q)/2$ .

### 6.1.9 Power Angle Characteristic of Synchronous Machines

The expressions for the active and reactive power supplied by a salient-pole generator at an infinite bus through an external reactance will be derived. It will be assumed that the generator is connected to the infinite bus by an external reactance  $X_e$ . From these expressions the equations for a nonsalient-pole (round rotor) machine are derived. The expressions including the armature and external resistances will be presented.

#### Operation as a Salient-Pole Generator (SPG)

Figure 6.22 shows the phasor diagram for a salient-pole generator supplying an inductive load, and connected to an infinite bus by an external reactance  $X_e$ .

The active power, in p.u., supplied to the infinite bus, neglecting resistances, is

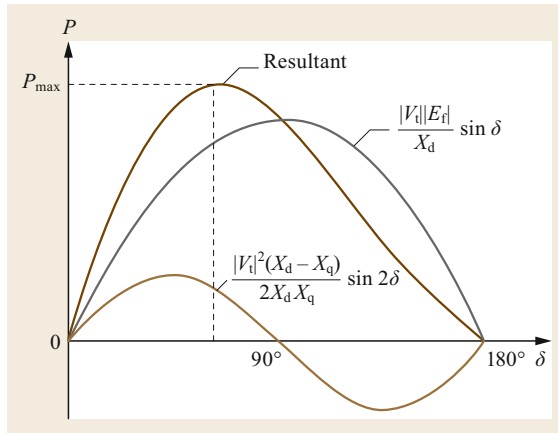

$$\begin{aligned}
 P &= P_f + P_r = \frac{E_f E_c}{X_D} \sin \delta + E_c^2 \frac{X_D - X_Q}{2X_D X_Q} \sin 2\delta \\
 &= P_{f\max} \sin \delta + P_{r\max} \sin 2\delta, \quad (6.86)
 \end{aligned}$$

**Fig. 6.22** Phasor diagram for lagging power factor

where  $X_D = X_d + X_e$  and  $X_Q = X_q + X_e$  and the angle  $\delta$  is called the power angle, torque angle or load angle.

The resultant active power  $P$  at the infinite bus has two terms. The first  $P_f$  is the power due to the field excitation, designated as excitation power and the second  $P_r$  is the power due to the differences in direct-axis and quadrature-axis reluctances, designated as the reluctance power. Figure 6.23 shows these two terms and the resultant power for a salient-pole generator.

The electromagnetic power or internal active power  $P_e$ , i.e., the power that is converted from mechanical to electrical, is the power at the infinite bus plus the losses in the armature resistance  $R_a$  and external resistance  $R_e$ ,

**Fig. 6.23** Power-angle curve of a salient-pole generator including the operation as a motor with resistances neglected

when considered

$$P_c = P + I_a^2 (R_a^2 + R_c^2). \quad (6.87)$$

The expression for reactive power is

$$Q = \frac{E_c (E_f - E_c \cos \delta) \cos \delta}{X_D} - \frac{E_c^2 \sin^2 \delta}{X_Q}. \quad (6.88)$$

Taken into consideration the armature and external resistances

$$P = \frac{E_f E_c (R_E \cos \delta + X_Q \sin \delta) + E_c^2 \frac{X_D - X_Q}{2} \sin 2\delta - E_c^2 R_E}{R_E^2 + X_D X_Q}, \quad (6.89)$$

$$Q = \frac{E_f E_c (X_Q \cos \delta - R_E \sin \delta) - E_c^2 (X_D \sin^2 \delta + X_Q \cos^2 \delta)}{R_E^2 + X_D X_Q}, \quad (6.90)$$

where  $R_E = R_a + R_c$ .

Note that the salient-pole generator can supply active power without excitation ( $E_f = 0$ ). In this case,  $P_f = 0$  and the power is due to  $P_r$ , that is, to the reluctance power that is very small when compared to the excitation power. Under this condition, the machine will absorb capacitive power irrespective of the angle  $\delta$ . In this case the machine would have transient instability when the excitation is lost.

#### Operation as a Non-Salient-Pole Generator (NSPG)

In the case of a nonsalient-pole generator where  $X_D \cong X_q \Rightarrow X_D \cong X_Q$  and with resistances neglected, the active power is

$$P = \frac{E_f E_c \sin \delta}{X_D} \quad (6.91)$$

and the term  $E_c^2 (X_D - X_Q) \sin 2\delta / (2X_D X_Q)$  due to reluctance power is null. The reactive power is

$$Q = \frac{E_f E_c \cos \delta}{X_D} - \frac{E_c^2}{X_D}. \quad (6.92)$$

Considering the resistances

$$P = \frac{E_f E_c (R_E \cos \delta + X_D \sin \delta) - E_c^2 R_E}{R_E^2 + X_D^2}, \quad (6.93)$$

$$Q = \frac{E_f E_c (X_D \cos \delta - R_E \sin \delta) - E_c^2 X_D}{R_E^2 + X_D^2}. \quad (6.94)$$

When  $E_f$  goes to zero this time, the round-rotor machine cannot supply any real power to the system. Under this condition, however, the machine will still absorb a large amount of capacitive power irrespective of the angle  $\delta$  and it would have transient instability.

#### Maximum Power

For maximum power  $\Rightarrow dP/d\delta = 0$  and  $d^2P/d\delta^2 < 0$ . For a salient-pole generator

$$\begin{aligned} \frac{dP}{d\delta} &= \frac{d}{d\delta} (P_{f\max} \sin \delta + P_{r\max} \sin 2\delta) = 0 \Rightarrow \\ \cos \delta &= -\frac{E_f X_Q}{4E_c (X_D - X_Q)} \\ &\pm \sqrt{\left[ \frac{E_f X_Q}{4E_c (X_D - X_Q)} \right]^2 + \frac{1}{2}}. \end{aligned} \quad (6.95)$$

Only positive values of the radical, giving  $\delta < 90^\circ$ , will correspond to maximum power, the other root being greater than 1.0 is not considered. The maximum active power is obtained by replacing  $\delta$  in expression (6.86).

#### Additional Remarks

The maximum power of a salient-pole generator (SPG) occurs at a power angle below  $90^\circ$ , while for a round rotor generator (NSPG) the maximum power occurs when the power angle is  $90^\circ$ . The influence of the resistances in these power angles are practically none.

The rise of power with power angle, the so called synchronizing power coefficient— $dP/d\delta$ —used to be an indication of stability or instability in steady state conditions, which is associated with small variations in the operating point, but without the action of automatic controls, such as excitation systems and speed governors.

To assure stability the synchronizing power coefficient must have a positive value. In the case of

a salient-pole generator  $dP/d\delta$ , for the same angle  $\delta$ , is greater than for a round rotor generator making the machine stiffer.

A general study of power-system stability is outside the scope of this book. If complete system equations are investigated, the power limit found may be either greater or smaller depending on circumstances; and, on the other hand, if the system is said to be stable after the determination of a positive value of  $dP/d\delta$ , it is assumed that the system introduces no other torques, such as negative damping torques arising from terms depending on rotor speed than rotor angle, which might produce instability.

The phasor diagram shown in Fig. 6.22, for a salient-pole machine, brings out the dependence of the power-angle on the cross-armature reaction effect  $I_q X_q$  on which the torque depends; while the excitation required for given working conditions—that is, the length of  $E_f$ —is largely settled by the direct-armature reaction  $I_d X_d$ .

### 6.1.10 Parallel Operation of Synchronous Generators

Considering two equal round-rotor generators in parallel, supplying the same active power to a load or system, with constant terminal voltage  $V_t$ . In the general case if they are supplying different armature currents  $I_{a1}$  and  $I_{a2}$ , being  $Z_L$  the load impedance. This situation is depicted in Fig. 6.24, where  $I_c$  is the circulating current, which will be later discussed. The following equations in per-unit or per phase may be written  $\dot{E}_{f1} = \dot{V}_t + j\dot{I}_{a1}X_s$ ,  $\dot{E}_{f2} = \dot{V}_t + j\dot{I}_{a2}X_s$ . Thus

$$\dot{E}_{f1} + \dot{E}_{f2} = 2\dot{V}_t + jX_s (\dot{I}_{a1} + \dot{I}_{a2}), \quad (6.96)$$

$$\dot{I}_{a1} + \dot{I}_{a2} = I_L = \frac{\dot{V}_t}{Z_L}, \quad (6.97)$$

$$\dot{E}_{f1} + \dot{E}_{f2} = 2\dot{V}_t + jX_s \frac{\dot{V}_t}{Z_L}. \quad (6.98)$$

Fig. 6.24 Two generators in parallel

From (6.98), if the excitation of machine 1  $E_{f1}$  increases or decreases, the excitation of machine 2 must decrease or increase  $E_{f2}$ , respectively, to maintain an unaltered terminal voltage  $V_t$ .

As the generators are supplying the same active power and considering that initially they are supplying the same reactive power to the load, their power factors ( $\cos \theta$ ) are the same, if  $I_a$  is the armature current of each generator, the load current  $I_L = 2I_a$ . Noting also that  $OA = V_t$ ,  $AB = jI_a X_s \Rightarrow OB = E_f$ , the excitation EMF of each generator. The phasor diagram of Fig. 6.25 shows this situation.

The active power per phase or in per-unit for each generator can be expressed by

$$P = \frac{E_f V_t}{X_s} \sin \delta = \text{const.}$$

$$\text{or } P = V_t I_a \cos \theta = \text{const.} \quad (6.99)$$

As  $V_t$  and  $X_s$  are constants, it follows that  $E_f \sin \delta$  and  $I_a \cos \theta$  are constants for each generator. Thus, the ends of phasor  $E_f$  are located on a horizontal line (CF) parallel to  $V_t$  and at a distance from it equal to  $E_f \sin \delta$ . Also, the active component of the armature currents are located on the vertical line (KE), that is perpendicular to  $V_t$  and a distance from point O equal to  $OH = I_a \cos \theta$ . These considerations are valid for whatever variations may occur in the excitation of the generators.

Supposing that the excitation EMF of generator 1 increases from  $E_f$  to  $E_{f1}$  (point F). It is seen that  $AF = jI_{a1} X_s$  is greater than  $AB = jI_a X_s$ , that means that there was an increase in the armature current ( $I_{a1} > I_a$ ), the generator 1 power factor angle was increased from  $\theta$  to  $\theta_1$  and consequently its inductive reactive current ( $I_{a1} \sin \theta_1$ ) also has increased, increasing its inductive reactive power to the load.

To find  $I_{a2}$ , a parallel from phasor  $I_{a1}$  is drawn at the end of  $I_L$ . At the point of intersection G with line KE,  $I_{a2}$  is obtained. Note that  $I_{a2}$  is a leading current and its reactive component is given by the distance GH. The reactive component of  $I_{a1}$  (HN) is greater than the reactive component of the load current (HI) by  $IN = GH$ , and this additional reactive current goes from generator 1 to generator 2. It does not appear in the external circuit, i.e., in the load circuit. This circulating or internal current ( $I_c$ ) flows in the armature windings of both generators, causing additional losses. Figure 6.24 shows the path of this current. To avoid this current, the field excitation of generator 1 should decrease, until current  $I_{a2}$  is inductive.

In conclusion, the distribution of reactive power among generators is realized by means of their excitation systems.

**Fig. 6.25** Effect of changing the excitation on two generators in parallel

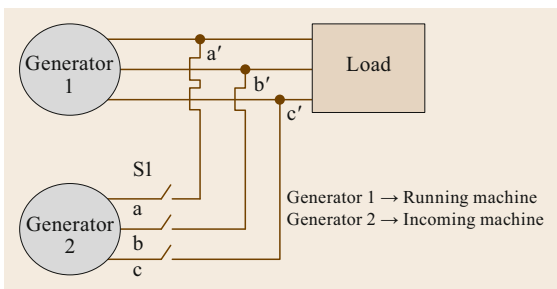

### 6.1.11 Synchronization of a Generator

Figure 6.26 illustrates a synchronous generator G1 supplying power to a load with another generator G2 that is about to be paralleled with G1 by closing the switch S1, which represents a circuit breaker. If the switch is closed at some arbitrary moment, the generators could be severely damaged and the load may lose power. If the voltages are different in the phases being tied together, there will be very large current flow when the switch is closed.

In order to be synchronized, an oncoming generator must meet the following conditions:

1. The generator voltage amplitude must be the same as the amplitude of the system voltage.
2. The phase sequence of the generator must be the same as that of the system.
3. The generator voltage must be in phase with the system voltage.
4. The generator frequency must be equal to the system frequency.

These conditions can be summarized in only one statement: At the instant of synchronization the instanta-

**Fig. 6.26** Synchronization

neous values of the potential differences among the generator terminals and those correspondents of the system, should be identical. Thus, with regard to Fig. 6.26

$$v_{ab} = v_{a'b'} , \quad v_{bc} = v_{b'c'} , \quad v_{ca} = v_{c'a'} , \quad (6.100)$$

where

$$\begin{aligned} v_{ab} &= V_m \cos(\omega t + \theta) , \\ v_{bc} &= V_m \cos(\omega t + \theta - 120) , \\ v_{ca} &= V_m \cos(\omega t + \theta - 240) \end{aligned} \quad (6.101)$$

$$\begin{aligned} v_{a'b'} &= V'_m \cos(\omega' t + \theta') , \\ v_{b'c'} &= V'_m \cos(\omega' t + \theta' - 120) , \\ v_{c'a'} &= V'_m \cos(\omega' t + \theta' - 240) . \end{aligned} \quad (6.102)$$

In (6.101) and (6.102), the phase sequence of the generator was considered as equal to that of the system. To synchronize a generator the following steps should be taken:

1. The field current should be adjusted so that the generator excitation voltage  $E_f$  is equal to the system voltage, i.e., equal to the generator terminal voltage  $V_t$ .
2. The phase sequence of the generator should be checked by means of a phase sequence indicator, that is connected to its terminals. For more details of indicators, see IEEE Std 115<sup>TM</sup> – 2009 [6.10]. If the phase sequence of the generator is not equal to that of the system, it can be corrected by swapping the connections on any two of the three-phases of the oncoming generator.
3. The speed regulator of the turbine should be adjusted so that the generator frequency is close to the system frequency, as it is very difficult to obtain equal frequencies. This means that the phase

**Fig. 6.27a,b** Synchronization with an angular difference. **(a)** The generator frequency is higher than that of the system. **(b)** The generator frequency is lower than that of the system

angle of the oncoming generator will change slowly relative to the phase angle of the running system.

- Use a synchroscope to verify the phase angle between  $E_f$  and  $V_t$ . This instrument has a pointer that continually indicates the phase angle between these two voltages. Although the degrees are not shown, the dial has a zero mark, at the top, to indicate when the voltages are in phase, and when they are  $180^\circ$  out of phase the pointer is at the bottom.
- If the generator frequency is slightly higher than the system frequency, the pointer rotates clockwise. Conversely, if the generator frequency is slightly lower, the pointer rotates counterclockwise. Then, at the moment the pointer crosses the zero mark, the circuit breaker is closed, connecting it to the system.

In most power stations, synchronization is done automatically.

The frequency of the oncoming generator is adjusted to a slightly higher frequency to ensure that when it is connected, it will come on-line supplying power as a generator, instead of consuming it as a motor.

### The Synchronization Power

If the magnitude of the generator EMF  $E_f$  is the same as that of the system  $V_t$ , but its frequency is higher, the phasor  $E_f$  will be ahead of the phasor  $V_t$ , and a difference of potential  $\Delta V$  will appear across the switch. An armature current  $I_a$  lagging  $90^\circ$  behind  $\Delta V$  will flow, as shown in Fig. 6.27a. Neglecting the armature resistance,

$$I_a \exp(j\theta) = -j \left[ \frac{E_f \exp(j\delta) - V_t \exp(j0)}{X_s} \right], \quad (6.103)$$

where  $E_f = V_t$ ,  $\theta = \delta/2$  and  $X_s I_a = 2V_t \sin(\delta/2)$ .

As the angle  $\delta$  is positive the generator will supply power to the system. If  $P_a$  is the accelerating power,  $P_m$  is the mechanical power supplied by the turbine just before synchronization, which is equal to the rotational losses, and  $P_e$  is the electrical power supplied by

the generator (neglecting power losses),  $P_a = P_m - P_e$ , where in per-unit or per phase, for a round-rotor generator  $P_e = E_f V_t / X_s \sin \delta = V_t^2 / X_s \sin \delta$ . As  $P_m$  is constant (the speed governor did not have time yet to increase  $P_m$ ),  $P_a$  is negative and the generator slows down until, after some small damped oscillations around  $V_t$ , the phasors  $E_f$  and  $V_t$  will be in phase, and  $I_a$  and  $\delta$  will be null.

If, instead the generator frequency is lower, the phasor  $E_f$  will be behind the phasor  $V_t$ , and a difference of potential  $\Delta V$  will appear across the switch. An armature current  $I_a$  will flow, as shown in Fig. 6.27b. The angle  $\delta$  is negative and the generator will receive power from the system. As a consequence, the generator speeds up until, after some small damped oscillations around  $V_t$ , the phasors  $E_f$  and  $V_t$  will be in phase, and  $I_a$  and  $\delta$  will be null.

The synchronization power, in p.u.,  $P_e = V_t^2 / X_s \sin \delta$ , is the power supplied or received when the generator is turning faster or slower with respect to the system, and it will be slowed down or accelerates, respectively, to match its frequency with that of the system. If the synchronization is done with the generator completely out of phase with the system voltage, the angle  $\delta$  will be  $180^\circ$ , and the current in the armature will be  $I_a = 2V_t / X_s$ . This is twice the three-phase short-circuit current of the incoming generator. The stresses in the windings can cause severe damage to the generator.

It is to be noted that in the expressions above the synchronous reactance in the steady state was considered, for simplicity of drawing the phasor diagrams. In reality, with a damper winding the subtransient reactance  $X_d''$  must be used. If the machine does not have a damper winding the transient reactance  $X_d'$  is the one to be used.

According to IEEE Std C50.12-2005 [6.15] for salient-pole and IEEE Std C50.13-2014 [6.16] for cylindrical-rotor synchronous generators the following limits, shown in Table 6.5, should not be exceeded.

**Table 6.5** Synchronizing limits [6.15, 16]

Breaker closing angle	$\pm 10^\circ$
Generator side voltage difference relative to system	0 to +5%
Frequency difference	$\pm 0.067$ Hz

The synchronization is helped by the damping windings, in which induced currents are due to the speed difference between the rotating armature and field magnetic fields. When the generator is connected to the system the speed of the armature field is determined by the system frequency; if the rotor turns at a speed lower than that of the armature field, the currents induced in the damping windings produce a torque that tends to accelerate the rotor. Conversely, if the rotor field turns at a speed greater than that of the system, the torque tends to slow down the rotor.

After synchronization, the generator active power should be adjusted by the speed governor of the turbine and its reactive power (power factor) by the excitation system.

### 6.1.12 Generator Excitation for Constant Terminal Voltage: Compounding Curve

The curves of Fig. 6.28 show how the field excitation of a synchronous machine should be varied to maintain constant terminal voltage (in general rated voltage) and constant power factor as the load is varied. These curves are called compounding curves.

It is known that for a round-rotor machine  $\dot{E}_f = \dot{V}_t + j\dot{I}_a X_s$ , neglecting  $R_a$ . If the power factor angle is  $\theta$ , the terminal voltage  $V_t$ , the excitation EMF  $E_f$  and

**Fig. 6.28** Generator excitation for constant terminal voltage and power factor

the armature current  $I_a$ , the following relation can be written

$$E_f = \sqrt{(V_t \pm I_a X_s \sin \theta)^2 + (I_a X_s \cos \theta)^2}, \quad (6.104)$$

where the plus sign is for an inductive load and the minus sign for a capacitive load.

From (6.104) the following conclusions can be drawn:

In an open-circuit,  $I_a = 0$  and  $E_f = V_t$  for whatever power factor. When the power factor is zero capacitive  $E_f = V_t - I_a X_s$ . Thus, when the load  $I_a$  increases the excitation must decrease to maintain  $V_t$  constant. In this case the armature reaction MMF is totally magnetizing, and the machine receives reactive power from the system. When the power factor is zero inductive,  $E_f = V_t + I_a X_s$ . Thus, when the load  $I_a$  increases the excitation must increase to compensate the voltage drop in the armature impedance and to maintain  $V_t$  constant. In this case the armature reaction MMF is totally demagnetizing, and the machine supplies reactive power to the system. Intermediate load power factors produce voltage/current characteristics shown in Fig. 6.28.

### 6.1.13 Generator Load Characteristic

This characteristic shows the behavior of the terminal voltage of a generator when the load changes, with constant excitation and load power factor. From (6.104) of Sect. 6.1.12 the following analysis can be done.

In an open-circuit,  $I_a = 0$  and  $V_t = E_f$  and all the curves in Fig. 6.29 begin at point 1 on the vertical axis, no matter the power factor. In short-circuit  $V_t = 0$ ,  $\theta = \pm 90^\circ$ , with the plus sign for an inductive load and the minus sign for a capacitive load, thus,  $I_a = E_f/X_s$ . When the load is pure inductive the power factor is equal to zero and  $\theta = -90^\circ$ . In this case  $V_t = E_f - I_a X_s$ , which is a straight line with the armature MMF demagnetizing the field MMF, and the terminal voltage decreases with the load increase. For a leading load of zero power factor  $V_t = E_f + I_a X_s$  and the armature MMF is totally magnetizing, increasing the field MMF, and the terminal voltage increases with the load increase. In this case very high terminal voltages can be produced, especially when the machine is radially connected to high voltage transmission lines, and the lines are disconnected at their far ends, a situation known as load rejection. Intermediate load power factors produce voltage/current characteristics shown in Fig. 6.29.

### 6.1.14 Generator Capability Chart

This chart shows the active and reactive power limits that generators can be safely operated, since the condi-

Fig. 6.29 Generator load characteristic

tion of zero inductive power factor up to zero capacitive power factor.

Synchronous generators are specified in function of the maximum apparent power in MVA that they can supply continuously without overheating for a given rated voltage (with a variation of  $\pm 5\%$ ), rated current and power factor. The field and armature currents for this condition are the maximum currents allowed in the field and armature windings, respectively. MW (active power) loading cannot exceed the turbine rating.

The chart is drawn in per-unit for rated terminal voltage, armature current and power factor, with resistance neglected, considering nonsaturated values for the reactances, in order to be conservative. The consideration of saturated values for the reactances will enlarge, a little bit, some of the limits presented.

### Cylindrical-Rotor Generator

To draw the capability curve of the synchronous generator, its voltage phasor diagram multiplied by  $jV_t/X_s$  is redrawn in Fig. 6.30. It is recognized that OMN is the complex power triangle, wherein OM is the nominal apparent power,  $P$  and  $Q$  are the nominal active and inductive reactive power, respectively, and  $\phi$  is the rated power factor. The segment  $O'O$  is the capacitive reactive power and a machine design with a high short-circuit relation (SCR) will increase the capacity of the machine in absorbing reactive power from the system, providing a better voltage control. The segment  $O'M$  corresponds to the maximum excitation power, that is

Fig. 6.30 Diagram showing the apparent, active, reactive and excitation power of a cylindrical-rotor generator

obtained for an excitation voltage equal to the rated excitation voltage  $E_f$ .

The steps in the construction of the capability chart are:

- With a center at  $O$  and radius  $OM$  a circle is drawn, that represents the limit of armature winding heating.
- With a center at  $O'$  and radius  $O'M$  a circle is drawn, that represents the limit of field winding heating.
- From point  $M$  drawing a straight line perpendicular to the active power axis  $P$ , the limit of maximum power of the turbine is obtained.
- The theoretical stability limit in the steady-state is obtained when  $\delta = 90^\circ$ , and the expression for the apparent power of the generator is given by

$$S_n = \frac{V_{tn} E_f}{X_s} - j \frac{V_{tn}^2}{X_s} = P_n - j Q_n \quad (6.105)$$

indicating that the theoretical stability limit in steady-state is given by a straight line ( $O'WUTS$ ) from point  $O'$ , perpendicular to the horizontal axis. It is not desirable to operate a generator at its steady-state theoretical stability limit because there will be no margin for an oscillation that may increase the angle  $\delta$ , causing the machine to lose stability. Thus, a margin of 10% (TU) in the active power with constant excitation  $E_f$  is considered and various circles with excitation constant are traced, determining the steady-state practical stability limit ( $O'VR$ ), as shown in Fig. 6.31.

If the excitation current goes to zero, the active power will be zero and excitation voltage induced in the armature  $E_f$  also will be zero and in this case,

$$\dot{E}_f = 0 = \dot{V}_{tn} + j \dot{I}_{an} X_s \Rightarrow \dot{I}_{an} = j \frac{\dot{V}_{tn}}{X_s} \quad (6.106)$$

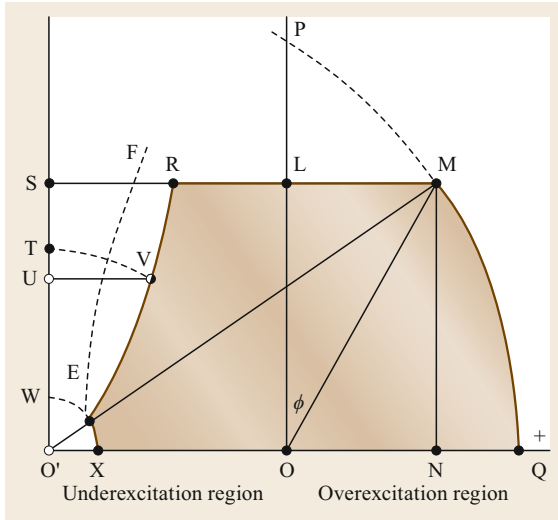

Fig. 6.31 Capability chart of a cylindrical-rotor generator

Thus the armature current will be capacitive indicating that the generator receives reactive power from the system, and as its electrical power is zero and the mechanical power is constant (at least in the following few seconds), the rotor will be accelerated and the machine starts to function as an induction generator until it is disconnected from the system by the loss-of excitation protection. Therefore, excitation current on the chart is normally limited to a value of 5–10% of its rated value (circle WX).

When the generator operates as overexcited, the field current is high and the retaining ring becomes saturated, so that the effects of the flux in the end region of the armature is small. However, in the underexcited region the field current is low and the retaining ring is not saturated, allowing an increase in armature end leakage flux, which adds to the flux produced by the field current, occasioning heating in the end core packets and clamping plates, that may severely limit the generator output, particularly in the case of a round rotor machine. Thus a limit is put on the amount of reactive power that can be absorbed, which is given by line EF [6.17]

**Salient-Pole Generator**

If in the voltage diagram of a salient-pole generator a parallel line to AB is drawn from point C, point F is determined on the horizontal axis, as shown in Fig. 6.32, where  $HC = AB = E_f$ ,  $BC = I_q(X_d - X_q)$  and  $FA = [V_{tn}(X_d - X_q)]/X_q$ .

If the diagram of Fig. 6.32 is multiplied by  $-jV_{tn}/X_d$ , a chart showing only powers quantities is obtained, as shown in Fig. 6.33.

Along the semi-circle FHA the excitation voltage is equal to zero. The field winding heating limit  $CC'K$

Fig. 6.32 Voltage diagram of a salient-pole generator

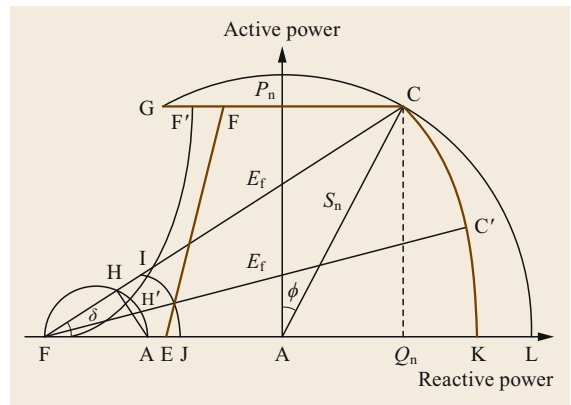

Fig. 6.33 Capability chart of a salient-pole generator

is obtained by drawing several lines from point F and marking distances  $H'C' = HC = E_f$  starting at the semi-circle. The limit of armature winding heating (curve GCL) and the limit of maximum power of the turbine (CG) are obtained following the same procedure as used in the case of cylindrical-rotor generator. When the excitation is zero the active and reactive power of the generator are

$$P = \frac{V_{tn}^2}{2} \left( \frac{1}{X_q} - \frac{1}{X_d} \right) \sin 2\delta, \tag{6.107}$$

$$Q = \frac{V_{tn}^2}{2} \left( \frac{1}{X_q} - \frac{1}{X_d} \right) \cos 2\delta - \frac{V_{tn}^2}{2} \left( \frac{1}{X_q} + \frac{1}{X_d} \right). \tag{6.108}$$

The generator can supply a certain active power. The locus of the points where the excitation voltage is equal to zero is given by the semi-circle FHA. In the chart, following the same observation for the case of a cylindrical-rotor generator, in order to avoid operation with zero excitation, the minimum excitation was considered equal to a value of 5–10% of rated excitation, obtaining the circle IJ.

**Fig. 6.34** Synchronous motor operation at constant load and variable excitation

At point A,  $\delta = 0$  and the reactive power is capacitive and equal to  $V_{in}^2/X_d$ . At point F, where  $\delta = 90^\circ$  the reactive power is also capacitive and equal to  $V_{in}^2/X_q$ , however, operation at this latter point is not allowed because in the case of a salient-pole machine the steady-state stability limit occurs for an angle  $\delta$  less than  $90^\circ$ . Besides that, operation inside the semi-circle of zero excitation would be only possible if the excitation system is designed for negative excitation current. The theoretical steady-state stability limit may be obtained by the following expression.

$$P = -\frac{\left(Q + \frac{V_{in}^2}{X_q}\right)^2}{Q + \frac{V_{in}^2}{X_d}} \tag{6.109}$$

In the chart the practical steady-state stability limit is given by curve FF', where a safety margin of around 10% was given from the theoretical steady-state stability limit, with constant excitation. The EF curve represents the heating limit of the frontal stator sheet packs.

### 6.1.15 Synchronous Motor: V Curves

When a synchronous motor delivers constant mechanical power while energized from a source of constant voltage and constant frequency, the armature current is a function of the field excitation. Considering the armature resistance and mechanical losses neglected and the theory of cylindrical-rotor applied, when the armature current is plotted against field excitation, the result is the so-called V curves, due to the shape of the curves. The following equations, in per-unit or per phase, apply

$$\begin{aligned} \dot{V}_t &= \dot{E}_f + \dot{I}_a(R_a + jX_s), \quad \text{with } R_a \text{ neglected} \\ \Rightarrow \dot{V}_t &= \dot{E}_f + j\dot{I}_a X_s, \end{aligned} \tag{6.110}$$

$$P_e = \frac{E_f V_t}{X_s} \sin \delta \text{ or } P_e = V_t I_a \cos \theta. \tag{6.111}$$

As  $P_e$  and  $V_t$  are constants

$$E_f \sin \delta = \text{const.} \tag{6.112}$$

Likewise,

$$\frac{P_e}{V_t} = I_a \cos \theta \Rightarrow I_a \cos \theta = \text{const.} \tag{6.113}$$

The expressions (6.112) and (6.113) are valid for any power factor value. Neglecting losses the mechanical power load is equal to the electrical power supplied to the motor from its terminal. The machine behaviour is described by means of the phasor diagram of Fig. 6.34. When the excitation EMF  $E_f$  increases from the condition of unity power factor, i.e., from the normal excitation  $E_{f2}$  to  $E_{f3}$ , the power angle  $\delta$  decreases so that the product  $E_f \sin \delta = P_e X_s / V_t$  is maintained constant and the phasor  $E_f$  moves along a line parallel to  $V_t$ . Also, the phasor  $I_a$  is located along a line perpendicular to  $V_t$  at a distance  $I_a \cos \theta = P_e / V_t$  from the origin. The minimum armature current occurs when the motor operates at a unity power factor.

The following conclusions can be obtained from Fig. 6.34:

- The machine as a motor operates over-excited and supplies reactive power to the grid when the power factor is capacitive, i.e., when the armature current leads the terminal voltage. If the machine was a generator it would receive reactive power when the power factor was capacitive, i.e., the armature current leads the terminal voltage.
- The machine as a motor operates under-excited and receives reactive power from the grid when the power factor is inductive, i.e., when the armature current lags the terminal voltage. If the machine was a generator it would supply reactive power when the

**Fig. 6.35** V curves of a synchronous motor indicating also the operation as a generator

power factor was inductive, i.e., the armature current lags the terminal voltage.

The nature of  $I_a$  versus excitation ( $I_f$ ) plot for various values of active power load is shown in Fig. 6.35. These are known as V-curves of a synchronous machine by virtue of their shape. Though the figure is drawn for motoring operation, an indication of operation as a generator is given as the V-curves for a generator are similar, but inverted.

#### Minimum Excitation and Stability Limit

From (6.109), the angle  $\delta$  continuously increases when the excitation is reduced. The minimum permissible excitation,  $E_f$  (min), for a specific value of constant active power occurs for  $\delta = 90^\circ$ . Thus

$$E_f(\text{min}) = \frac{PX_s}{V_t} \quad (6.114)$$

Minimum field current and the corresponding armature current for a given pu load at the limit of stability is indicated, in Fig. 6.35, by the dashed curve AB. At the stability limit the motor power factor is inductive, while in a generator the stability limit occurs for a capacitive power factor. In both cases, for motor and generator, the stability limit occurs in a region of minimum field excitation.

#### Synchronous Compensator

A synchronous compensator is a synchronous machine, usually of the salient-pole type, that has neither a prime mover nor a mechanical load; it is in effect a synchronous motor running idle. The V curve for zero mechanical power in Fig. 6.35 approximately represents

synchronous compensator operation. When rotational losses and armature resistance are neglected, the real power of a synchronous compensator is zero, and consequently the torque angle  $\delta = 0$ . The reactive power in per-unit or per phase is given by

$$Q = \frac{V_t E_f - V_t^2}{X_s} \quad (6.115)$$

By controlling excitation  $E_f$ , it can supply or absorb reactive power and maintain the terminal voltage  $V_t$  constant.

**Observation.** In a synchronous machine the active electrical power exchanged with the bus-bars is controlled by the mechanical shaft power, by means of the speed governor, irrespective of excitation. The excitation system, on the other hand, controls only the power factor of the machine without affecting the real power flow. For example, if a generator needs to supply more active power into the bus-bars, the throttle (gates) must be opened admitting more steam (water) into the turbine (coupled to the generator) thereby supplying more mechanical power into the shaft. As a consequence the power angle  $\delta$  increases and so does the electrical power output. However, if it is desired to adjust the machine power factor, its excitation should be varied.

#### 6.1.16 Voltage–Frequency Limits

The voltage and frequency limits, as per IEEE C50.12 [6.15] and IEEE C50.13 [6.16] standards, must be in accordance with the values shown in Fig. 6.36. That is, the generators shall be thermally capable of continuous operation within the confines of their ca-

**Fig. 6.36** Continuous and short-time limits of voltage–frequency variations, according to IEEE C50.12 and IEEE C50.13 [6.15, 16]

pability curves over the range of  $\pm 5\%$  in voltage and  $\pm 2\%$  in frequency, as defined by the brown area.

To minimize the reduction of the generator’s life-time due to the effects of temperature, operation outside the brown area and within the gray line should be limited in extent, duration and frequency of occurrence.

IEEE C37.106-2003 standard [6.18] addresses abnormal frequency protection for power generating plants. It recognizes that the generator’s prime mover is more susceptible to damage from off-frequency operation than the generator itself. Specifically turbine blade fatigue is the main concern. The length of the blades and its design dictates their resonant frequencies. Turbine blades are designed to have their natural frequencies displaced sufficiently from rated speed and multiples of rated speed. Operation at frequencies other than rated or near-rated speed is time-restricted to the limits shown for the frequency bands provided by the manufacturer. Figure 6.37 shows the frequency limits of a typical steam turbine.

### 6.1.17 Excitation Systems

The excitation system fulfills two main functions:

- It produces DC voltage (and power) to force current to flow in the field windings of the generator.
- It provides a means for regulating the terminal voltage of the generator to match a desired set point, as well as providing damping for power system oscillations and through its fast response, contributes to improving system transient stability.

**Fig. 6.37** Frequency limits of a typical steam turbine [6.19]

Prior to the 1960s, generators were generally provided with rotating exciters that fed the generator field through a slip ring arrangement, a rotating pilot exciter feeding the main exciter field.

Since the 1970s, the most common arrangement for hydrogenerators is a static excitation system where the main field excitation is regulated by a controlled rectifier. One of these static excitation systems, shown in Fig. 6.38 is the *potential source controlled rectifier high initial response exciter*, known as the *bus-fed static exciter*, where excitation power is supplied through a transformer from the main generator terminals and a six-pulse thyristor bridge controls the main field excitation. Field flashing equipment is provided to build up generator terminal voltage during starting. Power for field flashing is provided either from the station battery or alternating current (AC) station service.

During system conditions that leads to self-excitation of the generator, causing abnormal voltages on machine terminals and possible damage to stator windings, a second thyristor bridge in antiparallel to the one shown in Fig. 6.38, can be used so that the machine inverts its field current and delay the self-excitation. As this second bridge is used for transient conditions it may be specified for a short time operation, for example 10 s. Also, negative field current can be used in a salient-pole synchronous machine, operating as a condenser, to increase the reactive power absorption. This can be useful for near high-voltage direct current (HVDC) stations or long transmission lines where extra reactive power absorption is required. Due to firing angle margin requirements of the thyristors, the magnitude of the negative ceiling voltage is normally less than the positive ceiling voltage, usually around 70% of the positive ceil-

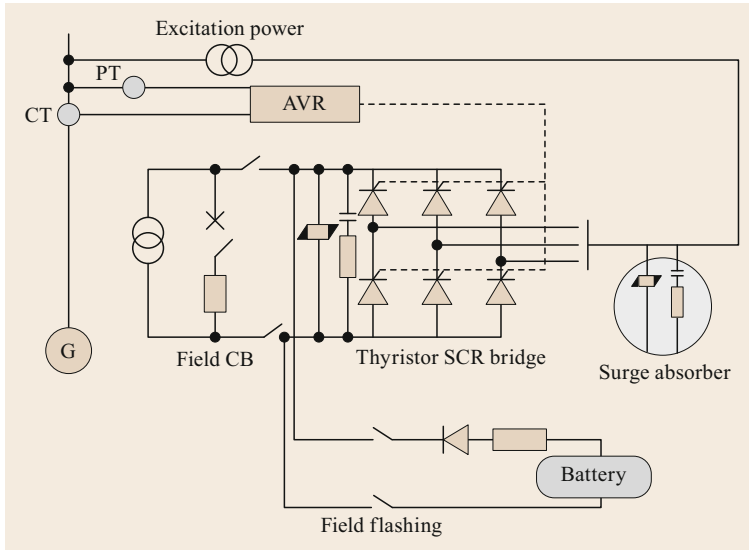

Fig. 6.38 Potential-source controlled-rectifier excitation system

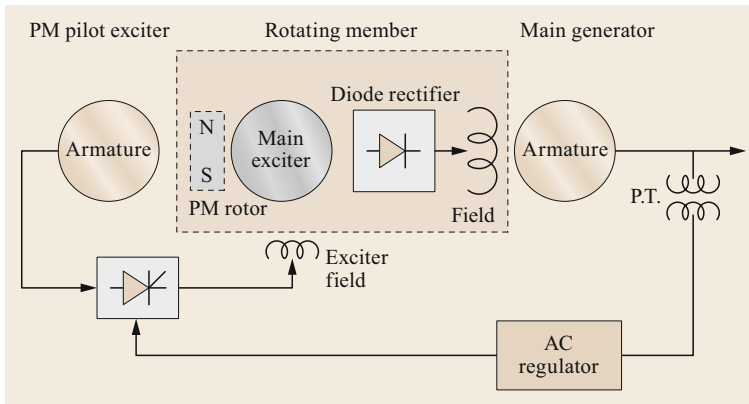

Fig. 6.39 Brushless excitation system

ing voltage, and in cases where it is used for transient conditions it may be specified for a short time operation, for example 10 s. Ceiling voltages of 3–5 p.u. where one per-unit voltage is defined as the generator field voltage required to produce one per-unit terminal (stator) voltage on the open-circuit airgap line at a specified field winding temperature, are considered usual for static exciters and brushless exciters. Values outside this range imply an increased excitation system cost.

Another system, a rotating exciter system, used for turbogenerators is the brushless exciter, i.e., an excitation system without carbon brushes and slip-rings. In turbogenerators the number of field winding turns is much less than in hydrogenerators requiring a large field current, which may cause a fast wear of brushes and sparking on slip rings, if used. Figure 6.39 presents a brushless excitation system. The brushless excitation

system consists of two major parts: pilot exciter and main exciter. The pilot exciter is a PMG (permanent magnet generator) whose field winding is mounted on the rotor shaft. Armature winding of the PMG is the stationary part mounted on a stator and supplying a thyristor bridge. The thyristor bridge/voltage regulator controls the field current to the main exciter due to which its AC output is also controlled and directly feeds the diode bridge rectifier whose output feeds the field winding of the turbogenerator. In this way the field current input to the field winding of the turbogenerator is controlled. The PMG is used because its AC output has a high frequency, for instance, if a PMG has 16 poles its AC output frequency will be 400 Hz ( $f = np/120$ ,  $n = 3000$  rpm) and as a consequence the ripple in the rectified DC output will be low. The time delays in the response to a controlling signal are short when compared with the time constant of the generator field.

### Excitation Limiters

The excitation system is provided with limiting control functions that prevent certain quantities from exceeding set limits, protecting both the excitation system and the synchronous machine. These limiting functions generally have no effect on the excitation output during normal operating conditions, but protect the exciter and machine during severe unit or power system disturbances in which the excitation system is pushed near or beyond defined operating limits. Typical excitation limiters include overvoltage (OV), volts/hertz (V/Hz), instantaneous and timed overexcitation limiter (OEL), underexcitation limiter (UEL), and stator overcurrent limiters (SCL). The effects of excitation limiters are described in IEEE Std 421.2 [6.20].

### Performance of Excitation Systems During Large Disturbances (Transient Stability)

A figure of merit for comparison among older nonhigh initial response rotating excitation systems is the excitation system nominal response, that is related to the ability of the excitation system to respond to large disturbances. The nominal response describes the rate of increase of the excitation system output voltage and is determined from the excitation system voltage response curve, shown in Fig. 6.40. This parameter has nowadays little practical significance as the modern static exciters or brushless can reach the ceiling voltage in less than 0.1 s.

Modern exciters have the advantage of providing extremely fast response times and high field ceiling voltages for forcing rapid changes in the generator terminal voltage during system faults. This is necessary to overcome the inherently large time constant in the response between terminal voltage and field voltage ( $T'_{d0}$ ,

**Fig. 6.40** Definition of excitation system nominal response

typically in the range of 4–10 s). Rapid terminal voltage forcing and higher ceiling voltages are necessary to improve transient stability of the power system during and immediately after system faults.

A large difference between the ceiling voltage and the rated field voltage indicates a large field forcing capability. Some excitation systems will have both positive and negative values of ceiling voltage. Positive ceiling voltage provides an indication of the voltage available to force the field current from rated field current toward ceiling current, while negative ceiling voltage provides an indication of the voltage available to force the field current to zero. Thus, large negative ceiling voltage aids in rapidly demagnetizing the synchronous machine.

### Performance of Excitation Systems During Small Disturbances (Small-Signal Stability)

The ceiling voltage and exciter nominal response criteria are useful for comparing the performance of different systems and they are valuable as design criteria that can be used to verify that the manufacturer fulfilled specification requirements. However, these single values criteria do not provide sufficient information in all instances for model parameter selection or verification. A match of these values can be achieved using models with different combinations of model parameters. Comparing model results with dynamic responses can reduce this ambiguity. Thus, dynamic response, also associated with small signal analysis, is a useful tool for large signal performance evaluation, especially for applications involving the refinement or validation of computer models. Small signal analysis provides a means of evaluating the response of the closed-loop excitation control system to incremental changes in system conditions. It is a convenient means for determining or verifying the performance of excitation systems. A typical dynamic response to a step input of a feedback control system is shown in Fig. 6.41. The principal characteristics of interest are the 10–90% rise time, overshoot, peak time, and settling time as indicated.

Performance indexes for small signal dynamic analysis of excitation systems are presented in Table 6.6.

The performance indexes in Table 6.6 are applicable to any feedback control system having a single major

**Table 6.6** Performance indexes for small signal dynamic analysis of excitation systems

Performance index	Range of expected values
Overshoot	0–60%
Rise time	0.025–2.5 s
Settling time	0.2–10 s
Damping ratio	0.25–1

**Fig. 6.41** Typical dynamic response of a feedback control system to a step change in input [6.20]

feedback loop, that is, a single ultimately controlled variable. As such, they are applicable to an excitation control system with the synchronous machine open-circuited or feeding an isolated load.

However, when a synchronous machine is connected to a power system, its operating level, and the parameters of the external system greatly influence performance. A complex multiloop, multivariable, high order control system is formed with a power system connection. The determination of eigenvalues by means of a state space technique gives a direct indication of system stability for the linearized system and is an effective method for the determination of the parameters that have most influence on system performance. In the case of undamped oscillations, power system stabilizers are applied to static or brushless excitation systems for damping the dynamic oscillations, using an input signal that could be derived from generator speed or electric power or accelerating power or frequency deviations. After, the system performance must be tested for large disturbances, and some further adjustments may be required on the controls of the system to assure stability [6.21, 22].

### 6.1.18 Synchronous Generators During a Short-Circuit

The short-circuit currents may cause mechanical and thermal damages in electrical machines if not cleared quickly. Their calculation is also important to ascertain

the rating of the protective switchgear, that must be able to deal with the worst possible conditions. Also, short-circuit currents create a large torque on the machine. Of particular importance is the initial shock torque on the stator housing, since the foundations must be designed to withstand it.

#### The Armature Current

From the instant when a three-phase fault occurs at the terminals of an unloaded generator the following stages may be distinguished:

- There is an increase in the armature currents and as a consequence, an increase in the alternating armature magnetic field, which in the absence of resistances, is located in the direct-axis and tends to demagnetize the magnetic field of the rotor. The theorem of the constant flux linkages says that: In an inductive circuit of negligible resistance that is closed on itself, with no external voltages in the circuit, the total flux linkage must remain constant. Thus currents are induced in the field and damping windings to keep the flux linkages constant.
- These armature currents not been sustained by an electromotive force (EMF) begin to decrease and the same happens with the field and damping windings currents until the steady state regime is reached.

The amplitude of the a phase short-circuit current for a three-phase fault, under open-circuit conditions neglecting armature resistance is given by the following expression

$$\begin{aligned}
 i_a = & \sqrt{2}E_{f0} \left[ \frac{1}{X_d} + \left( \frac{1}{X'_d} - \frac{1}{X_d} \right) e^{-t/T'_d} \right. \\
 & \left. + \left( \frac{1}{X''_d} - \frac{1}{X'_d} \right) e^{-t/T''_d} \right] \cos(\omega t + \theta_0) \\
 & - \sqrt{2}E_{f0} e^{-t/T_a} \left( \frac{X''_d + X''_q}{2X''_d X''_q} \right) \cos \theta_0 \\
 & - \sqrt{2}E_{f0} e^{-t/T_a} \left( \frac{X''_q - X''_d}{2X''_d X''_q} \right) \cos(2\omega t + \theta_0),
 \end{aligned} \tag{6.116}$$

where:

$E_{f0}$  is the rms phase to neutral EMF induced in the armature by the excitation field on open-circuit. It is equal to the rms phase to neutral generator terminal voltage  $V_t$  on open-circuit

- $\theta_0$  is the angle between the direct-axis of the rotor and the magnetic axis of phase a when the short-circuit occurs, that is, at  $t = 0$
- $\omega$  is the synchronous speed in electrical radians per second and
- $\theta = \omega t + \theta_0$  is the angle between the direct-axis of the rotor and the magnetic axis of phase a for  $t > 0$ .

The currents in phases b and c are obtained by replacing  $\theta_0$  in the expression for  $i_a$  by  $\theta_0 - 120^\circ$  and  $\theta_0 - 240^\circ$ , respectively.

In the expression for  $i_a$  there are the following terms:

- A symmetrical alternating current of fundamental frequency consisting of:
  - A steady-state undamped component of amplitude  $\sqrt{2}E_{f0}/X_d$
  - A transient component with initial amplitude  $\sqrt{2}E_{f0}(1/X'_d - 1/X_d)$ , damped with time constant  $T'_d$
  - A subtransient component with initial amplitude  $\sqrt{2}E_{f0}(1/X''_d - 1/X'_d)$ , damped with time constant  $T''_d$
- A unidirectional or asymmetrical current with initial amplitude  $\sqrt{2}E_{f0}(X'_d + X''_q/2X'_dX''_q) \cos \theta_0$ , damped with time constant  $T_a$ . This component is usually called the direct current (DC) component.
- A second-harmonic current with initial amplitude  $\sqrt{2}E_{f0}(X''_q - X''_d/2X'_dX''_q)$ , damped with time constant  $T_a$ .

The value of the current in all three-phases, when the short-circuit occurs ( $t = 0$ ), is equal to zero as the machine is in open-circuit. The initial amplitude of the alternating current of fundamental frequency occurs at the instant of the short-circuit and is equal to  $\sqrt{2}E_{f0}/X''_d$ . Its subtransient component has a fast decay as the time constant  $T''_d$  is very small. The transient component presents a slow decay due to the time constant  $T'_d$ . The steady state component is the permanent short-circuit current.

The unidirectional or continuous short-circuit current, designated by  $i_{dc}$ , in phase a, does not exist at the instant  $t = 0$ , when the short-circuit occurs at angle  $\theta_0 = \pm 90^\circ$ . However, these currents are not zero in phases b and c because of the  $120^\circ$  displacement among the phases. These components decay with time constant  $T_a$ .

The second-harmonic current is very small as it depends on the difference between the two subtransient reactances and is usually neglected.

Fig. 6.42 Oscillograms of the armature and field currents after a short-circuit on an initially unloaded generator

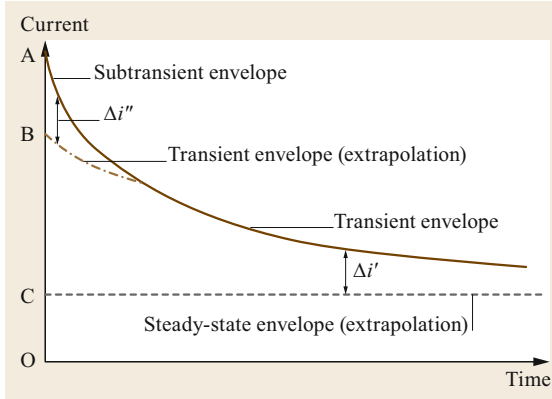

Figure 6.42 shows the curves of armature current after a short-circuit and the corresponding field current. Envelope lines are drawn through the peaks of the alternating current waves and dotted lines are drawn half-way between the envelope curves. Thus the current can be divided into a unidirectional component represented by the dotted lines, and an alternating component of supply frequency. Both components start with a certain initial value that reduces as time proceeds. The initial values of the alternating components are determined by tracing the envelope curves back to zero time. The field current is addressed in a separate article [6.23].

The unidirectional currents correspond to the fourth term in (6.116) and by the fourth terms of the corresponding expressions for the currents in phases b and c. The initial values of these currents are different in the three-phases b, and c, being proportional to  $\cos \theta_0$ ,  $\cos(\theta_0 - 120^\circ)$ , and  $\cos(\theta_0 - 240^\circ)$  respectively, but all three currents die away to zero with the same time constant  $T_a$ .

As said before if the short-circuit occurs in phase a at  $\theta_0 = \pm 90^\circ$  there will be no unidirectional or asymmetrical component and the short-circuit current will

**Fig. 6.43** Symmetrical alternating component of the three-phase fault current for phase a

**Fig. 6.44** Envelope of the symmetrical alternating component of the fault current for phase a

only have the alternating component of fundamental frequency in this phase and it will be symmetrical in relation to the horizontal axis, as shown by the Fig. 6.43.

The envelope of the symmetrical alternating component of the fault current is shown in the Fig. 6.44.

The subtransient current envelope is

$$\Delta i'' = i_d'' - i_d' = \sqrt{2} (I_d'' - I_d') e^{-t/T_d''} \quad (6.117)$$

and the transient current envelope is

$$\Delta i' = i_d' - i_d = \sqrt{2} (I_d' - I_d) e^{-t/T_d'} \quad (6.118)$$

$I_d''$ ,  $I_d'$ , and  $I_d$  are the rms values of the respective currents.

The expression for the envelope of the symmetrical alternating current is

$$I_a = \sqrt{2} E_{f0} \left[ \frac{1}{X_d} + \left( \frac{1}{X_d'} - \frac{1}{X_d} \right) e^{-t/T_d'} + \left( \frac{1}{X_d''} - \frac{1}{X_d'} \right) e^{-t/T_d''} \right] \quad (6.119)$$

or in terms of currents the equation for the envelope can be written as

$$I_a = \sqrt{2} \left[ I_d + (I_d' - I_d) e^{-t/T_d'} + (I_d'' - I_d') e^{-t/T_d''} \right]. \quad (6.120)$$

The subtransient component of fault current is superimposed on the transient and steady-state components. From the envelopes of the symmetrical alternating currents, the currents and the direct-axis reactances can be calculated.

The initial rms value of the subtransient short-circuit current may be calculated from Fig. 6.44 for a specific phase, and is given by

$$I_d'' = \frac{OA}{\sqrt{2}} = \frac{E_{f0}}{X_d''} \quad (6.121)$$

This value is obtained by extending the envelope of the subtransient short-circuit current to the vertical axis.

For each phase the values of the difference between the envelope of the subtransient current and the envelope of the transient current should be plotted on a semilogarithmic scale on the vertical axis, with time on the horizontal axis, thus obtaining the subtransient component of fault current  $\Delta i''$ . The result is expected to be very nearly a straight line. Extending this line back to zero time gives the initial value of the subtransient component of fault current. The sum of this component  $\Delta i''$ , the initial transient component  $\Delta i'$ , and the sustained component, for each phase, gives the corresponding maximum initial value of subtransient current, whose rms value is  $I_d''$ . The values of  $I_d''$  determined in this way are more accurate than those obtained by extrapolating the envelopes back to the beginning of the short-circuit. The three values are averaged to obtain the final value of  $I_d''$  and the subtransient reactance is calculated by

$$X_d'' = \frac{E_{f0}}{I_d''} \quad (6.122)$$

The direct-axis short-circuit subtransient time constant  $T_d''$  can be determined from the semilogarithmic graph of the subtransient alternating component of the short-circuit current.

The transient component of fault current is superimposed on the steady-state component. The initial rms value of the transient short-circuit current for a specific phase may be calculated from Fig. 6.44, and is given by

$$I'_d = \frac{OB}{\sqrt{2}}. \quad (6.123)$$

Two other values of the rms value of the transient current are calculated for the other two phases. These values are averaged and a final rms value for  $I'_d$  is obtained. The transient reactance is

$$X'_d = \frac{E_{f0}}{I'_d}. \quad (6.124)$$

The direct-axis short-circuit transient time constant  $T''_d$  can be determined from one of the graphs of the transient alternating component of the short-circuit current.

The rms value of the steady-state short-circuit current from Fig. 6.44 is given by

$$I_d = \frac{OC}{\sqrt{2}} = \frac{E_{f0}}{X_d} \quad (6.125)$$

and the synchronous reactance is

$$X_d = \frac{E_{f0}}{I_d}. \quad (6.126)$$

Note that  $X_d > X'_d > X''_d$ . The time constants  $T''_d$ ,  $T'_d$ , and  $T_a$  may all be found from the oscillograms of the armature currents shown in Fig. 6.43 and 6.44, and the technique for doing this is explained in detail in [6.24] and will not be repeated here.

### The Field Current

The field current is given by

$$i_f = i_{f0} + i_{f0} \left( \frac{X_d - X'_d}{X'_d} \right) \left[ e^{-t/T'_d} - \left( 1 - \frac{T_{kd}}{T''_d} \right) e^{-t/T''_d} - \frac{T_{kd}}{T''_d} e^{-t/T_a} \cos \omega t \right]. \quad (6.127)$$

In the oscillogram of the field current from Fig. 6.42 the total current consists of a unidirectional or asymmetrical component given by the dotted line and an alternating component. The alternating component corresponds to the last term of (6.127). It is of fundamental frequency and dies away with time constant  $T_a$ . The unidirectional or asymmetrical component starts with the steady value  $i_{f0}$  and rises suddenly at the instant of the short-circuit and follows the dotted line until it finally returns to the steady value [6.23].  $T_{kd}$  is the direct-axis damper leakage time constant. Its value varies from

0.01 to 0.05 s for salient-pole machines and from 0.01 to 0.03 s for cylindrical-rotor machines.

Note that there is a correspondence between the field current (6.127) and the armature currents (6.116). The theorem of the constant flux linkages says that: In an inductive circuit of negligible resistance that is closed on itself, with no external voltages in the circuit, the total flux linkage must remain constant.

Thus, the unidirectional armature currents appear to maintain the flux linkage constant in each phase of the armature and not being sustained by a voltage in the armature will decrease with the time constant  $T_a$ . These unidirectional armature currents establish a stationary pulsating field in the airgap that induces a voltage and current of fundamental frequency in the field circuit which is rotating at synchronous speed.

### The Electromagnetic Torque

For a three-phase short-circuit, the electromagnetic torque is given by

$$T_e = E_{f0}^2 \left[ \frac{1}{X_d} + \left( \frac{1}{X'_d} - \frac{1}{X_d} \right) e^{-t/T'_d} + \left( \frac{1}{X'_d} - \frac{1}{X_d} \right) e^{-t/T'_d} \right] e^{-t/T_a} \sin(\omega t) + \frac{E_{f0}^2}{2} \left( \frac{X'_d - X''_d}{X'_d X''_d} \right) e^{-2t/T_a} \sin(2\omega t). \quad (6.128)$$

The principal component of the electromagnetic torque oscillates at normal frequency and has an initial amplitude  $E_{f0}^2/X_d$ . The double frequency torque represented by the second term of (6.128) is very small.

### 6.1.19 The Electromechanical Equation

If  $J$  is the moment of inertia of the generator, including the turbine, in  $\text{kg m}^2$ ,  $\alpha$  is the rotor angular acceleration in mechanical radians/ $\text{s}^2$  and  $T_a$  is the net torque on the rotor in N m, which includes the shaft (mechanical) torque  $T_m$ , corrected for torque due to rotational losses (friction and windage), and  $T_e$  is the electromagnetic torque due to the process of electromechanical energy conversion, then

$$T_a = J\alpha = T_m - T_e. \quad (6.129)$$

In steady-state operation  $T_m = T_e$  and there is no acceleration. However, during disturbances  $T_a$  is different from zero, and with  $\omega_r$  as the rotor angular speed in mechanical radians/s, where  $\omega_r = d\theta_r/dt$ , where  $\theta_r$  is the rotor angle in mechanical radians and  $t$  the time in seconds,

$$J \frac{d\omega_r}{dt} = T_a = T_m - T_e = J \frac{d^2\theta_r}{dt^2} = T_m - T_e. \quad (6.130)$$

The angular position of the rotor  $\theta_c$  (electrical radians) in relation to a fixed reference axis, can be expressed by the equation, where  $\delta$  is the angle between the phasors  $E_f$  and  $V_t$  rotating at synchronous speed  $\omega_0$  (electrical radians per second)

$$\theta_c = \frac{\pi}{2} + \delta + \omega_0 t \Rightarrow \frac{d^2\theta_c}{dt^2} = \frac{d^2\delta}{dt^2} = \frac{p}{2} \frac{d^2\theta_r}{dt^2}. \quad (6.131)$$

The angle  $\delta$ , in rad E/s, measures the angular position of the rotor in relation to an axis that is rotating at synchronous speed (axis of phasor  $V_t$ ). The factor  $p/2$  converts angle in mechanical radians, into angle in electrical radians. By substitution of (6.131) into (6.130),

$$J \frac{2}{p} \frac{d^2\delta}{dt^2} = T_m - T_c. \quad (6.132)$$

Equation (6.132) can be written in terms of the inertia constant  $H$ , that is defined as the kinetic energy stored at rated speed in megajoule (MJ) divided by the rated apparent power  $S$  of the machine in MVA, i.e.,

$$H = \frac{1}{2} \frac{J\omega_0^2}{S} \text{ (MJ/MVA)}. \quad (6.133)$$

By substituting (6.133) into (6.129) and adding a term corresponding to the damping torque due to the damper winding, where  $D$  is the damping coefficient, the resultant equation, known as the electromechanical equation or swing equation is,

$$\left( \frac{2H}{\omega_0} \right) \frac{d^2\delta}{dt^2} = \bar{T}_m - \bar{T}_c - \left( \frac{D}{\omega_0} \right) \frac{d\delta}{dt}, \quad (6.134)$$

where  $\delta$  is in electrical radians and  $\bar{T}_m$  and  $\bar{T}_c$  are in per-unit.

For turbogenerators around 30 up to 60% of the total inertia is due to the turbine, while in hydrogenerators 4 up to 15% is due to the turbine, the greater percentiles increase with the size of the machine. For turbogenerators the value for  $H$  varies from 3 up to 10 s, while for hydrogenerators it varies from 2 up to 5 s.

### 6.1.20 Design Considerations

#### Apparent Nominal Power: Output Equation

There is a well-defined relation between the principal dimensions of a rotating machine and its volt-ampère or horsepower rating, in terms of quantities that define the specific utilization of the materials of its magnetic and electric circuits. This relation, called the output

equation, is given for a 3-phase generator, by the expression

$$S = 1.11 K_w \pi^2 B_{av} A D^2 L n \times 10^{-6} \text{ (MVA)}, \quad (6.135)$$

where  $S$  = three-phase output power (MVA),  $K_w$  = winding factor,  $B_{av}$  = specific magnetic loading (T),  $A$  = specific electric loading (A/m),  $D$  = inner stator diameter (m),  $L$  = axial length of the core (m), and  $n$  = speed in rps.

Thus, the rating of the machine is proportional to the average gap density  $B_{av}$ , the armature surface current density  $A$ , the volume of the rotating member (represented by the  $D^2L$  product), and the speed of rotation.

For convenience in design, the following specific loadings are defined, where  $\Phi$  is the flux per pole (Wb),  $p$  the number of poles,  $N$  is the number of turns in series per phase and  $I$  is the effective value of stator current (A):

a) Specific magnetic loading,

$$B_{av} = \frac{\Phi p}{\pi D L} \text{ (T)}. \quad (6.136)$$

b) Specific electric loading, i.e., the number of ampere-conductors per meter length of stator surface circumference or the peripheral current density,

$$A = \frac{2mNI}{\pi D} \left( \frac{A}{m} \right), \quad m = 3 = \text{number of phases}. \quad (6.137)$$

Calling  $C$  the output coefficient,

$$C = 1.11 K_w \pi^2 B_{av} A \times 10^{-6} \text{ (MVA)}. \quad (6.138)$$

The output equation may be written as

$$S = C D^2 L n \text{ (MVA)}. \quad (6.139)$$

$S$  is the output power for a generator or the input power for motors. In terms of mechanical output for motors in horsepower (HP),

$$S = \frac{\text{HP} \times 745.7 \times 10^{-6}}{\eta \cos \theta} \text{ (MVA)}, \quad (6.140)$$

where  $\eta$  and  $\cos \theta$  are the efficiency and power factor of the motor, respectively.

Turbogenerators are normally designed with two/four poles with a speed of 3000/1500 rpm for a frequency of 50 Hz, or with a speed of 3600/1800 rpm for a frequency of 60 Hz. Hence, the peripheral speed  $v = \pi D_r n$ , where  $D_r$  is the rotor diameter, is very high and increases with diameter. The centrifugal forces in

the rotor cause an increase in the mechanical forces in the teeth, windings and end-bells. Thus, for a given volume since the diameter of turbo generators has to be kept small, their axial length must be large.

However, in the case of hydrogenerators the speed is low and a large number of poles are necessary. This will increase the diameter of the machine and for a given volume the length of the machine reduces. Hence, hydro generators have a large diameter and small axial length in contrast to turbo generators.

For the same rating, due to the higher speed of turbo generators than for hydro generators, the volume of turbo generators are lower than the volume of hydro generators.

**Additional Considerations.** To increase the output of a machine for a given speed the following alternatives may be possible:

- a) Altering the dimensions enables a notable increase in output to be achieved. For example, increasing both the stator diameter (and consequently the rotor diameter) and the active length by 10% raises the output by approximately 33%. Using a 300 MVA rating as reference, this would allow an increase to about 400 MVA.  
However, a larger stator diameter rotor and active length greatly increase the windage losses. For instance, the surface friction loss, which represents a significant portion of the windage and therefore the total losses rises as the fourth power of the stator diameter and linearly with an increasing active length.
- b) Increase in the specific magnetic loading  $B_{av}$ . However,  $B_{av}$  is limited by saturation in parts of the magnetic circuit. Also, an increase in  $B_{av}$  leads to higher flux in the iron parts of the machine, that results in increased iron losses and reduced efficiency.
- c) Increase in the specific electric loading  $A$  by increasing the armature current, that determines to a large extent the  $I^2R$  loss leading to a high temperature rise, and subsequent need for improvements in the cooling system. The stray-load losses will increase with current too.  $I^2R$  loss can be decreased by decreasing the resistance. This means conductors of larger cross section, that in turn calls for increased slot dimensions; wider slots imply narrower teeth and correspondingly higher flux densities; and deeper slots imply greater leakage reactance.
- d) It is evident that the physical dimensions and the quantitative characteristics of the magnetic and electric circuits are all interrelated, and that the problem for the designer is to adjust their magni-

tudes so that they are not only mutually consistent, but also to ensure that the resultant machine will meet specifications and standards.

#### Short-Circuit Relation (SCR)

As defined previously, the SCR for cylindrical-rotor machines, also called nonsalient-pole (NSPL) and salient-pole machines (SPM) is given by

$$\begin{aligned} \text{SCR} &= \frac{1}{X_s \text{ p.u. (sat)}} \quad (\text{NSPM}) \\ &= \frac{1}{X_d \text{ p.u. (sat)}} \quad (\text{SPM}) . \end{aligned} \quad (6.141)$$

The effects of the SCR on the machine performance and design are as follows:

- a) When the SCR is high (low synchronous reactance):
  - The transient stability limit is improved.
  - The machine has a better voltage regulation.
  - The synchronous, transient and subtransient reactances are also lower. So, the short-circuit currents from the machine increases, implying more costly switchgear in the generation station, as well as an increase in the forces and stresses on the machine end windings under sudden short-circuits.
  - The machine has a larger airgap, and as a consequence a large volume and an increase in losses.
  - The influence of the demagnetizing armature reaction flux on the field winding flux decreases, improving the performance of the excitation system in these conditions.
  - The machine can absorb more reactive power from the transmission system, specially when it operates as synchronous compensator.
  - The cost of the machine increases.
- b) When the SCR is low (high synchronous reactance):
  - The voltage regulation is impaired.
  - The transient stability limit decreases likely resulting in more onerous excitation system requirements, for example higher ceiling voltages and/or faster rise times.
  - The parallel operation becomes somewhat difficult due to low synchronizing power.
  - The short-circuit current decreases.
  - There is the possibility of self excitation when the generator feeds long transmission lines, as this would lead to a large terminal voltage on load rejection due to line charging.

With fast-acting excitation systems the voltage regulation and stability limits are enhanced and the influence of the SCR on the machine stability performance dimin-

ishes. Increasing a nonsalient-pole generator SCR from 0.4 to 0.5 may result in an increase in total volume of about 5–10%.

In salient-pole generators, depending on their sizes and construction, the SCR varies from 0.80 up to 1.20 p.u., while in nonsalient-poles machines the SCR may lie between 0.35–0.60 p.u., these being the lower values for larger machines.

IEEE C50.12 [6.15] also states that the short-circuit ratio of salient-pole generators should be fixed by agreement. If not specified by the purchaser it should be no less than 0.80 p.u.

IEEE C50.13 [6.16]. states that the short-circuit ratio should be fixed by agreement and if not specified by the purchaser it should be no less than 0.35 p.u.

### Length of the Air-Gap

The air-gap in a synchronous machine affects the value of the SCR and hence it influences many other parameters. The choice of airgap length is very critical in the case of synchronous machines. The following are the advantages and disadvantages of a larger airgap and as a consequence lower synchronous reactances and higher SCR.

Advantages:

- Stability: Higher value of stability limit
- Regulation: Smaller value of inherent regulation
- Synchronizing power: Higher value of synchronizing power
- Cooling: Better cooling
- Noise: Reduction in noise
- Magnetic pull: Smaller value of unbalanced magnetic pull

Disadvantages:

- Field MMF: A larger value of field MMF is required
- Size: Larger diameter and hence larger size
- Magnetic leakage: Increased magnetic leakage
- Weight of copper: Higher weight of copper in the field winding
- Cost: Increase in the overall cost.

The airgap length should be designed while considering the above factors.

### Effects of a Reduction in the Number of Stator Series Turns per Phase ( $N_{ph}$ )

The reduction in  $N_{ph}$  will lead to a decrease in armature excitation voltage  $E_f$  and as a consequence in terminal voltage  $V_m$ . To avoid that, the excitation flux per pole  $\Phi_f$  must be increased. As the flux density  $B_f$  should be, in general, at its value at the knee of the magne-

tization curve in order to avoid excessive generation of odd harmonics, and not to increase the iron losses, which would lead to a high temperature rise in the core, the airgap area per pole  $A_g$  must be increased. That is,  $A_g \cong \pi DL/p$ , where  $D$  = stator diameter;  $L$  = stator length;  $p$  = number of poles. Then, an increase in the airgap area involves an increase in the rotor and stator diameters without modifying the airgap length and/or an increase in  $L$ .

### Direct-Axis Transient and Subtransient Synchronous Reactances

A reduction in  $X_d$ , i.e., an increase in SCR also reduces the direct-axis transient and subtransient synchronous reactances. With lower values for these reactances the generator will supply more power during the subtransient and transient periods, which is beneficial to transient stability. On the other hand the short-circuit current will increase and the manufacturer should be consulted to verify if the generator can be submitted to the stresses resulting from this increase in the SCR.

### Damper Windings Ratio: $X'_q/X''_d$ (Salient-Pole Machines)

During normal operation, the generator is operating at synchronous speed. The damper windings also move at the same speed. Thus, they are inactive.

During a transient, the generator speed changes. The damper windings are now moving at a different speed than the synchronous speed. The currents induced in the damper windings generate an opposing torque to the relative motion. This action helps return the rotor to its normal speed.

Some considerations about damper windings:

- The damper torque is always a braking torque. Therefore it has the same effect on the angular motion of the rotor as a decrease of mechanical input torque. Stability of the machine is improved.
- In general, where beneficial effects can be obtained with the use of damper windings, the benefits are greater for a continuous damper than for non-continuous dampers. The non-continuous damper winding lends itself somewhat easier to the removal of a pole but not to a sufficient extent to be a consideration in the choice of type to install.
- When the generators are submitted to high over-speeds, it is desirable for mechanical reasons to have only flexible connections among the poles.
- The lowest overvoltage on the unfaulty phase and the greatest torque and damper power occur with the continuous damper.
- The reduction in overvoltage when continuous dampers are used is an important factor in the

reliable operation of lightning arresters and other equipment in the power station, that, otherwise, could be damaged during load rejection.

- A ratio  $X_q''/X_d''$  as low as 1.35 can be obtained with non-continuous and below width continuous dampers.

Damper windings are to a lesser extent used in turbogenerators as the steel rotor cores of such machines provide paths for eddy currents and thus produce similar effects as dampers.

### Power Factor (pf)

When the voltages, speed, temperatures and the active power from the turbine are maintained constant, if the pf decreases the armature reaction increases and the field current must increase to maintain the airgap flux. Both the field and armature amperes-turns increase. For instance, a reduction in pf from 0.95 to 0.90, increases armature current from  $1/0.95 = 1.052$  p.u. to  $1/0.90 = 1.111$  p.u., i.e., an increase of 5.6%. This may require more conductors in the field and armature to control the increase in temperature for the same insulation and cooling systems. The apparent power of the machine also increases due to the greater reactive power capacity of the generator when the pf decreases. Thus, the cost of the machine increases. As an estimate, the design of a generator for a pf of 0.90 would imply an increase in cost between 2.5–5.5% when compared with a pf of 0.95.

If generators are located a great distance from load centers, a pf of 0.95 may be suitable, while if they are located near load centers a lower power factor may be desirable to control the system voltage, that might reduce or eliminate other methods of voltage control.

### Terminal Voltage

The expression below gives the rms phase to phase terminal voltage  $V_t$  of a machine with windings connected in star formation

$$V_t = \frac{3.85q_s n_s f k_w \Phi_f}{mC}, \quad (6.142)$$

where  $q_s$  = total slots in the stator,  $n_s$  = number of conductors in each slot,  $f$  = frequency,  $k_w$  = winding factor,  $\Phi_f$  = field flux per pole,  $m$  = number of phases and  $C$  = number of parallel paths in the armature.

From (6.142), we can conclude:

- Increasing the field flux per pole may be allowed up to a certain limit due to saturation in parts of the magnetic circuit. A high flux implies an increase in iron losses and reducing efficiency.

- If the number of slots increase the voltage increases, but the machine cost increases.
- If the number of parallel paths increases the terminal voltage decreases.

### Inertia Constant

The minimum inertia requirements are usually determined from hydraulic system considerations, since inertia affects the maximum rate of closure of turbine gates and the corresponding pressure transients, as well as the stability of the hydraulic system. The inertia constant is a function of the apparent nominal power of the generator and of the moment of inertia  $J$  of the rotating parts (turbine + generator), multiplied by the square of the radius of gyration. It is given by

$$H = 5.48 \times 10^{-9} J \frac{(\text{rpm})^2}{\text{MVA}_{\text{rating}}} \quad (\text{s}). \quad (6.143)$$

The speed is tied with the specific speed  $N_s$ , that is a characteristic of each design of a turbine runner and varies with the head and type of turbine. The speed can be determined by

$$\text{rpm} = \frac{N_s h^{5/4}}{\sqrt{P}}, \quad (6.144)$$

where  $P$  is the power developed by the turbine and  $h$  is the net head.

A greater value of  $H$  has influence on the behavior of the machine during transient conditions of operation, improving the stability of the generator. Once the rated voltage and current are set up, the MVA is fixed. Then, to increase  $H$  it will be necessary to increase the rotor diameter. This will increase the size of the machine and may require reinforcement of the foundations of the power house. The efficiency of the generator will decrease due to the increase in mechanical losses.

## 6.1.21 Advanced Technologies

Some advanced technologies in synchronous generators and motors such as: superconducting generators and motors; permanent magnet motors; switched reluctance motors and line start permanent magnet motors, are presented.

### Superconductor Synchronous Generator (SSG) and Compensator

A SSG is expected to have about 1/3 of the overall volume of an equivalent conventional generator, so that a power station can accommodate more generators for the same space. They are the promising alternative for increasing generation efficiency, reducing weight and

improving power system stability, in comparison with conventional generators. As HTS (high-temperature superconductor) tapes are sensitive to AC fields and AC currents, their use in electrical machines is economically attractive in DC windings, as in rotor field windings of synchronous machines [6.25]. Advanced heat and electric insulation along with cryogenic refrigeration technology is required by the superconducting generators to maintain the low temperature requirement and the functionality of the superconducting coil. The stator windings carry alternating currents. However, the cooling system has greater cost, size and weight when compared with conventional generators, and the motor bearings and lubrication oil need to be able to withstand cold temperatures or need to be insulated from the cold rotor.

A major benefit of HTS generators is lowered armature reactances. The value of synchronous reactance may be from 1/5 to 1/4 lower than that of a conventional generator, consequently in normal operation the load angle is much lower, resulting in larger margins against loss of stability. The reactive power absorption increases substantially. The efficiency of the generator, usually in the range of 98.0–99.0%, can be increased by 0.3–0.5%, depending on the design of the cooling system.

A marine superconducting generator, rated 4 MVA, 60 Hz, and 3600 rpm, was manufactured in 2002. The rotor winding is made of HTS conductors. The armature winding is fixed to the stator core by nonmagnetic fibre plastic elements [6.26]. This generator is now operating as a synchronous compensator in a 20 kV distribution network, after undertaking a long test program.

### Superconductor Synchronous Compensator (SSC)

An 8 MVAR, 13.8 kV high-temperature superconductor synchronous compensator (SSC) was developed and has been in operation since the end of 2004. The stator winding is of the conventional type while the rotor is made of superconducting coils. In a normal field winding of a synchronous machine, the coils expand and contract when there is load variation due to an increase or decrease in the temperature of the conductors. This results in insulation fatigue that can lead to premature failure of the field winding. In the case of the use of superconductive coils this is not verified because the conductors operate at a constant temperature and have practically no resistance, leading to a longer life expectancy of the winding. This can be explained by means of Fig. 6.45, which presents the V-curves for conventional synchronous compensators and SSC, where it can be noted that the field current of a conventional machine to generate its rated power should be

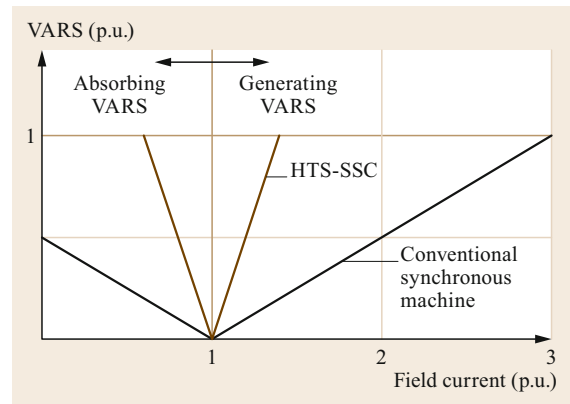

Fig. 6.45 V-curves for conventional and high-temperature superconductor synchronous compensator (SSC) machines

increased by about three times its value at no-load. As a consequence there is an increase in the resistive losses in the field winding by a factor of nine, causing heating in the coils. In the case of the SSC this is practically nonexistent, with the field current being increased, to generate its nominal power, less than 1.5 times its no-load value [6.27].

A static var compensator (SVC) and a static synchronous compensator (STATCOM) vary their reactive power with the square of the voltage and directly with the voltage, respectively, while in SSCs their reactive power is independent of the system voltage and can reach several times its nominal power with a static excitation system, and may avoid the occurrence of a voltage collapse in the system, presenting a performance superior to that obtained with an SVC or a STATCOM.

In addition, SSCs do not produce harmonics such as SVCs and STATCOMs, and do not require filters. Although to date the SSCs have been manufactured for relatively small nominal power, with economies of scale due to increasing use, their cost will be reduced and their use is particularly advantageous in systems that present problems of voltage collapse or abrupt voltage variations.

### Superconducting Motors

In superconducting motors, like superconducting generators, HTS nonresistance coils replace the conventional copper field winding, leading to a sharp reduction of electrical losses in the rotor. The HTS field winding can carry larger currents producing stronger magnetic fields in comparison with a conventional copper winding motor, resulting in increased power density and a smaller size for the motor, reducing its dimensions and weight, while the motor efficiency increases and the operating costs reduce.

They will find application in ratings above 1000 HP, especially in large industries such as chemical, oil and gas refining, steel milling, pulp and paper processing, and other heavy-duty applications. An important application for HTS motors will be in transportation systems, particularly naval and commercial ship propulsion, because of their small size and less weight savings, that are an important benefit where limited space is a key requirement.

A HTS ship propulsion motor of 36.5 MW has been successfully tested. This motor has less than half the size of a conventional motor, reduces the ship weight and frees up space. This development raises the possibility of building an HTS wind generator, particularly those for offshore farms [6.28].

### Permanent Magnet Motors

Permanent magnet (PM) synchronous motors largely used in servo motor applications, are being increasingly used in industrial motor drive systems. The traditional aluminum rotor cage of an induction motor is replaced by a powerful ceramic or rare earth neodymium iron boron (NdFeB) magnets attached to the surface of the rotor or to the rotor interior to establish a permanent magnetic field. The joule losses in the rotor are significantly reduced. As the PM motor is designed for variable speed operation, it must be controlled by a variable speed drive (VSD). PM motors have been demonstrated to exceed proposed super premium efficiency levels (IE4), even when controller losses are included. They have a high power factor [6.29].

PM motors due to their high torque, light weight, and low inertia, are often specified for regenerative elevator drives and electric vehicle hub motor drives. Industrial applications suitable for PM motors include: Adjustable speed pumps, winders, crane and hoist systems, fans and compressors, conveyors, plus extruders, and printing presses.

### Switched Reluctance Motors

The rotor of a switched reluctance (SR) motor does not have magnets (unlike the PM motor), bars, or windings. It is essentially a piece of shaped iron and exploits the fact that forces from a magnetic field on the rotor

iron can be many times greater than those on the current carrying conductors. A SR drive system requires, like a PM motor, an electronic power converter to control the torque and speed. The controller eliminates low speed cogging by switching motor phases on and off in relation to the rotor position. They allow repeated starting under full-load. The rotor produces no heat at stall, so prolonged operation at stall is also possible. Switching losses for the SR motor controller are also reduced to about half of those for an AC motor inverter [6.30].

They may be used in low-speed, high-torque applications, such as: refrigerant compressors, extruders and conveyors, centrifuges, weaving looms, and pumps for reverse osmosis systems, as well as with blowers and high-speed pumps. Like the PM motors, the SR motors are available in NEMA and IEC frames. SR motors with drives are available in the 30–335 HP size range with base speeds from 200 to 10 000 rpm or more depending upon application requirements.

### Line Start Permanent Magnet Motors (LSPMs)

A LSPM has a conventional three-phase distributed winding in the stator (identical to conventional induction motors), but its rotor has an aluminum cage and internal permanent magnets. It operates at a fixed, synchronous speed regardless of the load. It can start and accelerates directly connected to the line, without the need for a controller. There are no resistance losses in the aluminum rotor cage, as it turns at synchronous speed, so that LSPM motors have higher efficiency than premium efficiency motors (IE3) and can achieve super premium efficiency levels (IE4). They operate with the same current and power factor as premium efficiency induction motors. Similar to PM motors, due to the high strength rotor magnets, care must be taken when removing or inserting the motor rotor.

LSPM motors are available in NEMA Design A ratings from 1 to 10 HP at a synchronous speed of 1800 rpm and from 1 to 5 HP at 1200 rpm. While the price of a LSPM motor is currently about double that of a high efficiency (IE2) class motor, attractive simple payback periods for the additional investment in a LSPM motor may be available for applications that operate for more than 6000 h per year [6.31].

## 6.2 Induction Machines

The three-phase induction motor is mostly used in industrial drives. It is also called an asynchronous motor because it does not run at a synchronous speed. It consists of two basic components: the stator or pri-

mary winding, and the rotor or secondary winding. The former supporting windings which receive energy from the supply circuit, the latter carrying windings in which current is induced. The stator of the motor con-

sists of two main parts: the stator frame and the stator core.

### 6.2.1 Construction

The stator frame of the motor is the outer most part of the motor, and with the associated end shields, transmit the torque to the base of the frame and supports the stator core and winding. It takes various forms depending upon the operating conditions to which the motor is to be subjected, such as: open, open drip-proof (ODP), guarded, splash-proof, totally-enclosed, totally-enclosed nonventilated (TENV), totally-enclosed fan-cooled (TEFC), weather protected (Type I), weather protected (Type II), encapsulated, explosion-proof and inverter duty. As these stator frames are related to cooling of the motor, they will be described in details in Sect. 6.2.2, *Cooling*.

The stator core carries three-phase windings and produces a rotating magnetic field. A terminal box connects the six terminals of the windings (two of each phase). Depending on the speed, the stator is wound for a definite number of poles. Normally the motor operates with a delta connected stator. The stator core is laminated to reduce eddy current losses. This laminated structure is made up of steel stampings that are about 0.3–0.6 mm thick and are isolated from each other. The stampings are slotted to receive the windings and are fixed to the stator frame. The slots are punched on the inner side of the stampings as shown in the Fig. 6.46. To reduce hysteresis losses the stampings are generally made up of high-grade silicon steel.

Depending on the rotor winding construction there are two types of three-phase induction motor.

#### (a) Squirrel-Cage Three-Phase Induction Motor

The rotor of the squirrel-cage three-phase induction motor consists of a cylinder of electrical steel laminations with slots on its periphery. The bearings that support the rotor shaft are either sleeve or ball bearings. Copper or aluminum bars are placed in the slots on the periphery of the rotor and are permanently short-circuited by copper or aluminum rings called end-rings, that do not add any external resistance in series with the rotor circuit for starting purposes. Since the voltage developed in the squirrel cage winding is very low, no intentional insulation layer is present between the bars and the rotor steel. In order to provide mechanical strength these rotor bars are welded or electrically braced or even bolted, to the end rings forming a complete closed circuit resembling a cage-like shape and hence the name, squirrel-cage induction motor. The rotor conducting bars are usually not parallel to the shaft,

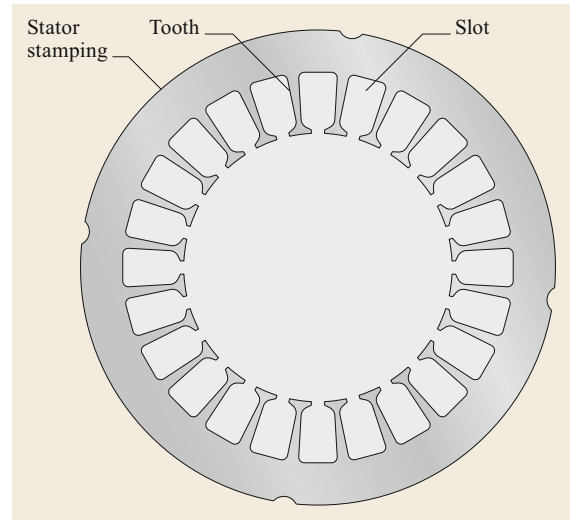

Fig. 6.46 Stator construction of an induction motor

Fig. 6.47 Rotor bars of a squirrel-cage motor

but are purposely given a slight skew as the skewing helps in reduction of magnetic hum, thus keeping the motor quiet, and helping to avoid *cogging*, i.e., the locking tendency of the rotor teeth to remain under the stator teeth due to the direct magnetic attraction between the two.

As the bars are permanently short-circuited by end rings, the rotor resistance is very small. The absence of commutator or slip ring and brushes make the construction of squirrel-cage three-phase induction motor very simple, reliable and robust and hence widely used in industry. These motors have the advantage of adapting any number of pole pairs. A squirrel-cage induction rotor is shown in Fig. 6.47.

The advantages of the squirrel-cage motor are:

- The cage rotor is cheaper, and the construction is robust.
- The absence of brushes reduces the risk of sparking.
- It requires less maintenance.

**Table 6.7** Maximum temperatures of some insulation classes

Insulation class	A	B	F	H
Maximum temperature (°C)	105	130	155	180

### (b) Wound-Rotor or Slip-Ring Three-Phase Induction Motor

Wound-rotor induction machines have a three-phase winding on the rotor, similar to the stator winding. The rotor winding is usually wye-connected with the terminals of the three phases connected to slip-rings, which are mounted on the end of the shaft, and where external circuits can be connected to the rotor, allowing external control of the machine. Wound-rotor motors can be started with low inrush current and with a high torque, by inserting high resistance into the rotor circuit. In normal operation, the windings at the slip-rings are short-circuited. Compared to a squirrel-cage rotor, the rotor of the slip-ring motor has more winding turns, the induced voltage is then higher, and the current lower. Wound-rotor induction machines are usually significantly more expensive than cage rotor machines. They are particularly attractive in some applications, such as:

- Speed control of very large machines
- Doubly-fed induction generation (used in wind turbines)
- To gradually bring up to speed high-inertia loads
- To drive loads that require high starting torque and low starting current (cranes, hoists, etc.).

## 6.2.2 Insulation and Cooling

### Insulation

The insulation system must ensure that short-circuits do not occur, that the conductors do not vibrate in spite of the magnetic forces, and that the heat developed in windings due to joule losses is transmitted to a heat sink. Insulation life is a function of the length of time it is exposed to temperature. The most common insulation classes are presented in Table 6.7, excerpted from NEMA standards [6.32].

Motors are designed with an allowable increase in temperature above ambient during operation. This is referred to as temperature rise (Table 6.8). The maximum allowable temperature rise during operation for a motor varies with respect to insulation class, altitude, and the motor service factor. The service factor is essentially a safety margin and refers to the motor's ability to deliver horsepower beyond its nameplate rating under specified conditions. Most three-phase motors are rated with a 1.0 or 1.15 service factor. If the ambi-

**Fig. 6.48** Allowable number of starts per hour for a class B motor driving a low inertia load

ent temperature exceeds 40°C or at elevations above 3300 feet, the motor service factor must be reduced or a higher horsepower rated motor should be specified. As an oversized motor will be under-loaded, the operating temperature rise is less and overheating is reduced [6.30].

During starting high energy flows into the motor, that may cause thermal-aging of the winding insulation. This is a fatigue phenomenon. Repeated exposure to excessive temperature, whether sustained over long periods or in often-repeated short cycles, will eventually break down the insulation material leading to a winding failure, and depending on the insulation system, that breakdown may begin between turns in a coil, or within the ground wall insulation layers. In the rotor of squirrel-cage motors the individual bars and end rings can undergo expansion because some parts reach higher temperatures than others. Bars can bend, lift out of their slots, or break loose from attachment to the rings. Repeated bending back and forth, even at a fairly low stress level, eventually can cause breakage. Thus, the number of starts per hour should be limited. Figure 6.48 shows for a class B motor driving a low inertia load at rated voltage and frequency, the number of starts allowed per hour. The stress on the motor can be reduced by means of a *soft start* mechanism (autotransformer, part-winding, electronic soft-start, etc.), increasing the number of starts per hour.

### Cooling

All rotating electrical machines dissipate heat as a result of joule losses, iron losses, stray losses and mechanical losses. These losses are higher during the process

**Table 6.8** Allowable rise and operating temperature limits for some insulation classes considering the service factor

Service factor	Enclosure	Insulation temperature	Class A (°C/°F)	Class B (°C/°F)	Class F (°C/°F)	Class H (°C/°F)
1.0/1.15	All	Ambient	40/104			
1.0	All	Allowable rise	60/140	80/176	105/221	125/257
1.0	All	Operating limit	100/212	120/248	145/293	165/329
1.15	All	Allowable rise	65/149	90/194	115/239	140/284
1.15	All	Operating limit	105/221	130/266	155/311	180/356

of starting the motor and dynamic braking, and increase with the size of the motor. Thus, insulation that can withstand higher temperatures and cooling to remove the heat from the windings, core and bearings, must be provided as the motor size increases. Fractional horsepower motors, generally, do not require forced cooling, while larger integral motors, usually incorporate a built in cooling fan to force air through the machine [6.33].

According to its enclosure type and cooling, motors can be classified in several categories. The most important are:

- a) *Open*. It has ventilating openings that allow external air to pass over and around the motor windings to provide cooling. This design is seldom used.
- b) *Open drip-proof (ODP)*. An open motor in which ventilation openings prevent liquids and solids, that fall from above at angles up to 15° from the vertical, from entering the interior of the motor and causing damage. When the motor is not in the horizontal position, such as when it is mounted on a wall, a special cover might be necessary to protect it. This type of enclose can be specified when the environment is free from contaminants and where wind-driven rain is not a consideration. Suitable for most indoor or protected areas.
- c) *Totally enclosed fan-cooled (TEFC)*. A totally enclosed motor with an external fan that blows air over the frame to dissipate heat more quickly. With this arrangement no outside air enters the interior of the motor. They can be used in dirty, moist, or mildly corrosive atmospheres, or where wind-driven rain is anticipated.
- d) *Totally enclosed nonventilated (TENV)*. Similar to TEFC but the motor is designed with a low enough temperature rise so that an external fan is not required for cooling, or duty is limited so the motor does not overheat. Not for use where combustible vapors are present.
- e) *Guarded*. An open motor in which all ventilation openings are limited to specified size and shape. This protects the intrusion of fingers or foreign objects into the motor.

- f) *Weather protected (Type I)*: Similar to an ODP motor with the addition of screens to prevent rain, snow and large particles from entering the motor. Suitable for most indoor or protected areas that have relatively clean environments.
- g) *Weather protected (Type II)*: In this type air is forced to change direction by 90° by means of baffles placed at the inlet of the motor, preventing water from entering the motor. It is suitable for outdoor applications with up to 100 mph winds driving rain at the motor.
- h) *Splash proof*. An open motor designed with ventilation openings that prevent liquid or solids particles from entering the motor at any angle less than 100° from the vertical.
- i) *Encapsulated*. The windings are covered with a heavy coating of material to provide protection from moisture, dirt, and abrasion.
- j) *Explosion proof*. Similar in appearance to a TEFC motor and designed to withstand an internal explosion and to prevent ignition of specified gases or vapors surrounding the motors. It is suitable for safe operation of the motor in hazardous environments.

Motors and modern generators rated less than about 100 MVA are almost always cooled by air flowing over the rotor and stator. IEC and NEMA standards describe the various types of cooling methods in detail.

### 6.2.3 Operating Principles

When an induction motor is connected to a three-phase power supply the stator currents create a rotating magnetic field that travels at synchronous speed in relation to the stator and rotor. Electromotive forces are induced in the stator and rotor windings, and currents circulate in the rotor windings, like currents in the secondary of a transformer. These rotor currents, when the rotor is at standstill, have the same frequency as the stator, however, when the rotor rotates the frequency of these currents are lower than the synchronous frequency of the stator currents. Thus the rotor magnetic field produced by the rotor currents, in relation to the rotor, travel at a speed lower than synchronous speed and

equal to the difference between the synchronous speed and the speed of the rotor, but at synchronous speed with respect to the stator. The two magnetic fields are then stationary and a constant torque is produced, that accelerates the rotor in the direction of the rotating stator magnetic field.

The stator is connected to a circuit with a voltage  $V_1$ . As mentioned, the three-phase currents enters the stator windings and creates a rotating magnetic field, called the main flux,  $\Phi_m$ , within the airgap, rotating at a speed  $n_1 = [(120f_1)/p]$  (rpm), linking both stator and rotor. This flux induces, in the stator and rotor, the EMFs  $E_1$  and  $E_2$ , respectively. With the rotor open-circuit and stationary, the current in the stator  $I_1$  is practically equal to the exciting current  $I_0$ , i.e.,  $I_1 = I_0$ , where  $I_0 = I_m + I_c$ , being  $I_{mc}$  the magnetizing component of  $I_0$ , that produces the main flux  $\Phi_m$  and  $I_c$  is the core-loss component of  $I_0$ , which supply hysteresis and eddy-current losses in the stator and rotor due to the main flux. In the case of the induction motor as compared to a transformer the exciting current  $I_0$  is considerably larger. In a transformer the excitation current varies from 2 to 5% of the rated current, whereas in an induction motor, due to the airgap, the excitation current is about 25–50% of the rated current, depending upon the size of the motor.

When currents flow in the rotor windings, a MMF wave is produced, and this MMF wave, i.e., the armature reaction, reacts upon the stator MMF wave, such that it opposes the stator MMF and tends to reduce the main flux and  $E_1$ . Then the stator is forced to draw more current ( $I_2'$ ) from the lines, thus compensating the armature reaction and sustaining the main flux, i.e.,  $E_1$ . As a consequence, the stator current  $I_1 = I_0 + I_2'$ . The primary and secondary leakage fluxes induces, in the windings, the leakage EMFs  $jI_1X_1$  and  $jI_2X_2$ , respectively. Considering the stator and rotor resistances  $R_1$  and  $R_2$ , the following equations, per phase, can be written for both types of rotors, noting that the stator voltage  $V_1$  has to counter balance the self induced EMF  $E_1$  and has to supply voltage drops  $I_1R_1$  and  $I_1X_1$ . The rotor induced EMF  $E_2$  has to supply the drop across rotor impedance.

$$\dot{V}_1 = -\dot{E}_1 + (R_1 + jX_1)\dot{I}_1 \quad \text{and} \quad \dot{E}_2 = (R_2 + jX_2)\dot{I}_2 \quad (6.145)$$

From (6.145) the phasor diagram of an induction motor on load can be obtained (Fig. 6.49). This diagram is very similar to the diagram of a loaded power transformer. The differences are that in the case of an induction motor the rotor (secondary) supplies a rotating mechanical load, while the transformer secondary supplies an electrical load. Note that  $\theta_1$  is the angle be-

Fig. 6.49 Phasor diagram of an induction motor

tween  $V_1$  and  $I_1$  and  $\cos \theta_1$  gives the power factor of the induction motor, while  $\cos \theta_2$  is the load power factor.

The EMFs induced in the stator  $E_1$  and rotor  $E_2$ , are given by

$$E_1 = 4.44f_1N_1k_{w1}\Phi_m \quad \text{and} \quad E_2 = 4.44f_2N_2k_{w2}\Phi_m, \quad (6.146)$$

where  $f$  = frequency,  $N$  = turns,  $k_w$  = winding factor and  $\Phi_m$  = main or resultant field. Stator quantities are designated by the index 1 and rotor quantities are designated by the index 2. The stator frequency is the synchronous frequency, thus  $f_1 = f_s$ .

The main or resultant field  $\Phi_m$  turns at synchronous speed ( $n_s$ ) and the rotor turns at a speed  $n$ . Then,  $\Phi_m$  cuts the rotor windings at a speed  $n_s - n$ . The rotor frequency  $f_2$  is

$$f_2 = \left( \frac{n_s - n}{n_s} \right) \left( \frac{p}{2} \frac{n_s}{60} \right) = sf_s, \quad (6.147)$$

where  $s$  is the rotor slip with relation to the stator, i.e.,

$$s = \left( \frac{n_s - n}{n_s} \right) \quad (6.148)$$

and

$$f_s = \left( \frac{p}{2} \frac{n_s}{60} \right), \quad (6.149)$$

where  $p$  is the number of poles and  $f_s$  is the synchronous frequency.

Two situations will be analyzed:

a) When the motor operates at rated speed or close to it.

In this case the slip is very low, and the rotor reactance  $X_2 = 2\pi f_2 L_{12} \cong 0$ , where  $L_{12}$  is the secondary leakage inductance.  $E_2$  is practically in phase with  $I_2$ . The load power factor is close to unity. The rotor current  $I_2$  is

$$I_2 = \frac{E_2}{R_2} = ks, \quad \text{i.e., directly proportional to the slip.}$$

b) When the motor operates with nonneglected slip (during acceleration).

In this case  $X_2 = 2\pi f_2 L_{12} = 2\pi s f_s L_{12}$  can not be neglected and the actual rotor current is

$$I_2 = \frac{E_2}{Z_2} = \frac{E_2}{\sqrt{R_2^2 + X_2^2}} = \frac{k_1}{\sqrt{(R_2/s)^2 + (2\pi f_s L_{12})^2}}. \quad (6.150)$$

The rotor current is no longer directly proportional to the slip. At starting  $s = 1, f_2 = f_s$  and the current has its maximum value.

### 6.2.4 Equivalent Circuit of an Induction Motor

Based on (6.145)–(6.150) and the phasor diagram, the equivalent circuit of a three-phase induction motor can be drawn, as shown in Fig. 6.50, where the circuits for the stator and rotor were represented separately, and according with (6.145)  $R_1$  and  $jX_1$  are the stator winding resistance and reactance, respectively;  $R_c$  is the core loss component,  $X_m$  is the magnetizing reactance;  $R_2$  and  $X_2$  are the rotor winding resistance and reactance, respectively. The effect of developed mechanical power and rotor copper loss is represented by the resistance  $R_2/s$ .

The equivalent circuit with the rotor (secondary) quantities referred to the stator (primary) is shown in Fig. 6.51, where  $R_2'$  is the rotor winding resistance referred to the stator winding and  $X_2'$  is the rotor winding inductance referred to the stator winding.

Some simplification results, without any significant error, when the core loss resistance  $R_c$  of the parallel branch is removed and the associated core loss is subtracted from the internal mechanical power  $P$ , i.e., the core loss is added to the rotational losses and stray-load losses. Such a procedure has the advantage of not needing to separate the core loss from the rotational losses during motor testing. The error introduced is very small and the circuit equivalent becomes that of Fig. 6.52 [6.34].

Fig. 6.50 Equivalent circuit of an induction motor with stator and rotor windings separately

Fig. 6.51 Equivalent circuit of an induction motor with the rotor winding referred to the stator

Fig. 6.52 Simplified equivalent circuit of an induction motor

For transferring quantities from the secondary to the primary, the secondary quantities should be multiplied by the factors:

- For voltage:  $(N_1 k_{w1}) / (N_2 k_{w2})$
- For current:  $(m_2 N_2 k_{w2}) / (m_1 N_1 k_{w1})$
- For resistance and reactance:  $m_1 (N_1 k_{w1})^2 / [m_2 (N_2 k_{w2})^2]$ .

The squirrel-cage induction motor produces the same number of poles as that of the stator. It is seen as a polyphase winding with  $m_2 = 2Q_2/p$  phases, where  $Q_2$  is the number of rotor bars, and the number of turns per phase  $N_2 = 1/2$ , because each phase consists of one conductor. The distribution and pitch factors are equal to 1.  $R_2$  and  $X_2$  are the values per bar. Considering the rotor skew,  $N_2$  in the previous equations has to be multiplied by the skew factor  $k_s$ , that is given by

$$k_s = \frac{\sin(\theta_s/2)}{\theta_s/2}, \quad (6.151)$$

where  $\theta_s$  is the skew angle in electrical radians.

### 6.2.5 Power and Torque Relations of an Induction Motor

#### Power Relations

The three-phase active power transferred from the stator to the rotor through the airgap is  $P_{sr} = 3(I_2')^2 R_2'/s$ , and the active power loss in the copper of the rotor is  $P_{copr} = 3(I_2')^2 R_2'$ . Thus the developed internal mechanical power  $P$  is

$$P = P_{sr} - P_{copr} = (1-s)P_{sr} = 3(I_2')^2 R_2' \frac{1-s}{s}. \quad (6.152)$$

Thus, the part  $(1-s)$  of the power transferred to the rotor by the stator is converted to mechanical power  $P$ . So, if an induction motor has a high slip it will have a low efficiency. Also, as  $R_2'/s = R_2' + R_2'(1-s)/s$ , the equivalent circuit of Fig. 6.52 could be redrawn by separating the resistance  $(R_2'/s)$  into two components, obtaining the copper loss in the rotor  $P_{copr} = 3(I_2')^2 R_2' = sP_{sr}$ , and the power that is converted to developed mechanical power  $P = [3(I_2')^2 R_2'(1-s)/s]$ .

The core losses  $P_{core}$  occur in normal operation basically in the stator, because the frequency of flux density variation in the rotor core of the induction machine is very low ( $f_2 = sf_1$ , where  $f_1$  is the stator synchronous frequency) under normal operating conditions so that the rotor has negligible core-losses.

The useful mechanical power or load power  $P_L$ , i.e., the mechanical power delivered at the shaft to a load is less than the developed internal mechanical power  $P$  by the rotational losses  $P_{rot}$  (the sum of bearing friction losses, brush friction losses in the case of wound rotors, windage losses) and by the stray-load losses or additional losses  $P_{add}$ . Stray-load losses are iron losses in the teeth and on the surface of rotor and stator caused by a ripple on the flux density wave due to the slot-openings of the stator and rotor, and also include the copper losses created by harmonic currents induced in the rotor windings by high-order stator MMF harmonics. It is assumed that stray-load losses may be subtracted directly from  $P$  like the rotational losses, thus they may be added to the rotational losses.

$$P = P_L + P_{rot} + P_{add}. \quad (6.153)$$

The heat developed by the losses increases the temperature of the machine and directly affects the specification of the insulation system, the thickness of the laminations and the material of the core, the type of bearings and the ventilation system. Some measures can be taken to reduce windage losses, such as: cast copper rotors lower rotor resistance losses; thinner laminations decrease the eddy current losses; premium grade steel

Fig. 6.53 Approximate equivalent circuit of an induction motor by Thévenin's theorem

sheets reduce the hysteresis losses; and making the rotor and stator surfaces as smooth as possible, and keeping the rotor-stator gap as large as practical without compromising electrical efficiency.

Applying Thévenin's theorem between points a and b of Fig. 6.52 the equivalent circuit is reduced to that shown in Fig. 6.53 and the voltage and impedance resultant are

$$V_{th} = V_1 \frac{X_m}{\sqrt{R_1^2 + (X_1 + X_m)^2}}, \quad (6.154)$$

$$Z_{th} = R_{th} + jX_{th} = \frac{jX_m(R_1 + jX_1)}{R_1 + j(X_1 + X_m)}. \quad (6.155)$$

The amplitude of the rotor current referred to the stator is

$$I_2' = \frac{V_{th}}{\sqrt{(R_{th} + R_2'/s)^2 + (X_{th} + X_2')^2}}. \quad (6.156)$$

The airgap three-phase power is given as  $P_{sr} = 3(I_2')^2 R_2'/s$ , and the developed internal mechanical power  $P = (1-s)P_{sr}$  may be written as

$$P = \frac{3(1-s)R_2'V_{th}^2}{s \left[ \left( R_{th} + \frac{R_2'}{s} \right)^2 + (X_{th} + X_2')^2 \right]}. \quad (6.157)$$

#### Torque Relations

The developed mechanical torque or internal or electromagnetic torque  $T$  on the rotor has to overcome the load (useful) torque  $T_L$  and the torque associated with the rotational and additional losses  $T_0$ . Dividing equation (6.154) by the rotor angular mechanical speed  $\omega_r$ ,

$$T = T_L + \frac{P_m + P_{add}}{\omega_r} = T_L + T_0, \quad (6.158)$$

where

$$\omega_r = (1-s)\omega_s \quad \text{and} \quad \omega_s = \frac{4\pi f}{p} \quad (\text{radians mec./s}). \quad (6.159)$$

Considering (6.157) the developed mechanical torque is

$$T = \frac{3 \frac{R'_2}{s} V_{th}^2}{\omega_s \left[ \left( R_{th} + \frac{R'_2}{s} \right)^2 + (X_{th} + X'_2)^2 \right]} \quad (6.160)$$

The maximum torque developed by the motor is determined by  $dT/ds = 0$ , and the corresponding slip is given by

$$s_{\max T} = \frac{R'_2}{\sqrt{R_{th}^2 + (X_{th} + X'_2)^2}} \quad (6.161)$$

Substituting (6.161) in (6.160) the maximum (breakdown) torque developed by the motor is

$$T_{\max} = \frac{3V_{th}^2}{2\omega_s \left[ R_{th} + \sqrt{R_{th}^2 + (X_{th} + X'_2)^2} \right]} \quad (6.162)$$

At starting  $s = 1$  ( $\omega_r = 0$ ) and  $T = T_p$  (starting torque, also designates as locked torque) and if theoretically  $s = 0$  ( $\omega_r = \omega_s$ ) the  $T = 0$ .

The operating torques of an electric motor (Fig. 6.54) are defined as:

- Full load torque: Is the torque necessary to produce its rated horsepower at full-load speed.
- Locked rotor or starting torque: Is the torque that it will develop at rest with rated voltage applied at rated frequency.
- Minimum (pull-up) torque: Is the minimum torque the motor develops while accelerating from standstill to the rated speed. If the load applied to the

**Fig. 6.54** Typical torque  $\times$  speed characteristic of NEMA class B induction motors

motor shaft exceeds the pull-up torque, but not the locked rotor torque, the motor will turn, but will never accelerate to the rated speed. Not all motors have a pull-up torque rating. Design D (high slip) motors, for example, do not.

- Breakdown (pull-out) torque: Is the maximum torque that it will develop with rated voltage applied at rated frequency.

### Effect of Harmonics on the Torque

According to Sect. 6.1.4 of the synchronous machines the MMF harmonics create flux harmonics that induce harmonic currents in the rotor. Besides the fundamental frequency harmonic, the effect of the fifth and seventh harmonics, which have greater influence on the performance of the machine, will be considered.

The slips for the first ( $s_1$ ), fifth ( $s_5$ ) and seventh ( $s_7$ ) harmonics are

$$s_1 = \frac{n_s - n}{n_s}, \quad s_5 = \frac{-(n_s/5) - n}{-n_s/5} = \frac{n_s + 5n}{n_s},$$

$$s_7 = \frac{(n_s/7) - n}{n_s/7} = \frac{n_s - 7n}{n_s}, \quad (6.163)$$

where  $n_s$  is the synchronous speed and  $n$  is the rotor speed.

When  $n$  varies from 0 (zero) up to  $n_s$ ,  $s_1$  varies from 1 to 0,  $s_5$  from 1 to 6 and  $s_7$  from 1 to  $-6$ . The torque due to fifth harmonic, that creates a flux on the stator in the opposite direction of the rotor direction (the direction of the fundamental frequency torque) is always negative. The torque due to the seventh harmonic, that creates a flux on the stator in the same direction of the rotor direction is positive for  $1 > s_1 > 6/7$  and null for  $s_1 = 6/7$ , and then becomes negative.

When the torques created by the fifth and seventh harmonic are added to the fundamental torque, the resultant torque, around the region where  $s_1$  is slightly greater than  $6/7$ , may be inferior to the load torque and the motor will stop.

### 6.2.6 Operation as a Brake and Generator

#### Operation as a Brake

Braking in induction motors refers to quickly bringing the speed of the motor to zero by a method called plugging. Plugging involves reversing the supply in two of the phases. This leads to a torque being developed in the opposite direction to the rotation of the motor,  $s > 1$ , the power  $P = (1 - s)P_{sr}$  developed by the motor will be negative, the motor speed starts to decrease, as the mechanical power delivered to the load is supplied by the kinetic energy of the motor and the motor comes to a stop. Once the motor stops, the reverse supply is cut

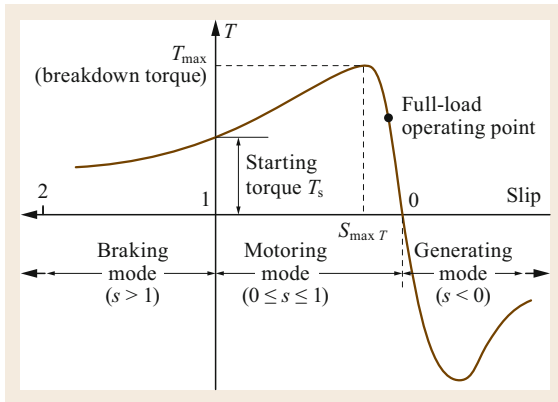

Fig. 6.55 Induction machine torque–slip curves

off to prevent the motor from running in the opposite direction. The rotor is secured by a mechanical brake.

### Operation as a Generator

For this operation an other machine drives the shaft so that the rotor speed is greater than synchronous speed, i.e.,  $\omega_r > \omega_s$ , i.e.,  $s < 0$ . The torque and power will be negative and the machine operates as an induction generator.

As the slip is negative the active component of the stator current changes its sign while the reactive component maintains the same sign as for motor operation. Then the machine delivers active power and receives reactive power. This supply of reactive power must come from the grid to which the machine is connected, preferentially by means of a shunt capacitor bank connected to the generator terminals, so as to relieve the power system from the supply. Induction generators are particularly suitable for wind generating stations as in this case speed is always a variable factor. Unlike synchronous generators, induction generators cannot be used for grid voltage control. Thus, the generator voltage must be maintained by the external power system to which the induction generator is connected.

The induction machine torque–slip curves for motor, brake and generator regions are shown in Fig. 6.55.

## 6.2.7 Determining of Induction Machine Parameters

Three tests are needed to determine the parameters in an induction machine model. Detailed testing is quite involved and is specified in IEEE Standard 112 [6.35].

### Direct Current Resistance Test

The stator resistance can be found by applying a DC voltage across two terminals of the motor and measuring the stator current. There will be no induced

Fig. 6.56a,b Determination of DC stator resistance. (a) Stator connected in star, (b) stator connected in delta

voltage on the rotor and no potential difference across the inductances and the parameters of the motor will be reduced to the stator winding resistance. Values may be obtained for a delta or wye stator connection. The values of the stator resistance for both connections are obtained, as shown in Fig. 6.56a,b.

### No-Load Test

The no-load test of an induction machine enables the core loss resistance  $R_c$ , magnetizing reactance  $X_m$ , and rotational losses  $P_{rot}$  (friction + windage losses) to be obtained. The following measurements are taken: the stator voltage  $V_1$ , the stator current  $I_1$  and the three-phase power  $P_{NL}$ .

During the no-load test, rated voltage and frequency are applied, the machine runs close to synchronous speed, the slip approaches zero causing the rotor current to fall to a very small value, and as a consequence the rotor copper losses can be neglected. Differently from the continuous magnetic core of a transformer, where at no-load the primary current is very small and the joule losses  $3RI^2$  can be neglected, the magnetizing path of an induction motor includes the airgap and its exciting current is around 25–50% of its rated current, implying that the joule losses in the stator cannot be neglected. The magnetizing branch is shunted by a very high impedance rotor branch and the resultant parallel impedance very nearly approaches that of the magnetizing branch, as shown in Fig. 6.57, where the stator current  $I_1$  is equal to the excitation current  $I_0$ .

The measured three-phase input active power is the total losses in the motor at no-load  $P_{NL}$ . These losses consist of the stator losses  $3I_1^2R_1$ , core losses  $P_{core} = 3E^2/R_c$  (hysteresis + eddy current losses) and rotational losses  $P_{rot}$ . The value of the per phase stator DC resistance  $R_1$ , should be corrected for the winding temperature during the test. The skin effect in the value of stator resistance, although the stator frequency is always equal to the line frequency, is small, being about 5–15% of the joule losses in the stator resistance, for

Fig. 6.57 Circuit with parameters for the no-load test

medium-size and large motors, and is usually neglected, and the stator resistance is considered as its DC value. Being  $E$  the EMF induced by the rotating flux in the stator winding at no-load, which is approximately equal to  $E \simeq V_1 - I_1 X_1$ , i.e., the voltage across the parallel branch, the equations for the input active power  $P_{NL}$  and reactive power  $Q_{NL}$  at no-load are

$$\begin{aligned} P_{NL} &= 3I_1^2 R_1 + 3 \frac{E^2}{R_c} + P_{\text{rot}} \quad \text{and} \\ Q_{NL} &= 3I_1^2 X_1 + 3 \frac{E^2}{X_m}. \end{aligned} \quad (6.164)$$

The friction and windage losses (rotational losses) can be determined, for example, by another test in which the rotor of the induction motor is driven by another machine at a speed equal to the no-load speed of the induction motor. The friction and windage losses (rotational losses) are supplied by the driving machine and are equal to its output power.

The friction and windage loss may also be determined by performing a linear regression analysis using three or more lower points of the power versus voltage squared curve. To determine the friction and windage loss, subtract the stator resistance loss (at the temperature of the test) from the total losses  $P_{NL}$  (i.e., input power) at each of the test voltage points and plot the resulting power curve versus voltage, extending the curve to zero voltage. The intercept with the zero voltage axis is the friction and windage loss. This intercept may be determined more accurately if the input power minus stator resistance loss is plotted against the voltage squared for values in the lower voltage range (IEEE standard 112 [6.35]).

Using the value of  $X_1$  from the locked rotor test, the EMF  $E \simeq V_1 - I_1 X_1$  is obtained and the core loss  $P_{\text{core}}$  at rated voltage may be calculated as

$$P_{\text{core}} = P_{NL} - 3I_1^2 R_1 - P_{\text{rot}} = 3 \frac{E^2}{R_c}. \quad (6.165)$$

Thus, the core loss resistance  $R_c$  is

$$R_c = 3 \frac{E^2}{P_{\text{core}}}. \quad (6.166)$$

As per Sect. 6.2.4 some simplification results, without any significant difference in the results, when the core loss is added to the rotational losses. Such a procedure is equivalent to represent the T branch of the equivalent circuit by the magnetizing reactance  $X_m$  only. In this case the no-load reactance is

$$X_{NL} = X_1 + X_m. \quad (6.167)$$

As the three-phase apparent power is  $S_{NL} = 3V_1 I_1$ , the no-load reactive power can be calculated as

$$Q_{NL} = \sqrt{S_{NL}^2 - P_{NL}^2} \quad (6.168)$$

and the no-load reactance is given by

$$X_{NL} = \frac{Q_{NL}}{3I_1^2}. \quad (6.169)$$

#### Locked-Rotor Test

The parameters  $R_2'$ ,  $X_2'$ , and  $X_1$  can be determined by this test. The following measurements are taken: stator terminal voltage  $V_1$ , stator current  $I_1$  and the three-phase power input  $P_{LR}$ . In the locked-rotor test, the rotor of the machine is prevented from rotating and the supply voltage is increased until a current of approximately rated value is obtained. If rated line voltage  $V_1$  is applied the current becomes high, about four to eight times the rated current, and the windings will be overheated. When the rotor is stationary (locked), the slip  $s = 1$ , and only a small exciting current flows in the exciting branch, resulting in small flux and core losses. At standstill there are no mechanical (rotational) losses. Therefore, the power input at standstill  $P_{LR}$  is mainly consumed by the copper losses of the stator and rotor windings, with the core losses neglected.

Accurate prediction of machine characteristics in the normal operating range will depend primarily upon the closeness by which  $R_2'$  represents the actual rotor resistance to currents of low frequency and, secondarily, upon the closeness by which  $X_2'$  represents the actual rotor leakage reactance to currents of low frequency. Typically, this test is done at 1/4 rated (nominal) frequency, i.e., at 15 Hz in a 60 Hz system, and then the reactances must be scaled to find the correct value at rated frequency. Thus, the reactance  $X_m$  will be preserved in the equivalent circuit for the determination of the parameters  $R_2'$ ,  $X_2'$ , and  $X_1$ , as shown in Fig. 6.52.

The three-phase reactive power input  $Q_{LR}$  with the rotor locked can be calculated as

$$Q_{LR} = \sqrt{S_{LR}^2 - P_{LR}^2}, \quad (6.170)$$

where the three-phase apparent power is

$$S_{LR} = 3V_1 I_1. \quad (6.171)$$

The resistance  $R_{LR}$  and the reactance  $X_{LR}$  with the rotor locked, corrected for the rated, can be determined by

$$R_{LR} = \frac{P_{LR}}{3I_1^2} \quad \text{and} \quad X_{LR} = \frac{f_n}{f_{LR}} \frac{Q_{LR}}{3I_1^2}. \quad (6.172)$$

The impedance of the equivalent circuit  $Z_{LR}$ , with  $s = 1$  and with the reactances at the rated frequency is given by

$$Z_{LR} = R_1 + jX_1 + (R'_2 + jX'_2) \quad \text{in parallel with } X_m. \quad (6.173)$$

As  $X_m \gg R'_2$  the rotor resistance and reactance at the rated frequency, are

$$R'_2 = (R_{LR} - R_1) \left( \frac{X'_2 + X_m}{X_m} \right)^2 \quad (6.174)$$

and

$$X'_2 = (X_{LR} - X_1) \left( \frac{X_m}{X_1 + X_m - X_{LR}} \right). \quad (6.175)$$

At this point, only the total leakage reactance is known. The relative values of stator and rotor leakage must be found from experience and are summarized in the Table 6.9.

Replacing in (6.175)  $X_m = X_{NL} - X_1$  from the no-load test (6.167) and using the relations in Table 6.9 for the appropriated motor type, the reactances  $X_1$  and

**Table 6.9** Relations of stator and rotor leakage reactances (Source: Standard IEEE 112 [6.35])

Motor type	$X_1/X'_2$
Wound rotor	1.00
Class A	1.00
Class B	0.67
Class C	0.43
Class D	1.00

$X'_2$  can be determined. With  $X_1$  the magnetizing reactance  $X_m$  can be obtained and from (6.174), the rotor resistance is found. For motors of less than the 20 kW rating, the effects of the frequency are negligible, and the locked-rotor test can be performed directly at the rated frequency.

## 6.2.8 Effects of Rotor Resistance

### Wound Rotor Motors

By inserting resistances in series with the rotor windings (Fig. 6.58), the resistance of the rotor circuit is increased, the starting torque and power factor are increased, while the starting current is decreased [6.36]. Also, by resistance control, the speed can be varied.

The resistances are connected to the terminal ends of the rotor windings by means of slip rings and brushes. The resistances are assembled as branches of a resistor bank unit. These resistance branches can be externally switched on and off in the resistor bank at different intervals, thus providing multiple stages of speed levels and torque capacity. The resistor bank may consist, for instance, of three resistances per phase making up a total of nine resistances in the entire resistor bank network. Thus, there are correspondingly three branches of resistances in the resistor bank. Each stage of the resistor branch is provided with its own individ-

**Fig. 6.58** Wound rotor three-phase induction motor

**Fig. 6.59a,b**  
Rotors of squirrel-cage motors.  
**(a)** Double-cage rotor. **(b)** Deep-bar rotor

ual magnetic contactor switches. Each of these resistor branches are shorted individually according to an order of operational sequence relative to the efficient running of the wound rotor motor. By suitable choice of the external resistances the maximum torque can occur at standstill. For normal running the rotor winding is short-circuited directly at the brushes, so that the efficiency of the motor is increased by removing the external resistances.

Modern wound-rotor controllers use solid-state devices in place of magnetic contactors to obtain stepless control, thus allowing smooth acceleration up to running speed.

The wound rotor main advantage over the squirrel-cage motor is that it offers greater flexibility for starting and speed control. They are used where the load requirements are high starting torque and variable speed, or where the motor is to be started under heavy load. Typical applications of these motors are crane and hoist control. Wound rotor motors are always started with full voltage as the starting current can be controlled by the resistance external to the rotor.

### Squirrel-Cage Motors

By use of suitable shapes and arrangements for rotor bars, squirrel-cage motors can be designed so that their rotor effective resistance at starting (60 Hz) is several times their resistance at rated conditions (2–4 Hz). The arrangements use the inductive effect of the slot leakage flux on the current distribution in the rotor bars. High starting torque and good running performance are achieved by incorporating two squirrel cages in the rotor, as illustrated in Fig. 6.59a or by the use of deep-bar rotors, as shown in Fig. 6.59b [6.37].

The double-cage induction motor consists of two layers of bars short-circuited by end rings. The outer cage bars are made of high resistivity material like aluminum, brass, bronze, etc. . . . , while the inner cage is made of copper that has a lower resistivity as compared to the materials used in the outer cage. The cross-sectional area of the outer bars is smaller than that of the inner bars. Thus the resistance of the outer cage is much higher than that of the inner cage. The slot-leakage flux is higher at the inner bars, so that the inductance of the inner bars is much higher than that of the outer bars.

At starting with  $s = 1$ ,  $f_2 = f_1$ , and due to the higher reactance and lower resistance of the inner cage in relation to the outer cage, the current in the inner cage is much smaller than that of the outer cage, and is approximately  $90^\circ$  out-of-phase with the induced voltage, resulting in a low starting torque, while the current in the outer cage is much higher and is practically in-phase with the induced voltage, resulting in a much higher starting torque. The outer cage is called the starting cage.

When the motor accelerates the rotor frequency  $f_2$  decreases, the inner cage reactance decreases, its current increases and as a consequence its torque increases. When the rated speed is reached, the rotor frequency  $f_2$  is very low, the reactances of the two cages are negligible, and the rotor current is divided between the two cages inversely proportional to their resistances. As the resistance of the outer cage is around 5–6 times the resistance of the inner cage, the current in the outer cage is much smaller than that of the inner cage, and the torque is basically due to the inner cage called the operating cage.

The current distribution in a deep-bar rotor undergoes a similar change from starting to running, producing high rotor resistance on starting and low resistance at normal speed.

For loads that require a large starting torque a double-cage or deep-bar motor is used, while for low starting loads a normal induction motor is usually used. Wound rotor motors are used to start large loads, that require a high starting torque and large starting periods.

## 6.2.9 Motor Applications

### Wound Rotor Motors

The applications of wound rotor motors are:

- To drive loads requiring high starting torque and where a lower starting current is required. Depending on the value of the external resistance the starting current may be less than 150% of the rated value.
- To drive high inertia loads.
- To drive loads that require a smooth acceleration.
- To drive loads that require speed control.
- The full load slip may be as low as 3% and the maximum torque above 200% of the full load value. The efficiency is about 90%.
- Are used in large pumps, conveyors, compressors, cranes, hoists, elevators, etc.

Their range of application is, generally, from 5 to 30 000 kW.

### Squirrel-Cage Motors

The national electrical manufacturers association (NEMA) has specified different design classes of three-phase squirrel-cage induction motors, based on their torque characteristics in relation to the speed and starting current. Typical torque speed curves for the most common design classes A–D are shown in Fig. 6.60.

The main features of these design classes are listed here:

- Class A motors have normal starting torque, high break down torque, high starting current of five to ten times the rated current, and less than 5% slip. The design has low resistance single cage rotor. The efficiency of the motor is high at full load. Because of the high starting current, a reduced voltage starter by means of an autotransformer, resistor/reactor or Y– $\Delta$  connection is required. Applications of Class A motors are fans, blowers, centrifugal pumps, etc. Range of application: 5–150 kW.
- Class B motors, known as *general purpose* motors, have about the same starting torque as Class A with

Fig. 6.60 Typical speed/torque characteristics of NEMA design classes A–D induction motors

starting current of five to six times the rated current and the efficiency and slip are comparable with the Class A. The starting torque and lower starting current are maintained by use of a double-cage or deep-bar rotor. They have a medium breakdown torque and full voltage starting, generally, can be used. The applications are same as that of Class A motors, i.e., in the range from 5 to 150 kW.

- Class C motors have high starting torque (around 250% of rated torque), low breakdown torque (190–200% of rated torque) and medium starting current (three to five times rated current). Such motors are of the double-cage bar, but with a higher rotor resistance than Class B motors in order to ensure that the maximum torque occurs at starting. Due to its high starting torque it has a fast acceleration. The loads are compressors, conveyors, reciprocating pumps and crushers. Range of application: 15–150 kW.
- Class D motors have a single-cage with high resistance bars, assuring a very high starting torque (higher than all the NEMA motor types), and low starting current. The rotor bars are made of high resistivity material such as brass instead of copper and the bars have a small cross-sectional area. The slip at maximum torque is, generally, above 50% and the

**Table 6.10** Summary of the performance of the motor design classes (Source: [6.38] with modifications)

	<b>Class A</b>	<b>Class B</b>	<b>Class C</b>	<b>Class D</b>
Type	Normal starting torque	General purpose	High starting torque	Very high starting torque
Starting torque	100% rated for larger motors, 200% rated, smaller motors	100% rated for larger motors, 200% rated, smaller motors	Approx. 250% rated	> 275% rated
Starting current	500–1000% rated	500–600% rated	300–500% rated	300–500% rated
Pullout torque	200–300% rated	≥ 200% rated	Slightly lower than Class B	Usually same as starting torque
Rated slip	< 0.05, lower than similar sized Class B	must be < 0.05, usually < 0.03	< 0.05, higher than Class B	High, typically 0.07–0.11, can be up to 0.17
Applications	Fans, blowers, pumps, machine tools	As for Class A	Compressors, pumps, conveyors	Punch presses, shears, elevators, extractors, winches, hoists
Notes	High starting inrush current causes power system problems, it can cause the supply voltage to sag and requires special starting techniques. More efficient than same sized Class B	Replacement for Class A due to lower starting current. The standard off-the shelf commodity motor	Applications that require high starting torques. Note that the pull up and pull-out torque can both be lower than the starting torque. Less efficient than Class B	Applications that require high starting torques. Are used to drive intermittent and high-impact loads. The efficiency at full-load is low

slip at rated speed is between 7 and 11%, as a consequence the rated efficiency is low. Are used to drive intermittent loads requiring rapid acceleration and high-impact loads as: punch presses, shears, elevators, extractors, winches, hoists, oil-well pumps and wiredrawing machines. When driving high-impact loads, as punch presses, they are provided with a flywheel to give energy to the load during the working stroke, smoothing out the peaks in the supply grid. Range of application: 15–150 kW

- Class E motors have low starting torques (but not inferior to 50% full load torque), normal starting current and low slip at rated load. For motors above 5 kW rating, starting current may be high, so they may require a starter, like Class A. The rotor has low resistance and correspondingly high efficiency. They are usually high-speed motors directly connected to loads that require low starting torques, such as fans and centrifugal pumps. Range of application: 30–150 kW.
- Class F motors have low starting torques like Class E, low starting current, that allows them to start at full voltage. The rotor is designed so that it gives high reactance at starting. The blocked rotor current and full load slip, with full applied voltage, is similar to that of Class B or C. The field of application is the same to that of Class E. Range of application: 30–150 kW.

A summary of the performance of the motor classes A–D is provided in Table 6.10.

### 6.2.10 Energy Efficient Motors

With ever-increasing energy cost the life-time operating cost of an induction motor can be traded against a high efficiency and high capital cost induction motors. With rising demand for high efficiency, energy efficient induction motors designers and manufacturers are stepping up their production of such motors. Some of the important techniques, that are employed to construct a high efficiency induction motor compared to the standard design, are listed here:

- Modification of stator slot design to allow a larger diameter wire resulting in reduced current density and reduced copper losses
- Increase of the stator and rotor core length to improve heat transfer out of the motor, thus reduction of the operating temperature
- Use of thinner laminations and of premium-grade core steel, with consequent reduction in eddy-current and hysteresis losses
- Rotor fans are designed with refined aerodynamic fin shapes to reduce windage loss
- Improved bearings.

When compared to standard efficient motors, high efficient motors have fewer losses and better cooling, resulting in less heat generated and a temperature decrease, on average, of 10 degrees centigrade in relation to standard motors. This has as an additional benefit an increase in insulation life. They have, generally, 30%

more lamination steel and 20% more copper than standard motors. Overall, energy efficient motors are better motors.

There is always a trade-off involved. A machine of more efficient design normally requires more material and therefore is bigger and costlier. In general, energy efficient motors can cost as much as 15% more than standard efficient motors. Users normally select the *lowest-cost* solution to a given requirement. However, it would be prudent to choose an energy-efficient motor as normally the increased capital cost would be offset by energy savings over the expected lifetime of the machine.

The full-load efficiency for motors in the range 0.75 to 0.75–375 kW varies from about 83 to 97%. The efficiency typically increases with the size of the motor. Motor losses being broken down roughly as:

- Friction and windage, 5–10%
- Iron or core losses, 20–25%
- Stator losses, 30–50%
- Rotor losses, 20–25%
- Stray load losses, 5–15%.

Various regulatory authorities in many countries have introduced and implemented legislation to encourage the manufacturing and use of higher efficiency electric motors.

### Energy Efficiency Standards

The international electrotechnical commission (IEC) has introduced standards relating to three-phase energy efficient motors. IEC 60034-30 [6.39] defines efficiency classes for a wide range of electric motors. IEC 60034-30-1 [6.40] (that became valid in 2014) takes a step further in widening the scope of motors subject to efficiency classes and introduces the IE4 class and IEC 60034-2-1 [6.41] specifies rules concerning efficiency testing methods. Motors rated 1 MW and above have a full-load efficiency between 95 and 98% and are of secondary importance when assigning efficiency classes.

In the IEC 60034-30-1 the following efficiency classes are defined for induction motors, where IE stands for international efficiency:

- IE1 (Standard Efficiency)
- IE2 (High Efficiency)
- IE3 (Premium Efficiency)
- IE4 (Super Premium Efficiency)

Figure 6.61 shows the correlation between required efficiency and output for the four efficiency classes. The efficiency values increase from IE1 to IE4.

Fig. 6.61 Efficiency and output for the four efficiency classes at 50 Hz

The scope of IEC 60034-30-1 standard is wider than that of IEC 60034-30, covering motors up to eight poles, rated voltage up to 1000 V, with a power range from 0.12 to 1000 kW, any ambient temperature within the range of  $-20$  to  $+60^{\circ}\text{C}$  and marked with an altitude up to 4000 m above sea level. Excluded are, among a few other exceptions, motors completely integrated into a machine (for example, pump, fan or compressor) that cannot be tested separately from the machine.

The efficiency levels defined in IEC 60034-30-1 are based on the low uncertainty test methods specified in IEC 60034-2-1 *Standard methods for determining losses and efficiency from tests*, which recognizes several methods for determining motor efficiency, each of which has certain advantages as to the accuracy, cost, and ease of testing, depending primarily on motor rating. Some of the methods in IEC 60034-2-1 are harmonized with national standards such as IEEE 112 Part B and CSA (Canadian Standards Association) C390.

An IE5 level, with the goal of further reducing losses by around 20% relative to IE4, is envisaged for a future edition of IEC standards.

### 6.2.11 Speed Control

The speed control of induction motors can be obtained by the following methods:

- a) Changing the terminal voltage
- b) Changing the number of pair of poles (part-winding)
- c) Changing the resistance in the rotor circuit
- d) By static slip power recovery
- e) By constant stator voltage frequency ratio (V/Hz)
- f) By vector control
- g) By double feeding.

### a) Changing the Terminal Voltage

The speed can be varied by reducing the voltage of constant frequency applied to the stator. This method is limited to certain drives, because the developed torque for a given speed is directly proportional to the square of the applied voltage, and in the case of constant load torque the current must increase with decreasing voltage, since the flux is proportional to the voltage. However, this method finds considerable application where the load torque decreases with a reduction of speed, as in the case of fans and pumps.

The stator voltage may be varied by means of variable impedance in series with the motor, but the use of thyristors between the line and the motor seems to offer the most economical and effective operation.

### b) Changing the Number of Pair of Poles

The stator winding can be designed so that by simple changes in coil connections the number of poles can be changed in the ratio 2 to 1, thus obtaining two synchronous speeds. With two independent sets of stator windings, each arranged for pole changing, as many as four synchronous speeds can be obtained: 600, 900, 1200 and 1800 rpm. The motor is invariably of the squirrel-cage type as the cage winding always reacts by producing a rotor field having the same number of poles as the inducing stator field. If a wound rotor motor is used additional complications are introduced because the rotor winding must also be rearranged for pole changing. In this method the speed can be changed in discrete steps and the elaborate stator winding makes the motor expensive.

### c) Changing the Resistance in the Rotor Circuit

With external resistors  $R_{ext}$  in the rotor circuit the slip for the maximum torque is,

$$s_{max T} = \frac{R'_2 + R_{ext}}{\sqrt{(R_1)^2 + (X_1 + X'_2)^2}} \quad (6.176)$$

From Fig. 6.62 it may be seen that the speed of operation can be varied by controlling the external resistance. If the value of  $R_{ext}$  is increased the slip for maximum torque increases and the maximum torque can occur at starting. This method is similar to the speed control of direct-current shunt motors by resistance in series with the armature. The steady-state speed is given by the intersection of the load and motor torque-speed curves as in all motor drives.

While by this method a high starting torque can be obtained, it causes the motor to develop excessive slip and high rotor losses at rated torque, that results in poor efficiency and poor speed regulation. This method may be applied to loads that have high static torque and loads

Fig. 6.62 Speed control by external resistances

having high inertia, like conveyors. In this type of speed control, the external resistances generate huge losses, and as a consequence large heat in the system, so it requires more maintenance [6.42].

However, the speed control can be obtained without mechanical switching of resistances by means of modern controllers using controllable switches, as shown in Fig. 6.63. The AC output voltage of the rotor is rectified by a diode bridge and fed to a parallel combination of fixed resistor  $R_h$  and a semiconductor switching device T. The DC supply is switched on and off at high frequency (typically 10 kHz or more) using electronic switching devices such as MOSFETs (metal-oxide-semiconductor field effect transistors), IGBTs (insulated gate bipolar transistors) or GTOs (gate turn-off thyristors) to provide a pulsed DC wave form. The average level of the output voltage can be controlled by varying the duty cycle of the semiconductor power device T. The effective resistance  $R_e$  between points A and B is

$$R_e = (1 - k)R_h \quad (6.177)$$

where  $k$  is the duty cycle of the controllable switch.

The rms value of current in each secondary phase is  $I_2 = I_d \sqrt{2/3}$ . The additional resistance of each secondary phase  $R_{2h}$ , is such that  $3R_{2h}I_2^2 = (1 - k)R_h I_d^2$ . Thus,

$$R_{2h} = (1 - k) \frac{R_h}{2} \quad (6.178)$$

**Fig. 6.63** Speed control by a controllable switch

#### d) By Static Slip Power Recovery

Neglecting joule losses in the resistance of the rotor windings the slip power ( $sP_{sr}$ ) in the rotor circuit may be returned to the system by means of a rectifier and an inverter operating with a delay angle between  $90^\circ$  and  $150^\circ$  approximately. The feedback power converter is connected to the power system, usually through a transformer that matches the output voltage of the converter to the power system, as shown in Fig. 6.64. If  $E_{20}$  is the value of the induced rotor EMF in each rotor phase when the rotor is at standstill, when the rotor rotates at a speed  $\omega_r = (1-s)\omega_s$  (rad/s) the value of the rotor EMF is  $E_2 = sE_{20}$  and the rotor frequency is  $f_r = sf_s$ . The average value of the voltage at the output of the rectifier is

$$V_{dr} = k_1 s E_{20}. \quad (6.179)$$

The AC voltage at the inverter terminals must be equal to the system voltage  $V_1 = (V_{LL}/\sqrt{3})$ . Thus, the DC voltage at the inverter is  $V_{di} = k_1 V_1 |\cos \alpha|$ , where  $\alpha$  is the delay angle and as the converter is operating as an inverter  $180^\circ > \alpha > 90^\circ$ . The smoothing inductor prevents the ripple in the voltage  $V_{dr}$  from causing excessive ripple in the DC current. As the resistance of the

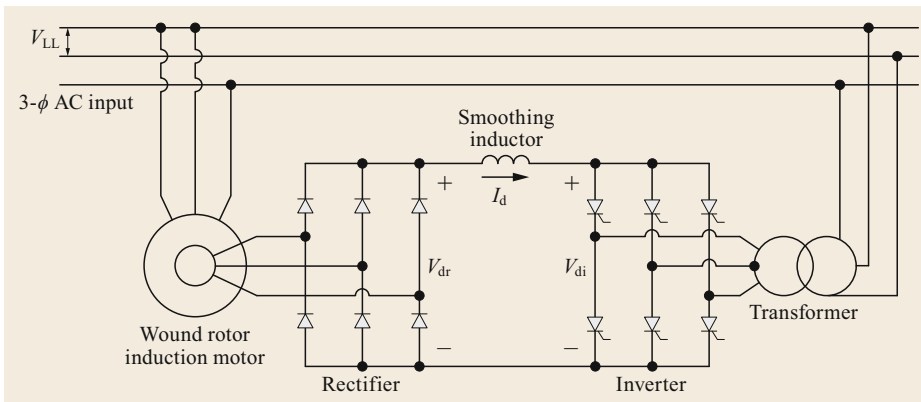

inductor is very small it is possible to equalize the voltages at the rectifier ( $V_{dr}$ ) and inverter ( $V_{di}$ ) terminals, obtaining

$$s = \frac{V_1}{E_{20}} |\cos \alpha|. \quad (6.180)$$

If  $|\cos \alpha|$  is varied from a value near to zero up to a value near to 1, the slip  $s$  will vary from a value near to zero up to a value near to  $s = V_1/E_{20}$  and the rotor speed will vary, approximately, from  $\omega_r = \omega_s$  to  $\omega_r = \omega_s(1 - V_1/E_{20})$ , respectively.

Figure 6.65 shows the characteristic torque-speed for several values of  $\alpha$ . The drop of the curves is due to the voltage drops in the motor and in the other parts of the scheme. The slip increases with the torque.

This scheme requires a wound rotor motor with slip rings and is known as a static Kramer scheme. It is used in applications such as pumps and blowers of great power, where the speed needs to be controlled only in a small range around its nominal value, because a small speed range results in a smaller rating of the converters, thus making this scheme competitive. Due to the harmonics generated by the converters filters are necessary at the DC and AC sides. For larger motors the energy

**Fig. 6.64** System for recovering the rotor slip power

**Fig. 6.65** Torque-speed control by a static slip power recovery

that is lost in the scheme with external resistors is now saved and returned to the grid, that amounts to significant cost savings.

#### e) By Constant Stator Voltage Frequency Ratio (V/Hz)

When the voltage drop in the impedance of the stator winding is neglected, the main or resultant magnetization flux  $\Phi_m$  is

$$\Phi_m \simeq \frac{V_1}{4.44f_1N_1k_{\omega 1}} \quad (6.181)$$

If the stator voltage  $V_1$  and frequency  $f_1$  are equal to their rated values, the flux will be equal to its rated value, but if the frequency is reduced below its rated value of 60 or 50 Hz maintaining the voltage  $V_1$  constant, the flux will increase beyond its rated value and it may cause saturation of the core and high losses in the motor. Thus to maintain the flux constant at its rated value the voltage  $V_1$  must increase in a linear proportion to  $f_1$ . For small values of slip, i.e., in normal operation, the rotor resistance is much greater than the rotor reactance, the load power factor will be high, and for a constant flux the developed torque is

$$T = k_1 (\omega_s - \omega_r) = k_1 \omega_{sl} \quad (6.182)$$

where  $\omega_{sl}$  is the slip speed and the corresponding slip frequency is given by

$$f_{sl} = f_s - f_r \quad (6.183)$$

Such a characteristic is shown in Fig. 6.66a for a synchronous frequency  $f_{s1} = 60$  Hz with a corresponding

slip speed  $\omega_{s1}$ , with three other values for the synchronous frequency:  $f_{s2}$ ,  $f_{s3}$  and  $f_{s4}$ , being  $f_{s1} > f_{s2} > f_{s3} > f_{s4}$ . The torque-speed characteristics shift horizontally in parallel for the four different values of synchronous frequency.

Considering that equal load torque is to be delivered at synchronous frequencies, for instance,  $f_1$  and  $f_2$ , the synchronous speeds are, respectively,  $\omega_{s1}$  and  $\omega_{s2}$ . From (6.182)  $\Rightarrow \omega_{s11} = \omega_{s12}$ , and the respective slip frequencies are also constant. The slip increases as the synchronous frequency decreases ( $s_1 = f_{s11}/f_1$  and  $s_2 = f_{s12}/f_2$ ). The rotor resistance losses increase as the synchronous speed decreases to reduce speed. However, in many loads such as centrifugal pumps, compressors and fans, the load torque varies by the square of the speed, and  $f_{sl}$  as well as the slip declines with decreasing frequency, as shown in Fig. 6.66b and the rotor losses remain small [6.43].

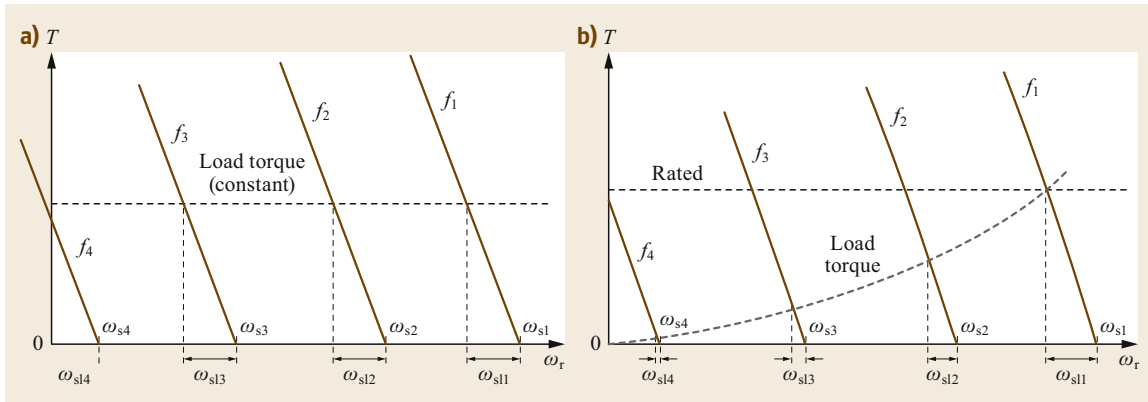

#### f) By Vector Control

All the previous methods of speed control are termed scalar speed controls. With the ever increasing use of electronic switches for speed control the vector control of induction motors is used when accurate torque and speed control is desired. Before introducing vector control some additional considerations are made with respect to scalar control of speed by voltage/frequency ratio.

The stator voltage/frequency ratio control method, as seen in the previous item, is the most scalar technique used to control the speed of the motor where the magnetizing flux of the motor is kept unchanged. The torque developed in the motor depends on the slip speed, and only speed feedback is required, simplifying the control system. It is generally applied when there is no need for a fast response or high precision of the control system, which is the case for most applications. Another scalar control method uses the torque control technique, in which the magnitude and frequency of the stator currents are adjusted so that the steady-state torque is controlled, while the magnetic field is again maintained constant. In this case, the speed feedback has to be supplemented by a current feedback that makes this method somewhat more complicated than that of the voltage/frequency ratio control method.

By scalar speed control the response of induction motors to changes in speed, due to load variations is relatively slow because the motor current cannot change instantaneously following the applied voltage, due to the delay caused by the inductance of the motor windings. However, fast responses and high precision speed control of the motor are possible by means of vector control, where the vector components of the stator current, i.e., its magnetizing current that produces the airgap flux and the in-phase current that produces the

**Fig. 6.66a,b** Torque-speed characteristics at small slip with constant flux: **(a)** constant load torque, **(b)** load torque varies as speed squared

torque are separately controlled. The necessity of controlling the magnetizing current is to keep the airgap flux constant at its optimum level, while the torque needed is controlled by the in-phase stator current. Vector control is a more complex technique than scalar control, the evolution of which was inevitable, because its superior dynamic performance, as compared with scalar control. It is also known as field-oriented control, because in the course of implementation the identification of the field flux of the motor is required. Before the introduction of vector control fast dynamic torque responses were only possible by the use of separately excited DC motors, where the magnetic fields created by the armature and field currents allow independent control of torque and flux in the motor [6.44].

The vector control gives fast transient response including fast acceleration and deceleration, precise control of torque, speed and position compared to scalar control. The vector control can be realized by closed loop (feedback) control or open loop (sensorless) control, also called, direct and indirect control, respectively. In direct control there is

**Closed Loop (Feedback) Control or Direct Torque Control.** Direct torque control (DTC) is one of the best control strategies of torque control, and thus speed control, of an induction motor. The aim is to effectively control the torque, as well as the flux. The method allows accurate, fast control and high dynamic speed response. It uses the adaptive motor model that is based on the mathematical expressions of the motor theory. The method requires the basic parameters of the motor such as stator resistance, self inductance, etc. to calculate the flux and torque, that are given to a two level comparator of the flux and torque. The outputs of the flux and torque comparators are given to a switch selection table, wherein the selected switch position is applied to an inverter without any modulation. With

the joint progress of power electronics and numerical electronics, it is possible to deal with the speed control with great accuracy, even at very low speeds. With these technological projections, various command approaches have been developed to master, in real time, the flux and the torque of the motor. Hence the name direct torque control (DTC), as the motor torque and flux become direct controlled variables.

#### *Open Loop (Sensorless) Control or Indirect Control.*

The currents in the three-phases of the stator are measured and initially converted to the  $\alpha, \beta$  two-phase system of coordinates, from which the rotor angle and velocity are estimated. These signals are then compared with reference values and controlled by using proportional integral (PI) controllers. Thus, in the sensorless speed control method there is no need to use a speed sensor as in the direct control method. The  $\alpha, \beta$  currents are converted to direct and quadrature-axis components,  $i_d$  and  $i_q$  by means of a Park transformation. The direct-axis current  $i_d$  controls the magnetic flux and the quadrature-axis current  $i_q$  controls the torque.

The output of the flux and torque controllers are  $d$  and  $q$  voltage components, that are transformed from the  $d, q$  coordinate system back to the  $\alpha, \beta$  coordinate system, and by means of an inverse Park transformation the  $a, b, c$  voltage components. Thus, using the space vector modulation technique, the corresponding inverter switching is pulse width modulated. There are different types of vector control techniques, such as: stator flux oriented control, rotor flux oriented control and magnetizing flux oriented control. The sensorless vector control is shown in Fig. 6.67. Sensorless control of AC drives is attractive for cost and reliability considerations. The speed sensor of the direct method is replaced by mathematical techniques. The sensorless control method can be used to control motor speed almost down to zero.

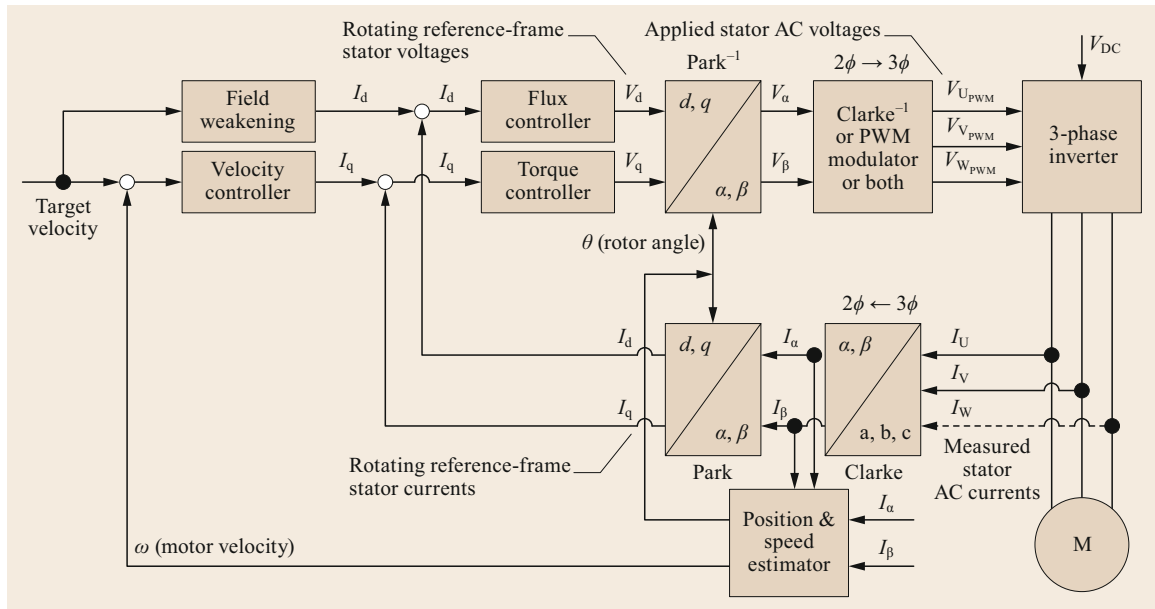

Fig. 6.67 Sensorless vector control of induction motors

**Servo Systems.** Many of the techniques involved in vector control are applicable to servo systems and consequently vector controlled systems are replacing some of the traditional servo systems.

### g) Speed Control by Double Feeding

In this method the stator windings are supplied with three-phase power at a synchronous frequency  $f_1$ , as usual, and the rotor windings are also fed with three-phase power at a variable frequency  $f_2$  by means of a PWM (pulse width modulation) converter. The speed of the stator MMF with respect to the stator is  $n_{s1} = (120f_1)/p$  and the speed of the rotor MMF with respect to the rotor is  $n_{s2} = (120f_2)/p$ . If the rotor is fed so that its MMF rotates in the same direction as the stator MMF, the rotor speed is  $n = n_{s1} - n_{s2}$ , but if the rotor is fed so that its MMF rotates in opposite direction to the stator MMF, then the rotor speed is  $n = n_{s1} + n_{s2}$ . Thus, the motor speed  $n$  may be adjusted below or above the synchronous speed by adjusting the rotor excitation frequency  $f_2$ , as

$$n = \frac{120(f_1 \pm f_2)}{p} \quad (6.184)$$

If  $f_2$  is zero, i.e., the rotor is supplied from a DC source, the motor speed  $n$  will be equal to the synchronous speed and the motor is a synchronous motor.

**Additional Considerations.** Before the development of semiconductor power electronics, it was difficult to

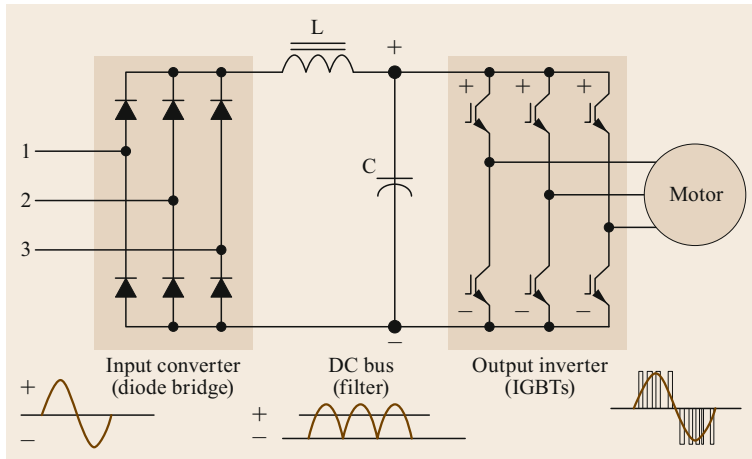

vary the frequency, and cage induction motors were mainly used in fixed speed applications. Pole changing finds its application when two or four speeds are required, thus it is a limited method for speed control. Changing the terminal voltage is restricted to certain drives, because the developed torque is reduced directly proportional to the square of the applied voltage. Variable external resistance control for wound rotor motors, allows speed control in a broad range, however the method suffers from low efficiency at reduced speeds and poor speed regulation with respect to a change in load. The advent of power electronics allows speed control by other methods with better efficiency, such as: static slip power recovery (for large wound rotor drives), stator voltage frequency ratio (V/Hz) and vector control. Due to its simplicity and compactness variable frequency driven squirrel-cage induction motors are displacing DC and wound rotor motors drives in many industrial variable speed applications.

### 6.2.12 Variable Speed Drives (VSDs)

This section summarizes the applications, benefits, technologies, problems and solutions when VSDs are used for controlling the torque and speed of induction motors. More extensive information can be found in references [6.45–48].

#### Applications and Benefits

A variable speed drive (VSD) is an adjustable-speed control used in electromechanical drive systems to con-

**Fig. 6.68** Pulse width modulated voltage source inverter (PWM-VSI)

control AC motor torque and speed by varying motor input voltage and frequency. It consists of an AC/DC rectifier, a DC link and a DC/AC inverter, mostly based on pulse width modulation (PWM).

VSDs are suitable to control the motor torque and speed to drive loads where the torque varies approximately with the square of the speed, such as centrifugal pumps, fans, blowers and similar applications, by supplying only the correct amount of energy that is needed. For these types of loads the energy-efficiency benefits of a VSD are high, eliminating control valves, dampers, throttles, bypasses, gears, transmissions and clutches, etc., and reducing cost and losses in partial load.

Loads where the change of power varies linearly with speed (constant torque loads) such as: air compressors, conveyors, escalators, positive-displacement pumps, hoists, cranes and similar applications also benefit from VSDs, that can continuously adjust the speed from almost standstill to full speed without steps, thus minimizing the required power, although the benefits are not so high because the required input power only varies linearly with speed.

Some loads such as: machine tools and traction applications, behave as constant power loads and they can benefit by the use of VSDs, that allow soft starting and stopping and less wear of the machinery involved. The cost and energy-efficiency benefits are small when compared with other types of loads.

As the total energy consumption by the electric motor systems in all sectors (industrial, commercial, residential, agriculture and transport) is about 45% of the total world electrical energy consumption, it can be foreseen that an appreciable amount of energy can be saved by the combination of VSDs and high-efficiency motors.

#### Technologies for VSDs

The different technologies for VSDs are listed here.

*a) Pulse Width Modulated Voltage Source Inverter (PWM-VSI).* Typically for motors of up to 3000 hp, but each manufacturer may list larger sizes. An uncontrolled rectifier (diode) transforms supply AC voltage to DC voltage to the inverter. Switches in the inverter are IGBTs, in general (Fig. 6.68). The inverter controls the magnitude and frequency of the AC output voltage by PWM of the inverter switches.

*b) Square-Wave Voltage Source Inverter (Square-Wave VSI).* Ranges available are typically up to 500 hp but can be up to 1000 hp. the converter rectifier switches are diodes with a DC chopper. The DC input voltage to the inverter must be controlled to control the magnitude of the inverter output voltage, that has a form similar to a square-wave. The inverter controls only the frequency of the AC output voltage.

*c) Current Source Inverter (CSI).* The rectifier and inverter use thyristors. The DC link uses large inductors to regulate current ripple, that makes the input to the inverter appears as a current source. Torque pulsations or cogging is common with the CSI design. Torque pulsations are the result of a high harmonic content in the output current of the drive. Torque pulsations result in stress to motor shafts and pumps, fans, conveyor (belts), or any ultimate driven load, requiring the installation of filters. For HVDC transmission systems basically SCRs are used due to their greater voltage and current capabilities.

*d) High Voltage Insulated Gate Bipolar Transistor (HVIGBT).* The HVIGBT consists of several IGBTs placed in series to develop a high voltage level, having the advantage of low stress on the motor insulation and low current harmonic content in the supply to the high voltage motor with no need of a filter. IGBTs are used due to the low energy necessary to switch them on, this

allows fast turn-on and turn-off times on the order of 1  $\mu$ s, a small on-state voltage, small snubberless switching, small conduction losses. Combined with zero or slightly negative gate drive current makes them a good choice for moderate speed, high voltage applications. Like lower voltage devices, the HVIGBT module includes a reverse connected fast/soft recovery free wheel.

*e) Integrated Gate Commuted Thyristors (IGCT).* An IGCT is a special type of thyristor similar to a gate turn-off thyristor (GTO). They can be turned-on and off by a gate signal, have lower conduction losses as compared to a GTO, and withstand higher rates of voltage rise ( $dv/dr$ ), such that no snubber is required for most applications. The IGCT faster turn-off times compared to that of a GTO allows it to operate at higher frequencies, up to several kHz for very short periods of time. However, because of high switching losses, the typical operating frequency is up to 500 Hz. An IGCT enables performance improvements of PWM converters for industrial and traction applications. IGCTs are the mature devices for high voltage drives today. They are available as multiple level voltage source inverters. With a series connection of elements its power range can be higher than 100 MW.

#### Problems and Solutions with the Application of VSDs

a) Problems that may arise with the application of VSDs are:

A VSD with faster rise time and higher switching frequencies above 5 kHz, can produce high voltage overshoots and voltage spikes, that can damage motor windings. This problem also happens when the cable length between the VSD and the motor is longer (above 50–100 feet, in general), resulting in a motor impedance greater than the impedance of the cable, thus reflecting the voltage wave and causing voltage overshoot and spikes at the motor terminals.

VSDs produce high frequency harmonic voltages and currents. These harmonics increase the hysteresis losses that are proportional to frequency, as well as eddy current losses that are proportional to the frequency squared, leading to additional core losses, and as a consequence a temperature increase of the core and windings surrounding the core. The harmonics also increase the joule and stray-load losses. Besides these effects there is the possibility of an interaction between the positive and negative sequence harmonic magnetic fields causing torsional oscillations of the motor shaft, that in turn, lead to shaft vibrations that may be amplified if the frequency of the oscillations coincides with the natural mechanical frequency of the shaft, resulting in severe damage to the motor shaft.

Even when overvoltage is not high enough to cause voltage spikes, the fast rise time pulses from a VSD may cause the appearance of currents flowing through the bearings. This current is due to a voltage called the shaft voltage that may appear due to a voltage imbalance at the motor terminals because the voltage output of a VSD is made up of a series of square waves.

b) To avoid eventual problems with VSDs the following possible solutions should be implemented as required.

To avoid overshoots:

- Use an inverter fed motor with a voltage of 230 V or less when possible.
- Use the lowest carrier frequency that satisfies the motor requirements. A lower switching frequency results in less overshoots per second.
- The control of multiple motors in parallel by the same VSD should be avoided. The use of multiple motors with a single control can result in a higher probability of having problems with repetitive high voltage overshoots at the terminals of the motor.
- If the peak voltage is over the recommended limit, a filter or reactor between the VSD and the motor must be used.
- Avoid long lead lengths. The maximum recommended cable distance between VSD and motor is about 50–100 feet or less, depends on the impedances of the cable and the motor. If a short cable is not possible and if the peak voltage is over the recommended limit, use a filter or reactor between the control and the motor.
- Use premium varnish conductors to reduce partial discharges.

To avoid excessive overheating:

- Oversize the motor and control
- Provide an independent cooling system (external ventilation) when the load is of the constant torque type, and the motor runs at low speed
- Install a drive filter.

To avoid shaft currents:

- Use an inverter fed motor with a voltage of 230 V or less when possible.
- Use the lowest carrier frequency that satisfies the motor requirements.
- Add a shaft grounding device to the motor. Some devices have a brush that rides on the motor shaft. Current does not go through the bearing but is instead conducted directly to ground through the brush. These brushes are especially selected to tol-

erate misalignment and maintain rotating contact throughout the brush's life when properly maintained.

- Use a motor with both bearings insulated. This approach will avoid damage to the motor's bearings.
- Use nonconductive couplings for restricted and loads or which may be damaged by bearing currents.
- Ensure that the control and motor are grounded per the manufacturers' instructions.

### 6.2.13 Power Quality

#### General Considerations About Power Quality

Power quality may be defined as the control of a power system, in order to assure the reliable operation of the entire system, including generation, transmission and ultimately electric power distribution, during steady-state and transient/dynamic conditions. The complexity of the system to move electric energy from the point of production to the point of consumption combined with variations in weather, generation, demand and other factors provide many opportunities for the quality of supply to be compromised. The quality of the electrical power may be described as a set of conditions and values for some parameters, whose deviations must be within prescribed limits so that they do not affect consumers and system performance. The following conditions and parameters must be observed and controlled in order to assure the power quality supply:

- Variations in voltage magnitude
- Harmonic content in the AC waveforms
- Variations in frequency
- Low power factor.

**Variations in Voltage Magnitude.** Undervoltage may occur, for instance, when there is the disconnection of a capacitor bank or an increase of the apparent power in lines and equipments over their nominal ratings, due to the loss of one element of the system, causing an overload in the power supply. The undervoltage is characterized by a decrease in voltage, typically to 80–90% of the nominal for more than 1 min. A voltage sag, a type of undervoltage, happens when the voltage decreases between 10 and 90% of nominal voltage with a duration varying from 3 s to 1 min, when a severe condition like a short-circuit happens. Overvoltage occurs when the voltage rises above 110% of the nominal for more than 1 min, for instance, due to a load disconnection. A swell is a momentary voltage increase in the range from 1.10 to 1.80 per unit of nominal voltage, with a duration varying from 0.5 cycles to 1 min, and it may be caused by a single line to ground fault and when

large capacitor banks are switched-on, for example. Abrupt, very brief increases in voltage, called *spikes*, *impulses*, or *surges*, are caused by nonlinear loads, such as VFDs operation or more severely by lightning. Another cause of problems is the voltage imbalance when the phase voltages are unequal. The primary source of voltage imbalances are single-phase loads on a three-phase circuit.

**Harmonic Content in the AC Waveforms.** One of the sources of voltages and currents departure from the ideal sinusoidal, is due to nonlinear drives, such as VSDs, where the harmonics cause distortions in the sinusoidal waveforms. The relative contribution of harmonics to the distortion of the ideal waveform is called total harmonic distortion (THD). Low harmonic content in a waveform is desirable because harmonics can cause many problems. Harmonics, arising within the customer's own installation if propagated onto the network may affect other customers and system operation. High voltage DC transmission systems with their associated rectifiers and inverters, and transformers due to saturation of their magnetic core also produce harmonics. Harmonic problems can be dealt with by a combination of good design practice and well proven harmonic reduction equipment.

**Variations in Frequency and Low Power Factor.** Frequency variations occur when the dynamic balance between load and generation is severely disturbed. The main cause of frequency variations that may affect the reliable performance of a power system and loads are due to short-circuits with the disconnection of more than one high-voltage transmission line and equipments on the bulk-power transmission system, and also by a large power plant going off-line or by the disconnection of a large block of load. On modern interconnected power systems, significant frequency variations are rare. Low power factors are due to the consumption of reactive power by the loads. They increase the losses in equipment, feeds, distribution and transmission lines, most of time requiring the addition of capacitors.

#### Power Quality Problems in Induction Motors

Electric motors are everywhere in modern society. In industry they comprise about 80% of the electrical load and their failure or disconnection cause loss of production and consequently economic losses. Motors are a prime example of the ways electrical equipment can be both a source and a victim of power quality disruptions in an industrial facility. Large motors can cause voltage sags in local and adjacent areas when they are started, individually or in groups. Induction motors can have a negative impact on a power factor, due to their

need for reactive energy. However, motors can also be negatively affected by disturbances in a number of ways, with results that can include decreased efficiency, reduced lifespan and even complete failure. Generally the factors mentioned above are the cause of several types of power quality problems commonly seen in induction motors, described as follows.

Overvoltage may cause, depending on the design of the motor, saturation of the core iron, leading to generation of harmonics and motor overheating. The induction motor torque may be increased significantly over the load torque and the motor may reach an undesirable overspeed. On the other hand an undervoltage decreases the torque and the current increases in order to supply the load torque. The decrease in torque may be enough as to not start the load or the motor may stall due to insufficient running torque. The increase in current results in greater joule losses in the rotor and stator, that may lead to overheating. A voltage imbalance may cause overheating of one or two phase windings, as well as shaft vibrations. Imbalance should be less than 1% in order to properly supply the load and the motor should not operate if the voltage imbalance exceeds 5%. The aforementioned situations result in a decrease in motor efficiency and shortens its life. A voltage sag usually leads to a motor disconnection from the supply by the protection system. Voltage transients stress motor-winding insulation, causing degradation over time, or even complete failure. All the voltage problems described can lead to a load disconnection impairing the power quality of the consumers supplied by the motors.

A major effect of harmonic voltages and currents in induction motors is increased heating, as already mentioned, due to iron and copper losses at the harmonic frequencies, especially due to the harmonics of low orders, that have larger magnitudes. The harmonic components thus affect the machine efficiency, and can also affect the torque developed. Harmonic currents in a motor can give rise to a higher audible noise emission as compared with sinusoidal excitation. The harmonics also produce a resultant flux distribution in the airgap, that can cause or enhance phenomena called cogging (refusal to start smoothly) or crawling (very high slip) in induction motors.

Each harmonic voltage, the fifth, seventh, eleventh, etc., will induce a corresponding harmonic current in the stator of the machine. Each of these harmonics is a positive or negative sequence symmetrical component of the total current. These currents will induce additional heating in the stator windings, thus adding to the temperature rise caused by the fundamental current.

Another generally greater concern is the flow of harmonic currents in the rotor. The flow of each current in the stator will produce a magnetomotive force in the

airgap that will induce current flow in the rotor of the machine. Just as each characteristic harmonic can be defined as being a positive or negative sequence, the rotation of that harmonic will be either forward or backward with respect to rotor rotation. The fifth harmonic will rotate in a backward direction (negative sequence), so a harmonic current will be induced in the rotor with a frequency corresponding to the net rotational difference between the fundamental airgap frequency and the fifth, i.e., the fifth plus one, or the sixth harmonic. Since the seventh harmonic will rotate in a forward direction (positive sequence), a harmonic current will be induced in the rotor with a frequency corresponding to the net rotational difference between the seventh and the fundamental airgap frequency, i.e., the seventh minus one, or the sixth harmonic. Thus, from a rotor heating standpoint, the fifth and the seventh harmonics in the stator combine to produce a sixth harmonic current in the rotor. The 11th and the 13th harmonics act in the same manner to produce the 12th harmonic current in the rotor, and so on with higher order harmonic pairs. There are two major concerns with these rotor harmonics:

- Resultant rotor heating
- Pulsating or reduced torques.

The amount of rotor heating that can be tolerated, as well as the amount that is incurred in a given case, depends on the type of rotor involved. Wound-rotor machinery is more likely to be more seriously affected than squirrel-cage rotor machinery, and deep bar squirrel-cage rotors are more affected than ordinary squirrel cages. Winding losses generally are of more concern than iron losses. The sum effect of the harmonics is a reduction in the efficiency and life of the machinery. Neither reduction is pronounced for normally encountered harmonic content, but the harmonic heating typically reduces performance to 90–95% of that which would be experienced with pure fundamental sine waves applied.

As noted before, the harmonics can also cause a pulsating torque output. This can affect product quality where motor loads are sensitive to such variations, e.g., in some synthetic fiber spinning or some metal working applications. In cases in which substantial inertia is coupled to the rotor shaft, e.g., in a motor-generator or engine-generator, the electrical harmonics can excite a mechanical resonance. The resulting mechanical oscillations can cause shaft fatigue and accelerated aging of the shaft and connected mechanical parts.

In an induction motor due to the airgap a large magnetizing current is needed to produce the required flux in the motor. At zero-load the active component of the current is very low while the magnetizing current is

high, and as a consequence the power factor is very low, between 10 and 20%. When the motor is loaded, the power factor increases because the active component of current increases while the magnetizing component remains about the same, and the power factor is between 85 and 90% at full load. A low power factor demands more current from the supply than a load with a high power factor. The higher currents increase the energy lost in the distribution and transmission systems and require larger wires and sometimes the installation of new equipment, such as power transformers, circuit-breakers, current transformers, etc. Because of the costs of larger equipment and the wasted energy, electrical utilities will usually charge a higher cost to industrial or commercial customers where there is a low power factor.

### 6.2.14 Advanced Motor Technologies

Advanced technologies such as the squirrel-cage AC induction motors that use die cast copper rotors and linear induction motors are briefly presented.

#### Die Cast Copper Rotor Motors

Until recently, die cast motor rotors were universally produced using aluminum because rotor fabrication by aluminum pressure die-casting was an established practice, and copper pressure die-casting was not. When die-casting copper rotors using conventional die-casting techniques, the short die life results from the large temperature difference between the pouring temperature of the liquid copper (melting temperature is 1083 °C) and the temperature of the die (typically 100–200 °C), while for aluminum the melting temperature is 660 °C. When the hot copper contacts the die, the resultant thermal expansion of the die surface results in the generation of extremely large plastic strains following each shot. However, this problem has been surpassed when the die is pre-heated and operating temperatures are increased to about 600 °C, so that the surface strain can be reduced into the elastic range, greatly reducing heat checking and so extending die life [6.49, 50].

Although the cost of die-casting a copper rotor is higher than that of die-casting an aluminum rotor, the overall cost of the motor utilizing the copper rotor can be lower. General purpose die cast copper rotor motor costs are about 11–17% higher than conventional premium efficiency motors (IE3 class), but the overall loss reductions may be around 25%. As the reduction in losses implies a lower temperature in the motor, the use of a small fan is possible, that in turn causes a reduction in friction and windage losses. Running the motor cooler is known to extend motor life. An empirical law suggests that a 10 °C reduction in operating

temperature will extend the motor life by a factor of two. Low losses implies less energy consumption, reducing the stress on the environment as a result of low CO<sub>2</sub> emissions. Copper rotor motors generally exceed the premium minimum full-load efficiency motors (IE3 class), by 0.6–2 percentage points. High efficiency implies reduced electrical energy consumption year after year due to significantly lower losses, with attractive payback and return on capital investment. Due to the higher efficiency of the copper rotor, the overall length of the rotor (and motor) can be decreased. Shortening the motor eliminates some of the rotor and stator laminations, decreases the amount of stator windings, and reduces the length of the shaft, reducing cost in each case. The increased cost of die-cast copper rotors is more than off-set by the cost savings elsewhere in the motor.

Copper rotor motors are being manufactured in small sizes where permanent magnet synchronous motors are also a choice for higher energy efficiency, although the latter are generally more expensive. Thus, die cast copper rotor motors, because of their higher efficiencies appear to be the appropriate advancement for the general industrial motor population. As the size of the motor increases the efficiency gains of the die cast copper rotor motors are expected to decrease, as over 200 HP other motor technologies will provide better efficiency improvement opportunities. However, for the majority of industrial motors, in the range 1–200 HP, die cast copper rotor motors are the newest technology for lowering motor operating costs, especially in the lower horsepower ranges. Die cast rotor motors come in NEMA and IEC frames, so they can be drop-in replacements for conventional motors [6.51].

#### Linear Induction Motor

In a linear induction motor (LIM) both the primary and secondary are laid out flat. The primary consists of a three-phase coil assembly, equivalent to the stator of a rotary motor. The secondary, known as a rotor in a traditional rotary induction motor is a plate, made of aluminum or copper. In fact the basic difference with respect to a conventional induction motor is the substitution of the angular movement by a linear movement. Thus, the properties of a linear induction motor are almost identical to those of a conventional induction motor. Thus, the slip is

$$s = \frac{v_s - v}{v_s}, \quad (6.185)$$

where  $v_s$  = synchronous linear speed and  $v$  = rotor speed.

When three-phase AC power is applied to the primary, a traveling flux wave with a wavelength of  $\lambda$

and linear velocity  $v_s = \lambda f$ , where  $f$  is the supply frequency, induces an electric current in the secondary plate. The induced electric current interacts with the magnetic flux to produce a linear force or thrust that moves the secondary plate in the direction of the traveling flux wave

$$F = \frac{P}{v_s}, \quad (6.186)$$

where  $F$  is the force or thrust and  $P$  is the power transferred from the stator to the rotor.

In general, the rotor has a single plate, while two flat stators are usually mounted, face to face, on opposite sides of the rotor to increase the power and to reduce the reluctance of the magnetic path. The direction of the motor can be reversed by interchanging any two stator leads. The speed of the motor can be varied by changing the input frequency using an adjustable frequency drive.

A typical three-phase linear induction motor is shown in Fig. 6.69. The primary core has grooves, and the windings are laid into them on top of each other. An aluminum plate above (not shown) serves as

**Fig. 6.69** Typical three-phase linear induction motor (from Wikipedia)

the secondary and will move relative to the primary if a three-phase AC is applied.

LIMs have been built in fractional-horse-power ratings up to several thousand horsepower. The main application of the LIM is in transportation and in electric traction systems. The primary is mounted on the train and the secondary is laid on the track. It is also used in: metallic conveyor belts, material handling in cranes, pumping of liquid metals, freight cars in yards, reciprocating motion for machine tools and actuators for the movement of doors.

Erli F. Figueiredo received his masters degree from the Rensselaer Polytechnic Institute (RPI), Troy, New York, and his doctorate degree from Rio de Janeiro Federal University. He was the head of the electrical system department at Rio de Janeiro State University, from 1998 to 2000 and from 2006 to 2008. From 2008 to 2014 he was chairman of the CIGRE study committee on “Rotating Electrical Machines” (SC A1). He was a distinguished member of CIGRE in 2012 and an honorary member of CIGRE in 2014. He has authored/co-authored numerous papers, CIGRE technical brochures and reports.

# Transformers

## 7. Transformers

Peter Werle , Hartmut Brendel 

All industrialized countries depend on functioning and flawless power transmission and distribution at various voltage levels, which is achieved through the use of power transformers. This implies that power transformers are among the most important (and expensive) devices used in power transmission and distribution systems. Indeed, transformers are indispensable, as they are used to transition between voltage levels at the junctions of energy supply systems. A transformer failure can therefore cause an interruption in the power supply, which can have terrible consequences. However, many transformers remain in service for many decades without showing any notable malfunctions, and these devices are generally considered to be reliable and efficient.

In this chapter, the fundamental design and functional principles of a power transformer are described in detail, differentiating between its active and passive parts. Power transformer testing is also discussed, referencing various international standards. Finally, various types of transformers are briefly introduced. Thus, the chapter provides a comprehensive overview of all the basic technical aspects of power transformers, although the servicing, maintenance, and asset management of transformers are only outlined here, as a more detailed discussion of these important topics would require an additional chapter.

## 7.1 Fundamentals

### 7.1.1 History

As is often the case for important inventions, the transformer was not devised by just one person. The design of this invaluable device is the cumulative result of a whole series of groundbreaking discoveries and inventions. In 1831, *Michael Faraday* discovered the principle of induction using a device that presented all of the characteristics of a transformer [7.1], as shown in Fig. 7.1a.

Faraday applied two windings of copper wires that were insulated from each other using fibers and calico on a soft-iron ring. As shown in Fig. 7.1b, he placed one winding around a magnetic needle and connected the other winding to a battery. By switching the battery supply on and off, Faraday generated an alternating current and was able to demonstrate magnetic induction in the second coil because the magnetic needle started to move. This arrangement of two separate windings that are magnetically coupled by a soft-iron ring fulfills

**Fig. 7.1** (a) Sketch of Faraday's experiment [7.1]. (b) Modern version of the experiment [7.2]

the principles of a transformer, but it took more than 50 years for Faraday to develop a practical use for this system [7.3].

In 1856, Cromwell Fleetwood Varley obtained an English patent (3059/1856) for the first apparatus with a closed magnetic circuit in the form of a shell-type transformer. However, a practical use for this circuit remained elusive during that period.

In 1882, Lucien Gaulard and John Gibbs invented a transformer with disc windings on an iron core (English patent 4362), as shown in Fig. 7.2. They called their transformer a *secondary generator*, which subsequently led to the classification of the transformer as an electrical machine – a classification that is still used today. At the same time, they also patented an energy distribution system based on alternating currents with transformers connected in parallel in a circular network several kilometers long. Light bulbs were connected to the secondary sides of the transformers; this represented the first commercial application of transformers.

In 1885, George Westinghouse purchased the transformer patents of Gaulard and Gibbs. In the same year, the Hungarians Károly Zipernowsky, Miksa Déri, and Ottó Bláthy received a patent (Deutsches Reichspatent, DRP 40414) for the parallel connection of generators, transformers, and consumers, and used the term *transformer* for the first time [7.4]. They developed a kind of shell-type transformer, as illustrated in Fig. 7.3, with a core made from soft magnetic wires wrapped around the coils. This represented the first example of a transformer with a closed iron core. It was subsequently manufactured by the company Ganz & Cie in Budapest and commercialized around the globe.

All of these breakthroughs relate to single-phase systems. Further development was achieved through the work of Westinghouse, based on Nikola Tesla's invention of two-phase alternating current, and this development allowed the alternating current promoted by Westinghouse and Tesla to prevail against the direct cur-

**Fig. 7.2** Model in the Museo Galileo (Florence, Italy) of the transformer constructed by Gaulard and Gibbs [7.4]

rent championed by Thomas Edison in the so-called battle of currents.

The three-phase system was essentially developed by Mikhail Dolivo-Dobrovolsky while he was working for the Berlin-based company Allgemeine Elektrizitäts-Gesellschaft (AEG), where he later took on managerial positions. He introduced the term *Drehstrom* (rotary current) for German-speaking countries; in other

**Fig. 7.3** The transformer manufactured by Ganz & Cie [7.4]

territories, the term *three-phase (alternating) current* is used. Energy transmission using a 15 kV three-phase system occurred for the first time in a successful experiment to transmit energy over the considerable distance (175 km) from the hydroelectric power plant in Lauffen (on the Neckar River in Germany) to the international electrotechnical exhibition of 1891 in Frankfurt [7.5]. Figure 7.4 shows the oil-insulated transformers that were used in this experiment. These transformers, made by AEG, were based on a design known as *temple core*. The basic principle of this oil-insulated transformer design resulting from the pioneering work of Dolivo-Dobrovolsky at AEG in the 1920s is still employed today.

After that, power transformer development continued in a discontinuous manner: phases of new inventions were repeatedly interrupted by new advances based on new materials and technologies. After 1945, there were particularly notable advances in oil-insulated power transformer reliability and service life. Among the most important innovations were the transitions from hot-rolled core sheets to cold-rolled textured sheets and from soft paper insulation to molded parts made from pressboard. These innovations, which were incorporated into transformer construction over a period of just a few years, had a major impact on the quality and longevity of transformers.

As already mentioned, the definition of a transformer as an electrical machine can be traced back to Gaulard and Gibbs, who defined the transformer as a *secondary generator*. Note that, in principle, all electrical machines can be considered *electromagnetic energy converters*.

According to the European Machinery Directive, a machine should contain at least one moving part [7.6]. This requirement is met by all rotating electrical machines. However, all of the components of a transformer

**Fig. 7.4** Three-phase oil-insulated transformer with a temple core, as constructed by the company AEG in 1891 [7.5]

are rigidly connected to each other. Thus, a transformer can be categorized as a stationary electrical machine that electromagnetically transfers electrical energy from one system with particular current and voltage values to another system with different current and voltage values at the same frequency [7.7].

It should be noted that the device referred to as a transformer in this chapter is actually known by various names, depending on the area of electrical engineering considered:

- In power engineering  $\Rightarrow$  power transformer
- In information technology  $\Rightarrow$  transducer
- In measurement technology  $\Rightarrow$  instrument transformer.

In the following, only transformers in the area of power electrical engineering are considered.

## 7.1.2 Functional Principle and Basic Design

In a transformer, two separate windings are coupled via a magnetic circuit in the form of an iron core, as depicted in Fig. 7.5.

**Fig. 7.5** Principal components of a transformer [7.2]

A magnetic field is generated in a transformer according to the following general principle:

*A moving electric charge generates a magnetic field of intensity  $H$ .*

The moving electric charge can be a current flowing in an electrical conductor with current density  $J$  or a time-varying displacement current density  $D$  caused by a temporally changing electrical field. Both types of moving charge are generalized as a flux  $\Theta$ . Mathematically, this is formulated as *Ampère's law*, the fourth of *Maxwell's equations*, which states that the ring integral around the closed curve  $x$  is equal to the sum of the current densities through the surface  $A$ , i.e., [7.7]

$$\oint_x \mathbf{H} dx = \iint_A \left( \mathbf{J} + \frac{\partial \mathbf{D}}{\partial t} \right) d\mathbf{A} = \Theta . \quad (7.1)$$

Transformers operate with quite slowly changing fields that are termed quasi-stationary fields. The displacement current in the highly conductive materials used in a transformer is negligible compared to the conduction current. Therefore, (7.1) can be simplified to

$$\oint_x \mathbf{H} dx = \iint_A \mathbf{J} d\mathbf{A} = \sum I = \Theta . \quad (7.2)$$

This equation directly links the magnetic field strength  $H$  to the current.

The closed loop integral of the magnetic field strength is equal to the current in the loop. From Fig. 7.6,  $\oint_x \mathbf{H} dx$  is  $i_1 + i_2 + i_3$ , which is equal to  $wi$ , where  $w$  is the number of turns of the winding in Fig. 7.7 and  $i$  is the current through the winding. The magnetic field strength  $H$  (in A/m) is independent of the surrounding medium. The magnetic flux density  $B$  (in  $V\,s/m^2 = T$ ) is a function of the magnetic field strength

**Fig. 7.6** Ring integral of the magnetic field strength

and the permeability  $\mu$  of the surrounding medium (as a proportionality factor). Thus, the expression

$$\mathbf{B} = \mu \mathbf{H} \quad (7.3)$$

is valid.

The permeability is the product of the vacuum permeability or magnetic constant  $\mu_0$  and the relative permeability  $\mu_r$ , i.e.,

$$\mu = \mu_0 \mu_r . \quad (7.4)$$

The value of the magnetic constant  $\mu_0$  is given by

$$\mu_0 = 4\pi \times 10^{-7} \frac{V\,s}{A\,m} = 1.257 \times 10^{-6} \frac{V\,s}{A\,m} . \quad (7.5)$$

The materials used for transformer cores are ferromagnetic ( $\mu_r \gg 1$ ); meaning that they can bundle a magnetic flux  $\Phi$  and conduct it along a specified path. The magnetic flux  $\Phi$  [V s] is given by the area integral of the magnetic flux density

$$\Phi = \iint_A \mathbf{B} d\mathbf{A} . \quad (7.6)$$

Fig. 7.7 Cylindrical winding with  $w$  turns

When the flux density over a surface  $A$  is constant, the flux  $\Phi$  is equal to the product of the flux density  $B$  and the surface area  $A$ , i.e.,

$$\Phi = B \cdot A. \quad (7.7)$$

If the primary voltage  $V_1$  in Fig. 7.5 is a direct current (DC) voltage and therefore  $I_1$  is a DC current, an electrical flow is generated and a constant magnetic flux  $\Phi$  builds up in the core, but no permanent voltage is induced in the secondary winding.

Only when  $V_1$  is an alternating voltage, and therefore  $I_1$  is an alternating current, an alternating voltage ( $V_2$ ) is induced in the secondary winding. This happens due to the alternating magnetic flux  $\Phi$  generated in the magnetic circuit by the presence of  $I_1$ , thus an electrical field  $E$  is induced according to the second of Maxwell's equations. This equation is called Faraday's law of induction, and can be written in an integral form as [7.8]

$$\oint_x E dx = -\frac{\partial}{\partial t} \iint_A B dA. \quad (7.8)$$

The voltage along the edge of the surface is the time derivative of the magnetic flux  $\Phi$  through the surface  $A$ . If the edge of this surface is a conductor loop (e.g., a winding turn of the secondary winding in Fig. 7.5), a voltage  $V_i$  is induced, as shown in Fig. 7.8.

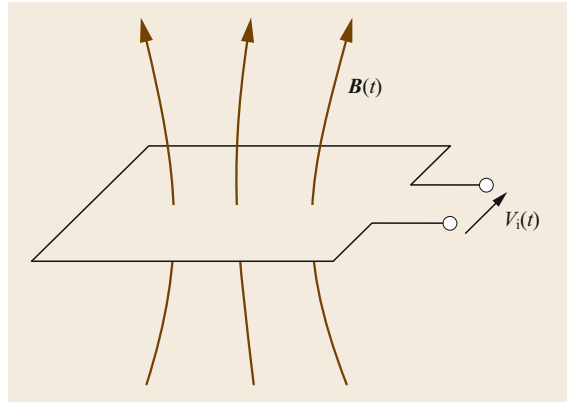

Fig. 7.8 Voltage  $V_i(t)$  induced in a time-varying magnetic field  $B(t)$

Assuming a varying flux  $\Phi$  through area  $A$ , the winding turn voltage  $V_i(t)$  of the conductor loop of area  $A$  is calculated according to Fig. 7.8 as

$$V_i(t) = -\frac{d\Phi(t)}{dt} = -A \cdot \frac{dB(t)}{dt}. \quad (7.9)$$

The negative sign in (7.9) indicates that the induced voltage is in the opposite direction to the magnetic field that creates it (Lenz's law). A voltage  $V_2$  is induced across all of the turns  $w_2$  of the secondary winding in Fig. 7.5.

$$V_2(t) = -w_2 \frac{d\Phi(t)}{dt} = -w_2 A \cdot \frac{dB(t)}{dt}. \quad (7.10)$$

This form of induction is called *mutual induction*.

If the magnetic flux is sinusoidal, the change in flux is zero at the maximum value of the flux, whereas the change in flux is greatest at the zero crossing of the sinusoidal function. Therefore, the induced voltage  $V_i(t)$  is phase shifted by a  $90^\circ$  lag with respect to the magnetic flux  $\Phi(t)$ . The maximum induced sinusoidal voltage can be calculated via

$$V_{\max} = w \left( \frac{d\Phi}{dt} \right)_{\max} = wA \cdot \left( \frac{dB}{dt} \right)_{\max}. \quad (7.11)$$

For sinusoidal functions such as  $\sin(\omega t)$  with a circular frequency  $\omega$  of

$$\omega = 2\pi f, \quad (7.12)$$

this results in

$$V_{\max} = w2\pi f \Phi_{\max} = w2\pi f A \cdot B_{\max}. \quad (7.13)$$

Since the root mean square (RMS) value of the induc-

**Fig. 7.9** Different conductor loops around a core with  $\mu_r = \infty$

tion voltage is  $V = V_{\max}/\sqrt{2}$ , the RMS value of the induced voltage can be obtained as

$$V_{1(\text{RMS})} = \frac{2\pi f}{\sqrt{2}} w \Phi_{\max} = \frac{2\pi f}{\sqrt{2}} w A \cdot B_{\max}. \quad (7.14)$$

This is known as the *transformer equation*. It shows that, for a transformer operating at a constant frequency  $f$ , the magnitude of the induced voltage is determined by the magnitude of the magnetic flux  $\Phi_{\max}$  [7.9].

According to Ampère's law, *no winding voltage is induced in incomplete windings*.

The iron core of the simple transformer shown in Fig. 7.5 has a particularly high magnetic conductivity and encloses the magnetic flux. Although it is not infinite, the relative permeability of the core material is so high that it can be assumed that all magnetic field lines pass through the iron core. Such a transformer with no leakage of magnetic flux is said to be *ideal*.

Therefore, the closed loop integrals of the areas enclosed by the conductors in the arrangements shown in Fig. 7.9 are identical, meaning that the induced voltages  $V_1$ ,  $V_2$ , and  $V_3$  are also identical, irrespective of the path shape. Thus, only the effective cross-sectional area of the core column  $A_{\text{Fe}}$  in Fig. 7.5 is relevant to the induction. For the secondary winding of the transformer shown in Fig. 7.5, the RMS of the induced voltage  $V_2$  can be determined via the transformer equation as

$$V_2 = \frac{2\pi f}{\sqrt{2}} w_2 \Phi_{\max} = \frac{2\pi f}{\sqrt{2}} w_2 A_{\text{Fe}} \cdot B_{\max}. \quad (7.15)$$

For a constant frequency, the magnitude of the induced voltage depends on the number of turns  $w$  and the effective core cross-section  $A_{\text{Fe}}$ . For power transformers, the primary voltage is usually specified by the network. However, the primary winding also encloses the core and therefore the magnetic flux, so a voltage is induced, which is known as the self-induction voltage

$V_1$ . This voltage is calculated as

$$V_1 = \frac{2\pi f}{\sqrt{2}} w_1 \Phi_{\max} = \frac{2\pi f}{\sqrt{2}} w_1 A_{\text{Fe}} \cdot B_{\max}. \quad (7.16)$$

For an ideal transformer, the primary voltage  $V_1$  applied determines the magnitude of the magnetic flux  $\Phi_{\max}$ . If the flux distribution in the core cross-section  $A_{\text{Fe}}$  is uniform, the resulting flux density  $B_{\max}$  determines the secondary induced voltage  $V_2$  [7.8]. Therefore, using (7.15) and (7.16), the voltage ratio for an ideal transformer can be determined as

$$\frac{V_1}{V_2} = \frac{\frac{2\pi f}{\sqrt{2}} w_1 \Phi_{\max}}{\frac{2\pi f}{\sqrt{2}} w_2 \Phi_{\max}} = \frac{w_1}{w_2}, \quad (7.17)$$

which results in

$$\frac{V_1}{V_2} = \frac{w_1}{w_2} = n. \quad (7.18)$$

According to the law of conservation of energy for an ideal lossless transformer, the equation

$$V_1 I_1 = V_2 I_2 \quad (7.19)$$

is valid, which yields the current ratio

$$\frac{I_1}{I_2} = \frac{V_2}{V_1} = \frac{w_2}{w_1} = \frac{1}{n}. \quad (7.20)$$

Given that the impedance  $Z = V/I$ , the impedance ratio can be determined as

$$\frac{Z_1}{Z_2} = \frac{V_1}{I_1} \cdot \frac{I_2}{V_2} = \frac{V_1 I_2}{V_2 I_1} = \left(\frac{w_1}{w_2}\right)^2 = n^2. \quad (7.21)$$

It is clear from the ratio equations that a transformer can be used for different purposes: voltage transformation is used to generate the high voltages needed to facilitate low-loss electrical energy transmission; current transformation is employed to produce the high currents needed by various industries (e.g., for melting processes); and impedance transformation is performed in transducers utilized in information technology applications.

### Technical Design

Any transformer can be divided into two parts: the active and passive parts (see Fig. 7.10).

*Components in the active part* (shown in yellow in Fig. 7.10):

- The magnetic circuit, consisting of the core with limbs, reflux limbs, and yokes
- Electrical circuits along with the windings and tap changers.

*Components in the passive part:*

- Supporting and pressing elements
- Bushings
- Containers, such as a tank, cover, or housing and the cooling system
- Protection, measuring, and control equipment, including their power supplies.

Sometimes the active part is considered to comprise all of the components that can be lifted out of the tank.

**Fig. 7.10** Components of a liquid-filled power transformer [7.10]. A: high voltage bushing, B: low voltage bushings, C: tertiary winding bushings, D: HV neutral bushing, E: LV neutral bushing – rigidly grounded, F: top of on-load tap changer (OLTC), G: diverter switch with separate compartment, H: selector, I: OLTC motor drive, J: winding block, K: part of the lead system, L: core, M: voltage dependent resistor, N: control cabinet, O: cooling radiators, P: cooling fans, Q: connection to current transformer

Depending on the transformer design, such a definition is only partially correct, because supporting elements and tank parts (such as the cover) are sometimes lifted out along with the main active components.

The components of a transformer are explained in more detail in the next section.

### 7.1.3 Single-Phase Considerations

According to the induction law, a single-phase transformer can only be operated in an alternating current (AC) network. This network usually has various consumers, so the transformer interacts with these consumers. This operational interaction is discussed in more detail in the following.

#### Equivalent Circuit

In order to investigate the interaction mentioned above, the transformer is simplified by representing it as an equivalent circuit with ideal components. For sinusoidal processes, the relationships between electrical parameters are presented using phasor diagrams. However, the transmission ratio for a real transformer is usually  $\gg 1$ , meaning that the voltage and current phasors have different lengths on the primary and secondary sides, which causes problems. Therefore, either the phasor scale must be adjusted or a transformation ratio of  $n = 1$  must be assumed. The latter is a simpler approach and is used below.

A circuit diagram of a single-phase transformer is shown in Fig. 7.11. The primary and secondary sides are each represented by a coil, so a secondary voltage  $V_2$  is induced through the coupling based on the primary voltage  $V_1$ .

It is clear from the circuit diagram shown in Fig. 7.11 that a single-phase transformer is a two-port network. If the coils or windings have the same number of turns (i.e., if  $n = 1$ ), the equivalent circuit can be simplified by using an inductive reactance  $X_k$ , as depicted in Fig. 7.12.

**Fig. 7.11** Circuit diagram of a single-phase transformer with primary and secondary windings

**Fig. 7.12** Single-phase transformer with windings represented by an inductive reactance  $X_k$

**Fig. 7.13** Accounting for core losses through  $R_{Fe}$

In order to determine the operational behavior of a real transformer, it is necessary to consider the following deviations from ideality and incorporate them into the equivalent circuit scheme:

1. The relative permeability of the iron core is not infinite ( $\mu_{Fe} \neq \infty$ ). The relationship between  $\mathbf{B}$  and  $\mathbf{H}$  is given by the hysteresis loop as the nonlinear dependence  $\mathbf{B} = f(\mathbf{H})$  (see the next section). Losses occur in the core material due to the change in direction of the magnetic flux in the iron core. These are called hysteresis losses.
2. The resistance of the core material is not infinite. According to the law of induction, eddy currents can also form within the core material, causing ohmic losses. Accordingly, when  $n = 1$ , the sum of the primary and secondary currents is not equal to zero in Fig. 7.12 ( $I_1 + I_2 \neq 0$ ). The hysteresis and eddy current losses in the transformer core are incorporated into the equivalent circuit diagram by including a resistor  $R_{Fe}$  connected in parallel, as shown in Fig. 7.13.
3. The relative permeability of the material surrounding the core and the windings (air, insulating fluid) is  $\mu_{air,fluid} \neq 1$ . This, together with the fact that the relative permeability of the iron core is not infinite ( $\mu_{Fe} \neq \infty$ ), implies that a small portion of the magnetic flux flows not only through the core but also through the surrounding materials. This part of the magnetic flux is called the leakage flux. The flux through the primary winding is larger than the flux through the secondary winding, as shown in Fig. 7.14.
4. The resistance of the conductor used in the windings is not zero. The current flowing through the primary and secondary windings generates ohmic losses. According to the law of induction, leakage fluxes can also prompt the formation of eddy currents within the winding material, which leads to further ohmic losses. The winding losses therefore consist of the ohmic losses of the winding conductors and the eddy current losses in them as a function of the leakage flux. In the equivalent circuit of the transformer, the primary and secondary

**Fig. 7.14** Main flux  $\Phi_k$  and leakage flux  $\Phi_S$

leakage fluxes are represented by leakage or stray inductances  $X_{S1}$  and  $X_{S2}$ , and the sums of the ohmic and eddy losses in the windings are denoted by the ohmic winding resistances  $R_1$  and  $R_2$ , as illustrated in Fig. 7.15.

Due to the voltage drops at the winding resistances and reactances, the primary and secondary voltages are not equal ( $V_1 \neq V_2$ ).

### No-Load Operation

No-load operation is the operating state of the transformer in which a voltage  $V_1$  is applied on the primary side with no load (consumer) on the secondary side, as illustrated in Fig. 7.16.

The applied voltage  $V_1$  produces the no-load current  $I_0$ . The no-load current consists of the iron leakage current  $I_v$  (a pure active current) and the magnetizing current  $I_\mu$  (a pure reactive current) to build up the magnetic flux. The no-load current  $I_0$  generates the alternating magnetic flux  $\Phi$  in the core, which induces the voltage  $V_2$  in the secondary winding and the self-induction voltage  $V$  in the primary winding. The small difference between the voltages  $V_1$  and  $V$  drives the tiny current  $I_0$ , which is delayed compared to  $V_1$ . In modern transformers, the no-load current is on the order of just 1–2% of the rated current on the primary side [7.11].

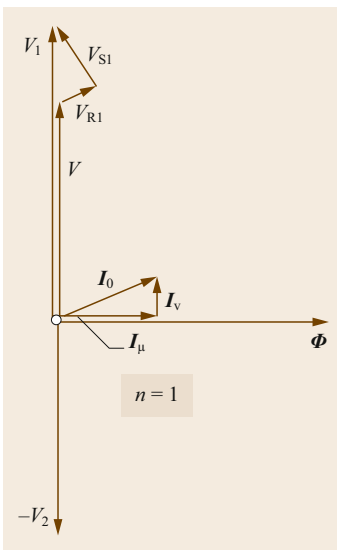

The phasor diagram for no-load operation is illustrated in Fig. 7.17. This diagram shows the no-load situation qualitatively, whereas the voltages  $V_{R1}$  and  $V_{S1}$

**Fig. 7.15** Equivalent circuit of a single-phase transformer

**Fig. 7.16** Equivalent circuit for no-load operation

**Fig. 7.17** Phasor diagram for no-load operation according to the equivalent circuit shown in Fig. 7.16

decreases sinusoidally, the magnetic flux increases sinusoidally, and no unusual stresses occur. However, if the transformer is energized at the zero crossing of the primary voltage  $V_1$ , the magnetic flux  $\Phi$  should be at its maximum value, which causes a high inrush magnetizing current to flow in order to establish the maximum magnetic flux so that the normal situation between  $V_1$  and  $\Phi$  is attained. Due to the high magnetization current, the core can be driven to saturation because the magnetization current can be up to 50 times higher than the normal magnetizing current in unfavorable circumstances [7.12]. Due to the ohmic resistance  $R_1$  and the leakage inductance  $X_{S1}$  of the primary winding, the inrush magnetization current is strongly attenuated and therefore decays rapidly. The inrush current can be limited in power networks by reducing the supply voltage as far as possible before energization. Another way to limit the inrush current is to use compensation inductances in the network.

can be neglected in reality, meaning that the voltages  $V_1$ ,  $V$ , and  $V_2$  are almost equal.

The magnitude of the no-load current  $I_0$  can be influenced by the construction of the transformer; in particular the design of the transformer core.

**Inrush Current.** When transformers are energized, current impulses with high amplitudes can occur. As shown in Fig. 7.16, the primary voltage  $V_1$  is shifted with respect to the magnetic flux  $\Phi$  by  $90^\circ$ . If the transformer is connected to the network at maximum voltage, the magnetic flux  $\Phi$  is zero. As the voltage

### Operation Under Load

When the transformer is loaded, a voltage  $V_1$  is applied on the primary side and a load  $Z_A$  is connected to the secondary side, as shown in Fig. 7.18. Hence, the current  $I_2$  flows through the secondary winding and the load. The primary current  $I_1$  flows through the primary winding and, despite the galvanic isolation between the primary and secondary circuits, load changes on the secondary side affect the current on the primary side.

The applied voltage  $V_1$  establishes the primary current  $I_1$ , which consists of the no-load current  $I_0$  and the current  $I_2$  corresponding to the secondary load.  $I_1$

**Fig. 7.18** Equivalent circuit for operation under load

**Fig. 7.19** (a) Phasor diagram for ohmic-inductive load. (b) Phasor diagram for ohmic-capacitive load

generates the primary voltage drops on  $R_1$  and  $X_{S1}$  and creates the magnetic flux  $\Phi$ , whereas the secondary current  $I_2$  generates voltage drops on  $R_2$  and  $X_{S2}$  and influences the magnetic flux  $\Phi$ .

The pointer diagrams for operation with an ohmic-inductive load and an ohmic-capacitive load are shown in Fig. 7.19a,b, respectively. The phasor diagrams are again presented for a transmission ratio  $n = 1$ , and some voltage drops and the no-load current are shown larger than in reality to highlight the qualitative correlations.

When the transformer is subjected to a more capacitive load, as assumed in Fig. 7.19b, the secondary winding and the capacitive load form an oscillating circuit, so the voltage  $V_2$  can be greater than  $V$ . This is called a capacitive voltage increase.

In reality, the phasor diagrams can be simplified by neglecting the no-load current  $I_0$  (which is much smaller than the rated current) so that the currents  $I_1$  and  $I_2$  coincide. If the voltage drops on the winding resistances  $V_{R1}$  and  $V_{R2}$  are combined to give  $V_R$  and the voltage drops  $V_{S1}$  and  $V_{S2}$  are combined to give  $V_S$ , the

phasor diagram shown in Fig. 7.20a is obtained. The triangle created by the voltages  $V_R$ ,  $V_S$ , and  $V_{sc}$  (short-circuit voltage) is called the Kapp triangle after its developer Gisbert Johann Eduard Kapp [7.13].

The Kapp triangle as shown in Fig. 7.20b describes the load-dependent longitudinal voltage drop of a transformer. This consists of an ohmic component and an inductive component.

If a transformer is short-circuited on the secondary side and the primary voltage  $V_1$  is increased until the rated current flows on the primary side, the primary voltage at this point is called the short-circuit voltage  $V_{sc}$ . Based on Fig. 7.20a, this voltage can be calculated as the sum of  $V_R$  and  $V_S$ . The voltage  $V_{sc}$  can be determined by splitting the voltages  $V_R$  and  $V_S$  back into the voltages  $V_{R1}$ ,  $V_{R2}$ ,  $V_{S1}$ , and  $V_{S2}$  and by considering the transformer ratio  $n$  and therefore the current  $I_2 = nI_1$ ; in other words,

$$V_{sc} = (V_{R1} + nV_{R2}) + (V_{S1} + nV_{S2}),$$

$$|V_{sc}| = \sqrt{(V_{R1} + nV_{R2})^2 + (V_{S1} + nV_{S2})^2}. \quad (7.22)$$

**Fig. 7.20** (a) Simplified phasor diagram (ohmic-inductive load). (b) Kapp triangle (shaded area)

Therefore, the short-circuit voltage  $V_{sc}$  of a transformer is the geometric sum of its internal voltage drops at nominal load.

A transformer can increase or decrease voltages, so it has two different transmission ratios and two different short-circuit voltages. However, normalizing the absolute short-circuit voltage to the primary nominal voltage via

$$v_{sc} = \frac{V_{sc}}{V_1} \times 100\% \quad (7.23)$$

gives a percentage value that is identical for both cases. The relative short-circuit voltage  $v_{sc}$  has the advantage that it is valid for both the primary and the secondary sides. At the same time, it allows different transformers to be compared. Analogous results can be achieved for the ohmic and inductive voltage drops, as shown below.

$$v_R = \frac{V_R}{V_1} \times 100, \quad (7.24)$$

$$v_S = \frac{V_S}{V_1} \times 100, \quad (7.25)$$

$$v_{sc} = \sqrt{v_R^2 + v_S^2}. \quad (7.26)$$

The short-circuit voltage influences:

- The magnitudes of the secondary voltage and the load-dependent voltage changes
- The magnitudes of the surge and continuous short-circuit currents
- The load distribution for transformers operating in parallel.

The short-circuit voltage  $V_{sc}$  is influenced by the design of the transformer and – in particular – the design of the windings.

From the vector diagrams shown in Figs. 7.19 and 7.20, it is clear that the magnitude of the secondary clamping voltage  $V_2$  depends on the load  $Z_A$  connected to the transformer. For resistive or inductive loads, the secondary voltage  $V_2$  decreases with increasing load. For capacitive loads, this voltage increases with increasing load. The influence of the type of load on the secondary voltage can be illustrated in a simplified form by an extended Kapp diagram. This assumes that the applied primary voltage  $V_1$  is constant for an ideal transformer with a transmission ratio  $n = 1$ , which is sufficiently accurate if a power network is connected to the primary side of the transformer. The extended Kapp diagram depicted in Fig. 7.21 can be drawn based on the equivalent circuit shown in Fig. 7.18. At its base point A, the Kapp triangle is drawn with  $V_{sc}$ ,  $V_R$ , and  $V_S$ . Semicircles with radii corresponding to the applied voltage  $V_1$  are drawn around A and B. Semicircle I with A at its center represents the locus curve for  $V_1$ , whereas semicircle II with B at its center is the locus curve for the secondary voltage  $V_2$ .

The diagram in Fig. 7.21 illustrates the decrease in  $V_2$  for an inductive load and the increase in voltage for a capacitive load.

**Efficiency.** The efficiency  $\eta$  of an electrical machine is defined as the ratio of the active output power  $P_{out}$  to the active input power  $P_{in}$ , i.e.,

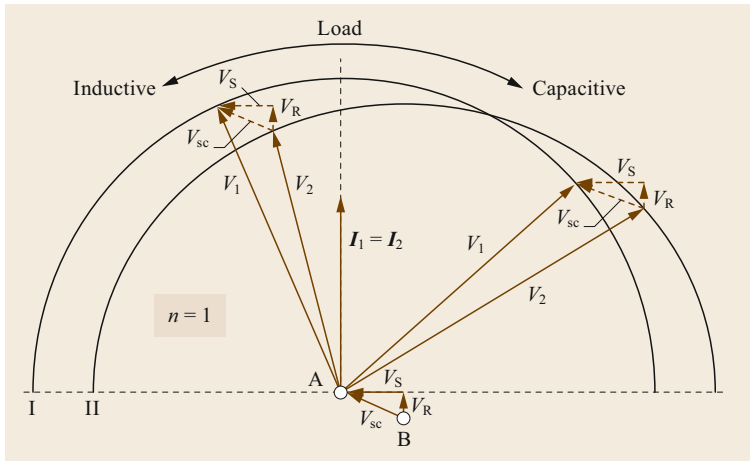

$$\eta = \frac{P_{out}}{P_{in}}. \quad (7.27)$$

The difference between these power terms corresponds to the total losses  $P_{loss}$ ; in other words,

$$P_{loss} = P_{in} - P_{out}. \quad (7.28)$$

Transformer losses can be divided into *no-load losses*  $P_0$  and *short-circuit losses*  $P_{sc}$ . The no-load losses (also known as iron losses) include hysteresis losses (re-magnetization losses) and the eddy current losses in the core. The short-circuit losses arise mainly from ohmic losses and the eddy current losses in the windings, meaning that these losses depend on the current. If a transformer is only partially loaded, the losses decrease quadratically according to  $P_{sc} = I^2 R$ , which means that the short-circuit losses drop to 36% ( $= L_f^2 P_{sc}$ ) of the load losses  $P_{sc}$  when the load is 60% (load factor  $L_f = 0.6$ ). Therefore, the total losses  $P_{loss}$  can be calculated via

$$P_{loss} = P_0 + L_f^2 P_{sc}. \quad (7.29)$$

**Fig. 7.21** Extended Kapp diagram illustrating the effect of load type

The efficiency is then determined as

$$\eta = \frac{P_{out}}{P_{loss} + P_{out}} \quad (7.30)$$

Today, the efficiency of a modern power transformer at rated power is usually above 98%. As an example, a modern generator step-up transformer with a power level of a few hundred MVA has a typical efficiency exceeding 99.5%.

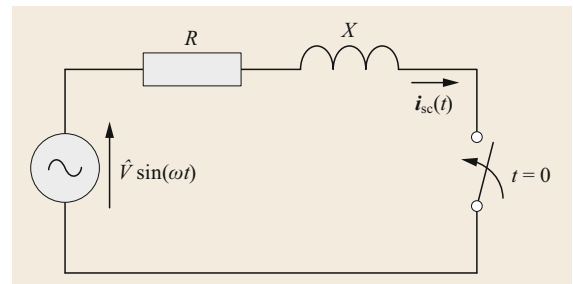

### Short-Circuit Behavior

During operation, power transformers can be exposed to short circuits in the electrical network. The closer the short circuit to the transformer, the greater its impact on the transformer. The worst-case scenario is a terminal short circuit on the secondary side. Every power transformer must be able to withstand a secondary terminal short circuit for a short period of time (typically only a few seconds, e.g., 2 s). Since the current often exceeds the rated current when there is a short circuit, the no-load current can be ignored in an equivalent circuit. With the collapse of the secondary voltage, the magnetic flux in the transformer core is also drastically reduced, and the short-circuit current is only limited by the internal resistances of the transformer. The circuit diagram of a transformer for short-circuit operation with the short-circuit current  $I_{sc}$  is shown in Fig. 7.22.

The complex impedance  $Z_i$  in the network includes the internal impedances  $R$  and  $X$  of the transformer and the impedances of the network transposed with the transmission ratio  $n$ . The latter depend on the location of the transformer and are therefore not taken into account when designing the transformer. This means that, in reality, the short-circuit current  $I_{sc}$  that occurs upon

**Fig. 7.22** Simplified equivalent circuit of a transformer for short-circuit operation

**Fig. 7.23** Equivalent circuit for a short circuit

a secondary-side terminal short circuit is always smaller than that considered in the design.

In the following considerations, only the complex internal resistance  $Z_i$  of the transformer is taken into account. During a short circuit, a balancing process that brings the transformer to stationary short-circuit conditions occurs. The simplified circuit shown in Fig. 7.23, in which the internal resistances  $R$  and  $X$  of the transformer are connected to an AC source, is used.

If the switch in Fig. 7.23 is closed, the current  $i_{sc}(t)$  is time dependent, as illustrated in Fig. 7.24. As can be seen, the current initially has a higher amplitude than the stationary short-circuit current.

**Fig. 7.24** Variation in the short-circuit current over time [7.9]

**Fig. 7.25** Three-phase bank using three single-phase transformers

For  $X = L$  (inductance), the time-dependent function  $i_{sc}(t)$  in Fig. 7.25 can be approximated by

$$i_{sc}(t) = \hat{I} \left[ \sin \left( \omega t - \frac{\pi}{2} \right) + e^{-\frac{R}{L}t} \right], \quad (7.31)$$

where  $\hat{I}$  is the peak current. The maximal value of the current is obtained for  $\omega t = \pi$  as

$$\hat{I}_{sc \max} = I_{sc} \sqrt{2} k, \quad (7.32)$$

where  $k$  is the correction factor determined via

$$k = 1 + e^{-\frac{\pi R}{X}} = 1 + e^{-\frac{\pi}{\tau}}. \quad (7.33)$$

For the typical ratio  $R/X = 1/8$ , the calculated correction factor  $k$  is 1.675, which results in a surge short-circuit current of  $\hat{I}_{sc \max} = 2.37 I_{sc}$ .

This surge short-circuit current dictates the forces that occur in the windings during a short circuit. The continuous or stationary short-circuit current  $I_{sc} = V_1/Z_i = V_{sc}/Z_i$  according to Fig. 7.22, and can be obtained from the relative short-circuit voltage using

$$I_{sc} = I_1 \frac{100}{v_{sc}}. \quad (7.34)$$

The relative short-circuit voltage  $v_{sc}$  for power transformers is typically between 3% and 12.5%, depending on the size of the transformer. According to (7.34), this results in continuous short-circuit currents that are 8 times higher for large transformers and 33 times higher for network transformers. Knowledge of the continuous short-circuit current is important when defining the permitted short-circuit duration and designing current transformers and circuit breakers.

### 7.1.4 Three-Phase Operation

Concatenating three  $120^\circ$  phase-shifted alternating voltages leads to the creation of a three-phase system that allows effective energy transmission. This is the system used in conventional electrical power transmission networks. It can be realized by combining three single-phase transformers to form a transformer bank, as shown in Fig. 7.25. Single-phase transformers are still used in modern networks with voltages of 750 kV or more, since three-phase units for such networks would be too large and heavy to transport. Indeed, single-phase transformers may even be installed in networks with lower voltages, as only one unit needs to be put out of operation when there is a single-phase failure, and a spare unit is often stored on-site, meaning that power interruption can be minimized. Thus, although this setup is much more expensive than using one three-phase transformer, this extra expense may be acceptable given that it should lead to increased reliability of the power supply.

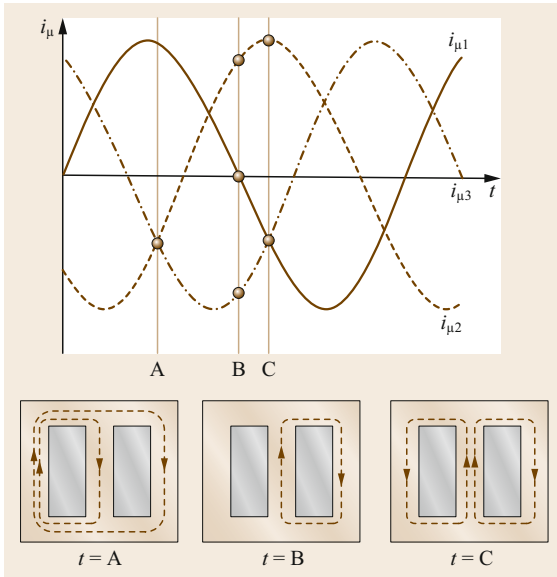

Transformers become highly effective when they include three or five limb cores. This approach was first adopted in 1891 with the utilization of the so-called temple core, as shown in Fig. 7.4. Ensuring that the voltages in the *symmetrical* three-phase network and thus the magnetic fluxes in the core legs of the transformers are zero saves materials and costs.

If the windings of three single-phase transformers are wound on only one leg, the cores can be assembled at an angle of  $120^\circ$  so that the unwound cores touch each other, as illustrated in Fig. 7.26.

When a symmetrical three-phase voltage is applied, the cores are magnetized. The voltages are phase shifted by  $120^\circ$ , so their geometric sum is zero. Therefore, the unwound core limb in the center can be eliminated and the wound limbs can either be joined together in a temple configuration or, as developed by Dolivo-Dobrovolsky for AEG, they can be joined together in one plane [7.14]. This is demonstrated in Fig. 7.27. It is assumed that the magnetic flux  $\Phi$  flows from the bottom to the top for a positive magnetizing current. Therefore, various magnetic fluxes  $\Phi(t)$  result in the core at times A, B, and C.

**Fig. 7.26** The magnetic fluxes in three single-phase cores add up to zero at the center [7.8]

**Fig. 7.27** Magnetic flux distribution in a three-leg core with a symmetrical load [7.8]

Figure 7.27 clearly shows that the center limb in Fig. 7.26 can be removed, so a core with three limbs is typically used for a three-phase system. Windings are mounted on each limb, and they can be connected separately on the low- and high-voltage sides (e.g., using a star or delta connection).

### Vector Groups

The connection possibilities for the three low-voltage or high-voltage windings on the three core limbs are shown in Fig. 7.28a–c. The zigzag connection represents a special case.

**Table 7.1** Abbreviations used for terminals and connections [7.10]

Winding		HV	LV
Terminals	Start	A B C	a b c
	End	X Y Z	x y z
Connections	Delta	D	d
	Star (wye)	Y	y
	Zigzag		z
	Open	I I I	i i i

For the delta connection, the phase-to-phase voltage (e.g.,  $V_{AB}$ ) is equal to the line voltage  $V_{AX} = V_A$ , whereas the line current  $I_{AX}$  is equal to the phase current  $I_A$  divided by  $\sqrt{3}$ . The delta connection is therefore not suitable for very high voltages because the full voltage is always applied to each winding. Consequently, the delta connection is more suitable for low-voltage (LV) windings, and it has the additional advantage that the current through the windings  $I_{AX}$  is smaller than the phase current  $I_A$ . The opposite is true of the star connection: the phase and line currents are equal but the line voltage  $V_A = V_{AX}$  is equal to the phase voltage  $V_{AB}$  divided by  $\sqrt{3}$ , which makes the star connection more suitable for high-voltage (HV) windings. The complicated zigzag circuit is a combination of the star and delta connections. It is particularly useful for compensating for unbalanced loads in the network, but it is only used for a small number of transformers because the winding production process is more complicated and the number of turns in the windings is 15% higher than in the star connection [7.15].

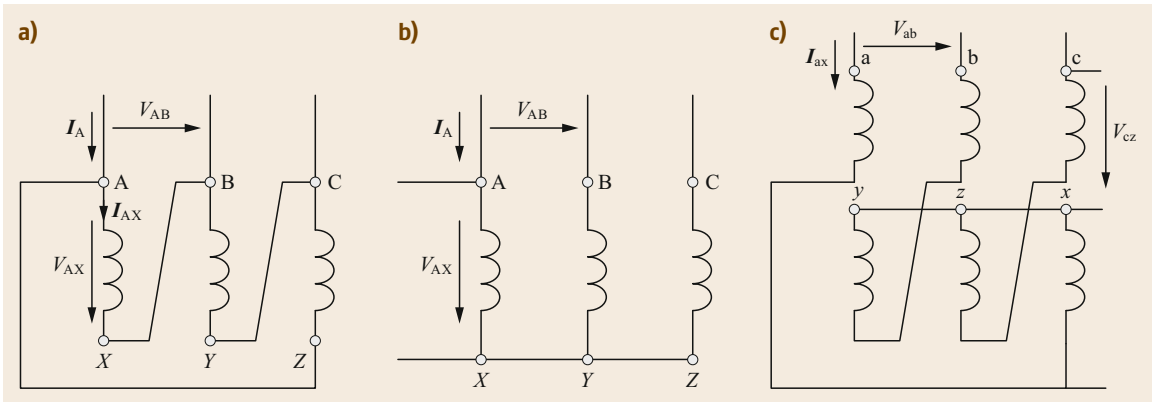

The connections Yy, Yd, Yz, Dy, Dd, and Dz (see the list of abbreviations used for various types of HV and LV connections in Table 7.1) are possible and are used in practice, whereas Zy, Zd, and Zz are theoretically possible but are not used.

The abbreviation Yy means that both the HV and LV windings are connected in a star, but, as illustrated in Fig. 7.29, there are various possible configurations for a Yy connection.

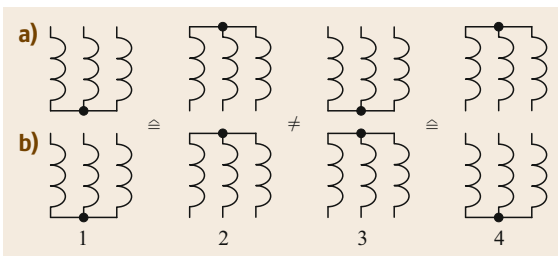

If the neutral winding is accessible from outside (a separate bushing on the tank), an N (for the HV side) or n (for the LV side) is added after the code letter for the type of connection. As an example, the *vector group* YNd5, which is typically used for generator step-up transformers, implies that:

- A star connection is used for the HV windings, and the star is accessible
- The LV windings are connected in a delta
- The high voltage is  $5 \times 30^\circ = 150^\circ$  ahead of the low voltage.

It can be shown that phase shifts of multiples of  $30^\circ$  between the HV and LV sides can be generated by

**Fig. 7.28** (a) Delta connection. (b) Star connection. (c) Zigzag connection

**Fig. 7.29a,b** Possible configurations for a Yy connection: (a) high-voltage windings; (b) low-voltage windings [7.8]

applying particular star, delta, and zigzag interconnections [7.16]. This is indicated by the number or phase-shift index at the end of each vector group, which corresponds to a multiple of  $30^\circ$ . The vector diagram for the vector group Yd5 is shown in Fig. 7.30.

Among the 42 possible vector groups, there are 12 that are particularly important. These are listed in Table 7.2. The vector groups Yy0, Yd5, Yd11, and Dy5 are the most popular.

**Operation Under Unsymmetrical Load**

As shown in Figs. 7.26 and 7.27, the number of core limbs can be reduced to three for a symmetrical load. In three-phase networks, however, asymmetrical loads can occur, with only one phase supplying a load in the

worst case. Therefore, in the following, a single-phase loaded transformer is considered.

Based on (7.3) and (7.7), the magnetic flux  $\Phi$  can be calculated for a core cross-section of  $A$  via

$$\Phi = B \cdot A = A \cdot \mu H . \tag{7.35}$$

According to Ampère’s law for a quasi-stationary field,

$$\oint_x H dx = \sum I = w i , \tag{7.36}$$

the magnetic field strength  $H$  is strongly dependent on the number of turns  $w$  in the winding and the current  $i$  through the winding. The closed loop integral can be simplified to

$$\oint_x H dx = H \Delta x = H L_{Fe} , \tag{7.37}$$

where  $L_{Fe}$  is the average core length through which the flux  $\Phi$  flows. This leads to

$$\Phi = A \cdot \mu H = \frac{A \cdot \mu w i}{L_{Fe}} \propto (w i) , \tag{7.38}$$

which implies that the magnetic flux in a core limb is directly proportional to the product of the number of turns  $w$  of the winding around the core limb and the magnetizing current  $i$  flowing through this winding.

**Fig. 7.30a–c** Vector diagram for the vector group Yd5: (a) HV windings (star connection), (b) LV windings (delta connection), and (c) phase shift between the HV and LV sides [7.13]

**Fig. 7.31** Single-phase loading of a Yy6 transformer

These considerations result in the scenario presented in Fig. 7.31. This figure shows the magnetic flux for a Yy6 transformer in which only one phase has a load ( $Z_a$ ).

As shown in Fig. 7.31, a magnetic flux is generated in each of the three core limbs, and all of these fluxes are oriented in the same direction, so the sum of the fluxes in the core yokes does not equal zero. As a consequence, core saturation is exceeded and the flux searches for another path, resulting in stray flux that passes through the tank walls for instance. Consequently, high losses caused by eddy currents and hysteresis losses lead to overheating in some areas, which can result in transformer failure in the worst case. These stray fluxes also induce voltages in the windings that significantly shift the potential of the star point. This leads to a voltage drop in the loaded phase, whereas the voltages of the unloaded phases increase. To avoid such a scenario, the star points of Yy transformers are permitted to be loaded with up to 10% of the rated current so long as there is no additionally installed compensation winding (e.g., a tertiary winding system in a delta connection). This is an important restriction on the use of Yy transformers in three-phase networks.

However, if a Yy transformer is equipped with an additional (tertiary) winding system in a delta connection, the tertiary windings compensate for an unbalanced load situation. In the case of a single-phase load, a current flows in the tertiary winding on the loaded phase and conditionally through the tertiary windings on the other two core limbs. These currents create counterfluxes that compensate for the uniformly oriented magnetic fluxes depicted in Fig. 7.31. For complete compensation, the tertiary windings must be dimensioned for one-third of the rated power of the transformer [7.18].

**Fig. 7.32** Single-phase loaded Dy5 transformer

Figure 7.32 shows a Dy5 transformer with only one phase connected to a load  $Z_a$ . In this case, it can be deduced that the current  $I_1$  flows directly through the network and not via the two unloaded phases when the transformer is single-phase loaded. It is therefore possible to fully load the star point of this vector group because the delta winding has a compensating effect.

For a LV-side zigzag connection, an asymmetrical load is distributed over two phases, as shown in Fig. 7.33. The voltages induced in the HV windings and the currents flowing through them generate magnetic fluxes that compensate for the magnetic fluxes generated on the LV side. The disadvantages of a zigzag connection are that a higher number of turns are needed for the windings, which are also more complicated to

**Fig. 7.33** Single-phase loaded Yz5 transformer

produce. Therefore, this vector group is rarely used for transformers with reduced power.

In summary, for transformers with a pure star connection, the star point can only be loaded up to 10% of the rated current. For all transformers with a delta-connected winding designed for at least one-third of the rated power, the star point can be fully loaded for as long as permitted by the design and the rating plate.

### Parallel Operation

According to the equivalent circuit diagram, transformers connected in parallel represent voltage sources connected in parallel, and must therefore fulfill certain conditions [7.19]:

1. *Parallel-connected transformers must have the same transformation ratios.*

If the transformation ratio deviates slightly, a compensation current  $I_A$  flows on the secondary side of the transformer. If the internal resistance of the transformer (see Sect. 7.1.3, *Short-Circuit Behavior*) is replaced with the quotient of the relative short-circuit voltage  $v_{sc}$  and the voltage deviation

$\Delta$  in percent, this compensation current can be calculated with sufficient accuracy via [7.8]

$$I_A = \frac{\Delta}{\frac{v_{sc1}}{I_1} + \frac{v_{sc2}}{I_2}} \quad (7.39)$$

If  $v_{sc1} = v_{sc2} = v_{sc}$  and  $I_1 = I_2 = I$ , then

$$I_A = \frac{\Delta}{2v_{sc}} I \quad (7.40)$$

Note that a small deviation of the transformation ratio can cause a significant current to flow continuously, even during no-load operation. This needs to be considered appropriately.

2. *The short-circuit voltages must be approximately the same (the maximum difference in short-circuit voltage should not exceed  $\pm 10\%$ ).*

Since the short-circuit voltages represent the internal resistances of the transformers, deviations lead to different load levels. The transformer with the lowest short-circuit voltage will be overloaded, while the transformer with the highest short-circuit voltage will not be fully utilized.

3. *The ratio of the rated powers should not be greater than 3 : 1.*

The ratio of the ohmic voltage drop to the leakage voltage drop changes as the rated power is increased. For larger transformers, the relative ohmic voltage drop decreases. As a result, the currents have different phase angles. The busbars of the parallel circuit are loaded with the geometric sum of the currents, which is smaller than the arithmetic sum of the currents. This limits the maximum power at the busbars and reduces the utilization factor of the system.

4. *The LV sides of the transformers connected in parallel must be in phase.*

Both the effective and the instantaneous values of the rated voltages must be the same. Therefore, no phase shift between the LV sides of the parallel-connected transformers is allowed. For example, connecting vector groups with phase-shift indices of 0 and 6 in parallel would result in a short circuit.

Transformers can be operated effectively in parallel as long as these operational conditions are consistently adhered to.

## 7.2 Active Part

### 7.2.1 Core

It was noted earlier that one way in which a real transformer deviates from an ideal one is that the relative permeability of the iron core is not infinite ( $\mu_{Fe} \neq \infty$ ).

In ferromagnetic materials, the magnetic moments of the atoms are aligned in parallel. The French physicist Pierre Ernest Weiss discovered that, in ferromagnetic materials, the process of magnetic alignment occurs in large regions (known as Weiss regions) that are

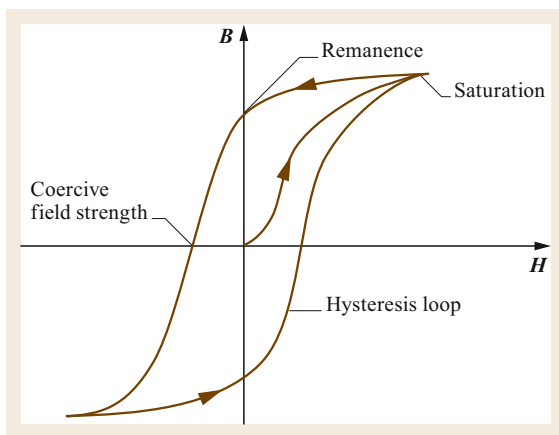

**Fig. 7.34** Schematic depicting the enlargement of Weiss regions

approximately 10–1000  $\mu\text{m}$  in size. The direction of magnetization is determined by the crystal lattice of the material. Boundaries between Weiss areas are called Bloch walls. Upon the application of a magnetic field that increases in strength over time, the Bloch walls shift to favor the creation of areas that are oriented towards the external field [7.20]. More and more areas change their polarities until saturation is reached, as shown in Fig. 7.34.

### Losses

The relationship between  $\mathbf{B}$  and  $\mathbf{H}$  is given by a nonlinear function  $\mathbf{B} = f(\mathbf{H})$  representing the hysteresis loop. The magnetic flux density  $\mathbf{B}$  is determined by the surrounding magnetic field strength  $\mathbf{H}$ . If  $\mathbf{H}$  increases above a certain threshold,  $\mathbf{B}$  increases only very slightly due to saturation. When the magnetic field decreases, the flux density decreases too, but a residual magnetism known as the *remanence* remains due to the aligned Weiss regions. This remanence only disappears when an opposite field with a coercive field strength is activated. The resulting curve (shown in Fig. 7.35) is called the hysteresis curve.

The nonlinear hysteresis curve makes the transformer into a nonlinear two-port. A sinusoidal primary voltage produces a sinusoidal primary current but

**Fig. 7.35** Hysteresis curve

a nonsinusoidal secondary voltage. For quasi-stationary fields, the effective flux in the transformer winding is the product of the current strength and the number of turns. As shown in Fig. 7.36, a nonlinear flow can be generated pointwise by mirroring the hysteresis curve [7.21].

The hysteresis curve cannot be represented as a cohesive mathematical function. This causes some problems when constructing transformers and attempting to perform calculations for them. In particular, the switch-on behavior and possible resonances in the network are influenced by the nonlinearity. Today, this can be calculated and simulated very precisely using numerical methods, but the effort involved is still significant because the nonlinearity generates unwanted harmonics in the network.

Remagnetization of the Weiss regions generates losses known as hysteresis losses  $P_{L\text{Hysteresis}}$ . These are proportional to the area of the hysteresis curve and are a component of the iron losses  $P_{L\text{Fe}}$ . However, the alternating magnetic flux induces a voltage in not only the surrounding windings but also the iron core itself. This voltage induced in the core drives eddy currents in the core perpendicular to the magnetic flux, resulting in eddy current losses  $P_{L\text{Eddy Currents}}$ . Thus,

$$P_{L\text{Fe}} = P_{L\text{Hysteresis}} + P_{L\text{Eddy Currents}} \quad (7.41)$$

The eddy current losses heat up the iron core. As these eddy currents flow perpendicular to the magnetic flux, they can be effectively reduced by laminating the core, as illustrated in Fig. 7.37.

Another effective way of reducing eddy currents in the iron core is to increase the ohmic resistance of the core material.

### Acoustic Noise

The transformer core produces noise due to magnetostriction. As already discussed, the Weiss regions align themselves when an alternating magnetic field is applied. As the dipoles rotate, the length of the material changes in the direction of the field. Depending on the material, this change in length can be as much as 2 mm/m [7.22]. Since the operating frequency for

**Fig. 7.36** Pointwise construction of the nonlinear flow due to hysteresis

**Fig. 7.37** Eddy currents in the iron core (*left*) and the use of core lamination to reduce these currents (*right*)

transformers and reactors in Europe is 50 Hz, noise with double this frequency (100 Hz) is typically generated. The noise generated in this way is directly dependent on the induction in the transformer. Since acoustic noise is an important type of noise pollution in urban centers, the noise from transformers must be limited. Noise development can be effectively reduced by lowering the induction from the normal range of 1.7–1.85 T to approximately 1.2 T. However, lowering the induction leads to a larger and more expensive transformer. Transformer noise can also be reduced by improving the clamping of the core, as this suppresses the transmission of the core noise via the tank walls to the surroundings of the transformer.

### Materials

Until the start of the 1960s, transformer cores were manufactured with hot-rolled core sheets. Core sheets with a thickness of 0.5–0.35 mm were first hot-rolled and then insulated with a layer of varnish. Due to their magnetic properties, these sheets allowed a maximum induction of  $\approx 1.55$  T based on the isotropic properties caused by the melt and the resulting hysteresis. In order to guarantee the strength of the limbs, both the core limbs and the upper and lower yokes were held together by insulated, nonmagnetic steel bolts that passed

through holes punched in the core sheets. These bolts braced nonmagnetic core clamping elements on both sides of the core, thus tightening the whole core. A further advantage of applying the varnish insulation to the core sheets was that the edges of the punched holes could be reinsulated with insulating lacquer. Unfortunately, the insulating lacquer was found to detach itself after several years of operation. The original insulating lacquer, which was made of water glass and named after its inventor, Drengenburg, formed an ochre-brown sludge after several years. Also, synthetic resin lacquers used subsequently were not permanently resistant to oil and high temperatures, which led to a reduction in the service life of the transformer due to repeated core burns. Rapidly increasing energy demands in the 1950s resulted in increasingly powerful and large transformers with high no-load losses, but this increase was ultimately limited by the low induction in the hot-rolled sheets, especially with regard to transportability. For this reason, new processes were developed in the USA in the mid-1950s in which transformer core sheets were alternately cold rolled as strips and then annealed again, yielding anisotropic grain orientation (texture) in the magnetic regions. During annealing, a very thin layer (2–5  $\mu\text{m}$ ; similar to an enamel layer) of inorganic material (phosphate) was applied as insulation to the very thin glass surface of the metal sheet. This new insulation proved to be long lasting and efficient even at extreme temperatures (several hundred  $^{\circ}\text{C}$ ).

Along with using a higher silicon content to increase the ohmic resistance, the core sheet quality was drastically improved. The packing density of the core sheets was increased, the sheet thickness was reduced to 0.23 mm, and the working induction in the cores was increased to over 1.8 T. Due to the higher silicon content and the application of selected alloys, magnetic aging of the sheets was prevented. This breakthrough, in conjunction with the development of indestructible

**Fig. 7.38** Evolution of losses in the core material over the last half-century according to Thyssen Krupp Electrical Steel [7.23]

core insulation, permitted the creation of transformer cores that age extremely slowly.

Hysteresis losses were effectively reduced by increasing the orientation of the grains, and eddy current losses were decreased by making the sheet thinner and by using a higher silicon content to increase the resistance of the sheet material. However, this approach also has its limits, because the number of sheets required for the core increases as the sheet is made thinner, resulting in the need for greater manufacturing effort and increasing costs.

The development of so-called Hi-B sheets with even stronger grain orientation and a special surface coating led to a further reduction in losses and decreased magnetostriction, suppressing acoustic noise. Current developmental work in the field of transformers includes attempts to reduce the size of the magnetic domain walls, thus reducing eddy current losses, by laser treatment of the sheet surfaces. Also, research aimed at refining the domain structure by optimizing the coating and eliminating near-surface crystal defects appears promising. Figure 7.38 illustrates the progress made in reducing specific sheet losses in recent years.

Recently, cores made of amorphous material have been produced for smaller transformers. The lack of

grain orientation eliminates hysteresis losses. The application of new core designs such as strip or tape-wound cores that have technological advantages also enables cost savings. However, amorphous material is yet to become established as a core material for larger power transformers. Since the core losses from the transformer occur during no-load operation, reducing these losses also saves a considerable amount of energy, aiding efforts to protect the environment and climate. In recent years, substantial loss reductions have been achieved with new metal sheets.

### Construction Types

The first three-phase transformers (employed along the previously mentioned Lauffen–Frankfurt test track in 1891) used a temple-type core construction, as shown in Fig. 7.39. This core type is still used today for three-phase reactors.

Later, core types diversified in two directions. In the USA, shell-type cores became popular, whereas the flat core types introduced by Dolino-Dobrowolski became established in Europe. Figure 7.40 shows various designs of the active parts of single- and three-phase transformers. The windings are colored red (LV side) or yellow (HV side).

Because they are vertically orientated, shell-type cores require little floor space but considerable height clearance during transportation. They are more complicated to produce, but represent the only option for power plants with little floor space. Flat-core types (so-called limb cores) require more floor space but a much lower height clearance during transportation. Due to the generally low height clearance available when transporting transformers by rail, flat-core types have established themselves in Europe. The five-limb core was developed for extremely large power trans-

**Fig. 7.39** Three-phase temple-type core

**Fig. 7.40a–e** Various designs of the active parts of single- and three-phase transformers. (a) Single-phase transformer with a shell-type core. (b) Three-phase transformer with a shell-type core [7.10]. (c) Single-phase transformer with a flat two-limb core. (d) Three-phase transformer with a flat three-limb core. (e) Three-phase transformer with a flat five-limb core

formers. Since some of the magnetic flux flows through the outer return flow limbs, which have half of the core's cross-section, the yokes can also be flatter in flat-core types, so that even three-phase transformers with a power range exceeding 1000 MVA can be built for rail transportation. There is also a design with two additional outer return limbs on the single-phase transformer, resulting in a four-limb core.

Since there is no insulation at the cut edges of the core laminations, transitions from the core limb to the yoke are designed to have one protruding lamination (achieved using bevel cuts). This means that each cut edge without sheet insulation is always opposite a larger sheet with insulation. This is known as step-lap construction. The sheets of limbs and yokes are cut at an angle such that the ends of the legs look like roofs (they are said to be roof cut).

#### Core Clamping and Grounding Systems

To press the core sheets together, core clamps made of wood or steel are used at the top and bottom. The core clamps on the two sides of the core are connected via bolts or straps. In order to absorb the short-circuit forces and the forces of the own transportation weights, the upper and lower core clamps are then connected to tie rods on each side of the core. Each transformer manufacturer has developed its own system of tie rods. Originally, four external tie rods were used on each side of a three-limb core. This configuration is still frequently used today for smaller and medium-sized

**Fig. 7.41** Transformer cores with step-lap and outer tie rods [7.24]

transformers. Figure 7.41 shows transformer cores with roof-cut, step-lap, and outer tie rods.

Internal tie rods that also act as vertical core clamps are used in large transformers. The tie rods are installed below the core clamps on the upper and lower yokes. Originally, hot-rolled cores were bolted through holes in the core sheets so that the core clamps on both sides of the core could be connected, but this type of construction cannot be used for cold-rolled cores. Punching holes through cold-rolled core sheets destroys the sheet insulation, and it is not possible to reliably reinsulate the punched holes with paint. Therefore, cold-rolled cores

**Fig. 7.42a,b** Modern three-limb (a) and five-limb (b) cores with inner tie rods [7.25]

are usually braced using circumferential strips of non-magnetic steel or fiberglass tape (see Fig. 7.42). The core clamps are still connected via bolts, but these are placed above and below the yokes, as can be seen in Fig. 7.42b. This approach also maintains the effective core cross-section, unlike passing bolts through holes in hot-rolled core sheets, which reduces the effective core cross-section.

Connecting the tie rods directly to the yokes would create short-circuit windings, so they are insulated from each other. The different parts of the clamping system as well as the core are connected to ground via cables, and the ends of these cables are sometimes accessible via small bushings on the tank cover. The core itself is grounded using a core sword, which is a metallic nonmagnetic sheet placed in between the core sheets. This creates a capacitive grounding impedance. If this grounding system is accessible via small bushings, it is possible to perform measurements during servicing to check that the core is still isolated from the clamping structure. This type of grounding is called CC/CL, which refers to core clamping and core lamination.

## 7.2.2 Windings

In a transformer, high voltages and large currents are concentrated into a small space, meaning that large electric and magnetic fields and high temperatures and forces are generated. This is due to the compact nature of the active parts of the transformer (mainly the windings and core).

### Calculation and Construction

In the following, the most important steps of the winding calculation are described. The basis of all transformer calculations, even when performing computer-

aided optimization, is the transformer equation (see Sect. 7.1)

$$V = \frac{2\pi f}{\sqrt{2}} w A_{\text{Fe}} \cdot B_{\text{max}} \quad (7.42)$$

Assuming that the primary voltage  $V$  and the frequency  $f$  are defined by the network and the maximum induction  $B_{\text{max}}$  is limited by the core material,  $B_{\text{max}}$  depends on the number of winding turns  $w$  and the effective core cross-section  $A_{\text{Fe}}$  via

$$B_{\text{max}} = \frac{V}{\frac{2\pi f}{\sqrt{2}} w A_{\text{Fe}}} \propto \frac{1}{w A_{\text{Fe}}} \quad (7.43)$$

This equation enables a certain degree of flexibility in transformer construction. For instance, the designer can choose a large core cross-section  $A_{\text{Fe}}$  and a smaller number of winding turns, leading to a reduced need for conductor material at the expense of requiring more core iron. On the other hand, the designer can increase the number of winding turns  $w$  to reduce the amount of core material needed. In order to find the optimal solution based on many additional boundary conditions, the calculation is performed iteratively until a certain optimization criterion is reached. This is done because various parameters are strongly dependent on each other, so if one of them is modified, many others will also be affected. Modern numerical calculation programs used by transformer manufacturers perform optimization based on not only technical parameters but also economic ones. If, for example, the global market price of the core lamination is low compared to the price of copper, transformers with larger core cross-sections  $A_{\text{Fe}}$  and fewer winding turns  $w$  are designed. If the conductor material used in the windings (preferably

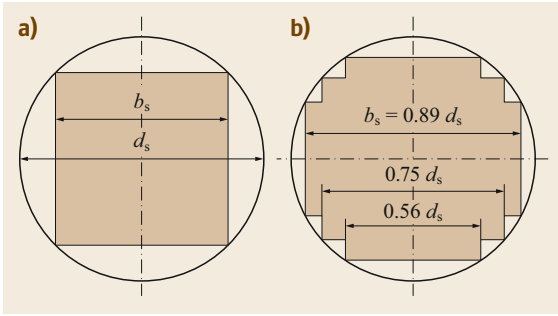

**Fig. 7.43** Simplified axial cut through the active parts of a three-phase transformer with a flat core

copper) is inexpensive but the core material is expensive, smaller core cross-sections and a larger number of winding turns are preferred. Therefore, it is possible that a transformer that was calculated and built a few years ago has identical technical data to a transformer that has just been calculated using a completely different active part design.

However, the design flexibility for transformers is limited by numerous boundary conditions. For large power transformers, the permissible transport height limits the leg length, and the distance between the legs cannot be increased infinitely, since the winding diameter is limited by the transport width. In addition to the specified technical data such as nominal voltage, test voltage, nominal power, vector group, maximum no-load and short-circuit losses, short-circuit impedance, temperatures, noise, and maximum dimensions and masses, there are also a large number of additional boundary conditions in the design, such as specified connection dimensions. Due to the variety of variables, optimization based on certain objective characteristics such as costs, losses, maximum performance, or other parameters is only possible if restrictive boundary conditions are assumed, even when using the latest calculation software. Since each modified calculation involves considerable design work, two different methods of dimensioning are used. For small and medium-sized transformers, a modular principle is often used; in other words, for the same core series, the windings are provided according to the specified voltage and vector group. This saves design costs and expenses associated with technological preparation, which are often markedly higher than the possible savings from opti-

mization (e.g., in terms of material prices). However, large power transformers are always recalculated and redesigned. The repetition rate for these designs is usually on average about 2–3 objects per calculation for manufacturers. In the following, the essential steps involved in the design and calculation of a transformer and its windings are addressed.

The dependencies of a simple design are shown in Fig. 7.43, which illustrates parts of a section through a three-phase core transformer with just one LV winding and one HV winding. The radial space available for the windings in the so-called core window (half the space between the core limbs) is reduced internally by the insulation distance of the windings from the core (a space that also serves to support the windings on the core limb). On the outside half, the insulation distance between the windings of the different phases must be subtracted. This distance must be correspondingly large and well designed in terms of insulation because the full phase voltage is applied between the adjacent windings on different limbs. The available winding space is reduced axially at the top and bottom by the insulation distances to the partially sharp-edged corners of the core yokes. Furthermore, the structures used for the short-circuit-proof axial bracing of the windings must also be accommodated within this distance. The sizes of the mentioned distances that reduce the winding space depend to a large extent on their type and design, and therefore vary from manufacturer to manufacturer. However, regardless of the manufacturer, the following simplified procedure for transformer design along with winding calculations and winding construction can be described, based on the simple design shown in Fig. 7.43:

**Fig. 7.44a,b** Simplified representation of the transition from the square leg cross-section (a) to the usual core grading (b)

1. *Initial data.*

The (phase-to-phase and phase-to-ground) voltages, currents, and the rated power within the transformer are calculated according to the specified data and (in particular) the specified vector group.

2. *Number of turns on the LV winding.*

The integer number of turns  $w_{LV}$  for the LV winding is calculated using (7.43), assuming typical maximum induction  $B_{max}$  and effective core cross-section  $A_{Fe}$  values for the specified rated power.

3. *Core sheet material, geometry, and dimensions.*

This includes specifying the core lamination material and lamination thickness, determining the geometric core cross-section through back calculation from the effective core cross-section (with the packing density of the core lamination considered to be a design-dependent empirical value from the respective manufacturer), determining the leg geometry along with the number of core leg steps and their size, and deriving the core leg diameter.

Circular windings are produced because this shape has the best ability to withstand short-circuit forces, so the lamination distribution must be adapted to the core diameter  $d_s$  by grading the lamination stacks, as shown in Fig. 7.44. The optimal lamination width  $b_s$  and the corresponding core steps are determined using mathematical optimization programs.

The core diameter  $d_s$  determined in this way serves as the starting point for the radial winding design.

4. *LV winding type, conductor cross-sections, parallel wires, number of layers, and length and width.*

This involves selecting the LV winding type, determining the required conductor cross-section based on empirical values, and initial geometrical dimensioning of the winding according to the parallel wires, number of layers, and the length and width.

5. *Number of turns for the HV winding.*

The number of turns for the HV winding  $w_{HV}$  is calculated based on the specified voltage ratio, taking the vector group into account.

6. *HV winding type, conductor cross-sections, parallel wires, number of layers, and length and width.*

This includes selecting the HV winding type, determining the required conductor cross-section based on empirical values, and initial geometrical dimensioning of the winding according to the parallel wires, number of layers, and the length and width.

7. *Stray voltage.*

The stray voltage  $V_s$  is determined as it provides the basis for determining the short-circuit voltage. Since the stray voltage is the main contributor by far to the short-circuit voltage in normal transformers, it is important to correctly dimension this parameter. In the event of a short circuit, the induction in the transformer core largely collapses. Therefore, the stationary short-circuit current  $I_k$  is essentially limited by the inductance  $X$  (see Sect. 7.1) that is formed by the stray field in and between the windings. The idealized distribution of the leakage flux for the two-winding transformer with just one stray duct mentioned above is shown in Fig. 7.45.

From the above representation, the percentage stray voltage drop  $v_s$  can be derived starting from

$$X = 2\pi f \mu_0 w^2 \frac{U}{h_w} \left( t_{12} + \frac{t_1 + t_2}{3} \right) \quad (\Omega) . \quad (7.44)$$

Here,  $U$  is the mean circumference of the stray gap. Using  $\mu_0 = 4\pi \times 10^{-7} \text{ N/A}^2$  and  $XI = V_s$ , we obtain

$$V_s = I 8\pi^2 f w^2 \frac{U}{h_w} \left( t_{12} + \frac{t_1 + t_2}{3} \right) \times 10^{-7} \quad (\text{V}) \quad (7.45)$$

if all dimensions are in meters. Upon introducing the relative stray voltage  $v_s = V_s/V \times 100$  as well as the winding turn voltage  $V_w$  with  $V = V_w w$ , normalizing the frequency to 50 Hz, and dividing the mean stray gap circumference  $U$  by the mean of the inner and outer coil circumferences  $(U_1 + U_2)/2$ , the following is achieved

$$v_s = 8\pi^2 50 \frac{f}{50} \frac{I}{V_w} w \times \frac{(U_1 + U_2)}{2h_w} \left( t_{12} + \frac{t_1 + t_2}{3} \right) \times 10^{-5} \quad (\%) . \quad (7.46)$$

The leakage flux distribution shown in Fig. 7.45 is idealized and based on various assumptions; for example, that the windings are completely surrounded

**Fig. 7.45** Idealized leakage flux in the leakage channel and in the windings

at the end sides by core laminations with infinite permeability. This is not the case in reality, so Fig. 7.46 shows the magnetic leakage field through the windings and the leakage field duct determined numerically with a 2-D model.

It can be seen that the magnetic stray field at the upper and lower ends of the winding deviates from the idealized field distribution. As it is still not possible – even with modern simulation tools – to calculate the leakage flux numerically in three dimensions because a complete 3-D model of all windings along with each individual conductor (including junctions, insulating parts, and leads) is required, a correction factor is used. This factor was developed by Walter Rogowski in Germany at the beginning of the last century. The Rogowski factor

**Fig. 7.46** Simulation of leakage flux using a 2-D model [7.10]

$k_R$  accurately determines the deviations of the actual field curve shown in Fig. 7.46 from the original assumed curve depicted in Fig. 7.45, and is calculated via

$$k_R = 1 - \frac{t_1 + t_{12} + t_2}{\pi h_w} \left( 1 - e^{-\frac{\pi h_w}{t_1 + t_{12} + t_2}} \right). \quad (7.47)$$

This leads to an equation for calculating the percentage stray voltage drop,

$$v_S = 8\pi^2 50 \frac{f}{50 V_w} \frac{\mathbf{I}}{w} \times 0.5 \frac{(U_1 + U_2)}{h_w} \times \left( t_{12} + \frac{t_1 + t_2}{3} \right) k_R \times 10^{-5} \quad (\%), \quad (7.48)$$

which can be simplified to

$$v_S \approx 2 \frac{f}{50 V_w} \frac{\mathbf{I}}{w} \frac{(U_1 + U_2)}{h_w} \times \left( t_{12} + \frac{t_1 + t_2}{3} \right) k_R \times 10^{-2} \quad (\%). \quad (7.49)$$

Today, various correction factors that allow precise calculations are available, even for complicated winding arrangements. For very large transformers where there is a risk of heating in the core clamping elements and tank walls due to eddy currents caused by the leakage flux, the maximum leakage flux in these components is determined via 2-D field calculations for simplified winding models. These results are then converted to be applicable in three-dimensional reality using correction factors based on empirical values.

If the determined stray voltage is not within the required range, the situation must be modified. Increasing the radial winding dimensions and the width of the stray channel causes an increase in the stray voltage, whereas increasing the winding length and thus the stray gap length reduces the stray voltage. Due to the eddy current losses explained below and the dependence of the ohmic winding losses on the winding circumference, the radial winding width must be kept as small as possible, which limits the flexibility of the electrical designer accordingly.

8. *Winding losses or short-circuit losses.*

The preliminary specifications of the winding dimensions, the stray channel width, and the stray channel length provide the fundamentals required to calculate the short-circuit losses. The ohmic resistance of each winding is the specific resistance of the winding material multiplied by the average turn circumference and the number of turns. The conductor losses are determined as the product of the squared current and the resistance. As the windings are not evenly penetrated by the stray field, even in the simplified diagram shown in Fig. 7.45, current displacement occurs, leading to increased resistance, which is accounted for in the calculations by introducing correction factors. Eddy currents and associated eddy current losses also occur in the windings, analogous to the core laminations. The alternating magnetic flux induces a voltage not only in the windings but also in the winding wire itself. This voltage drives eddy currents in the conductor perpendicular to the magnetic flux lines, which additionally heat up the windings and contribute to the total losses from the windings. According to the idealized stray flux distribution in the windings shown in Fig. 7.45, the conductors that are closest to the stray channel are subjected to the highest stress and therefore become the hottest. In this case, subdividing the conductor width can provide effective compensation. Because the stray field decreases with distance from the stray channel, there are different induced voltages in parallel conductors, leading to additional compensation currents. In order to avoid these balancing currents that also increase the temperature and the losses, the conductors are twisted parallel to the stray channel. These conductors are called transposed conductors. The percentage voltage drop  $v_R$  can be then determined from the sum of the ohmic losses and eddy current losses. At the same time, it is important to check that the heat caused by the losses in the windings can be effectively dissipated. This can be roughly

estimated by considering both the losses and the available cooling surfaces of the windings.

9. *Determining the short-circuit voltage.*

As discussed in the last section, the percentage short-circuit voltage can be calculated via

$$v_{sc} = \sqrt{v_R^2 + v_S^2}. \quad (7.50)$$

Thus, the calculated voltages  $v_R$  and  $v_S$  must be adjusted until the specified short-circuit voltage is achieved.

10. *Core design and determining the no-load losses.*

Provided the winding height and the diameter of the outer winding have been specified, the dimensions of various aspects of the core, such as the leg diameter, the center limb distance between the legs, and the leg length can be determined by adding the empirical values for the distances in Fig. 7.43 to the respective dimensions. It is then possible to calculate the core losses. These are determined from the respective inductions  $B_{max}$  for the core limbs and the yokes, which should be as equal as possible, and by multiplying by the respective sheet masses, taking into account material parameters and design correction factors. If parameters specified by the customer or standard specifications are not achieved, the calculation process is restarted. If the calculated core losses are too low, the transformer may be too large and heavy and thus too expensive. If the no-load losses are too high, either the number of winding turns or the leg cross-section  $A_{Fe}$  must be increased, see (7.43). Both of these actions cause the induction and therefore the no-load losses to decrease. However, the effect of decreasing the induction by increasing the effective cross-sectional area of the core limb is limited, just like the effect of lengthening the core limb to increase the number of winding turns, because both procedures increase the core mass and therefore the no-load losses.

11. *Determining the voltage stress in windings and leads.*

Winding insulation is dimensioned according to the test voltages, which are defined in national and international standards. For example, a modern 400 kV power transformer is usually tested by applying a voltage of 630 kV for 1 min, a switching impulse voltage of 1175 kV, and a lightning impulse voltage of 1425 kV, based on the IEC standards. It must be able to withstand these overvoltages without showing any defects that could lead to partial discharges (PDs). Normally, the insulation structure of the windings would have to be calculated and dimensioned axially towards the yokes and radially

**Fig. 7.47** Windings with soft paper insulation and so-called goosenecks, which are formed under axial winding pressure

towards the core leg and the adjacent winding for complicated insulation arrangements such as that illustrated in Fig. 7.47. Design engineers account for the fact that insulation can withstand much higher electrical field strengths if the field is active for a very short time (lightning and switching impulses) than if the field is active for a much longer period (e.g., 1 min in the applied voltage test). Therefore conversion factors (which vary slightly from manufacturer to manufacturer) are used to make the various short-term and long-term voltage stresses comparable. If the test voltage is multiplied by a correction factor, a uniform comparison value for different voltage stresses can be derived: the so-called design insulation level (DIL), which represents the maximum voltage stress permitted for the insulation. For normal power transformers, the 1 min applied voltage test is usually assigned a correction factor of 1. High DIL values for the switching or lightning impulse tests are only obtained using the conversion factors when the switching or lightning impulse stresses are particularly high. This process has led to standardized insulation design.

Paper impregnated with mineral oil has proven to be the ideal insulator for high voltages, whereas insulation systems based on epoxy resin or gas can be used up to medium voltage levels. Therefore, transformers can be split into three categories: liquid-filled transformers, gas-insulated transformers, and dry-type transformers. Mineral-oil-filled transform-

ers are very complex to manufacture, and when the windings are pressed so-called goosenecks can be formed, with fatal consequences (reduced cooling, PD generation), as shown in Fig. 7.47. However, the development of molded parts made from pressboard by the Swiss company *Weidmann AG* in the 1960s led to the creation of a much more technologically stable manufacturing process and better insulation [7.26, 27].

Insulation schemes have developed and improved over time. Insulation of winding ends is now carried out radially using pressboard barriers and axially with angle ring segments made from pressboard moldings and pressboard rings, as shown in Fig. 7.48. High field strengths at the corners of windings are reduced by shielding rings with conductive foils that are connected to the potential of the winding exit, as shown in Fig. 7.49.

To accelerate and thus optimize the winding assembly process, the components of the insulation are increasingly being preassembled by suppliers [7.28]. Electric field strengths and creepage distances are taken into account when designing an insulating arrangement. In the past, this was often a very difficult task, but engineers now have access to powerful workstations that can perform 2-D and 3-D calculations; the latter became available at the beginning of this century. Since most of the insulation arrangements used today were actually developed in the 1960s when computers were not available, there is still room to improve these insulation arrangements.

**Fig. 7.48** Upper edge field insulation made with molded pressboard parts, which eliminates goosenecks. The components of the insulation follow the electrical field better than the arrangement shown in Fig. 7.47

**Fig. 7.49** Upper and lower edge field insulation with shield rings and yoke collars (angle-shaped barriers) made of pressboard segments. High-voltage windings are enclosed by angle-shaped barriers towards the yokes and shield rings at the winding ends for dielectric control

Switching and lightning voltages are not sinusoidal and include higher frequencies due to their shapes. Therefore, it is rather complicated to calculate the propagation of these surge waves in the windings. Calculations of detailed equivalent circuits have, however, led to improvements in winding design, such as the development of interleaved disc windings.

- Following the calculations of the winding insulation, the short-circuit strength must be verified.
12. *Determining short-circuit forces and calculating the winding pressure and compaction.*

According to the Lorentz force law, a force is exerted on each current-carrying conductor in a magnetic field. This force is always perpendicular to the field lines of the magnetic field and the direction of the current. Assuming the ideal stray field distribution shown in Fig. 7.45, the conductors of the windings are only stressed by radial forces. The forces on the inner winding are directed toward the inside, and those on the outer winding are directed towards the outside, as shown in Fig. 7.50. This figure also shows that the force has an axial component as well as a radial one at the ends of the windings, as also indicated by Fig. 7.51. The axial forces result in axial pressures in the windings, as shown in Fig. 7.52 [7.29].

Winding wires are usually insulated with paper and the winding supports are made of pressboard. These insulating materials deform plastically under high pressure, which reduces the winding tension. This can destroy the winding because the reduced winding tension cause the winding to vibrate more, which leads to a grinding of the insulation until the winding is destroyed. Thus, after the production and drying processes, the windings are axially prepressed under forces and pressures that are at least as large as those that occur during a short circuit. This allows the effect of a short circuit to be simu-

**Fig. 7.50** Stray field distribution and short-circuit forces in windings

**Fig. 7.52** Axial forces and pressure in the windings (A axial current forces, B resulting axial pressure)

**Fig. 7.51** Short-circuit forces on the top of a winding

**Fig. 7.53** Conductor tilting under high axial stress

lated in advance, and ensures that further loosening of the windings cannot occur in an extreme case. In addition, the axial forces can tilt the conductors as shown in Fig. 7.53 if the geometric conductor dimensions are unfavorable (i.e., if the width is too small in the radial direction and the axial length exceeds the maximum value). This must be considered during the design process too. As a rule of thumb, the finished windings are actually prepressed by applying forces and pressures that are almost up to the tilting limit, markedly beyond those associated

with axial short-circuit forces. If calculations indicate that the wires are already tilting away when the axial force applied is equivalent to that encountered during a short circuit, the designer must redesign the windings, even though many other calculations will have already been carried out. This is necessary because selecting other winding wires changes almost all of the other parameters.

However, short-circuit stress causes not only radial and axial forces in the winding wires but also tangential tensile forces, as shown in Fig. 7.54 [7.30]. If the tangential pressure stress on the windings is too high, *buckling* occurs during the short circuit, as illustrated in Fig. 7.55.

Every power transformer must be able to withstand an external short circuit for a short time (usually 2 s). For calculation purposes, the short circuit is assumed to occur directly at the transformer terminals. However, if a short circuit occurs within the trans-

Fig. 7.54 Tangential tensile forces

Fig. 7.55 Buckling due to high short-circuit forces

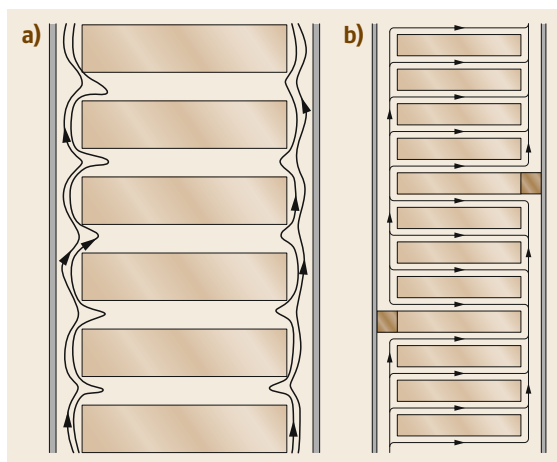

Fig. 7.56a,b Cooling without (a) and with (b) guided oil flows

former, the situation is completely different, and the consequence is often the catastrophic destruction of the transformer.

### 13. Calculating the cooling of the windings and winding hot spots.

Once the winding dimensions have been determined, the cooling of the windings and winding hot spots must be calculated. Cooling liquids such as mineral oils are incompressible, meaning that heat flow calculations are simpler for oil-cooled than for air-cooled transformers. However, the viscosity of the insulating liquid is temperature dependent.

In the past, windings were usually cooled exclusively by the thermosiphon effect, which is based on the difference in density between hot and cold insulating fluid. In this approach, the heated oil

risks in the insulation channels of the windings, which hinders the cooling process, especially for disk windings. Increasing power ratings led to increased heat generation in the windings, making improvements necessary.

One of these improvements was the transition to guided oil flows, as shown in Fig. 7.56. In this process, barriers that take the form of oil control segments around the winding in the axial cooling channels force oil to flow over the entire surface of each disc coil. For even better cooling performance, pressure chambers are built into the winding blocks at the lower end of the windings. These chambers are filled with oil under pressure, which is then forced into the oil channels of the windings.

The insulation is usually made of cellulose, which is subject to thermal aging. For this reason, maintaining an appropriate temperature range is crucial to achieving a long transformer service life. The hot spot temperature in the upper area of the winding is the most important factor to consider. In addition, the temperature jump between the oil inlet and outlet for the winding must be maintained precisely to ensure the stability of the entire cooling system. The whole temperature distribution is usually calculated through analogy: by simulating the temperature transitions as thermal resistances based on precise measurements and calculating the overall effect linearly in the form of a thermal resistance network.

If any problems are encountered during the temperature calculations, the calculations are usually performed again until all of the requirements are fulfilled. This process depends on the software used and the experience of the designer. Modern computer programs carry out the calculations several hundred times to optimize the system.

Once the designer has finally successfully dimensioned the windings using the procedure described above, and assigned values to all of the specified parameters, the mechanical designers begin their work. They prepare production and assembly drawings according to the specified winding data. Since engineering hours are expensive, the proportion of the transformer manufacturing process that is devoted to electrical and mechanical design is a decisive cost factor.

### Conductors and Insulating Materials

Today, the conductors used in windings are generally made of high-purity copper. In the past, winding conductors were also made out of aluminum due to a lack of affordable copper. Although aluminum is lighter than copper, it also has a higher specific resistance, resulting in larger windings that also require larger cores. However, changes in the prices of these two materials in the

global market have caused aluminum windings to be virtually phased out.

Winding conductors usually have rectangular cross-sections with slightly rounded corners to suppress the generation of excessive electric field strengths. Smaller transformers with round conductors that are usually insulated with enamel lacquer are also manufactured. To enhance the packing density, these round conductors are flattened on both sides. In dry-type transformers, the conductors are often cast directly with resin, or special resin-impregnated fiberglass insulation is used. Rectangular copper conductors are used in fluid-insulated transformers. These are usually insulated with overlapping layers of thin paper up to the required thickness, as shown in Fig. 7.57a.

Transposed conductors, as shown in Fig. 7.57b, were developed to reduce eddy current losses and have largely replaced so-called twisted winding, which is a special form of single-layer winding containing several parallel conductors that are twisted at intervals, as shown in Fig. 7.58. Today, twisted winding is usually only used in smaller transformers or in high-current windings, where either the geometry or the price prohibits the use of transposed conductors.

Especially when the windings are highly thermally stressed, for example in industrial transformers or traction transformers, the paper insulation is replaced with thermally upgraded paper or (even better, but much more expensive) aramid paper. The decisive factor when selecting the insulation material is the thermal class, as shown in Table 7.3.

Dry-type transformers designed for thermal classes E–H require special insulation materials. The insulation materials previously used for class H contained asbestos, which is carcinogenic, so it is no longer allowed.

Conductors used in windings can also take the form of a foil made of copper or aluminum. The utilization of foils drastically reduces eddy current losses while offering a high current-carrying capacity. They are mainly used as LV windings in distribution transformers.

**Fig. 7.57**  
 (a) Conductor strand with paper insulation.  
 (b) Continuously transposed conductors

**Table 7.3** Thermal classes for transformers according to the relevant IEC standard [7.31, 32]

	Transformer part	Thermal resistance class				
		A	E	B	F	H
Dry-type transformer	Windings (K)	60	75	80	100	125
Oil transformer	Windings (K)	65	Normal			
		70	Forced cooling			
	Oil in upper layer (°C)	60	Normal case (conservator)			
		55	Without conservator and airtight closure			
	Iron core and other parts	Excessive temperatures must not damage neighboring parts				

**Fig. 7.58** Twisted winding

hand, from the perspective of manufacturing technology, disc winding is a cylindrical winding made of disc coils. In the following, the most important windings are categorized according to manufacturing technology.

**Layer Winding.** Layer winding, as shown in Fig. 7.59a, is the simplest type of cylindrical winding. It is manufactured on horizontally rotating winding machines and is mainly used for small and medium-sized transformers. Its advantage is its low manufacturing cost, but its disadvantage is its relatively low withstand capability to incoming voltage peaks. This can be increased by reinforcing the insulation of the wires at the edge of the winding and by using edge collars.

In the regulating windings shown in Fig. 7.59b, the individual regulating steps are wound as individual loop-layer windings. This is the most frequently used winding type for regulating windings. The loops that are wound into each other are connected or disconnected depending on the voltage regulation, resulting in an even axial distribution of the magnetic field and eliminating large transverse fields, thus reducing the short-circuit strength of the transformer.

### Winding Types

The long history of transformer development has resulted in the creation of many different types of windings. The most important of these can be categorized based on the following characteristics:

1. Geometric shape (e.g., foil, cylindrical, and disc windings)
2. Function in the transformer (e.g., LV, HV, tertiary voltage (TV), regulating windings (RW))
3. Manufacturing technology (e.g., layer, helical, and disc windings).

Note that the disc winding referred to in geometric categorization is a special form of winding in which the LV and HV disc coils alternate. Therefore, the stray channels are parallel to each other, leading to extremely low stray voltages. This design is therefore used only for special high-current and test transformers. On the other

**Fig. 7.59** (a) Layer winding with edge collar. (b) Single-layer winding used as a regulating winding

**Fig. 7.60** Single-layer helical winding

**Helical Winding.** This winding type using transposed conductors was developed for windings with particularly high currents and combines the advantages of layer and disc winding. Several conductors are wound in parallel in the form of a helical coil as shown in Fig. 7.60, whereby the individual winding turns are kept apart by spacers. This type of winding is available in single and double layers; in the latter case, the conductors are twisted in the layer transition.

**Disc Winding.** Disc winding (see Fig. 7.61) is usually employed instead of layer winding when the winding has a large number of turns (as required for high voltages), as disc winding can better withstand transient overvoltages due to an improved capacitive behavior. To avoid the need to reconnect the conductors between the discs after each coil, the second disc is wound in stock and then rewound such that no solder joints are created. Although disc winding is better suited than layer winding to fast transient voltages, these voltages drop in a very nonlinear manner over a few turns, especially at the beginning of the winding in the middle or at the top

**Fig. 7.61** Disc winding

**Fig. 7.62a,b** Comparison of conventional disc winding (a) with interleaved disc winding (b)

of the disc. Inadmissibly high field strengths can arise between the conductors and also between the discs. By interleaving the conductors (i.e., returning the conductors as shown in Fig. 7.62), the capacities between them are artificially increased. This achieves a linear distribution of the transient voltages that penetrates further along the winding. In this way, high local field strengths at the top of the winding can be avoided.

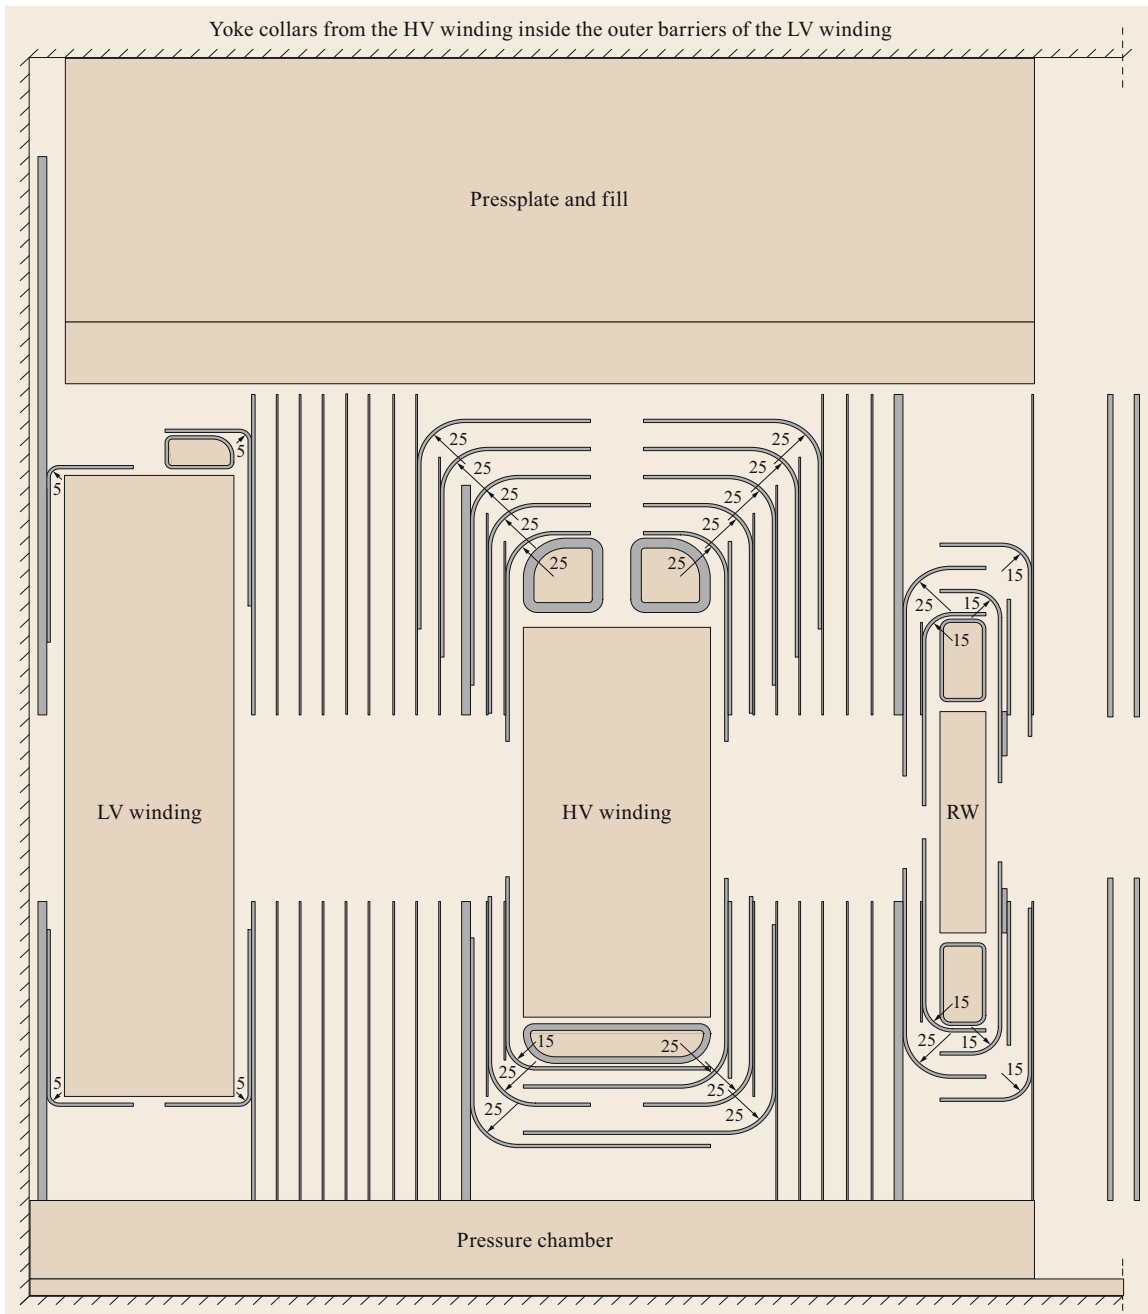

Interleaved windings for large transformers (such as that shown in Fig. 7.62) are usually manufactured on vertically rotating, height-adjustable winding benches.

#### Drying, Compression, and Winding Block Assembly

A winding block consists of all the windings together with their radial and axial supports and press structures. This block is mounted concentrically around one core leg.

**Drying.** In liquid-insulated transformers that mainly use cellulose-based insulating materials such as paper, pressboard, or press wood, the insulation can absorb moisture from the air, reducing the insulating performance. The windings must therefore be dried immediately after manufacturing using thermo-vacuum drying processes.

**Compression.** Subsequent to drying, the windings are compressed axially and then tensioned under low pres-

**Fig. 7.63** Block layout of a 400 kV power transformer with oil-directed cooling via a pressure chamber [7.32]

sure. Two winding pressing processes can be distinguished:

- Hydraulic soft pressing in a vacuum drying oven during drying is a complex (and therefore expensive) but gentle process with high compression efficiency.

- Conventional mechanical winding pressing after drying is less complex and therefore less expensive.

**Winding Block Assembly.** The windings must be assembled concentrically from the inside to the outside while being radially insulated from each other with barriers and oil ducts. The axial end insulations consist

of yoke collars comprising overlapping segments with axial spacer rings between them. Two technological approaches to winding assembly are available:

1. The windings are assembled one after the other directly on the transformer core leg, from the inside to the outside. The winding insulations are completed in the upper area after assembly on the core leg, and the windings are dried and braced together with the active part of the transformer. This approach to assembly takes longer and risks axial elongation of the individual windings due to moisture absorption from the air.
2. A winding block is built separately outside the active part. The windings are preassembled in a block, dried, compressed again, and then mounted in one piece on the core leg. This is much faster and avoids the disadvantages of the first method, but is more complex technologically and in terms of preparation. In this process, hydraulic soft pressing can be used effectively for all windings on the entire winding block.

The main insulation diagram for the winding block of a 400 kV power transformer with three windings (LV, HV, and RWs from inside to outside) shown in Fig. 7.63 represents the classic winding distribution of an oil-immersed power transformer.

### 7.2.3 Tap Changers

Aside from applying magnetic current regulation using the saturation properties of magnetic materials (e.g., using transductors), which is only employed in very special transformers, the most effective way of regulating a transformer in the grid is to change its ratio by modifying the number of windings on one side. For historical reasons, regulation is implemented on the LV side in North America, whereas the rest of the world regulates the voltage by changing the number of turns on the HV side, usually at the neutral point. There are three basic schemes for this type of voltage regulation, as shown in Fig. 7.64. In this figure, the left bar always represents the LV winding and the right bar represents the HV winding, which can be divided into a main and a regulation winding. The regulation winding can consist of a fine winding only or a fine winding and a coarse winding. The neutral point is connected to the regulating winding such that the number of active winding turns can be changed, meaning that the voltage can be adjusted.

Voltage regulation requires a switch that can connect the neutral to different taps on the winding in order to increase or decrease the number of effective turns.

**Fig. 7.64a–c** Voltage regulation schemes: (a) linear, (b) plus-minus, and (c) coarse and fine

This switch is called an on-load tap changer if the voltage can be regulated during operation or an off-load tap changer if it cannot. Depending on the number of voltage steps or taps involved, a lot of conductors (leads) for each phase are needed between the winding blocks and the tap changer, which is usually located on the front side of the active part. Even if the regulation is done on the HV side, several hundred amperes of current can flow through these lead conductors, so their weight is not negligible. Furthermore, forces are applied to these leads during a short circuit, so the whole lead system must be mechanically supported.

#### Lead Support System

The design of the lead support system depends on the manufacturer. Some manufacturers use solid and thickly insulated round copper conductors for the leads because they are very strong. This results in high insulation costs and a lack of mounting flexibility, and requires a complex connection technology. Other manufacturers use industrially insulated round copper stranded wires, allowing greater mounting flexibility at the expense of lower mechanical strength. In principle, all lead support systems have a similar design, which is shown in Fig. 7.65 [7.33].

Patented U-shaped pressboard channels that can enhance the mechanical stability, creepage path strength, and installation are available under a registered trademark [7.34], as shown in Fig. 7.66a,b.

#### Off-Load Tap Changers

Off-load tap changers (see Fig. 7.67) are relatively simple devices that can only be operated without voltage. Modern off-load tap changers have 2–11 positions and

**Fig. 7.65** Leads and lead support system

can handle voltages across the whole tap-changer system of up to 60 kV and maximum currents of 1250 A. Off-load tap changers are widely used in smaller distribution transformers, but are often not operated for years. In such cases, chemical processes in the oil can lead to the formation of deposits, increasing the resistance at the contact surface and generating hot spots on the corroded contact during operation. For this reason, off-load tap changers must be cleaned regularly.

#### On-Load Tap Changers

The main challenge when switching the ratio of a transformer under load is to avoid interruptions in the current flow, because the transformer will then act like an ignition transformer in a vehicle and will probably be damaged. Modern on-load tap changers (OLTC) operate according to the *Jantzen principle*, named after its inventor, in which the switching process is rapid and is performed by contacts operated by energy-

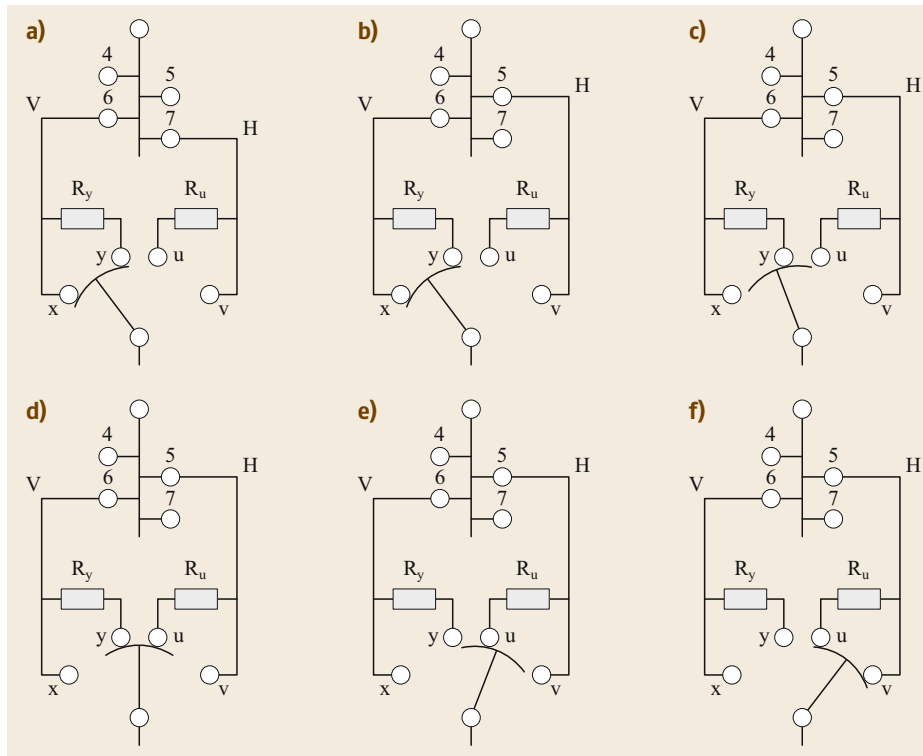

**Fig. 7.67** Off-load tap changers used for voltage adjustment in a high-current test transformer [7.36]

storage devices and switchover resistors without interrupting the current flow. The process used is illustrated by Fig. 7.68. Here, the starting position is tap 6 (Fig. 7.68a), which needs to be switched to tap 5. Therefore, the selector H must move from position 7 to

**Fig. 7.66** (a) Lead support system with special channels for the leads [7.35]. (b) Diagram showing the lead support system in more detail [7.34]

**Fig. 7.68a,b** The Jantzen principle for tap changers [7.37]

position 5 (Fig. 7.68b), after which the diverter switch is operated (Fig. 7.68c–f). In Fig. 7.68d, the switch short-circuits taps 5 and 6 through resistors, which are dimensioned such that the current through the short-circuit loop is in the range of the rated current. In the next step, the connection to tap 6 is interrupted and the connection to tap 5 is established, first via a resistor and then (in the final step) via a direct connection, thus bypassing the resistor. The switch from tap 6 to tap 5 is then complete.

When the contacts open during the changeover process, arcs occur that are only extinguished when the current passes the zero crossing. This results in strong discharges in oil, which is why the tap changer is located in a separate sealed compartment containing oil and is not integrated into the transformer tank. The relevant stages are preselected by the selector, which is located below the diverter switch compartment and installed inside the transformer tank (see Fig. 7.69). When using plus–minus or coarse–fine regulation (see Fig. 7.64), the selector must be equipped with a separate additional changeover switch.

If the tap changer is not working properly, serious damage can be caused to not only the tap changer itself but also the transformer windings – especially regulating windings. Due to the arcing, which leads to burnt contacts and degraded oil, on-load tap changers need

to be periodically serviced. In recent years, improved OLTCs in which the contacts work in vacuum have been developed. This can prolong the service life of the device, but there are also some disadvantages of a vacuum on-load tap changer that make it necessary to check the types of transformers that it can be used with. Figure 7.69 shows a conventional on-load tap changer [7.38].

## 7.2.4 Bushings and Lead Exits

### Structure and Types of Bushings

While unencapsulated dry-type transformers can be connected directly to the network, transformers that use tanks require components that conduct the current through the metallic tank and insulate the high potential of the conductor from the ground potential of the tank. This is achieved through the use of bushings – typically oil-air bushings (i.e., one part of the bushing is in oil, the other part is in air), which can be divided into LV bushings, high-current LV bushings, and HV bushings.

**Low-Voltage Bushings.** For nominal voltages of up to  $\approx 36$  kV, simple, standardized bushings are sufficient, as shown in Fig. 7.70. These consist of an insulator with an inner conductor and are sealed on the cover of the transformer by flat seals or round rubber

**Fig. 7.69** On-load tap changer with a diverter (red frame), selector (blue frame), and motor drive (silver cabinet)

seals. Due to their low voltages and the resulting low field strengths between the conductor potential and the edge of the feedthrough hole in the tank cover, the electric field does not need to be controlled.

**High-Current Bushings.** A high-current bushing is a special type of LV bushing, as shown in Fig. 7.70 [7.39]. Although high-current bushings do not differ fundamentally from LV bushings, they can conduct currents of up to 30 kA. These high currents generate large magnetic fields around the conductor, which can cause enormous eddy currents in the tank cover (which is up to 30 mm thick), and these eddy currents can cause the tank cover to glow if constructive countermeasures are not taken. Therefore, nonmagnetic steel is used around the high-current bushing holes in the tank cover.

**High-Voltage Bushings.** For higher voltages, so-called condenser bushings are used, which are equipped with metal foils radially and are graded axially towards their ends, as shown in Fig. 7.71. The metal foils have equipotential surfaces, so the electrical field

**Fig. 7.70a,b** Low-voltage (a) and high-current (b) bushings

is controlled and homogenized. The foils also act as capacitors, so the voltage and PDs can be evaluated at an integrated measurement tap at the flange of the bushing. The bushing is connected to one of the outer metal layers, forming a capacitive divider.

As can be seen in Fig. 7.71, a HV bushing consists of a solid conductor around which insulating material is wrapped, together with conductive layers at certain distances from the central conductor. An insulator made of porcelain or silicone rubber is used on the outside of the bushing, and the central conductor of the condenser body extends into the liquid-filled transformer tank without any additional insulation. Various types of bushings can be distinguished based on the insulation material used:

- OIP (oil-impregnated paper)
- RBP (resin-bonded paper)
- RIP (resin-impregnated paper)
- RIS (resin-impregnated synthetics).

Although OIP bushings are the oldest type of bushing, they are still used today, in contrast to RBP bushings, which can create a lot of problems when they age. RIP bushings are state of the art, although they may be replaced in the future by the newest technology: RIS bushings. In the latter, the paper used in RIP bushings is replaced with a synthetic material that absorbs less moisture and is more resistant to aging. It should be noted that the lifetime of a transformer usually exceeds the lifetime of a HV bushing, so HV bushings need to be replaced after few decades [7.40]. A bushing failure will often lead to the catastrophic failure of the whole transformer, and the resulting damage will be much more

**Fig. 7.71**  
High-voltage  
bushing [7.7]

expensive than the cost of a new bushing. Thankfully, there are various diagnostic techniques for assessing the condition of a HV bushing.

#### Lead Exits

The components of the transformer that connect the windings directly to the bushings are called lead exits or line leads.

**LV Lead Exits.** The lead exits on the low-voltage side have a similar construction to the leads of the regulation winding shown in Fig. 7.65. Either parallel round conductors or bars made of copper (or, in rare cases, aluminum) are used when there are high currents. It is important to fix the bars in the transformer so that they are protected against short-circuit forces. When there are high currents, the magnetic field generated by the conductors must be included in the stray voltage calculation.

**HV Lead Exits.** For rated voltages of up to 220 kV, the lead exits consist of thick, round conductors that are insulated with thick crepe paper and fixed like the standard lead exits. The field strengths must be observed, and creepage distance stresses on the holders must be limited. For rated voltages above 220 kV, and especially those above 400 kV, the field strength approaches the critical region, so special connections must be used. In this case, the lead exits pass through insulated shielding tubes made out of metal that are connected to the lead exit potential. These thin-walled shielding tubes made from aluminum or copper reduce and homogenize the electrical field strength. The diameter of the tube used increases with the nominal voltage (e.g., a diameter of at least 80 mm is used for a nominal voltage of 400 kV). The insulation on the screen tubes, which is also made thicker for higher voltages, has two negative effects:

1. In thick insulation, dielectric losses can cause heating, which eventually leads to thermal breakdown.
2. In the presence of various dielectric materials, the field strengths are distributed according to the inverse ratio of their permittivities. The permittivities of crepe paper and pressboard are in the range of 3.5–3.8, while the permittivity of insulating oil is 2.2. This means that field stress is higher in the oil, which has a lower dielectric strength than paper and pressboard.

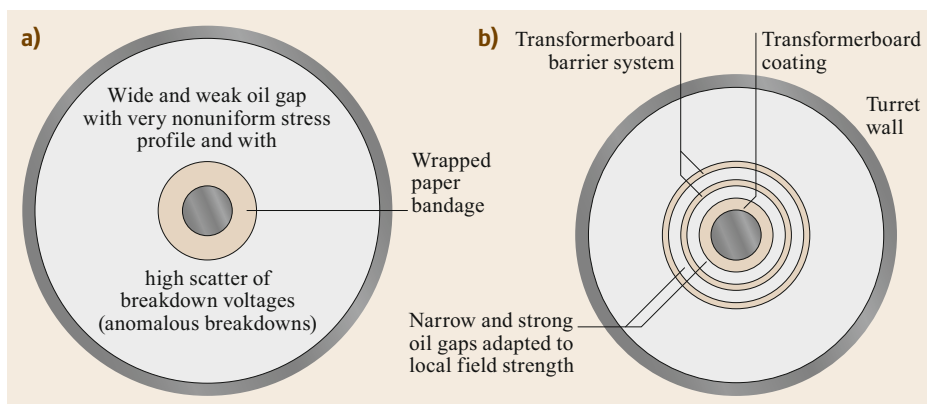

This problem was solved through the development of lead exits with barrier insulation [7.41]. The theoretical basis for this approach (see Fig. 7.72) was developed by a team of researchers and presented in 1998 [7.42].

Instead of pressboard barriers, another approach uses barriers that are made from calendered special crepe paper over flexible strips, which makes the barriers more resistant to breakdown. This approach allows any number of bends to be realized in the lead exit with minimal effort [7.43–45]. Figure 7.73 shows a model and a real-world example of a flexible lead exit system.

### 7.2.5 Cooling Types and Insulating Fluids

The cooling systems used in transformers are internationally standardized and categorized. Each type of cooling system is assigned a two- or four-character code, as described below:

- First character: type of coolant inside the transformer.
- O: Mineral oil or similar with a flash point below 300 °C
  - A: Air (for dry-type transformers)
  - K: Alternative liquid with a flash point above 300 °C

**Fig. 7.72a,b** Comparison between (a) conventional and (b) barrier lead exits. The dielectric strength of the barrier insulation is high, whereas the field enhancement in the oil gaps and the insulation volume (and thus the related costs) are minimal [7.42]

**Fig. 7.73** 3-D model of a flexible lead exit system, and a real-world example of a lead exit with three bends (right)

Second character: method used to circulate the internal coolant.

N: Natural

F: Forced

D: Directed (directly pumped through the windings from the bottom)

Third character: type of external coolant.

A: Air

W: Water

Fourth character: method used to circulate the external coolant.

N: Natural

F: Forced.

The cooling types AN or AF are used for dry-type transformers; additional fans are installed at the transformer if the air is forced. More effort is required for liquid-filled transformers, which usually have higher power ratings, so a medium-sized power transformer below 50 MVA will often use ONAN, whereas such a transformer below 100 MVA will often use ONAF. Water-cooled OFWF systems in which there is forced oil flow driven by pumps are used for industrial or

large power transformers. The best cooling that can be achieved is ODWF (oil/directed/water/forced), which is, however, also the most expensive cooling method.

### Insulating and Cooling Fluids

The most popular transformer coolants are now discussed.

**Mineral Oil.** The transformers used in the experiment in Frankfurt in 1891 were filled with oil. Since then, there have been notable advances in the use of mineral oil in transformers, as well as setbacks. The first oils were not stable over the long term. In the 1950s and 1960s, oils that formed black, soot-like deposits on the active parts were used. Later, it was discovered that certain types of oils were contaminated with toxic polychlorinated biphenyls (PCBs). In the 1990s, certain types of oils were found to release corrosive sulfur, leading to partial discharges and ultimately to breakdowns. Modern transformer oils may be refined from crude oil or produced synthetically from natural gas. Inhibitors can be added to delay the aging of the oil. Thus, today, inhibited mineral oil and inhibited gas-to-liquid (GtL) oil are the most cutting-edge oils that are

used in transformers. Considering the total volume of each type of liquid used in transformers worldwide, oil is by far the most important, representing over 95% of the total volume of all liquids used in transformers.

**Other Insulating Fluids.** Other insulating fluids are usually more expensive than mineral oil, but they can have the advantage of being more environmentally friendly or having higher flash points. Their dielectric properties are usually different from those of oil. Thus, given their different permittivities and electrical field strengths, it is not possible to swap from mineral oil to another insulating fluid in a transformer design without performing appropriate verification. Due to the fact that oil has a market share among all transformer insulation fluids of more than 95%, the most important alternatives to mineral oil are mentioned only briefly below:

- Silicone liquids (still seldom used)
- Synthetic esters
- Natural esters.

There are only a few companies in the world that produce synthetic and natural esters, but the market share is slowly increasing (especially in the distribution and wind-energy sectors), albeit from a low level. Natural esters cannot be used in free-breathing transformers (i.e., transformers that have a conservator – an oil expansion vessel – with no membrane) because the natural ester would be in direct contact with ambient air in such transformer, leading to highly accelerated aging of the liquid.

## 7.2.6 Tank and Protection System

### Dry-Type Transformers

Dry-type transformers cannot be operated outside because the resin does not exhibit long-term UV stability. Furthermore, these transformers are not usually designed to operate under ambient conditions such as rain

and snow, so dry-type transformers are installed inside. Given that dry-type transformers of up to 145 kV are available [7.46], some larger units can have a special housing, but these cases are rare.

Dry-type transformers are usually equipped with a temperature monitoring system that prevents overtemperatures and can detect abnormal hot spots.

### Liquid-Filled Transformers

Small distribution transformers are usually manufactured with finned vessels, and it is becoming increasingly common for them to be hermetically sealed. Medium-sized power transformers are usually built with housings that are equipped with radiators onto which additional fans can be mounted. Hermetic arrangements are possible up to approximately 100 MVA, but are difficult for higher power ratings than this. Power transformers are either built with a tank and a cover or with a bell-type tank with a bell-shaped cover. When this cover is removed, the active part, which stands in a kind of tub that forms the rest of the housing, is freely accessible. As demonstrated by the examples shown in Fig. 7.74, it is easy to distinguish between a free-breathing transformer equipped with a conservator and a hermetically sealed transformer without an oil expansion vessel on the top of the tank. In recent years, a membrane has often been integrated into the conservator to reduce the absorption of oxygen and moisture from the ambient air and thus suppress insulating fluid aging.

The most important protection system for power transformers is the *Buchholz relay*, as shown in Fig. 7.75. This relay was developed in 1921 and named after its inventor Max Buchholz. It is installed in the pipe from the tank to the expansion vessel, collects gas, and monitors the oil flow speed in the pipe. It is equipped with at least one float that triggers a warning in the event of slow gas development or an oil loss. Furthermore, a damper detects the rapid oil or gas flow caused by a sudden fault, thus the transformer is tripped.

## 7.3 Testing Power Transformers

There are various reasons for testing a transformer, but three are particularly common:

- The final acceptance test (FAT) of a new transformer after it has been manufactured
- The acceptance test of a repaired transformer
- Diagnostic/service tests.

The scope of the tests performed as well as the sequence of tests and the equipment used vary depending on the type of testing performed.

The final acceptance test is performed on a new transformer after it has been manufactured, in order to verify that the transformer fulfills the contractual specification as well as the requirements of applicable standards. In addition, the FAT is part of the internal quality assurance or management system of the manufacturer. Thus, the results of this final quality check should be used to gauge whether the transformer can be put into service.

Sometimes a transformer is produced and tested in a workshop but is then completely disassembled and

**Fig. 7.74a–c** Examples of (a) small, (b) medium-sized, and (c) large (400 MVA, three-phase) power transformers [7.47]

**Fig. 7.75** Scheme of a Buchholz relay [7.48]

transported to the site, where it is reassembled again. In this context, completely disassembled means that the whole active part is disassembled; it is not the case that only bushings or the conservator are/is removed, which is the usual approach for transformer transportation. This very special case can occur if it is not possible to transport the assembled unit to the site due to several restrictions (e.g., when the transformer is to be installed underground). In such cases, the customer and the manufacturer must agree upon the tests that should be repeated (and passed) before the transformer is put into operation. CIGRE Working Group WG A2.59 deals with these questions and provides some recommendations regarding this matter [7.49].

The second category is similar to the first because tests must be performed after a repair to check the specification and quality of the repair. However, since some components of the transformer may be reused, and depending on how long the asset has been in operation,

the voltage tests performed after a repair are carried out at a lower voltage level than used in the FAT, which is in accordance with the standards. Due to the fact that the number of repairs performed on-site is increasing [7.50], the number of on-site tests is also rising, which has led to the development of special equipment for on-site tests over the last decades. The scope of these tests after a repair is similar to the scope of the tests performed during the FAT, as long as the tests are performed in a high-voltage test field. If the tests are performed on-site, the scope of the tests is usually reduced due to the higher complexity involved, increased costs, and problems with the availability of the test equipment to be used.

For diagnostic tests, the scope of the tests is usually significantly reduced compared to the scope of the tests performed during a FAT, because only tests that are useful for detecting a possible failure are carried out. One example is when an induced voltage test with partial discharge (PD) measurement is performed because DGA (dissolved gas analysis) has indicated PD activity. Therefore, only certain tests are performed, but often with additional special equipment. Thus, for the PD example, aside from the electrical PD measurement (which is implemented in the same way as during the FAT), acoustic or UHF (ultra high frequency) PD detection techniques are applied to localize the source of the PD, which is required before the risk of failure can be quantified. Therefore, most of the tests performed during the FAT can also be used to assess the condition of the transformer, which enables efficient asset management [7.51] because each test probes the likelihood of a different type of failure. This why many of these tests are also carried out during maintenance or a service [7.52].

### 7.3.1 Types of Tests

Compared to other components of the HV transmission systems, power transformer testing is far more complicated. This is simply because so many more tests are available and necessary for power transformers. Furthermore, most HV assets only require single-phase HV tests, whereas single- and three-phase dielectric tests are necessary for a three-phase transformer. Each test that is available for a power transformer can be categorized as one or more of the following:

- A routine test (RT)
- A type test (TT)
- A special test (ST)
- A diagnostic test (DT).

All transformers must undergo routine tests as part of the FAT, whereas type tests are performed on just one representative transformer among a group of transformers that are identical in construction. Special tests do not belong in the previously mentioned categories and are usually agreed upon by the customer and the manufacturer. Diagnostic tests include all tests that may aid the identification of the cause of a failure, so such tests are mainly performed on transformers that are in service or on a transformer that did not pass the acceptance test and requires further failure analysis. All routine tests and diagnostic tests can be performed on-site, so these tests are also used during a service and during maintenance to assess the condition of the transformer. Of course, some of these tests are quite complex and therefore expensive, so they are only carried out if there are certain indications or problems.

Due to the fact that transformers are often unique and specially designed components, the scope of the testing is usually defined by the customer or agreed upon by the customer and manufacturer. Table 7.4 provides an overview of the most important tests and their categories as well as the corresponding IEC and IEEE (Institute of Electrical and Electronics Engineers) standards. The tests listed in the table increase in measurement complexity and the stress exerted on the transformer from top to bottom.

Table 7.4 shows that tests on power transformers are multifarious and extensive, so not all of the tests mentioned in the table are discussed in detail below. More information or detail can be obtained from the corresponding IEC and IEEE standards mentioned in the table, or from relevant literature [7.77, 78] (there are books that focus entirely on the testing of power transformers).

In the following, short descriptions of the tests together with some remarks about them are presented [7.77].

#### Tests of the Liquid Insulation

The liquid that is used in power transformers can be subjected to different physicochemical and electrical tests. The standard oil test (SOT) affords information on the condition of the liquid insulation. Thus, the main parameters are tested, such as the breakdown voltage, dielectric dissipation factor, moisture content, acidity, interfacial tension, inhibitor content, and the purity of the oil. It is necessary to perform the SOT before any HV test and before the transformer is put into operation because the dielectric strength of the liquid must fulfill the requirements defined in the standards mentioned above. If, for example, the breakdown voltage of the liquid is not appropriate considering the voltage level of the transformer, the transformer can neither be tested nor be put into service. The SOT is also performed regularly during the whole lifetime of the transformer because the measured parameters provide insight into the performance and aging of the whole insulation system. If the liquid no longer fulfills the requirements, a special cleaning procedure (e.g., a regeneration) must be performed [7.79].

Another test that must be carried out regularly is a dissolved gas analysis (DGA), which is among the most well-established diagnostic methods for liquid-immersed power transformers. When there is a defect, specific gases are generated that dissolve in the liquid. For example, partial discharges produce predominantly hydrogen and methane. Based on the concentrations and the ratio of these fault gases, a DGA can provide information on the nature of the fault [7.80]. In addition, the rate of increase of the fault gas concentration within a certain time interval delivers information about the severity of the fault. There are a number of interpretation guidelines for the data acquired via DGA measurements; examples include [7.81, 82]. The IEC standard 60599 enables faults to be assessed and evaluated by distinguishing between types of electrical faults (PD, D1, and D2: partial discharges, low-energy discharges, and high-energy discharges, respectively) and thermal faults (by dividing them into three temperature ranges: T1, T2, and T3), and by gauging the degree of paper aging (via the CO<sub>2</sub>/CO ratio). In addition, a low oxygen concentration indicates oxidation processes for free-breathing transformers. Furthermore, when there is a severe failure, a huge amount of gas can be produced that cannot rapidly dissolve fully in the oil, meaning that gas bubbles rise to the top and can be collected in the Buchholz relay (for instance). These free gases can also be analyzed and compared to the results of a DGA, allowing additional conclusions about the failure to be drawn.

Regarding HV tests, it is recommended that a DGA should be performed both before and after the tests in order to check whether there are any small weak points

<sup>a</sup> Sometimes/depending on the size of the transformer

in the active part. A temperature rise test is usually accompanied by several DGA measurements in order to verify whether hot spots are present inside the active part, and to determine if the fault gases have exceeded certain limits.

#### Functional Tests

All auxiliary equipment must be subjected to functional testing. For example, the fans or pumps of the cooling system and all of the control equipment must be tested to check that it is operating appropriately. In addition, all of the auxiliary wiring must pass a 60 s dielectric AC separate-source test to prove that the insulation system is suitable.

If the transformer is equipped with a tap changer, this system must also be tested. If this is an on-load tap changer, various switching operations must be carried out with the transformer energized and deenergized.

#### Voltage Ratio and Vector Group

The transmission or voltage ratio must be evaluated for all tap positions by directly measuring the voltages on the primary and secondary sides using voltmeters, or by using ratio-measuring bridges. For three-phase transformers, this measurement is usually conducted for one phase at a time. The maximum error in the relative ratio or the deviation of the measured from the nominal ratio in percent should be within  $\pm 0.5\%$  or less than than 0.1 times the actual short-circuit voltage (whichever is lower) according to IEC 60076-1.

Furthermore, it is essential to check the vector group of the transformer and the phase displacement between the LV and HV side for each phase. This is especially important when the transformers are operated in parallel.

Several compact systems are on the market that integrate voltage ratio, vector group, and winding resistance measurements into one system. Such devices are usually fitted to a small trolley, which makes it easier to position the measuring system at appropriate points close to transformers of differing sizes.

#### Frequency Response

Some additional tests have become increasingly popular over the last decades. These are used as diagnostic tests for transformers that are in service and to obtain a *fingerprint* during the FAT of a new transformer. They are based on systems theory, which states that if a system is changed, the system response must also change. Therefore, the system response (the fingerprint) is measured and compared with a previous response (the reference fingerprint) of the same system. If a reference fingerprint is not available, the result is compared with either the response of a similar system or a simulated reference. In the following, two methods that are increasingly being used in transformer testing and servicing are described. Both methods examine a system response: one probes the dielectric system response (FDS), whereas the other examines the electric system response (FRA).

Frequency-domain spectroscopy (FDS) involves the measurement of the dielectric dissipation factor over the frequency range of 1 mHz to 1 kHz. The response is then compared to a reference that depends on the insulation system of the transformer – in particular concerning the relation of the amount of liquid to solid insulation – and this comparison allows the average moisture content in the solid insulation to be gauged [7.83].

In frequency-response analysis (FRA), an electrical transfer function (typically a voltage–voltage transfer function) is measured for each phase of the LV and HV sides over a typical frequency range of 1 kHz to 1 MHz. Afterwards, the measured transfer function is compared with a corresponding measurement performed during the FAT or (more commonly, since FRA measurements were not performed during the FAT for older transformers) with the measured transfer function of another phase. Differences between the transfer functions can indicate winding deformations or core problems, although the precise interpretation of these differences is still being researched [7.84].

Small portable devices that can perform these methods are available. These devices are often connected to a computer such as a laptop, as this allows the measurements to be controlled and the resulting data to be evaluated and visualized graphically using a software package.

#### Dielectric Dissipation Factor and Capacitance

The dielectric dissipation factor ( $\tan \delta$ ) of an insulation system is defined in the relevant IEC standard as the relation between the active and the reactive power when a sinusoidal voltage is applied to the insulation. The power factor PF is defined in the relevant IEEE standard as the relation between the active and the apparent power. The relation between the dielectric dissipation factor and the power factor is

$$\text{PF} = \frac{\tan \delta}{\sqrt{1 + \tan^2 \delta}}. \quad (7.51)$$

The value of the dissipation factor is usually small, and it is clear from the equation that the difference between the dielectric dissipation factor and the power factor is often negligible for small values of the dissipation factor. The dielectric dissipation factor or the power factor as well as the capacitance of the insulation system can be measured using the famous Schering bridge [7.85]. The dissipation factor can be used to assess the condition of the insulation, although this factor depends on many parameters such as the temperature, frequency, and electrical field strength. Compact systems of a similar size to the voltage ratio measurement devices mentioned above are available to measure the dissipation factor.

#### Winding Resistance

The winding resistance is defined as the temperature-dependent ohmic DC resistance of a winding. It is measured at room temperature and then converted to the winding resistance at the standard temperature of 75 °C.

The winding resistance is used to extrapolate the copper losses ( $I^2R$ ) of the transformer, as well as for diagnostic purposes. Measuring the winding resistance allows the path of the electrical current to be probed: it can highlight contact problems at the tap changer or between windings and bushings, interruptions within the windings, and even significant interturn short circuits. For transformers with tap changers, the winding resistances of all phases are measured at all tap changer positions. In this case, to avoid unacceptable heating, the direct current supplied may not exceed 10% of the nominal winding current according to IEEE Std. C57.12.90-2015, but it must also be at least 1.2 times the value of the no-load current to ensure core saturation.

Different approaches are used to measure the resistance. A simple method involves injecting a current into the winding and measuring the corresponding voltage drop across it. Ohm's law can then be used to calculate the winding resistance. Another method is to utilize a bridge to measure the resistance by balancing the two arms of the bridge circuit. Thus, a comparison is performed, with a known resistance to determine the exact value of an unknown resistor.

#### Insulation Resistance

The insulation resistance between winding systems or between windings to ground is measured. To do this, an applied voltage test is performed: one winding system is short-circuited and connected to a voltage source, while the other winding systems are short-circuited and connected to ground. A DC voltage of a few kV is then applied and the insulation resistance is measured in M $\Omega$  using a typically small and portable device.

The insulation resistance depends on various parameters; aside from the design of the transformer, external influences such as humidity and dirt on the bushings significantly affect the insulation resistance. It also depends on the duration of application of the voltage because of dielectric effects in the insulating medium, so the resistance is often measured after 15, 60, or 600 s. The ratio of the resistance after 60 s of voltage stress to that after 15 s of voltage stress ( $R_{60}/R_{15}$ ) is often in the range 1.3–3, and its value is linked to the quality of the insulating medium. Furthermore, values of the polarization index (PI; i.e., the ratio  $R_{600}/R_{60}$ ) that are above 2 are indicative of good insulation, while values of less than 1 indicate unsatisfactory insulation.

As a rule of thumb, the insulation resistance should be at least 1 M $\Omega$  per kV of nominal voltage, so an insulation resistance of at least 110 M $\Omega$  is required for a 110 kV transformer. The insulation resistance of a new transformer is usually more than ten times higher

than this rule of thumb, and is therefore in the  $G\Omega$  range [7.86].

#### No-Load Losses and Harmonics of the No-Load Current

The no-load losses are guaranteed by the manufacturer because they are an important influence on the operational economics, given that they occur whenever the transformer is energized. The setup for measuring the no-load losses is rather simple: one winding system is energized with the nominal voltage at the nominal frequency, while none of the other winding systems are connected to a load. It is necessary to energize the transformer with an appropriate voltage waveform and the exact nominal frequency since the no-load losses strongly depend on the waveform of the voltage as well as the frequency. In the tests, the voltage is usually decreased from 115 to 110, 100, 90, and 80%, because overexcitation at the beginning reduces any effects on the remanence (caused by DC winding resistance measurements for example). The active power must be remeasured with a calibrated power analyzer, and the measured value is corrected to the no-load losses using a factor that considers the harmonics in the voltage waveform.

The no-load losses can also be used to diagnose the condition of the core of an old transformer, so they are usually measured before an old transformer undergoes a repair or an overhaul.

As a special additional test, the harmonics of the no-load current can also be measured. In the past, or for older transformers, information on the harmonic content of the no-load current was used to adjust the transformer protection relays, especially when electromechanical systems were used. However, such measurements have become less important for modern power transformers because their no-load currents are below 1% of the nominal current.

#### Sound Level Measurements

The measurement of the sound level is a special test that is becoming increasingly important because transformers are being installed closer and closer to populated areas, where there are various rules and regulations concerning sound emissions. In order to check that a transformer is operating within specified noise limits or the noise range guaranteed by the manufacturer, sound level measurements can be performed in various configurations: no-load/load, cooling on/off, and pumps on/off.

Aside from the cooling system, the sound generated by an operational transformer is a combination of core noise (no-load sound) and winding noise (load sound). The no-load noise arises from magnetostriction (small

elastic variations in the length of a magnetic material) of the core, whereas the load noise is a result of vibrations of the windings and the tank due to magnetic forces caused by the load current. For modern low-induction transformers, the load noise is usually louder than the no-load noise. The sound level measurement procedure is quite complicated because a lot of sound level measurement points need to be recorded and evaluated given the sizable dimensions of large power transformers.

A simple sound measurement can also be used to make a rough estimation of the condition of the core or core clamping, but this is a seldom-used procedure and is usually only performed under no-load conditions.

#### Short-Circuit Voltage and Load Losses

By definition, the short-circuit voltage is the AC voltage that must be applied to the primary terminals of a transformer that is short-circuited on the secondary side so that nominal currents flow on the primary side, in which case the absorbed active power of the transformer corresponds to the load losses. Both the short-circuit voltage and the load losses are guaranteed by the manufacturer and must therefore be measured precisely using calibrated power analyzers. For transformers with tap changers, the short-circuit voltage must be determined for the two extremes as well as for the main tap position, because the short-circuit voltage is important when operating two or more transformers in parallel.

The difference between the measured and calculated load losses provides insight into the eddy losses caused by the leakage fluxes in metal mechanical parts of the transformer (e.g., the tank walls).

Depending on the size of the transformer and the test equipment available, capacitive compensation is usually needed to perform the test. Therefore, capacitor banks are connected in parallel to the transformer, increasing the effort required for the test. In order to measure the short-circuit voltage on-site, usually low voltage is applied to the primary side while the secondary side is short-circuited. The current and voltage on the primary side are then measured, and the measured voltage is multiplied by the ratio of the rated current to the measured current to obtain the short-circuit voltage. The reason for determining the short-circuit voltage on-site is that this measurement can be also used as a diagnostic procedure, because the short-circuit voltage is very sensitive to changes in the winding structure, meaning that it can be used to detect winding deformations.

#### Temperature-Rise Test

When a transformer is operating, heat is produced, which increases the temperature of the internal struc-

ture of the transformer. Since temperature is one of the main influences on the overload capability and life expectancy of a transformer, the temperature-rise test is of great importance to both manufacturers and operators. The temperature-rise test uses the same setup as employed to determine the short-circuit voltage and load losses, and is performed to check that the temperature rises for the windings and the oil are compliant with the values guaranteed by the manufacturer. A two-step approach is performed:

- The rise in top-oil temperature when the total losses are injected is determined
- The average winding temperature rise for rated currents is evaluated.

In step 1, the voltage is regulated such that the total losses are the sum of the load losses and the no-load losses. During this test, the current is slightly above the rated current, and the test ends when the top-oil temperature reaches a steady state. The rise in the top-oil temperature can then be determined as the difference between the top-oil temperature and the temperature of the external cooling medium (the ambient temperature for air-cooled systems or the water inlet temperature for water-cooled transformers).

After the top-oil temperature rise has been determined, the test immediately moves on to the second step, in which the current is reduced to the rated current for a 1 h period. After that, the winding resistances must be measured to determine the average temperature of the windings and therefore the average winding temperature rise as defined in the standards.

Sometimes fiber-optic temperature sensors are installed in the windings or the active part of the transformer. These are used to determine the temperature distribution across the active part as well as the hot-spot temperature during the temperature rise test. The sensors are installed during production and subsequently (when the transformer is operational) integrated into a monitoring system to produce a thermal image of the transformer [7.87] that is used to optimize the cooling efficiency or calculate the aging factor due to thermal stress.

As mentioned before, the temperature-rise test is often accompanied by DGA tests because an analysis of the gases dissolved in the oil can be used to detect possible local overheating that does not show up as an unusual temperature rise during the test.

### Zero-Sequence Measurement

Asymmetrically loaded three-phase systems can be calculated using the method of symmetrical components. In this method, an asymmetrically loaded three-phase

**Fig. 7.76**  
Zero-sequence  
impedance for a star  
winding

system is divided into three superimposed subsystems: the positive-sequence phase system, the negative-sequence phase system, and the zero-sequence phase system. Each of these three systems comprises corresponding symmetrical voltage, current, and impedance components. For transformers, the positive-sequence impedance is usually equal to the negative-sequence impedance, whereas the zero-sequence impedance can significantly differ from the other two impedances.

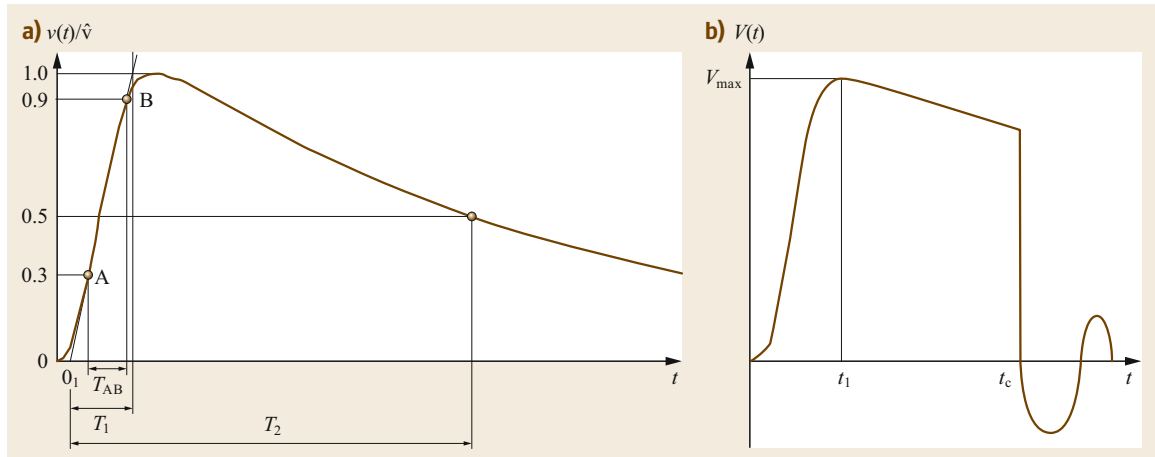

The zero-sequence impedance can only be determined for star or zigzag winding connections, and is measured at the rated frequency between the interconnected terminals of the winding system and its neutral point.

If the voltage  $V$  is applied between the interconnected winding terminals and the neutral, as shown in Fig. 7.76, the zero-sequence impedance  $Z_0$  can be calculated as

$$Z_0 = \frac{V}{I} = 3 \frac{V}{I}. \quad (7.52)$$

For the setup shown in Fig. 7.76, it is important to note that the current at the neutral point must not exceed the maximum permissible value. Also, the zero-sequence magnetic flux should be considered for different transformer designs. For example, for an YNyn transformer with a three-limb core, if the voltage  $V$  is applied between Y and N while the LV side yn is open, the flux – which is  $\Phi/3$  in each limb – needs to close over the tank walls, cover, clamping construction, etc. This may generate excessive heat in these metallic parts, so the measured current should be drastically reduced compared to the rated current. If the YNyn transformer has a five-limb core, the situation is completely different because the two outer limbs are available to close the flux, and because a YNyn transformer with a five-limb core usually has a delta tertiary winding that will generate an appropriate compensation current [7.88].

This example shows that the zero-sequence impedance depends strongly on the design (i.e., the vector group and core construction) of the transformer, meaning that various test circuits are used to measure

**Fig. 7.77a,b** Lightning impulse voltage: (a) full waveform with front time  $T_1$  and time to half-value period  $T_2$  and (b) chopped at the tail ( $t_1$  is the front time and  $t_c$  is the time until chopping is performed)

the zero-sequence impedances of transformers with various high and low winding connections. Therefore, in some cases, the test circuit to be used will need to be agreed upon between the manufacturer and the operator.

#### Dielectric Tests

Dielectric tests include the most important transformer tests – those that verify the integrity of the transformer under operational and also abnormal stresses. This requires the application of voltage levels that are significantly above the nominal voltage stress. Therefore, unsurprisingly, transformers that do not pass the final acceptance test have often failed one of the following dielectric tests:

- Impulse tests
- Applied voltage test
- Induced voltage test with PD measurement.

The levels used in these dielectric tests are defined in the standards and depend on the voltage  $V_m$ , which is the highest rms phase-to-phase voltage in a three-phase system for which a transformer winding is designed in respect to its insulation according to IEC 60076-3.

**Impulse Tests.** Transformers must be subjected to impulse tests to verify the integrity of their insulation during transient overvoltages, which may appear due to atmospheric lightning or switching operations in the network. There are therefore two different impulse tests: the lightning impulse (LI) test and the switching impulse (SI) test. The LI test can be subdivided into a full voltage wave test and a test where the voltage wave is chopped at either the front or the tail, as shown

in Fig. 7.77. Impulse tests are routinely performed for transformers that are designed to operate above a certain voltage level, but the voltage limit is different for full LI tests, chopped LI tests, and SI tests. In addition, these limits are slightly different in the IEC and IEEE standards.

According to Fig. 7.77, the typical 1.2/50  $\mu\text{s}$  full lightning impulse waveform can be characterized by three values:

- The peak voltage (the test voltage with a tolerance of  $\pm 3\%$ )
- The front time  $T_1 = 1.2 \mu\text{s} \pm 30\%$
- The time to half value  $T_2 = 50 \mu\text{s} \pm 20\%$ .

For a chopped LI, instead of the time to half value, the waveform is characterized by the time until chopping is performed,  $T_c$ . A SI has a similar waveform to a LI, so both impulses can be generated with the same system but with different setups of the Marx generator (designed in 1923 by Erwin Marx in Braunschweig, Germany).

However, the SI is longer than the LI. Therefore, according to the IEC standards, the time to peak  $T_p$  of a SI must be at least  $100 \mu\text{s}$ , the time  $T_d$  spent above 90% of the specified amplitude must be at least  $200 \mu\text{s}$ , and the time to zero  $T_z$  must have a minimum value of 1 ms. Due to the longer voltage stress on the SI, its test level is lower than that of the LI, whereas the test level of the chopped LI is usually 110% of the full LI. The LI and SI tests are usually carried out with negative polarity in order to avoid external flashovers, and both tests start with a reduced voltage level as a calibration impulse. Afterwards, three full waveforms are typically applied. This test sequence must be performed on all

phases. The tap-changer positions change for each of the three phases of a three-phase transformer during the LI tests, so the two extreme tap positions as well as the main tap position are used once. For SI tests, it is often necessary to apply a number of reduced impulses with opposite polarities prior to each test impulse in order to avoid core saturation and therefore reduced impedance, which will influence the SI waveform.

Generally, the transformer passes these tests if there is no voltage breakdown during the tests and when the calibration and full impulses for the recorded LI waveforms are almost identical.

**Applied Voltage Test.** During the separate-source AC withstand test or the so-called applied voltage test, the integrity of the main insulation is examined, meaning that the insulation between the windings themselves, between the windings and the ground, and between all connections to ground and to each other is tested. The setup is rather simple and is also used for insulation resistance measurements: all winding systems (HV, LV, TV) are interconnected or short-circuited (all terminals of a winding system as well as the neutral, if applicable, are connected to each other), the winding system that is being tested is connected to the test voltage, and all other windings and parts are grounded. This procedure is repeated until all of the winding systems have been tested. The applied voltage test is usually performed at the rated frequency, and the test voltage is applied for 60 s, as specified by the IEC. The test is passed if the voltage does not collapse and there are no other fault indications, such as a sudden increase in the test current.

For large power transformers, the neutral often has a reduced level of insulation compared to the phase exits. Thus, for such nonuniform windings, the test level must be determined according to the test level specified for the neutral.

**Induced Voltage Test with PD Measurement.** The induced voltage test is one of the most conclusive tests of the quality of the transformer insulation system. During this test, the insulation between turns, discs, windings, and terminals at different phases is evaluated by applying electrical stress from a voltage that is around 1.5 times higher than the rated voltage to all of them simultaneously. Any deficiencies in the design, insulation dimensioning, or manufacturing process will cause weaknesses in the insulation system of the transformer, leading to PD activity during the induced voltage test. These weak points can be detected by simultaneously performing electrical PD measurements according to IEC 60270. Since the test voltage is

higher than the rated voltage, the test frequency is usually increased to at least twice the rated frequency in order to avoid core saturation.

The relevant IEC and IEEE standards exhibit some important differences for the induced voltage test. In fact, these differences between the standards are more significant than for any other test mentioned so far, and include dissimilar voltage limits for the PD measurement as well as differences in the procedure itself, the test setups, and the test duration. In general, the induced voltage is increased stepwise until the HV test level is reached, and this voltage is maintained for a rather short time (around a minute, depending on the voltage frequency). The voltage is then reduced stepwise. Both standards state that the first step down after the highest test voltage should be held for up to 1 h (this time mainly depends on the voltage  $V_m$  of the transformer). The test is passed if there is no collapse of the voltage, the PD levels do not reach certain limits, and the PD activity does not show any increasing trend.

The PD measurements performed during the induced voltage test are usually electrical PD measurements, as they can be calibrated and can be used to detect various failures that generate PD activity. If the transformer does not pass the test due to PD activity, additional PD measurement techniques such as acoustic or UHF methods can be used to determine the location of the PD fault. However, for the following main reasons, these techniques should not be used during the induced voltage test to judge whether the system has acceptable levels of PD activity [7.89, 90]:

- Neither acoustic nor UHF PD techniques can be calibrated. Thus, the apparent charge associated with the PD cannot be measured and compared with the PD acceptance criteria. This means that these techniques do not comply with the standards.
- Neither acoustic nor UHF PD methods can reliably detect an increasing trend in PD activity.
- Neither acoustic nor UHF PD measurements are able to detect all defect types, since their sensitivity depends on the location of the sensor.

For these reasons, the recommended PD measurement is an electrical measurement according to IEC 60270.

PD measurement is the most sensitive method of detecting weak points in the insulation system, so the induced voltage test with PD measurement is usually the last test that the transformer is subjected to. If a defect developed during previous tests but was not detected in those tests, it will most likely be detected during the PD measurement, so carrying out this test ensures that even small defects will be discovered.

### Short-Circuit Withstand Test

A short-circuit withstand test cannot usually be performed in the high-voltage test lab of the manufacturer because a high-voltage and high-power laboratory is needed, and there are only a few such labs around the world. Therefore, this is a special test, and one that requires agreement between the manufacturer and the purchaser regarding the setup to be used. In general, this expensive test checks the overall performance of the insulation system of a transformer in the case of a severe short circuit that produces strong mechanical forces. This test should be implemented on a new transformer that has just passed the FAT. In the test, the fully assembled transformer is subjected to a number of short circuits within a period that is usually shorter than 1 s (and often between 0.25 and 0.5 s). Either of the following actions may be performed:

- A breaker is closed in order to apply a short circuit to the energized transformer (post-established failure)
- A breaker between the power supply and the primary side of the transformer which is short-circuited on the secondary side is closed (pre-established failure).

Post-established failure is closer to reality, so this test is often preferred. However, due to the great expense of this test as well as the fact that a transformer failure usually leads to catastrophic damage and extremely high costs, so-called mock-up tests are becoming increasingly popular as an alternative to testing new complete transformers. During a mock-up test, a special model of the transformer or a certain part of the transformer is tested in order to prove the general integrity and mechanical stability of the design [7.91].

### Test Sequence

The international standards IEC 60076-1/60076-3 and IEEE Std. C57.12.90-2015 both provide some general advice and remarks regarding the test sequence. They recommend performing the tests in a way that ensures that the stress experienced by the transformer increases gradually rather than rapidly. Regarding the overall sequence of all the tests mentioned above, the standards provide recommendations but also state that an agreement between the manufacturer and the purchaser regarding the sequence is still allowed. On the other hand, more obligatory instructions are given regarding the sequence that should be used for the dielectric tests. In general, the following sequence seems to comply with the standards [7.77]:

- Basic tests without power (oil, ratio, vector group, FDS, FRA, etc.)

- No-load test (followed by a sound level test if required)
- Short-circuit voltage and load losses
- Zero-sequence impedance (if specified)
- Dielectric tests:
  - Switching impulse tests (if required)
  - Lightning impulse tests (if required)
  - Applied voltage test
  - Induced voltage test with PD measurement.

Depending on the size of the transformer and the number of tests specified, a period of some days up to 2 weeks in the high-voltage laboratory are typically needed to perform the FAT.

### 7.3.2 High-Voltage Test Equipment

High-voltage tests are usually performed in the high-voltage laboratory of the manufacturer, which should contain the following devices:

- A Marx generator for impulse tests
- A single-phase transformer for the applied voltage test
- A motor-generator set connected to a three-phase adaption transformer for the induced voltage test (including filters that enable sensitive PD measurement)
- Capacitor bank for the compensation required during load loss tests.

However, there is an increasing trend for performing high-voltage tests on power transformers on-site; for instance, after a repair on-site, after the complex transportation of a new transformer, or for diagnostic purposes. Therefore, in the following, state-of-the-art techniques for performing high-voltage tests on-site are presented.

#### High-Voltage Tests On-Site

Aside from the electrical and economic parameters, the requirements for high-voltage test systems that are used to test transformers on-site are mainly a compact design for simpler transportation, mechanical stability, fast installation, and operability with only a few personnel. The newest technologies allow this, so there are systems on the market that can be used to perform complete dielectric tests, even on the largest transformers. These systems are usually installed in containers, guaranteeing efficient transportation around the world.

Motor-generator sets were often used in the past for high-voltage AC tests on-site. However, these are usually quite heavy and therefore difficult to transport, and so modern techniques are superseding these old

Fig. 7.78 HV-AC mobile test system

systems. The example shown in Fig. 7.78 focuses on a state-of-the-art three-phase AC test system installed in a 40 ft container. This system essentially consists of the following four devices [7.92]:

- Control and measurement system
- Static frequency converter (SFC)
- Adaption transformer
- Reactor for the single-phase applied voltage test.

The heart of the system, as shown in Fig. 7.78, is the static frequency converter, in which an external three-phase supply voltage is first rectified, so the direct voltage is buffered by a capacitor bank. The DC voltage then feeds an inverter module, which consists of insulated-gate bipolar transistors (IGBTs) and is driven by a microcontroller, thus generating sinusoidal modulated voltage pulses of adjustable frequency and amplitude. A controlled power sine-wave filter connected to the converter output is used to filter the fundamental wave, which finally feeds a step-up transformer [7.93]. This SFC system is integrated into two cabinets, each with dimensions of approximately 2 m (height)  $\times$  1 m (width)  $\times$  0.5 m (depth).

The adaption transformer has various bushings on its cover, allowing various voltage ratios and various vector groups to be realized in order to adjust the adaption transformer to the transformer being tested as well as possible. In the case of an induced voltage test, the adaption transformer is then connected to the transformer being tested using special HV cables and superior filters (see Fig. 7.79) that reduce the noise from the voltage source, permitting sensitive PD measurements.

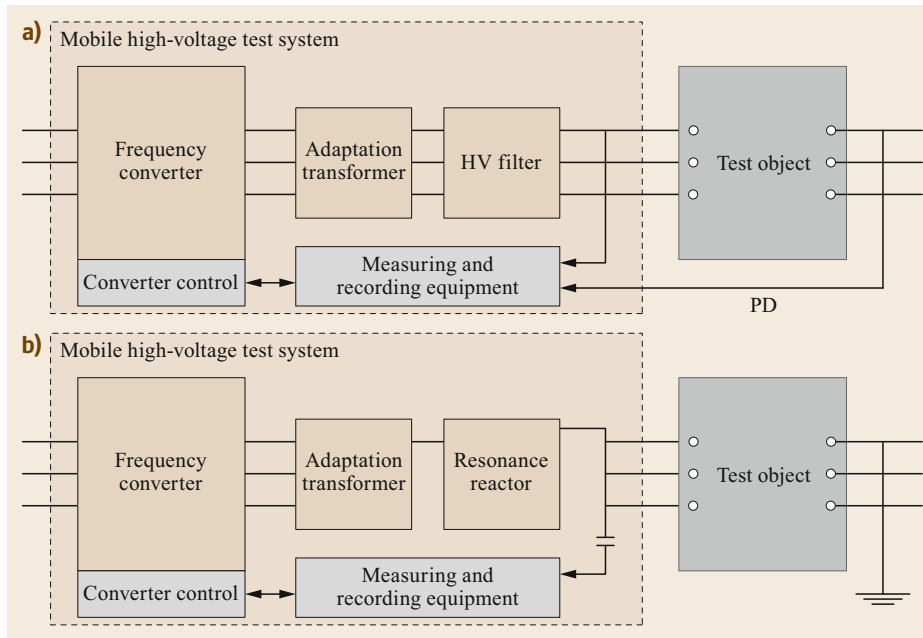

In an applied voltage test, the transformer being tested is connected to a reactor, supplied by one phase of the adaption transformer, as illustrated by Fig. 7.79. The frequency converter is then automatically tuned to the resonant frequency of the reactor in series with the tested transformer, which represents a capacitor in an equivalent circuit. The ability to tune the frequency in the region between 15 and 200 Hz in 0.1 Hz steps is one of the advantages of modern converters. A high-voltage divider that is parallel with the transformer being tested and is directly connected to the reactor is used to measure the applied voltage.

All tests are controlled from the control room using a compact device tower that contains the control system to which a power analyzer and the PD measurement apparatus are connected.

This system can have a converter power of up to 1350 kW and a 2 MVA adaption transformer with an output of 90 kV, so induced voltage tests can be performed up to 90 kV with a total harmonic distortion that is typically below 2% [7.94]. Applied voltage tests of up to 500 kV are possible with a reactor, which is usually enough for even the largest transformers because nonuniform winding systems are used at high voltage levels.

The power from an adaption transformer is somewhat higher than that from a frequency converter because a compensation module (also installed in a cabinet) can be connected on the low-voltage side of the transformer, as shown in Fig. 7.78. More information on this can be found in [7.95].

Electrical PD measurements usually utilize the measuring taps at the HV bushings of the tested transformer (see Fig. 7.79), or – rarely – separate capacitive coupling

**Fig. 7.79a,b** Setups used for induced (a) and applied (b) voltage tests

**Fig. 7.80a,b** Heat run tests (a) with a connected capacitive compensation module (b)

capacitors. The noise level on-site obviously depends on the environmental conditions and on the filters integrated into the PD measuring equipment, so noise levels of between 50 and 100 pC are typically achieved, although 10 pC is possible under favorable conditions [7.96].

If the power of the mobile test system described above is insufficient, it is theoretically possible to run up to eight systems in parallel, although this will not be economically efficient. Thus, a maximum of two parallel operating systems are used in rare cases. For heat run tests, additional capacitive compensation can be used. This can also be installed into a 40 ft container, as shown in Fig. 7.80. In other words, all HV AC tests can now be performed on-site [7.97].

It should be mentioned that the SFC technique used in mobile AC test systems is also increasingly being used in stationary HV test laboratories instead of old motor-generator sets. In such cases, the previously mentioned SFC modules are generally used, but several of these modules are connected in parallel to increase the power. Using this approach, HV-SFC systems with active powers of more than 8 MW have been built, and much higher power levels are undoubtedly possible [7.98].

Aside from AC voltage tests, it is sometimes necessary to perform impulse voltage tests on-site, and systems are available to achieve this. Figure 7.81 shows a mobile impulse generator system with a charging volt-

**Fig. 7.81** A mobile impulse test system

age of 2 MV and an energy of 300 kJ [7.99]. Lightning impulse tests up to 1800 kV and switching impulse tests up to 1300 kV can be performed using this system, which is installed in a 40 ft container. The ten-stage Marx generator in the container is transported horizontally. The roof of the container must be opened before the impulse generator is erected automatically using a hydraulic system. This procedure takes less than 1 h and requires no manpower [7.100].

The voltage divider needed for the test (see Fig. 7.81) is stored together with the generator. A special telescopic system is used to ensure the appropriate distance from the divider, so neither a crane nor special tools are needed to erect the system, which can of course be used to test other HV equipment [7.101].

These examples demonstrate that it is possible to perform HV tests of power transformers on-site, even for the largest units that are located far from labs.

## 7.4 Types of Transformers

Transformers can be categorized into types based on their main applications in the electrical network or in industry. Power transformers can be divided into dry-type transformers and liquid-filled transformers. Dry-type transformers have insulation made from epoxy resin, enamelled wires, or gas, whereas liquid-filled transformers – also called oil-immersed transformers – use an insulating fluid in combination with paper insulation around the wires. Insulating liquids are usually based on mineral oil. However, synthetic or natural esters and silicone liquids are becoming more popular because they are more environmentally friendly and have higher flashpoints than mineral oil. Transformers that are filled with a gas such as SF<sub>6</sub> have a market share of less than 1%, but are useful in special applications, such as underground installations with special fire safety requirements [7.102]. Dry-type transformers are now available up to a voltage level of 100 kV and a power level of around 60 MVA [7.103]. However, only a few dry-type transformers with such high voltage and power levels have become available, so typical applications of dry-type transformers involve the medium voltage

level, with a power rating of less than 10 MVA. In contrast, liquid-filled transformers are available up to the highest voltage levels – e.g., 1200 kV in India [7.104] – and the highest power levels, so three-phase power transformers with more than 1 GVA have been installed. Due to the enhanced cooling characteristics and superior dielectric properties of liquid-paper insulation, there are almost no restrictions on the voltage and power levels of transformers that use such insulation, but there is a limit on the weight of the components; the main restriction is therefore the transportability of the transformers [7.105]. A huge generator step-up (GSU) transformer with a power level of around 1 GVA can have a total weight of more than 500 t, so it would normally be transported without oil, which reduces the weight transported by around 100 t.

Below, different types of transformers used for various applications are briefly introduced, and typical differences in design are discussed. However, it should be noted that large transformers in particular are tailor-made, so it is not possible to provide universal design rules for them.

### 7.4.1 GSU Transformers

The traditional generator step-up (GSU) transformer is located in a large power-generation plant. These oil-filled transformers often use kraft paper or thermally upgraded paper on the HV side, whereas a special varnish coating that provides enhanced mechanical stability after it has undergone the oven process may be used on the LV side. They are typically built as core-type units, and a five-limb core is often used for power levels above several 100 MVA. GSUs may also be built as shell-type units, although the estimated market share of such units is less than 20%. The main function of GSU transformers is to elevate the voltage from the generator, which is normally less than 30 kV, to the transmission network voltage, which normally exceeds several 100 kV. This is why GSU transformers typically have a voltage transformation ratio above 1:10, which is higher than those for some other types of transformers. Step-up transformers usually use a star-delta (Yd) vector group, have an on-load tap changer (OLTC), and can be implemented as either a three-phase unit or three single-phase units. The cooling systems of large GSUs are often oil-forced (OF) or oil-directed (OD) in combination with air-forced (AF) or even water-forced (WF), so a service lifetime of approximately 30 years and a risk of failure of around 1% per year have been estimated for these GSUs by a CIGRE working group [7.106]. As shown in Fig. 7.82, large GSUs have a conservator, which may be unsealed (as a free-breathing transformer) or sealed with a membrane, which is the state of the art.

Due to the global demand for more renewable energy, more and more wind and solar parks are being installed. The transformers used in these power generation systems are also generator step-up transformers, but with power levels that are often below 10 MVA and

**Fig. 7.82** 1100 MVA step-up transformer with a nominal voltage of 19 kV/345 kV [7.10]

voltage levels on the HV side of a few tens of kV. Therefore, sealed liquid-filled or dry-type transformers that usually contain epoxy-resin insulation are used. They are equipped with an off-load tap changer, not an on-load tap changer. Under typical conditions, conventional large GSU transformers operate with a high constant load, whereas wind-park GSUs are subjected to drastic changes in the load. Furthermore, in many cases, the transformers are installed inside the wind power station, so the size of the transformer must be minimized. Thus, instead of mineral oil, a synthetic or natural ester is used in combination with aramid paper, as this allows the transformer to be operated at higher temperatures during strong wind periods. In addition, these liquids are more environmentally friendly and therefore facilitate a green energy strategy. In such cases, the cooling system is usually KNAN, because the transformers should be as maintenance-free as possible, but AF is also applied in some cases.

### 7.4.2 Substation Transformers

Substation transformers serve as interconnections between different points of the network and act as step-down and regulating units. They are installed across the transmission network at voltage levels of 100 kV and higher and operate at a wide range of voltages. The transmission ratios of these transformers are typically less than 1:5. Substation transformers, as depicted in Fig. 7.83, are usually filled with mineral oil, have an on-load tap changer, and are mainly designed as core-type units, although shell-type units are occasionally produced (their market share is less than 5%).

The cooling systems of such transformers vary according to the design requirements. Normal configurations are oil-natural (ON) or oil-forced (OF) and air-natural (AN) or air-forced (AF). For higher power levels, free-breathing systems are widely used, but the conservators are increasingly being equipped with membranes. Sealed units with a gas cushion are also constructed, and expansion radiators can be used up to power levels of approximately 150 MVA [7.107].

If the HV and LV sides of a substation transformer have voltage levels above the 100 kV level, a star-star (Yy) vector group is normally used, and a tertiary system with a voltage of a few tens of kV is added to the active part of the transformer to facilitate induced voltage tests. In HV tests, typical voltages ranging up to almost 100 kV can be generated for the induced voltage tests, so the device under test (DUT) should have a winding system with a nominal voltage of a few tens of kV that can be used for excitation during the FAT.

The service life of a substation transformer can exceed 40 years, as they (usually) do not operate contin-

**Fig. 7.83** Transformer in a substation [7.10]

uously under high load, which also explains the reduced failure risk of approximately 0.5% per year for a substation transformer as compared to a GSU transformer, based on the CIGRE statistic mentioned above [7.106].

### 7.4.3 Autotransformers

Autotransformers have a special design in which the same winding system is used for the HV and LV sides, as shown in Fig. 7.84. This construction is only reasonable for relatively small transmission ratios that usually do not exceed 1:5, so autotransformers can be used as substation transformers at all voltage levels and power rates. Therefore, the other design characteristics (the preferred insulation, core, and cooling) of autotransformers are similar to those of substation transformers. Construction as either a three-phase unit (as shown in Fig. 7.85) or a single-phase unit is possible, but each phase of a three-phase unit will typically have a separate on-load tap changer.

Especially for low transmission ratios, the compact construction of an autotransformer means that less material is used during construction, so cost, weight, and volume savings become possible. That said, there are,

**Fig. 7.84** The functional principle of an autotransformer

**Fig. 7.85** 220/110/10 kV and 250 MVA autotransformer [7.38]

of course, certain disadvantages of autotransformers. For instance, due to the galvanic connection between the HV and LV sides, there is the possibility that the HV will be on the common winding and therefore on the LV side of the transformer during a failure. In order to avoid such a breakdown on the LV side, it is necessary to design the LV part to withstand higher voltages. Furthermore, the main leakage flux between the primary and secondary windings is relatively small, resulting in a low impedance. Thus, high short-circuit currents may occur if there is a fault. The main disadvantage of the galvanic connection between the voltage systems is that the zero-sequence currents generated by line-to-earth failures (the most common short circuits in the network) are transferred from one voltage system to the other. All of the equipment and protection for both voltage systems must be designed for those short-circuit currents.

However, the expected lifetime and failure rate of autotransformers are comparable to those of substation transformers.

As can be seen in Fig. 7.85, a tertiary system (in this case with a nominal voltage of 10 kV) is also necessary when performing an induced voltage test on an autotransformer.

#### 7.4.4 Distribution Transformers

These transformers operate at the medium-voltage level and distribute the energy to the low-voltage network, to which the end users are connected. Due to the low voltages and the typical power levels of these transformers (below 10 MVA), they can be liquid-filled transformers or dry-type transformers with epoxy-resin insulation (Fig. 7.86). These transformers have a core-type design and tend to have an ONAN cooling system. They are equipped with an off-load tap changer, but due to the drive to switch to renewable energy sources, so-called RONT (adjustable local network transformer; *regelbarer Ortsnetztransformator* in German) systems that have an on-load tap changer are increasingly being installed [7.108]. For liquid-filled transformers, sealed systems are preferred, but free-breathing transformers (without conservator membrane) are also available.

The service life of this type of transformer, which often uses a delta-star (Dy) vector group, generally exceeds 50 years due to its low utilization rate.

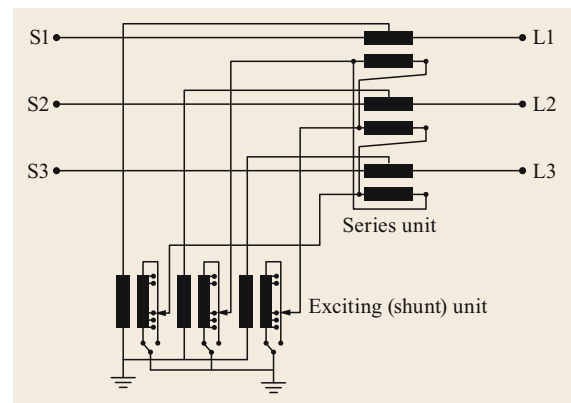

**Fig. 7.86** 2 MVA 36/0.4 kV dry-type distribution transformer [7.109]

#### 7.4.5 Phase Shifters

Phase-shifting transformers, sometimes called phase-angle regulators (PAR) or quadrature/quad boosters, are the largest and most expensive transformer units. They are used to regulate the power flow between electrical networks, so they are often located, for example, at transnational interconnections with nominal voltages of 400 kV or more. They work by adding a voltage that is usually shifted from the line voltage by  $90^\circ$ , thus changing the phase angle of the line voltage and allowing the load flow to be controlled. Sometimes a voltage that is phase shifted by only  $60^\circ$  compared to the line voltage is added to the line voltage. Phase shifters usually consist of two active parts – a series unit and an exciter unit (often called a shunt unit). The output of the exciter unit supplies the series unit, the secondary winding of which is connected to the line (as shown in the schematic presented in Fig. 7.87), although many different connection schemes are possible. Usually (in more than 90% of all phase shifters), the exciter unit is connected in YNyn while the series unit is connected in III<sub>d</sub>, and the terminals on the *source* side are generally named S1, S2, and S3 whereas the *load*-side terminals are called L1, L2, and L3.

As depicted in Fig. 7.87, the shunt unit consists of windings that are connected across the phases to generate an output voltage that is shifted by  $90^\circ$  in comparison to the input or supply voltage. By using this voltage as the input voltage to the series unit, the output voltage will be the sum of two voltage vectors: the supply voltage and the  $90^\circ$  quadrature voltage. This yields an output voltage that is shifted by a certain degree or angle compared to the supply voltage, and this angle can be adjusted using an OLTC inside the shunt unit in

**Fig. 7.87** Schematic representation of a phase-shifting transformer

**Fig. 7.88** Phase-shifting transformer [7.110]

order to vary the magnitude of the  $90^\circ$  quadrature component.

As illustrated in Fig. 7.88, large phase-shifter transformers with power ratings of up to the 1500 MVA level are installed in two tanks, resulting in a total weight that can exceed 1000t. The two tanks are therefore transported separately and connected on-site. Typical phase shifters have a core-type design, are filled with mineral oil and use a forced-forced cooling system, employ a conservator with an integrated membrane, and have a transmission ratio of 1:1. For nominal voltages above 110kV, tertiary windings are often necessary for induced voltage tests, similar to substation transformers or autotransformers. Another property that they share with autotransformers is the fact that each phase usually has a separate OLTC, which is necessary to change the phase angle of the line voltage.

The typical lifetime and failure rate of a phase shifter are estimated to lie between those of a GSU and a substation transformer.

#### 7.4.6 HVDC Transformer

High-voltage direct-current (HVDC) power transmission is usually quite expensive, but it has some advantages over high-voltage alternating-current (HVAC) power transmission. For instance, HVDC does not generate any reactive power, so there is no need for compensation. For very long distances, or when the capacitance of the transmission line would be too high (e.g., if an offshore wind park is connected through a 100km long undersea cable to an onshore station), HVDC connections are preferred. HVDC systems up to a voltage level of 1100kV are currently in use, meaning that HVDC transformers stand alongside phase shifters as the largest and most expensive types of transformers.

A simplified scheme of a basic HVDC transmission system is presented in Fig. 7.89, from which it is obvious that two converter stations are necessary for the whole transmission line. Each station consists of a HVDC transformer and a valve system, which makes HVDC transmission expensive. Figure 7.90 shows a 12-pulse rectifier, which is typically used in such systems, fed by a HVDC transformer, which usually has a star and a delta valve winding. However, for large voltages and high power levels, the symbol of the HVDC transformer shown in Fig. 7.90 actually corresponds to several single-phase transformers. Thus, HVDC transformers are normally single-phase transformers. Sometimes the core of a HVDC transformer will consist of two main limbs and two return limbs, with one valve winding placed on each main limb, whereas the primary winding is split into equal parts on the two main limbs. In that case, the valve windings are connected outside the transformer to a star and delta system, each feeding a six-pulse converter. Another configuration uses only one main limb and two return limbs, so primary and valve windings are placed on the main limb.

Figure 7.91 shows a large HVDC transformer with the primary bushing on the top and the two valve bushings on the front of the tank. HVDC transformers are also equipped with an OLTC that usually has a wide tapping range in order to control the service voltage adequately. HVDC transformers commonly use an oil-immersed paper insulation system, forced cooling, and a conservator with an integrated membrane. It is thought that the lifetime and failure risk of a large HVDC transformer is similar to that of a large GSU transformer.

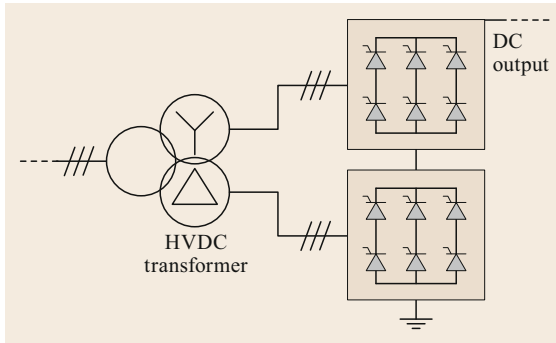

HVDC transformers are subjected to additional tests during the FAT. A separate-source DC voltage withstand test as well as a polarity reversal test are performed according to IEC 61378-2 [7.112] on the valve windings. From a design perspective, it is necessary to account for the fact that currents flowing through the windings of HVDC transformers contain certain harmonics that influence the losses of the transformer.

#### 7.4.7 Arc-Furnace Transformer

Arc-furnace transformers are used in the metallurgical industry for smelting purposes. When they are connected to the electrical network, they reduce the voltage to levels that are often around 1 kV or less in order to obtain high currents that are used in the melting process. Their mode of operation resembles short-circuit operation and requires special design considerations that are atypical for other types of transformers. The most unusual characteristic is the position of the LV winding, which is not the innermost winding close to the core (as is usually the

**Fig. 7.89** AC-DC-AC connection scheme

**Fig. 7.90** Converter station with a 12-pulse converter

**Fig. 7.91** 800 kV HVDC transformer [7.111]

case) but the outermost winding because of the high currents that need to be transferred to the outside of the tank. This is often achieved not through the use of traditional bushings but with a special bus bar system integrated into the tank wall, as shown in Fig. 7.92.

Usually, arc-furnace transformers are filled with mineral oil and employ thermally upgraded or aramid paper. However, because aramid paper is expensive, mixed insulation is sometimes used. In this mixed insulation scheme, only certain LV winding parts are insulated with aramid paper; the other parts use thermally upgraded paper to reduce the costs. On the HV side, voltages of 100 kV or more are possible, while on the LV side, only a few kV will be generated, with power rates reaching approximately 200 MVA, meaning that extremely large systems can be produced. Normally a core-type design is used, and three- or single-phase systems are available, typically with the Diii or Ii vector group. Each phase in the three-phase system usually

**Fig. 7.92** Arc-furnace transformer [7.10]

has its own OLTC, which is operated much more often than in any other transformer. Therefore, systems for purifying the oil in the OLTC compartment are also often installed. Large arc-furnace transformers are free-breathing transformers or have a membrane inside the conservator. An enhanced cooling system is commonly installed, so a forced-forced cooling system is typically used, often with water as the coolant.

The mode of operation of an arc-furnace transformer is close to the continuous full-load regime, typically combined with overloading situations that have a negative impact on the lifetime (estimated at 20–30 years).

#### 7.4.8 Rectifier and Converter Transformers

Rectifier transformers are typically used in the metallurgical and chemical industries and therefore exhibit some similarities with arc-furnace transformers,

**Fig. 7.93** Active part of a rectifier transformer [7.113]

whereas converter transformers are used for variable-speed drives in different areas.

In a normal 12-pulse rectifier unit, two output winding systems are installed in a double-tier design – one system in a delta and one in a star connection. Due to the high currents (which can exceed 100 kA) at the output windings, large copper bus bars are needed to form the star or delta connection, so these low-voltage windings are the outermost windings (see Fig. 7.93), just as in arc-furnace transformers. Another way in which they resemble arc-furnace transformers is that a special bus bar system is integrated into a tank wall to transfer the high currents to an external valve unit.

Due to the direct connection between the transformer and the converter, the load currents contain higher harmonics (just as in HVDC transformers), leading to increased losses. Regulating transformers are commonly used between the supplying network and the rectifier transformer in order to adapt the voltage for the rectifier transformer. A regulating transformer usually has a lower current harmonic content than a rectifier transformer because the harmonics of the combined 12-pulse system are lower than those for the individual 6-pulse system. Often, an additional filter is installed to further reduce the harmonics transferred to the network and to compensate the high reactive power generated by the rectifier. On occasion, the regulating transformer and the rectifier transformer are installed in the same tank, resulting in a compact but heavy arrangement.

These transformers are usually filled with oil and use thermally upgraded paper, sometimes in combination with aramid paper. Such transformers tend to employ a core-type design and a conservator equipped

with a membrane. With a forced cooling system, power ratings of up to around 200 MVA are achievable.

The lifetime of such a transformer is assumed to be similar to that of an arc-furnace transformer. However, dry-type rectifier and especially converter transformers with epoxy-resin insulation have also been constructed; these have power levels of up to a few 10 MVA.

### 7.4.9 Traction Transformers

Traction transformers are used in railway vehicles and therefore have some special characteristics such as compactness, mechanical robustness, reduced downtime and maintenance, and high reliability. There is also a particular focus on their safety and environmental behavior. They have special load profiles with supply frequencies ranging from 16.7 to 60 Hz, depending on the country. A typical traction transformer is a single-phase transformer with an input voltage of up to 25 kV at 50 Hz or up to 15 kV at 16.7 Hz and a rated power of up to around 10 MVA for liquid-filled systems. The input voltage is stepped down to a voltage in the kV range, which is often used to feed a rectifier that is employed to run DC traction motors. Nevertheless, some systems use a DC input voltage, in which case the traction transformer unit has an internal converter.

An important design goal is to increase the efficiency of traction systems, which is influenced by the transformer losses and the short-circuit impedance (this impedance has a significant effect on the converter efficiency). Further design aims are to reduce the volume and weight of a traction transformer without decreasing its mechanical stability. This can be achieved by reducing the amount of material used in its construction, although this leads to increased temperatures. Therefore, insulation systems that can withstand higher temperatures are preferred; instead of paper, glass-fiber insulation and aramid-paper insulation are often used in combination with high-temperature liquids instead of mineral oil in a free-breathing system. Nowadays, dry-type traction transformers are also available up to a power level of  $\approx 4$  MVA. These are insulated with epoxy resin, as shown in Fig. 7.94.

Both types typically use a core type with two limbs, employ a forced cooling system, and have many bushings (oil type) or output connections (dry type) to feed systems such as the motor, a heating and cooling system, and the internal supply. In contrast to most other transformer types, traction transformers are similar to distribution transformers in that they are mass-produced, so large quantities of these transformers are manufactured. Furthermore, these transformers must pass special mechanical and safety tests because they are mounted on rolling stock systems.

Fig. 7.94 (a) Liquid-filled and (b) dry-type traction transformers [7.114]

### 7.4.10 Test Transformers

High-voltage quality-control tests of newly manufactured HV components are mandatory. These tests are usually applied voltage tests, so a single-phase test transformer is needed to apply the test voltage. The main exception is the induced voltage test, which is usually performed as a three-phase test for a three-phase transformer. In such cases, the voltage is typically generated by a motor-generator set connected to an adaption transformer with a wide tapping range that can deliver the required test voltage at the higher frequencies (e.g., 150 or 200 Hz) provided by the motor-generator set. These adaption transformers are single-piece units produced according to the specific requirements of the test field operator. They are usually designed as sealed or open liquid-filled core-type transformers with three limbs and normal cooling, and with voltages on the HV side that are typically below 100 kV and power ratings of a few 10 MVA.

However, for the applied voltage test, single-phase transformers with voltages of 1 MV or more are needed, depending on the device to be tested. This is realized in practice through the use of a cascade of identical single-phase test transformers, as shown in Fig. 7.95. As can be seen, the second transformer operates on the HV level of the first transformer, and the third transformer operates on the output voltage level of the second transformer. Therefore, the total output voltage of the cascade is equal to  $n$  times of the output voltage of each single-phase transformer, where  $n$  is the number of stages in the cascade.

These single-phase transformers use oil-paper insulation and a tank made out of insulating material, as shown in Fig. 7.96, so they can be stacked on top of each other to form a cascade. Another possibility is to use a normal tank design made out of steel, as shown in Fig. 7.95, where the transformers representing the second and higher stages of the cascade need to be placed

Fig. 7.95 Three-stage Fischer cascade showing the voltage ( $U$ ) and power ( $P$ ) distributions [7.115]

on insulators. A disadvantage of cascading is the resulting imbalanced temperature distribution of the stacked single-phase transformers: the initial stages have higher temperatures because they deliver higher power than the subsequent stages, as shown in Fig. 7.95.

Among all transformer types, these single-phase transformers have the highest transmission ratios (approximate range: 1:100 to 1:1000), so a substantial distance between the LV and HV sides is needed, resulting in increased stray flux and thus higher short-circuit impedance. As a consequence, the short-circuit current is limited and the short-circuit stability is increased.

The lifetime of a test transformer is usually quite high – often exceeding 50 or 60 years – because they are only utilized sporadically.

### 7.4.11 Variable Differential Transformers

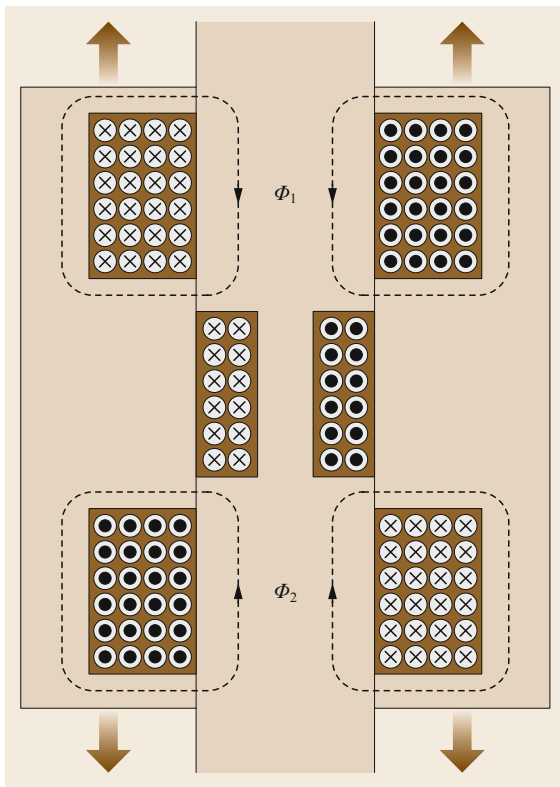

A variable differential transformer allows stepless regulation of the output voltage based on the relative

**Fig. 7.96** Schematic design of a single-phase test transformer

displacement between a secondary coil, which is placed in slots on one core limb, and two identical primary coils, which are connected in parallel and placed on a movable yoke. Figure 7.97 shows a schematic of the working principle of such a transformer.

The primary coils are positioned such that they create magnetic flows in opposite directions. The voltage

**Fig. 7.97** Schematic of the functional principle of a variable differential transformer

induced in the secondary coil depends on the position of the movable primary coils. Figure 7.98 shows three possible positions of the movable yoke [7.116]. At position 1 (Fig. 7.98a), the magnetic flux  $\Phi_1$  closes the magnetic circuit through the secondary coil and induces a voltage  $V = V_{\max}$ . At position 2 (Fig. 7.98b), the magnetic flux through the secondary coil is zero and so the induced voltage  $V = 0$ . Finally, at position 3 (Fig. 7.98c), the voltage induced in the secondary coil is  $V = -V_{\max}$ .

Since intermediate positions are also accessible, continuous regulation of the voltage induced in the secondary coil between  $V_{\max}$  and  $-V_{\max}$  is possible. However, the mechanical complexity of these transformers significantly limits their practical use in high-power applications, although they are sometimes used for testing.

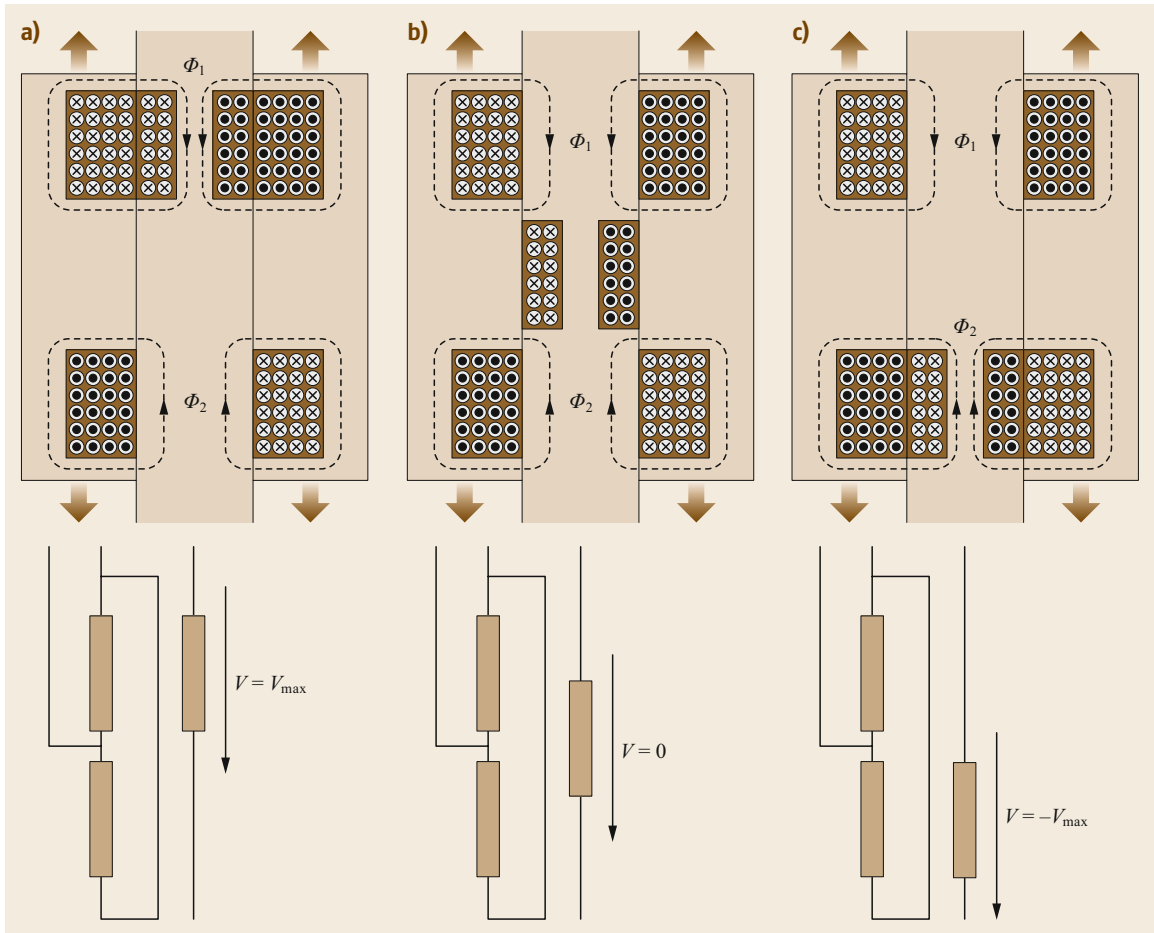

### 7.4.12 Other Types of Transformers

There are also many other special types of transformers, because power transformers are often tailor-made to specific customer requirements, and a wide range of such requirements are now technically feasible. Additional transformer types include instrument transformers, isolation transformers, welding transformers, and many different kinds that are used with low voltages and in electronics but are not considered in this chapter because they are not power transformers. However, it should be mentioned that reactors, which are also important components of the electrical energy transmission and distribution network, bear some similarities to power transformers in their design and construction. Large reactors are single- or three-phase systems that contain similar components to power transformers, such as windings, a core, bushings, a tank, a conservator, and oil-immersed paper insulation. The main difference is the structure of the reactor core, which has nonmagnetic gaps in the core limbs. However, there are other differences too, such as in the tightening of the active part and the high-voltage testing of reactors, which often requires special equipment. Reactors can be divided into the following categories [7.10]:

- Shunt reactors
- Current-limiting reactors
- Neutral grounding reactors
- Capacitor damping reactors
- Tuning or filter reactors
- Arc-suppression reactors
- Smoothing reactors.

Among these, shunt reactors are of particular importance up to the highest voltage levels, since they are used to compensate reactive power in transmission networks. Figure 7.99 illustrates a three-phase shunt re-

**Fig. 7.98a–c** Schematic showing how the voltage induced in the secondary coil of a variable differential transformer depends on the position of the movable coils. Cases (a) and (c) illustrate the maximum positive (a)/negative (c) induced output voltage. Between these extreme values all output voltage are possible, thus in case (b) the output voltage is adjusted to 0 V

actor, which looks like a transformer at first glance, but can be identified as a reactor by noting the absence of LV bushings.

Peter Werle received his PhD in electrical engineering from the University of Hannover. Before becoming Director of the Schering Institute in 2014, he was General Manager of the ABB Transformer Service in Germany. He is active in the VDE, DKE, IEC, and CIGRÉ, the inventor of more than 20 patents, and has authored/coauthored more than 300 publications in the fields of high-voltage engineering and asset management.

### Hartmut Brendel

Retired Head of Technical Development,  
ABB Transformer Service  
Consultant for Transformers and HV  
Applications  
Halle, Germany

Hartmut Brendel studied electrical engineering at the Technical University of Ilmenau. He worked for more than thirty years as an electrical and mechanical designer in the transformer business. Before his retirement, he was Head of Technical Development at the Engineering Solutions division of ABB in Halle (Saale), Germany. He has been a technical consultant on transformers and high-voltage applications since 2014.

# High Voltage

## 8. High Voltage Equipment

Hiroki Ito

This chapter focuses on substation equipment, which is used in power systems to transport and distribute the electric energy from power-generation plants to households, offices, and factories efficiently. In transmission and distribution networks, switching equipment such as circuit breakers and disconnecting switches is required to open and close circuits in power systems. When a fault occurs, circuit breakers are needed to clear the fault quickly to ensure system stability. Circuit breakers must also be able to carry a load current without excessive heating and withstand the system voltage during normal and abnormal conditions.

Measuring equipment such as instrument transformers and overvoltage protection units such as surge arresters are also used in power systems. Surge arresters are installed at different locations in power systems to limit lightning-induced and switching-induced overvoltages to a specified protection level below the withstand voltage of the equipment.

It is also mainly devoted to technical description of switching equipment used in both high-voltage alternating current (HVAC) and high-voltage direct current (HVDC) power systems. Fundamental interrupting and switching phenomena for different switching equipment are discussed.

Readers should note that more detailed and specific information on switching equipment can be found in many technical brochures and documents published by CIGRE, including the CIGRE Green Book on switching equipment.

## 8.1 High-Voltage Equipment in Power Systems

Power systems with various types of substation equipment efficiently transport and distribute the electric energy from power-generation plants to households, offices, and factories. Alternating current (AC) power systems are generally used for energy transportation because the voltage can easily be stepped up and down to reduce energy losses during transportation, but direct current (DC) power systems have recently increased in popularity. The number of applications of DC power systems have recently increased due to rapid development of power electronics technology and the need for a long distance connection of offshore or remote wind farms and/or large hydro power generators. HVDC transmission has several benefits such as lower transmission losses, fewer lines required for the same power transmission, and less system stability problems in comparison with HVAC transmission.

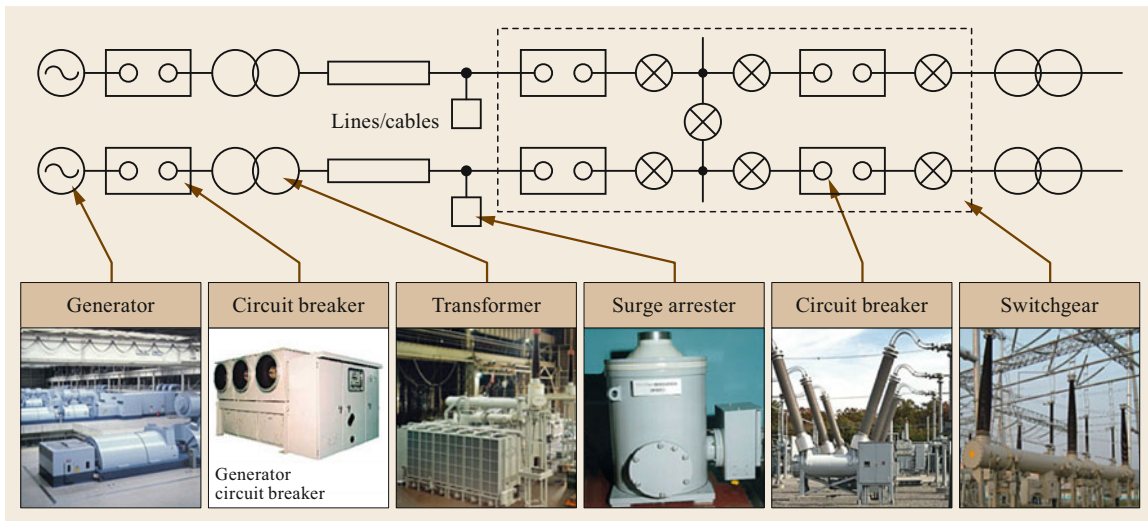

When power systems were first invented, there was what is now known as the *war of the currents*. Thomas Edison developed the first DC-based electric power transmission system in 1882, which was then used to

provide 110 V DC current to some households in the US. However, from the early 1880s on, with the development of power transformers in Europe and in the US, respectively, that enabled the voltage to be easily stepped up and down, AC-based power distribution systems began to grow in popularity compared to DC-based systems because it was possible to transmit electricity over much longer distances and through cheaper wires using AC. Therefore, by the early 1890s, AC power systems dominated the market, ending the war of the currents in 1892. The first circuit breaker was developed in the early twentieth century, which enabled to disseminate electricity networks, because circuit breakers can quickly disconnect a faulted circuit and allow continuous transmission and distribution in the healthy networks.

Figure 8.1 shows a typical AC power system from power generation to energy transportation and distribution. Power generators convert mechanical energy into electric energy, while aluminum and copper conductors in overhead lines and underground cables transport the

**Fig. 8.1** Typical AC power system

**Fig. 8.2** Typical AC substation equipment

electric energy to where it is needed. In substations, power transformers step up the voltage at the source side and step it down at the load side. Along with measuring equipment and overvoltage protection units such as surge arresters, switching equipment is used to close a circuit or interrupt a nominal or fault current.

Depending on the system voltage used, transmission networks are generally classified into ultrahigh voltage (UHV), extra-high-voltage (EHV), and high-voltage (HV) networks, whereas distribution networks are classified into medium-voltage (MV) and low-voltage (LV) networks. MV generally refers to voltages up to and including 52 kV, and HV to voltages higher than 52 kV. Some countries do not have a MV classification; in those countries, all voltages higher than 1 kV are generally considered to be HV. EHV usually refers to a voltage range of around 230 kV (this value can vary from country to country) to 800 kV. UHV generally refers to voltages exceeding 800 kV.

Power systems are required to efficiently transport the electricity from the generator to the load site, while maintaining the voltage and frequency within the specified levels. For this purpose, switching equipment is required to perform the following operations:

- Energizing and deenergizing cables, overhead lines, and power transformers
- Connecting and disconnecting to shunt capacitors or shunt reactors
- Transferring the current from one circuit to another
- Interrupting a fault current and isolating a faulty part of the system
- Isolating particular substation equipment for maintenance or to allow it to be replaced.

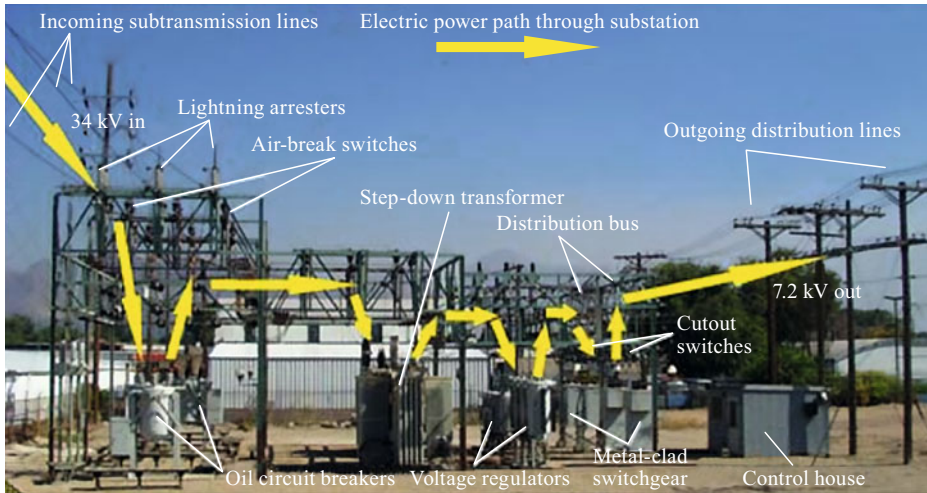

In the next section, we introduce various types of substation equipment such as circuit breakers, disconnecting switches, earthing switches, surge arresters, and instrument transformers.

### 8.1.1 Substation Equipment

Figure 8.2 shows a one-line diagram of a typical substation, including the main substation equipment. The substation serves several functions: it transforms voltage from low to high and vice versa and it switches circuits off and on. To achieve these functions, the substation has power transformers, circuit breakers, and metal oxide surge arresters that protect the system and equipment from excessive overvoltages. Figure 8.3 shows a photograph of a typical MV substation, including power transformers, circuit breakers (circuit switches), and surge arresters. The voltage received from the incoming overhead line (34 kV) is changed to an appropriate level (7.2 kV) before the electricity is directed into the outgoing distribution line at the substation.

The main switching equipment in the substation is a circuit breaker, which is used to quickly clear a fault and ensure system stability. The circuit breaker must be able to carry the load current without excessive heating and withstand the system voltage during normal and abnormal conditions. Unlike a fuse, a circuit breaker can be reclosed either manually or automatically to resume normal operation.

A circuit breaker with interrupters inside a tank insulated from earth potential is termed a live-tank circuit breaker (Fig. 8.4). The tank is normally composed of porcelain or a composite of insulators. The conductor

**Fig. 8.3** Photograph of a typical substation. (From the website of Occupational Safety & Health Administration, United States Department of Labor; <https://www.osha.gov>)

can be connected directly to the live part of the breaker terminals.

In contrast, a circuit breaker with interrupters inside an earthed metal enclosure is termed a dead-tank circuit breaker (Fig. 8.5). The conductor carrying the system voltage from the interrupters is fed outside through bushings.

A disconnecting switch is a type of switching equipment capable of opening and closing a circuit where only a negligible current is flowing through the electrodes, without significantly changing the voltage across the terminals of each pole of the disconnecting switch. It is capable of carrying currents under normal circuit conditions as well as currents under abnormal circuit conditions (e.g., a short circuit) for a specified time. Disconnecting switches are employed to interrupt small currents of 1 A or less, since they are operated under live conditions.

There are various types of air-break disconnecting switches: vertical break, center side break, double side

break, knee, and pantograph, as shown in Fig. 8.6. Vertical break disconnecting switches are usually mounted horizontally, but some are vertically mounted. Center side break disconnecting switches require wider phase spacing. Knee-type disconnecting switches are favored

**Fig. 8.5** Photograph of a 550 kV AC dead-tank circuit breaker. (Courtesy of Chugoku Electric Power)

**Fig. 8.4** Photograph of a 550 kV live-tank SF<sub>6</sub> gas circuit breaker. (Courtesy of Dominion Energy)

**Fig. 8.6** Typical disconnecting switches

**Fig. 8.7** Photograph of 77 kV composite-type MOSAs in a substation. (Courtesy of Chubu Electric Power)

when the clearance above the switch is restricted. The pantograph type is the most compact design for installation.

An earthing switch is manually or automatically closed for earthing/grounding and insulating a circuit before working on that circuit. It is open during normal power transmission operation.

An instrument transformer is a measuring device that uses the secondary current or voltage, which is essentially proportional to the primary current or voltage.

A surge arrester can limit the duration and (frequently) the amplitude of the voltage, and is therefore used to protect the system and equipment from excessive overvoltages due to lightning strikes or switching operations. One important role of a surge arrester is to maintain the reliability of the power system and equipment, as described in more detail below.

All types of substation equipment are assigned a rated voltage by the manufacturer of the equipment. The manufacturer-specified performance of the equipment in a power system corresponds to the performance achieved at the rated voltage.

### 8.1.2 Surge Arresters

There are two different types of overvoltages in a power system: those generated by lightning strokes and those produced by switching operations. Substation equipment must be able to withstand these overvoltages up to the specified overvoltage withstand level. Surge arresters [8.1] perform an important role in suppressing excessive overvoltages in substations (Fig. 8.7) and in transmission lines (Fig. 8.8).

Surge arresters are installed at different locations in substations to limit lightning-induced and switching-induced overvoltages to a specified protection level, which should (in principle) be below the withstand voltage of the equipment. An ideal surge arrester would

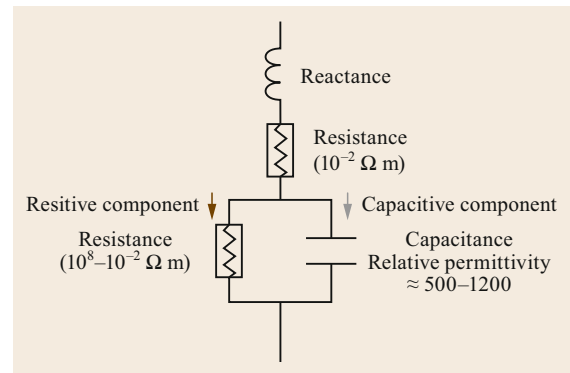

**Fig. 8.8** Photograph of a MOSA with a gap used in a transmission line. (Courtesy of Chubu Electric Power)

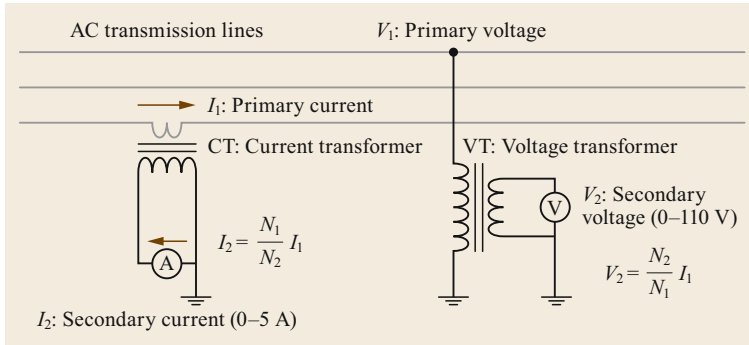

convert from an insulating state to a conducting one at a specified voltage in order to maintain the voltage level and avoid an excessive overvoltage, and would shift from a conducting state to an insulating one as soon as the voltage across the surge arrester drops below the specified voltage level. Therefore, a surge arrester only has to absorb the energy associated with the overvoltage.

Figure 8.9 shows the equivalent circuit of a metal-oxide surge arrester (MOSA) element. The current-voltage characteristic of the MOSA presents a degree of nonlinearity, which results in a low protection level (due to the dispersion of the resistive current-voltage characteristic at high current) and low power dissipation at the operating voltage of the system. A MOSA can be connected to the system without the need for a series of spark gaps that disconnect the varistors from the operating voltage. However, this is only possible if the current-voltage characteristic of the MOSA remains stable over time and if the correct MOSA has been selected for use given the voltage stresses that occur in service. Surge arresters must also be thermally stable. The current through the metal-oxide varistor block at the operating voltage has to stay well within the current-voltage characteristic.

When the residual current flows through the metal-oxide varistor, it remains capacitive and the voltage

**Fig. 8.9** Equivalent circuit of a MOSA disk element

**Fig. 8.10** Principles of conventional instrument transformers (CT and VT)

across the varistor elements is determined by their capacitance and thus influenced by stray capacitances. Stray capacitances to earth cause a deviation from the linear axial voltage distribution, because of higher voltage stress imposed on the upper elements in the arresters. This deviation is influenced by physical parameters of the arrester such as its height, number, and length of arrester elements and its grading rings.

With increasing varistor temperature during operation, the ohmic current component of the varistor increases the linearity of the voltage distribution in the arrester. Grading rings are often inserted as a passive and effective measure to improve the voltage distribution.

The design and operation of surge arresters has changed radically over the last thirty years from valve-type or spark-gap-type silicon carbide (SiC) surge arresters to gapless metal-oxide (MO) or zinc-oxide (ZnO) surge arresters.

A MOSA essentially consists of billions of microscopic junctions of metal-oxide grains that turn on and off in microseconds to create a current path from the top terminal to the earth terminal of the arrester. Therefore, it can be regarded as a very fast-acting electronic switch that is open to operating voltages. The current-voltage characteristic of the metal-oxide material offers the nonlinearity necessary to fulfill the contradictory requirements of an adequate protection level at overvoltages and low energy dissipation at the system operating voltage. MOSAs are suitable for protection against switching overvoltages at all operating voltages.

Traditionally, metal-oxide surge arresters were housed in porcelain. For satisfactory performance, it is important that the units are hermetically sealed for the lifetime of the arrester discs. The sealing arrangement at each end of a porcelain-housed arrester consists of a stainless-steel plate with a rubber gasket. A rapid increase in the internal arc pressure due to a failure may cause the sealing plate to open and the gases to flow

out through venting ducts. Since these ducts are oriented towards each other, this results in an external arc, relieving the internal pressure and preventing the insulator from being violently shattered.

The benefits of a leak-tight design employing the polymers highlighted in Fig. 8.7 are now generally accepted, which has resulted in a shift from porcelain to polymer (composite-type) housing. The bonding of the silicone rubber with the active parts in polymer-housed arresters is very reliable, so gaskets or sealing rings are not required. When failure occurs, the arc easily burns through the soft silicone material, permitting the rapid release of the resultant gases. Hence, the special pressure-relief vents incorporated into porcelain housing to avoid explosions are not required with composite-type housing.

**Fig. 8.12** Basic configuration of a conventional current transformer (CT)

### 8.1.3 Instrument Transformers

Instrument transformers are electrical devices that are used to probe the voltage and current in an AC power system and to generate an information signal that can be sent to measuring instruments, meters, and protective or control systems. The fundamental function of instrument transformers is to step down the high voltage and current present in transmission and distribution systems to low voltage (110–120 V) and current (5 A) levels. The term *instrument transformer* encompasses both current transformers and voltage transformers [8.2].

Current transformers (CTs) and voltage transformers (VTs) convert the primary current and voltage to the secondary current and voltage, respectively. The secondary current and voltage are essentially proportional to the primary current and voltage, respectively, and differ from them by a phase angle that is approximately zero for an appropriate connection. The windings of CTs or VTs connected to the primary side are isolated from those of the secondary side, and there is usually a meter or relay in the secondary circuit. Due to the low

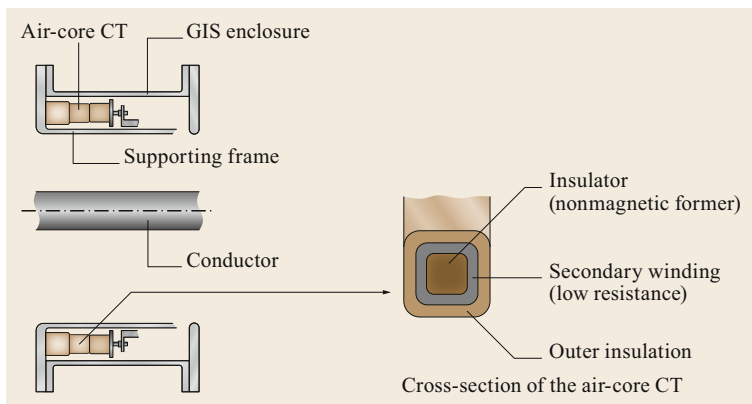

voltage and current levels in the secondary circuit, the power consumption of instrument transformers and protective circuits is advantageously low.

CTs and VTs are used to step down the primary current and voltage of power systems to lower levels so that they can be measured by an ammeter or voltmeter with a small rating (e.g., 5 A or 110 V). Figure 8.10 shows a conventional CT and VT arrangement on transmission lines, where the secondary circuit is isolated from the primary circuit with a transformer. Figure 8.11 shows a conventional 550 kV electromagnetic-type current transformer.

The winding of a conventional CT at the primary side has only a few turns or, more commonly, consists of a primary conductor (bar) with just one turn. On the other hand, the winding of a CT on the secondary side normally has a large number of turns (Fig. 8.12). The secondary winding is directly connected to an ammeter. As the ammeter has a stray impedance, the secondary circuit of a CT usually operates under short-circuit conditions. One terminal of the secondary circuit is earthed to avoid overvoltage.

Conventional CTs with an iron core have long been widely applied for current measurements in AC power systems. However, nonconventional CTs such as a CT with an air core, an electronic CT (ECT) with a Rogowski coil, and an optical CT have recently found increasing application in this context due to some technical advantages: nonsaturation, a wide dynamic range, a compact design, and a low weight. Conventional CTs used in EHV and UHV power systems require a heavy iron core with a large diameter to avoid core saturation, especially for gas-insulated switchgear (GIS) applications, as shown in Fig. 8.13.

The magnetization ( $M$ ) of a magnetic core normally increases with the external magnetic field ( $H$ ) or the magnetizing current through the core (caused by the magnetic field). However, the magnetization eventu-

**Fig. 8.13** Configuration of an air-core CT for EHV-class GIS

**Fig. 8.14** Hysteresis loop (MH-characteristic) of an air-core CT for EHV-class GIS

**Fig. 8.15** Use of the Faraday effect in an optical CT

ally saturates when the external magnetic field reaches a certain threshold value where the magnetic field cannot increase the magnetization of the core further. This threshold value depends on the ferromagnetic material involved. Above the saturation level, an instrument transformer does not respond linearly with magnetic flux to increases in current in the primary circuit, meaning that the secondary current is no longer proportional to the primary current.

Figure 8.14 shows a schematic of the magnetic hysteresis loop (the  $M$ - $H$  characteristic of the ferromagnetic core). As the magnetic field ( $H$ ) increases, the magnetization ( $M$ ) approaches the saturation value. Above the saturation level, the total magnetic flux density continues to increase with increasing magnetic field, but only very slowly.

When the magnetic field decreases to zero, the magnetization does not become zero because the atoms in the core retain some inherent level of magnetic orientation. This is called the magnetic remanence or the residual flux of the core. The polarity of the magnetic field must be reversed to demagnetize the core.

Air-core CTs and Rogowski coils use a nonmagnetic former instead of an iron core for the secondary winding in order to eliminate core saturation. Unlike conventional CTs, the output signal of a nonconventional CT is a voltage because it detects the voltage induced by the magnetic flux (induced by the primary current) passing through the secondary winding. The output signal from an air-core CT with low impedance in the secondary winding can be connected directly to a protection device. The output signal from a Rogowski

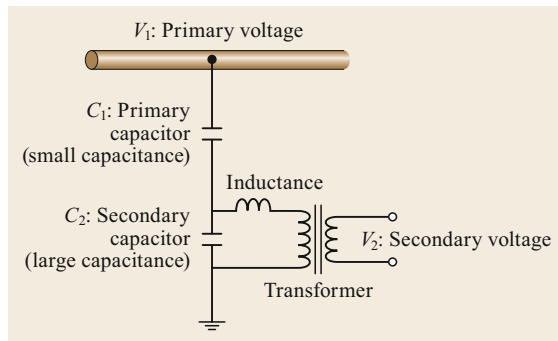

**Fig. 8.16** Use of a Rogowski coil for current measurement

coil for ECT, which has high impedance in the secondary winding, is converted to a digital (optical) output near to substation equipment such as GIS and circuit breakers and then transmitted to a protection device. An optical CT uses the Faraday effect (Faraday rotation) for current measurement. Faraday rotation is a magneto-optical phenomenon resulting from the interaction between light and a magnetic field in a medium. It causes the plane of polarization to rotate to an extent that is linearly proportional to the magnetic field in the direction of propagation, as shown in Fig. 8.15. Table 8.1 summarizes the different principles used by these CTs.

The Rogowski coil is a CT with a very high load impedance but without a ferromagnetic core. The output signal is a function of the first derivative of the current. The secondary winding is wound around a toroid of insulating material. The Rogowski coil is normally connected to measuring or protection equipment through an amplifier. Figure 8.16 shows a schematic of a typical Rogowski coil sensor.

CTs are designed to provide an output of either 1 or 5 A, even when using a modern programmable protection relay, which does not present a problem because the CT ratio can be adjusted to the input received from the CT. Therefore, the output from the CT needs to meet the input requirements of the protection relay. Various ratios (such as 3000/2000/1000/1A) can be supplied by a CT. This allows the lowest current to be measured initially with a ratio of 1000/1A. When the current demand grows, the ratio can be changed to 2000/1A or 3000/1A. CTs with ratios of 2000/1600/1200/800/600/500/400/1A are suitable for measuring a primary current of between 2000 and 400 A. High-voltage CTs are often insulated with mineral oil or SF<sub>6</sub> gas, while medium- and low-voltage CTs are normally insulated with solid epoxy casting resin.

A VT or potential transformer (PT) steps the voltage of the power system down to a lower level. There

**Fig. 8.17** Typical configuration of a capacitor voltage transformer (CVT)

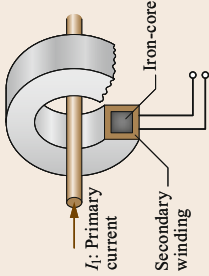

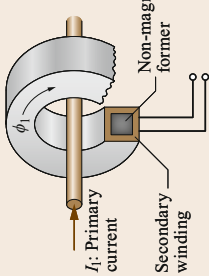

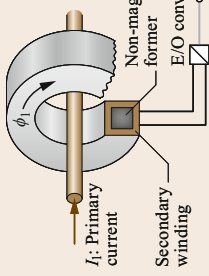

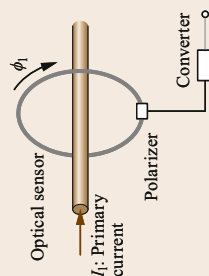

are three major types of VTs or PTs: conventional electromagnetic, capacitor, and optical sensor. A conventional electromagnetic VT uses a transformer with primary and secondary windings. A capacitor voltage transformer (CVT) uses a capacitive potential divider, which provides an economic benefit compared with an electromagnetic VT, especially for higher-voltage applications. The optical voltage transformer exploits the Faraday effect and detects the rotation of polarized light passing through optical materials.

The primary winding of a conventional VT is connected to the line (main circuit) on one side and earthed on the other terminal. The secondary winding of the VT has a few turns that are directly connected to a voltmeter with high impedance and isolated from the primary circuit. The secondary circuit normally operates in the open, with one terminal earthed to ensure safety.

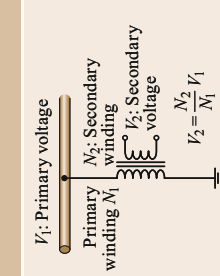

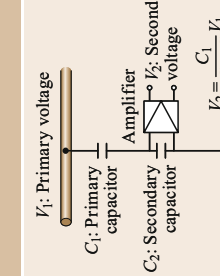

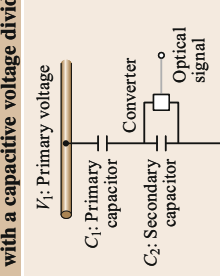

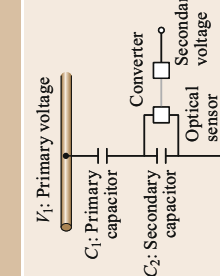

A conventional VT requires a large iron core, especially for EHV and UHV applications. Figure 8.17 shows the typical configuration of a CVT, which provides a low-voltage signal for metering or operating a protective relay. A CVT normally consists of three parts: two dividing capacitors, an inductance to tune the device to the line frequency, and a voltage transformer to isolate the voltage from metering devices or protective relays. Capacitor  $C_1$  is often composed of a stack of smaller capacitors connected in series. This provides a large voltage drop across  $C_1$  and a relatively small voltage drop across  $C_2$ . The dividing capacitors reduce the level of insulation required for the voltage transformer. This makes CVTs more economical than conventional voltage transformers when they are used at transmission levels.

The output voltage of a CVT is converted into a digital signal near equipment and may be transmitted to protection systems. Table 8.2 summarizes the principles of the different types of VTs. Figure 8.18 shows a typical 300kV CVT and a 72kV inductive voltage transformer.

**Fig. 8.18** (a) A 300 kV capacitor voltage transformer (CVT). (b) A 72 kV inductive voltage transformer

Oscillations of lower and higher harmonics of the power frequency (known as *ferroresonance*) can be induced by switching operations in power systems due to a resonant interaction between the nonlinear reactance of the electromagnetic voltage transformer (VT) and the capacitances of the network and equipment (e.g., the grading or coupling capacitors of circuit breakers). Ferroresonance can damage electromagnetic VTs through overheating and/or overvoltage stress.

On the other hand, when ferroresonance occurs in CVTs, it normally originates from the interaction of internal components of the VT—specifically the nonlinear inductance—with the stray capacitances of the HV winding. A large amount of magnetic energy is stored in the compensation reactor during a secondary short circuit. This energy is released in the primary winding, which can lead to the saturation of the transformer core when the secondary short-circuit current is interrupted. The high-voltage peaks caused by core saturation can endanger the insulation of the VT and the reactor and may eventually destroy these components. These voltage peaks usually occur at subharmonic frequencies:  $1/5$ ,  $1/4$ ,  $1/3$ , or  $1/2$  of the rated power frequency.

Countermeasures are usually deployed for ferroresonance to prevent faults and the destruction of the voltage transformer. For electromagnetic VTs, ferroresonance is usually suppressed by connecting a damping resistor to the tertiary winding of the VT or to the open delta connection of the tertiary windings of the three VTs in a switching bay. The resistor can either be permanently connected or temporarily inserted by placing a reactor in series with the resistor. The reactor effectively acts as a switch and closes when the voltage peaks occur. Sometimes it is not possible to suppress rated power-frequency ferroresonance by means of a damping resistor, but ferroresonance can be prevented from occurring in such cases by judiciously positioning equipment. For capacitive VTs (CVT), ferroresonance damping devices are an integral part of the IT sensing system. An additional resistor and its switching reactor are included within the electromagnetic unit of the CVT, or the overvoltage peaks are reduced by an active-gap surge arrester or an external arc gap.

Table 8.3 summarizes the major differences between CT and PT.

**Table 8.3** Differences between a CT and a PT

Current transformer (CT)	Potential transformer (PT)
Connected to the main circuit in series	Connected to the main circuit in parallel

Secondary circuit operates under short-circuit conditions	Secondary circuit operates under open-circuit conditions
One terminal of the secondary circuit is earthed to avoid insulation breakdown	One terminal of the secondary circuit is earthed for safety reasons

### 8.1.4 Series Capacitor, Shunt Capacitor, and Shunt Reactor Compensation

#### Reactive Power Control

Electricity must be supplied with a constant voltage and at a constant power frequency. Since loads are frequently switched on and off, the balance between the amount of electricity supplied (power generation) and the amount of electricity consumed (demand) must be maintained in real time using a demand control system. The utilities normally employ ancillary spinning reserves in addition to bulk base power generators since electricity cannot be effectively stored in large quantities.

The active power is controlled by this marginal power supply capability. However, if the supply is insufficient (due, perhaps, to a large-scale loss of generators), it may be necessary to reduce the active power consumption by disconnecting some parts of the load. The reactive power can also be controlled by reserve generators as well as by static compensation devices such as capacitors and reactors. Synchronous generators are one of the most important components of the power system for maintaining the active and reactive power balance.

Figure 8.19 shows a schematic of a transmission line connected to generators at both ends. The generators and step-up transformers provide a constant voltage at the bus terminal. However, the system voltage decreases slightly at the midpoint due to reactive power consumption under heavy load conditions. In contrast, the system voltage increases slightly at the midpoint under light load conditions.

In general, static shunt capacitors are applied in transmission lines to inject reactive power into the system, whereas static shunt reactors are applied to consume reactive power, leading to an improved power factor. Figure 8.20 shows that the system voltage is slightly compensated at the middle point by connecting either shunt capacitors under heavy load conditions or shunt

**Fig. 8.19** System voltage distribution along a transmission line under heavy and light load conditions**Fig. 8.20** System voltage distribution along a line when a capacitor or a reactor is connected

**Fig. 8.21** Transmission lines with series capacitors

reactors under normal load conditions. The circuit breakers that are used to switch the static shunt capacitors and reactors on and off frequently operate under reactive power control, which may result in undesirable switching transients. Controlled switching can effectively reduce switching surges by controlling the switching instants of the circuit breakers (Sect. 8.4). More recently, compensators based on power electronic devices—the static VAR compensator (SVC) and the static synchronous compensator (STATCOM)—have also been used to effectively control the reactive power. For example, a STATCOM can control the reactive power by adjusting the amplitude of the supply voltage, which is phase synchronized with the transmission network.

The reactive power in a power system can also be controlled by connecting series compensation equipment to the transmission lines, as shown in Fig. 8.21. Series capacitors are sometimes applied to long transmission lines in order to reduce the line reactance, resulting in increased transmission capacity.

However, great care must be taken when using series capacitors due to potential disadvantages such as subsynchronous resonance of turbine generator shafts and increased transient recovery voltage (TRV) peaks imposed on the terminal of circuit breakers. Standards do not cover the interrupting duties of circuit breakers applied to series-compensated lines.

### Shunt Reactors

Transmission lines or underground cables, particularly those used for voltages of 72.5 kV and above, can produce a large amount of capacitive reactive power that can cause the voltage profile of the transmission network to exceed its maximum level.

Shunt reactors absorb reactive power and influence voltage regulation by reducing the voltage profile. Power transfer from a highly variable renewable-energy source can require the installation of more shunt reactors at the transmission level to control the increase in capacitive reactive power that occurs when the infeed from the energy source is low (when there is no wind at a wind farm, for instance). When they do not carry a large amount of active power, transmission lines exhibit strong line charging due to the Ferranti effect. Shunt reactors keep the voltage within the desired margins.

**Fig. 8.22** Photograph of a 20 kV, 22.5 MVA shunt reactor bank. (Courtesy of J-POWER)

Shunt reactors can be installed as a three-phase unit or as three single-phase units depending on the rated reactive power, the system voltage, or planning and design criteria. The shunt reactor can be permanently connected (a fixed shunt reactor) or switched through a circuit breaker, and it can be installed at the transmission line terminals or connected to the substation busbar. Figure 8.22 shows an example of a 20 kV shunt reactor that has a similar structure to a power transformer with some cooling units.

Variable shunt reactors with a tap changer are applied when precise and slow voltage regulation is required, whereas switched shunt reactors are used for less coarse but flexible voltage regulation. Gapped, oil-immersed shunt reactors with an iron core are employed for large reactive power ratings and high voltage levels in order to minimize losses and reduce audible noise and vibration. For lower voltage levels and smaller reactive power ratings, dry-type shunt reactors are used, sometimes without an iron core to lower the cost.

**Fig. 8.23** Photograph of a 23 kV, 22.5 MVA shunt capacitor bank

### Capacitor Banks

Capacitor banks produce reactive power to compensate for the inductive reactive power that originates from transformers, transmission lines that are loaded above their switching impulse protection level, or inductive loads. The use of capacitor banks increases the transmission capacity, reduces losses due to the improved power factor, and leads to a better voltage profile.

A capacitor bank consists of several capacitors of the same rating that are connected in series or parallel, Fig. 8.23. Capacitor banks can be permanently connected (fixed capacitor bank) or switched through a circuit breaker, and can be installed at the transmission line terminals or at the substation busbar. For voltage ratings of 72.5 kV and higher, each bank has its own circuit breaker. The inrush or outrush currents can be kept under control in an active manner (by controlled switching or with a preinsertion impedance) or in a passive fashion with series reactors.

Series reactors (also called damping reactors) can help to reduce resonance in the network. Power transfer from a highly variable renewable-energy source can require the installation of more capacitor banks at the transmission level to cope with the increase in inductive reactive power that occurs when the infeed from the energy source is high (when there is excessive wind at a wind farm, for instance).

### Series Capacitors

There have recently been some technical advances in the use of series compensation with power electronics. Overvoltage protection schemes have progressed from a sole bypass spark gap to a bypass spark gap with a MOSA or even to fast-acting thyristor-controlled series capacitors (TCSCs) or fast protective devices (FPDs), which can reduce the number of MOSAs needed.

Before the 1980s, when spark gaps were of the self-discharging type, series compensation banks had to be bypassed during (internal or external) line faults, in-

fluencing system availability. MOSAs facilitate series-compensated power transfer in healthy transmission lines by protecting series compensations from power frequency overvoltages [8.3].

Since TCSCs can control the degree of compensation rapidly and flexibly, they can mitigate the risk of subsynchronous resonance (SSR) in power grids and improve power system transient stability by damping low-frequency power oscillations. In thyristor-protected series compensations (TPSCs), the spark gap is replaced by thyristor valves. Since a thyristor valve responds more rapidly and is more accurate than a spark gap, the TRV peak in circuit breakers located on the line side is reduced and energy dissipation from MOSAs is also minimized [8.4].

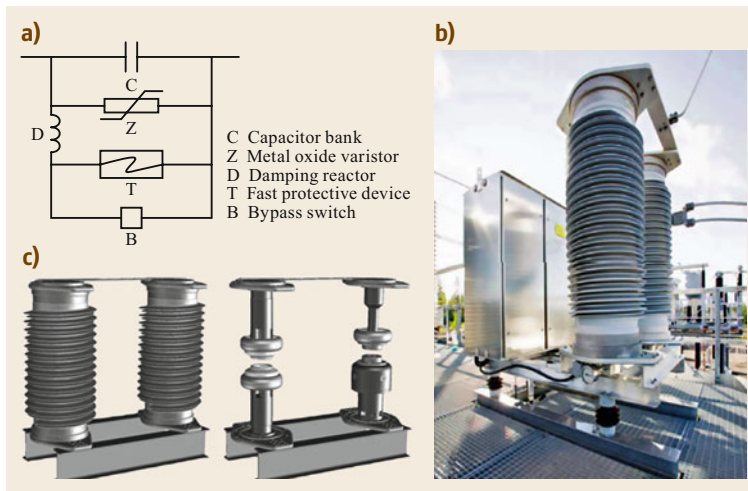

Furthermore, a FPD in which the spark gap is replaced with an immediate bypass on command has been developed and applied to series compensations. This FPD consists of a fast-closing switch in parallel with a sealed plasma triggering gap. FPDs can operate at a very low series-compensation voltage.

Technologies used instead of a triggering gap include a trigatron triggered spark gap, a voltage transformer triggered gap, and a plasma spark gap. These conventional technologies are described in detail in technical brochures. The main gaps for both the trigatron and the voltage transformer triggered spark gap operate in almost the same way. The main gap is required to carry a large power frequency fault current and to maintain a consistent spark-overvoltage characteristic for a long duration in multiple operations.

The FPD consists of a hermetically sealed and very fast-acting forced trigger spark gap called an arc plasma injector (API) that is connected in parallel to a mechanical switch termed a fast contact (FC), as shown in Fig. 8.24. The two switches are housed in two composite chambers filled with high-pressure gas. To activate the FPD, a triggering pulse is issued to the API, which can bypass the series-compensation bank. Simultaneously, a command is issued to close the FC within a few ms.

The specification of a MOSA must be able to cope with the worst-case maximum residual voltage. The number of MOSA elements used depends on the energy-dissipating ability of a single MOSA element as well as the current that is divided among the parallel columns. To divide the current equally among the parallel MOSA columns, the residual voltages need to be precisely matched.

Reliability surveys have reported that some MOSAs have failed at energies smaller than indicated by their specifications. This issue was not found to be related to aging problems. In China, UHV bypass switches are normally designed with a T-shaped structure. High-quality WCu material is used for the contacts to stabilize the arc

**Fig. 8.24** (a) Circuit diagram, (b) structure and, (c) a photograph of a fast protective device (FPD) installation

**Fig. 8.25a,b** Photographs of post insulators in a 420 kV AC substation (a) and a 500 kV DC converter station (b) [8.5]

resistance performance. The mass of the insulation rod is reduced and the driving angle and its guide structure are optimized to improve operation performance.

The bypass disconnector must be able to transfer the current to the series compensation and vice versa. Due to the existence of a damping circuit, a voltage will be generated between the contacts of the bypass disconnector during current transfer. A parallel switching branch can be applied at the same time as the main disconnector contact; this parallel switching branch consists of an arcing contact and a 12 kV vacuum breaker connected in series.

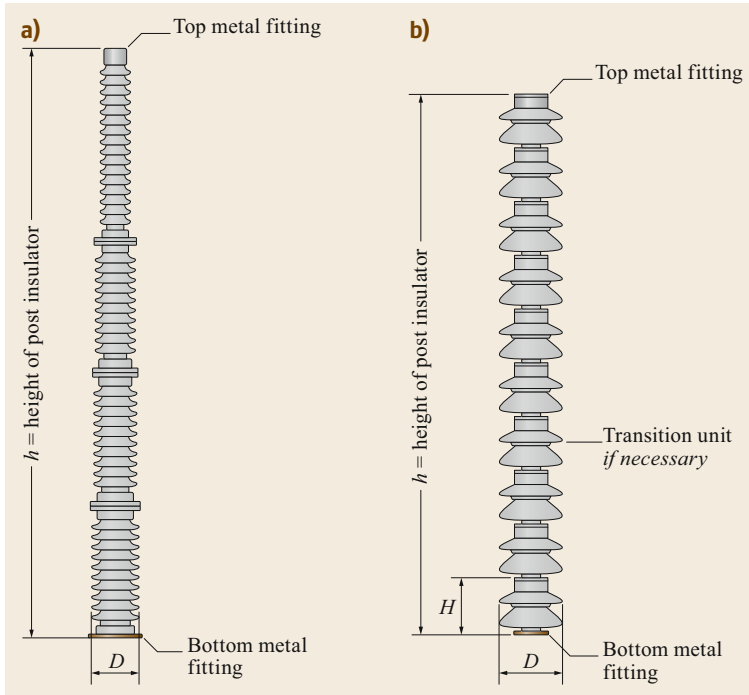

### 8.1.5 Substation Post Insulators

Post insulators provide mechanical support and electrical insulation for high-voltage substation equipment. They are most commonly mounted vertically on a steel

support structure, but may also be mounted horizontally or underhung. A post insulator is an insulator that is intended to give rigid support to a live part that must be insulated from the ground or from another live part, Fig. 8.25.

#### Insulation Material and Type

Post insulators can be classified into two main categories depending on the insulating material used: porcelain and composite. Porcelain is traditionally used in post insulators because this material is very solid, reliable, and well proven. However, composite post insulators have become increasingly popular in recent years because of their design flexibility and relatively light weight, their withstand performance with respect to internal pressure, seismic events, and high contamination, and their ease of handling when they are being manufactured or installed.

**Fig. 8.26a,b** Typical porcelain post insulators. (a) Solid-core cylindrical post insulator. (b) Pedestal post insulator

**(a) Porcelain Post Insulators.** Porcelain post insulators come in two types: solid-core cylindrical and pedestal, which are made up of stacks of single insulator units, as shown in Fig. 8.26. These post insulators are made from wet-processed porcelain machined to the desired specification and are coated with a hard, weatherproof glaze before being kiln dried to give them high electrical and mechanical strength. Galvanized iron or cast aluminum fittings are attached to the insulator ends using Portland cement.

Solid-core cylindrical post insulators consist of solid porcelain with a glazed surface. In some cases, this surface may be coated with silicone rubber for

improved pollution performance. For manufacturing reasons, the length of an individual insulator unit is limited. Although the feasible length of an insulator units has increased over time, most post insulators used for higher voltages comprise two or more insulator units that are stacked together in an insulating column to provide the required arcing distance.

Pedestal post insulators have standardized top and bottom fittings between which the insulator stacks are built in order to meet the specification of the post insulator.

**(b) Composite Post Insulators.** Because they are a relatively new technology, composite post insulators (Fig. 8.27) are not as commonly used as porcelain post insulators, but they have found increasing use in recent years. Composite post insulators can have a hollow core or a solid core.

**Solid-core design:** The solid cores used in composite post insulators commonly consist of fiber-glass-reinforced resin rods that provide mechanical strength (similar to line composite insulators). The housing and sheds are made from a polymeric material, most often silicon rubber.

**Hollow-core design:** A hollow core used in a composite post insulator generally consists of a tube that provides mechanical support. In this design, there is also an external insulating part—the housing, including sheds, which provides the necessary creepage distance and protects the tube from the environment (this

**Fig. 8.27** A composite post insulator [8.6]

concept is similar to that used for composite insulators used in other high-voltage equipment, such as circuit breakers and instrument transformers). Composite hollow-core post insulators may be filled with a gaseous, liquid, or solid insulating material (such as urethane foam).

A key advantage of composite post insulators is that the polymeric materials used in them exhibit hydrophobicity, which means that they repel water. Sometimes the polymeric material also repels pollution on the insulator surface, in which case the material is referred to as a hydrophobic transfer material. In theory, this means that a shorter creepage distance may be used in a composite post insulator than in a porcelain post insulator.

### 8.1.6 Technical Requirements and Design Parameters

Post insulator design involves optimizing various parameters to ensure that the post insulator is capable of withstanding specific levels of electrical, mechanical, and environmental stress.

#### (a) Electrical Performance

The main parameters that influence the electrical performance of a post insulator are the arcing distance, creepage distance, and housing profile. Post insulators are designed and tested to withstand specified lightning and switching impulses as well as power frequencies (certain types of post insulators also have a defined minimum puncture voltage). For composite post insulators, the grading of the electric field along the insulator may be another important aspect that impacts the expected life. This grading can be achieved by applying grading rings and adjusting the sizes and shapes of the flanges during the design phase.

#### (b) Mechanical Performance

The length, the core diameter and material, and the design of the end fittings as well as the method used to attach them are regarded as the design parameters that exert the strongest influence on the mechanical performance of a post insulator. The mechanical design of a post insulator must take into account mechanical stresses, such as those arising from short circuits, seismic activity, and external loads. Porcelain post insulators are categorized into mechanical strength classes based on the failing load of the insulator in a bending test. Composite post insulators also undergo a bending test.

#### (c) Environmental Performance

The design phase also involves selecting the shed profile and the number of sheds that will allow good

dielectric withstand at a particular pollution level under wet conditions, thus fulfilling the requirements defined in the standards [8.7–10].

#### Standards and Type Tests

Substation post insulators are covered by a relatively large number of IEC standards:

- IEC 60168:1994 (on tests of indoor and outdoor post insulators made from ceramic or glass for systems with nominal voltages of more than 1000 V)
- IEC 60273:1990 (on characteristics of indoor and outdoor post insulators for systems with nominal voltages of more than 1000 V)
- IEC/TS 60815-2:2008 (on the selection and dimensioning of high-voltage ceramic and glass insulators intended for use in AC systems under polluted conditions) [8.9]
- IEC/TS 60815-3:2008 (on the selection and dimensioning of high-voltage polymeric insulators intended for use in AC systems under polluted conditions) [8.10]
- IEC/TR 61462 (on definitions, test methods, acceptance criteria, and design recommendations for composite hollow-core insulators for use in outdoor and indoor electrical equipment)
- IEC 61462:2007 (on definitions, test methods, acceptance criteria, and design recommendations for pressurized and unpressurized composite hollow-core insulators for use in electrical equipment with rated voltages of more than 1000 V)
- IEC 62217:2012 (on general definitions, test methods, and acceptance criteria for polymeric insulators for indoor and outdoor use in HV systems)
- IEC 62231-1:2015 (on definitions, test methods, and acceptance criteria for composite post insulators for use in substations with AC voltages of 1000 V to 245 kV)
- IEC 62772:2016 (on definitions, test methods, and acceptance criteria for composite hollow-core post insulators for use in substations with AC voltages of more than 1000 V and DC voltages of more than 1500 V).

In general, porcelain post insulators are covered by IEC 60168 and IEC 60273. IEC/TS 60815-2 is applied when it is necessary to dimension for polluted conditions.

IEC 62231-1 covers solid-core but not hollow-core composite insulators. Hollow-core composite insulators are covered by IEC 61462, which does not cover post insulators and is limited to designs with voltages of up to 245 kV. Material-related qualification is covered by IEC 62217, and dimensioning for polluted condi-

tions by IEC/TS 60815-3. IEC 62772 refers to the other relevant standards and creates a system that covers all hollow-core composite insulators.

The following type tests are normally carried out for post insulators in accordance with IEC 60168 and IEC 62231:

- Dry lightning-impulse withstand voltage test
- Wet switching-impulse withstand voltage test (only for insulators in systems with the highest voltages of 300 kV or more)
- Wet power-frequency withstand voltage test
- Mechanical failing load test.

## 8.2 History and Principles of High-Voltage Circuit Breakers

The development of circuit breakers is closely linked to the remarkable growth in the demand for higher-voltage transmission systems with large short-circuit capacities. Since the late 1800s, a wide range of interrupting technologies that use oil, air, vacuum, and SF<sub>6</sub> gas as interrupting media have been developed and have contributed to the construction of large-capacity power transmission systems.

### 8.2.1 History of Circuit Breaker Development

The first circuit breaker, which was of the bulk oil type, was developed by *Kelman* [8.11] in the early 1900s. It consisted of a crude arrangement of switches in separate wooden barrels connected in series and operated simultaneously. Bulk oil circuit breakers evolved over subsequent decades. The main advances were made in the United States by *Slepian* of Westinghouse [8.12] and *Prince* and *Skeats* of General Electric [8.13].

In Europe, bulk oil circuit breakers reigned until the early 1950s, but were then completely supplanted by minimum oil circuit breakers. Bulk oil circuit breakers with eight breaks in series are used in systems with voltages of up to 360 kV, while minimum oil circuit breakers with up to ten breaks in series are used in systems with voltages of up to 420 kV. It should be noted that some utilities are still using these types of oil circuit breakers.

The air-blast circuit breaker was developed in Europe, initially by *Whitney* and *Wedmore* of the British Electrical Research Association [8.14, 15] in 1926 and subsequently in Germany and Switzerland in the 1930s and 1940s. Air-blast circuit breakers became popular in the 1960s and enabled the construction of extra-high-voltage systems of 500 kV and above. This type of circuit breaker was manufactured until the early 1980s, when they were superseded by less expensive and complex SF<sub>6</sub> puffer-type circuit breakers. Air magnetic circuit breakers, a variant of air-blast circuit breakers, were used at medium voltages of up to 52 kV.

SF<sub>6</sub> gas was recognized for its unique dielectric properties in the 1920s, when *Cooper* of General Electric [8.16] applied for a patent on its use in capacitors and gas insulated cables. However, the SF<sub>6</sub> gas circuit breaker did not appear on the market until the mid-to-late 1950s [8.17]. The application of SF<sub>6</sub> gas to current interruption was patented by *Lingal, Browne, and Storm* of Westinghouse in 1956 [8.18]. The first SF<sub>6</sub> gas circuit breakers were designed with dual pressure, based on axial gas blast principles.

The puffer-type SF<sub>6</sub> circuit breaker, which is often referred to as the single-pressure circuit breaker, was developed in the 1970s based on a principle invented by *Prince* [8.17], who also designed the impulse-type bulk oil circuit breaker [8.12], where the oil flow is produced by a piston driven by the operating mechanism. Further development of SF<sub>6</sub> circuit breakers led to rotating arc

**Fig. 8.28** Evolution of the interruption capacity per break, encompassing different circuit-breaker types

**Fig. 8.29** Approximate manufacturing periods for different circuit-breaker types

**Fig. 8.30** Kelman's oil circuit breaker built in 1901 (40 kV, 300A) [8.19]

technology for voltages up to 72 kV and self-blast technology for voltages above 72 kV.

Vacuum interrupters were also developed in the 1920s [8.20], but the first commercial vacuum circuit breakers did not appear until the 1960s. The vacuum circuit breaker is still commonly used today at medium voltages and is also available for transmission voltages of up to 170 kV [8.21].

Figure 8.28 provides a historical perspective on the interruption capability per break, encompassing all of the above circuit breaker technologies. It is clear that there have been a couple of technology transitions. The first technical transition—from oil to air—occurred around 1960, which led to the construction of EHV networks; another transition—from air to SF<sub>6</sub>—occurred around 1970, which led to improved high-capacity circuit breakers and enhanced network reliability.

The application time lines for the six major circuit-breaker types are shown in Fig. 8.29. Oil circuit breakers were manufactured from around 1910 until 1990. Air circuit breakers were mainly manufactured from 1950 to 1980. SF<sub>6</sub> circuit breakers have dominated since 1970. Vacuum circuit breakers also have a long history of production.

The first circuit breaker had a switch immersed in a large tank filled with mineral oil, which served as

**Fig. 8.31** An early oil-immersed circuit breaker design

**Fig. 8.32** A cross-sectional drawing of a 145 kV, 63 kA bulk-oil circuit breaker

**Fig. 8.33** Photograph of some 345 kV, 63 kA oil circuit breakers

an extinguishing and insulating medium. Figures 8.30 and 8.31 show a photograph and the design of an early oil-immersed circuit breaker, respectively. Figure 8.32 presents a cross-sectional drawing of a more modern bulk-oil circuit breaker rated at 145 kV and 63 kA. Figure 8.33 shows a photograph of oil circuit breakers rated at 345 kV, which is the highest rated voltage achieved with mineral oil. These circuit breakers were originally designed for an interrupting duty of 40 kA, but were subsequently modified to allow an interrupting duty of 63 kA through the use of internal shields to prevent voltage flashovers to the tank wall during interruption.

During the current interruption process, the arc vaporizes the oil and creates hydrogen gas. The compressed hydrogen gas blasts into the arc, cooling it down. Hydrogen gas has good conductivity, which is a desirable quality for an arc-quenching medium. However, this design presents a significant risk of explosion and fire if an interrupting failure occurs. Later minimum oil circuit breakers were designed to have an effective

and compact cooling enclosure. The contacts and arcing chamber were placed in a porcelain insulator instead of a bulky metal tank. Despite these risks, oil circuit breakers were manufactured until the 1990s.

Air-blast circuit breakers were developed around 1950 and were used in the first 735 kV networks in Canada, which employed a 800 kV multibreak interrupter design. Given that breaking currents are increasing in today's rapidly developing networks, circuit breakers using SF<sub>6</sub> as the interrupting medium are currently favored in high-voltage networks. Figure 8.34 shows an example of the latest generation of 800 kV air-blast circuit breakers.

The first generation of SF<sub>6</sub> gas circuit breakers included high- and low-pressure gas chambers equipped with moving and fixed contacts in an enclosure filled with SF<sub>6</sub>. High-pressure gas was blown into the arc generated between the contacts in the low-pressure chambers. Figure 8.35 shows an example of a double-pressure gas circuit breaker. In current designs, most of the SF<sub>6</sub> gas is in a single pressure chamber, and the SF<sub>6</sub> is compressed in a puffer cylinder under the control

**Fig. 8.34** Photograph of an example of the latest generation of 800 kV air-blast circuit breakers. (Courtesy of GE, produced by Alstom)

**Fig. 8.35** A 240 kV double-pressure gas circuit breaker

**Fig. 8.36** 245 kV, 50 kA double-break and single-break SF<sub>6</sub> puffer circuit breakers. (Courtesy of ABB, produced by ASEA)

of an operating mechanism and then blasted through a nozzle into the arc. Figure 8.36 shows an example of 245 kV, 50 kA double-break and single-break SF<sub>6</sub> puffer circuit breakers.

In a vacuum circuit breaker, the contacts are operated in a vacuum enclosure. When the vacuum circuit breaker separates the contacts, an arc is generated by the metal ions vaporized from the contact surface. The arc is quickly extinguished because the metallic vapor, electrons, and ions produced during the arc rapidly diffuse and condense on the surfaces of the contacts, resulting in a swift recovery of dielectric strength. Vacuum circuit breakers are commonly used in medium-voltage distribution systems and are available for transmission voltage ratings of up to 170 kV (Fig. 8.37).

The opening and closing operations of mechanical circuit breakers normally generate arc discharge phenomena between the contacts. In the 1940s, *Cassie* [8.22], *Mayr* [8.23], *Cassie and Mason* [8.23, 24], and *Browne* [8.25] showed that interrupting phenomena could be reproduced analytically through the application of dynamic arc equations with a couple of arc parameters in conjunction with circuit equations for power systems [8.26, 27]. Intensive investigations aimed at identifying novel interrupting media with improved properties were performed by the Electric Power Research Institute (EPRI) in the United States [8.28, 29]. Those studies revealed the physical properties of

**Fig. 8.37** Photograph (taken in 1972) of 168 kV, 40 kA vacuum circuit breakers. (Courtesy of Meidensha)

many potential interrupting media. Furthermore, thermofluid dynamics simulation has made it possible to analyze arc interrupting behavior in great detail using more precise arc models [8.30, 31]. The main interrupting phenomena encountered with circuit breakers based on various interrupting media are now described.

### 8.2.2 Interrupting Phenomena for Oil and Air Circuit Breakers

The interrupting process in a mechanical circuit breaker is normally accompanied by an arc that is generated between the contacts after contact separation. This arc is the main switching element of the mechanical circuit breaker. It is used to transform the circuit breaker from the conducting state to the insulating state economically for all ratings of a power system.

For an AC system, the arc interrupting process normally occurs at one of the periodic current zeros associated with the power frequency. A plasma—an electrically conductive hot ionized gas comprising charged particles such as electrons and positive or negative ions—is generated by the arc, and this can carry a large current though a normally nonconductive interrupting medium such as oil, air, SF<sub>6</sub> gas, or a vacuum with and without metal vapor.

In the hot arc plasma, collisions between moving charged and neutral particles create new charged particles while some of the electrons and positive ions recombine into neutral particles (i.e., deionize).

Low-voltage circuit breakers normally use air to extinguish the arc. Figure 8.38 shows a magnetically driven air circuit breaker equipped with some arc chutes consisting of mutually insulated parallel plates. The arc

**Fig. 8.38** A magnetically driven air circuit breaker

**Fig. 8.39** Arc interruption in an oil circuit breaker

chutes divide the arc into smaller and extended arc lengths to aid cooling, which increases the arc voltage and thus limits the current through the circuit breaker. The current-carrying parts near the contacts deflect the arc into the arc chutes using the magnetic force from the current path. Magnetic blowout coils or permanent magnets are also used to deflect the arc into the arc chutes.

Oil circuit breakers utilize vaporized mineral oil to extinguish the arc. Mineral oil has better insulating and interrupting properties than air. In an oil circuit breaker, the fixed and moving contacts are immersed in an enclosure filled with oil. When the contacts are separated

**Fig. 8.40** Configuration of a minimum oil circuit breaker

under load-carrying or short-circuit current conditions, an arc is generated, and the oil is heated by the arc and vaporized, whereupon it decomposes into (mostly) hydrogen gas (small amounts of methane, ethylene, and acetylene are also generated). This ultimately leads to a highly compressed hydrogen bubble around the arc. The bubble displaces the oil near to the arc and effectively cools the arc (Fig. 8.39), and it prevents reignition when the power frequency produces the next current zero. Figure 8.40 shows the typical configuration of a minimum oil circuit breaker.

### 8.2.3 Interrupting Phenomena for Gas Circuit Breakers

Gas circuit breakers normally use a gas such as air, sulfur hexafluoride ( $\text{SF}_6$ ), or gas mixtures that include  $\text{SF}_6$  as insulating and interrupting media to extinguish the arc generated between the contacts.  $\text{SF}_6$  has become the dominant insulating and interrupting medium used in circuit breakers today because it has some unique characteristics that make it ideally suited for this purpose. Some of these characteristics are described below.

#### (a) Density of $\text{SF}_6$

The dielectric properties of  $\text{SF}_6$  are strongly dependent on its density. Figures 8.41 and 8.42, respectively, show how the  $\text{SF}_6$  gas density and  $\text{SF}_6$  gas composition depend on the temperature. The density follows the ideal gas equation up to 1600 K, regardless of the

Fig. 8.41 Density of SF<sub>6</sub> gas versus temperature [8.30]

Fig. 8.42 Decomposition of SF<sub>6</sub> versus temperature [8.30]

pressure. When the temperature exceeds 1600 K, the measured SF<sub>6</sub> gas density is found to be lower than that given by the ideal gas equation (Fig. 8.41). This change occurs due to the decomposition of the gas, as shown in Fig. 8.42. Above approximately 2000 K, SF<sub>6</sub> gas decomposition is markedly enhanced, resulting in

the generation of charged species such as S<sup>+</sup>, S<sub>2</sub><sup>+</sup>, F<sup>+</sup>, and electrons. When the temperature exceeds 4000 K, the SF<sub>6</sub> gas is completely decomposed, resulting in the presence of many different particles. Electrons account for about 1% of all the particles present at temperatures between 8000 and 9000 K. The temperature below the boundary of 8000–9000 K band shows the isolating state. In contrast, the temperature above the boundary band shows the conductive state.

### (b) Thermal Conductivity and Electrical Conductivity of SF<sub>6</sub>

The thermal and electrical conductivity of the medium affect the heat loss from the arc plasma with a small diameter arc around current zero, which can strongly affect the arc interruption capabilities of the circuit breaker. You can find an image of an arc with small diameter at the bottom part of Figure 8.49. In particular, SF<sub>6</sub> can make a narrow arc with smaller diameter as compared with other interrupting media. Figure 8.43 shows the thermal conductivity of SF<sub>6</sub> as a function of temperature. Upon increasing the temperature from 300 K, the first peak in the thermal conductivity appears around 1800 K. On the other hand, the electrical conductivity (Fig. 8.44) increases with temperature because the proportion of electrons (with respect to all particles) rises due to increased ionization. The proportion of electrons is 1% and the electrical conductivity increases between 8000 and 9000 K, which is much higher than the temperature (1800 K) at which the thermal conductivity peaks.

The thermal conductivity generally increases with temperature, and presents distinct peaks in the temperature interval corresponding to the decomposition of SF<sub>6</sub> gas (around 1800–2000 K). This means that the arc shows enhanced thermal conductivity but low electrical conductivity, resulting in good cooling performance, when it is close to this temperature region during the low-current period.

### (c) Specific Heat of SF<sub>6</sub>

The specific heat shown in Fig. 8.45 has two distinctive peaks which can be seen at around 2000 and 20 000 K. The heat capacity becomes larger around these temperatures. When considering a contact heat input, the arc will stay at these temperatures since larger energy is required to increase the temperature in the 2000 and 20 000 K regions. In the high-current region, the arc temperature stays around 20 000 K due to the larger specific heat in the high-temperature region. This is why the core temperature of an arc with a large current does not increase much beyond 20 000 K.

In order to understand why SF<sub>6</sub> gas allows effective arc cooling due to adiabatic expansion, the result of

Fig. 8.43a,b Thermal conductivity of SF<sub>6</sub> versus temperature [8.30]

Fig. 8.44 Electrical conductivity of SF<sub>6</sub> versus temperature [8.30]

mixing two gas volumes—a large-volume ( $V_0 = 1$ ) arc at 20 000 K (corresponding to a large-current state) and a small-volume ( $V_d = 0.1$ ) arc at 1700 K (corresponding to a current of almost zero) at 0.6 MPa—in an isentropic cooling process can be investigated (Fig. 8.47). After mixing the gases, the temperature is found to be

Fig. 8.45 Dependence of the specific heat on the temperature at 0.1 MPa

2600 K (the pressure is 0.35 MPa), which is within the temperature interval corresponding to particularly high heat conduction, leading to enhanced cooling.

The specific heat ratio ( $C_p/C_v$ ) of SF<sub>6</sub> is 1.08, which is considerably lower than those of air and hydrogen (around 1.4). A hot gas with a relatively low specific heat rate, such as SF<sub>6</sub>, requires the removal of less heat to cool it to the dielectric level during an isentropic cooling process involving a volume change.

In a SF<sub>6</sub> gas circuit breaker, the arc is usually generated in a cylindrical insulating nozzle, as this allows the arc to be cooled effectively by controlling the SF<sub>6</sub>

Fig. 8.46 Thermal capacity of SF<sub>6</sub> gas [8.30]

Fig. 8.47 Mixing two volumes of SF<sub>6</sub> gas with different temperatures

gas blowing into the arc. The hot gas generated by the arc is then exhausted from the open contact of the interrupter chamber. The insulating nozzles are generally made from polytetrafluoroethylene (PTFE), which can control and restrict arc movement inside the nozzle.

In an interrupter that uses SF<sub>6</sub> gas as the interrupting medium, a gas flow is induced to flow over the arc, which results in thermal exchange between the arc and the medium, ultimately extinguishing the arc. Various possible arc-quenching configurations are shown in Fig. 8.48.

Figure 8.48a illustrates a plain break. In this case, there is no preconfigured gas flow; instead, the temperature (or density) gradient caused by the arc and gravity induces a gas flow that in turn affects the temperature distribution and extinguishes the arc. Another example, shown in Fig. 8.48b, makes use of the pressure built up by the arc. The resulting pressure gradient causes a gas flow that cools the interrupted arc. In the structure shown in Fig. 8.48c, a high-pressure SF<sub>6</sub> gas flow is generated by a gas compressor for example. This flow is passed over the arc, thus extinguishing it. Figure 8.48d shows an arrangement in which the gas pressure needed to induce a gas flow is generated by the mechanical motion of a cylinder passing over a piston. The resulting gas flow is then directed over the arc. This arc-quenching approach leads to a so-called puffer-type

Fig. 8.48 Various arc-quenching arrangements for SF<sub>6</sub> blasting. (a) Plain break, (b) self-blast, (c) double-pressure blast, (d) puffer blast

**Fig. 8.49** Arc quenching process with a gas circuit breaker

circuit breaker. Modern circuit breakers use this basic concept in some form.

The pressure buildup in the puffer chamber and the energy exchange with the arc are the most important concepts in arc interruption. The mechanical motion of the arcing contact, especially in the puffer chamber, is affected by the existence of the arc because of the interaction of the pressure buildup in the puffer chamber with the arc current.

The SF<sub>6</sub> arc plasma generated between the contacts of a gas circuit breaker is a conductor due to the presence of charged particles such as ions and electrons. These charged particles originate from decomposed SF<sub>6</sub> gas as well as contact material that is ionized through arc current heating. Radiative heat transfer from the arc to the surrounding materials, the evaporation of nozzle materials (loss due to latent heat), along with convection from the turbulent gas flow and conduction all contribute to arc cooling, which changes the characteristics of the arc. The thermodynamic characteristics of SF<sub>6</sub> gas are largely responsible for its excellent arc cooling mechanism (switching function) and its interrupting and dielectric withstand capabilities.

In particular, a gas circuit breaker with SF<sub>6</sub> loses most of its electrical conductivity when the temperature of the vanishing arc drops below 2000 K.

Figure 8.49 shows a schematic of arc currents generated across the contacts of a single-pressure-type SF<sub>6</sub>

gas circuit breaker. The temperature of an arc with a large current (several tens of kA) is 15 000–20 000 K, resulting in a high-density conductive plasma with a low arc voltage. The temperature of an arc carrying a small current (almost zero) is 2000–5000 K. The arc voltage shows a suppression peak before a current zero.

Every time the current passes through zero after contact separation, the circuit breaker has an opportunity to extinguish the arc. When the arc current reaches zero, the conductivity ( $g$ ) of the vanishing arc across the contacts is still nonnegligible, so the arc maintains a very small current due to the presence of charged particles where there used to be an arc column. This current is called the residual or post-arc current ( $I$ ). The residual current contributes to the energy input due to ohmic heating ( $I^2/g$ ) by the electric field across the contacts, which can raise the temperature and conductivity, while the cooling induced by a gas flow contributes to energy loss and tends to reduce the conductivity.

Figure 8.50 shows an example of a physical model for the arc interrupting process near to a current zero in the case of a gas circuit breaker. The arc is heated by ohmic heating and cooled by heat transfer due to a gas flow, heat conduction to the ambient temperature, and radiation [8.33]. The balance between the energy input and the cooling will determine the success or failure of the interruption.

**Fig. 8.50** Arc interrupting process in a gas circuit breaker [8.32]

**Fig. 8.51** Temperature profiles of SF<sub>6</sub> and N<sub>2</sub> arcs at currents of 20 A and 200 A

Figure 8.51 shows calculated temperature profiles for SF<sub>6</sub> and N<sub>2</sub> arcs at stable currents of 20 and 200 A. Compared with the profile for a N<sub>2</sub> arc, that for a SF<sub>6</sub> arc shows a smaller arc diameter, implying a larger temperature gradient and increased heat conduction. The SF<sub>6</sub> arc diameter increases with the temperature at the center of the arc for larger currents. However, the maximum diameter occurs at around 20 000 K because the thermal capacity is highest around this temperature, as described before.

During the large arc current period, the arc shows high conductivity and a temperature of 15 000–20 000 K. The arc conductivity gradually decreases with decreasing current during the small arc current period. The arc is extinguished when the cooling due to the gas flow exceeds the ohmic heating due to the residual current generated by the electrical field during the short period (up to a few milliseconds) of post-arc current. Then the dielectric recovery between the contacts competes with the TRV during the transient recovery period. When the dielectric recovery surpasses the TRV at all times, the interruption has been successfully completed.

**Fig. 8.52** The four periods of a current interruption process

**Fig. 8.53** Critical instants that determine interruption success or failure

Figure 8.52 shows the four periods of the current interruption process. There are two notable regions for interruption: the thermal interrupting region during the post-arc current period just after current interruption, and the dielectric interrupting region during the transient recovery voltage period.

Figure 8.53 shows the two critical regions that determine the success or failure of interruption: the thermal interrupting region and the dielectric interrupting (recovery) region. A circuit breaker must meet the interrupting requirements during these two interrupting regions under various network conditions.

After a current zero, there is a residual current that increases the energy of the vanishing arc by ohmic heating. When a circuit breaker cannot provide sufficient cooling, thermal reignition may occur. Figure 8.54 gives an example of the current and voltage variations that occur in the thermal interrupting region during a successful and a failed current interruption. When thermal reignition occurs, the residual current through the vanishing arc will increase the temperature and an arc current will be reestablished. When a restriking occurs at a current zero, a circuit breaker will have one of two possibilities for interrupting the current at subsequent current zeros. The recovery voltage during the thermal interrupting region is very small, so reignition does not generate harmful transients to the system and the equipment in the power system.

After the thermal interrupting region, the TRV is applied between the contacts, and the moving contact continues to operate until it reaches the fully open position. The dielectric strength across the contacts generally increases with the contact gaps. When the TRV exceeds the dielectric strength across the contacts during the dielectric interrupting region, a dielectric breakdown called a restrike occurs. Figure 8.55 compares the current and voltage variations that occur during successful and failed current interruptions in the dielectric interrupting region. When a restrike happens, the arc is immediately restored and the current is reestablished. The restrike may generate transients that could be harmful to the system and the equipment in the power system.

**Fig. 8.54** (a) Success and (b) failure (reignition) during thermal interrupting process

**Fig. 8.55** (a) Success and (b) failure (restrike: voltage breakdown) during the dielectric interrupting process

**Fig. 8.56** Dielectric recovery characteristics between the contacts of a circuit breaker for various scenarios

**Fig. 8.57** Comparison of the dielectric recovery characteristics obtained with various transient recovery voltages (labels *a*, *b*, and *c* are explained in the text)

Figure 8.56 shows the dielectric recovery characteristics between the contacts of a circuit breaker during no-load switching, a small fault current interruption, and a large fault current interruption. When a gas circuit breaker interrupts a low current, the dielectric recovery withstand voltage starts to increase rapidly after current interruption at current zero as the distance between the contacts increases. When a circuit breaker interrupts a large fault current, the dielectric recovery withstand voltage tends to recover slowly compared to when a small current interruption occurs.

Figure 8.57 schematically shows a comparison of the dielectric recovery characteristics obtained with three transient recovery voltages for different switching duties. For successful dielectric interruption, the dielectric recovery withstand voltage between the contacts of a circuit breaker must exceed the transient recovery voltage after current interruption at all times (case *a* in Fig. 8.57).

A high rate of rise in recovery voltage (RRRV) leads to a dielectric restrike (case *b* in Fig. 8.57). Such TRVs are typically obtained during transformer limited faults and series reactor faults. When the RRRV exceeds the rate of rise of the dielectric recovery characteristic, a dielectric interrupting failure will occur. On the other hand, a fault interruption in a long transmission line may generate a high TRV peak. A dielectric interrupting failure will also occur if the TRV peak exceeds the dielectric recovery characteristic (case *c* in Fig. 8.57).

The whole interruption process is successfully completed when both the thermal interrupting and dielectric interrupting regions have been successfully cleared. Many interrupting tests are required to clarify the thermal and dielectric interrupting capabilities of a circuit breaker under the various switching duties expected in a power system. When performing type tests in a high-power laboratory, given that the initial part of the TRV can influence current interruption, it is important to check that the time delay for the recovery voltage after a current zero does not exceed standard values under network conditions.

#### 8.2.4 Interrupting Phenomena for Vacuum Circuit Breakers

In vacuum circuit breakers [8.34], there are a couple of disk-shaped electrodes in the vacuum enclosure (vacuum tube) that are separated by a small gap (possibly less than 2–4 mm) and are employed to extinguish the arc. Figures 8.58 and 8.59 show a cutaway and schematic, respectively, of the configuration of a typical vacuum interrupter.

While gas circuit breakers use an interrupting medium to carry the current, vacuum circuit breakers do not contain any material to sustain the plasma except for the metal vapor emitted from the cathode and anode contact surfaces (which are also termed the cathode and anode spots). The vacuum pressure inside a vacuum interrupter is normally maintained at  $10^{-6}$  Pa. The dielectric withstand is excellent with a small contact gap. The vaporized contact material (typically a Cu-Cr alloy) plays an important role in the switching function (between current carrying and current interruption) of a vacuum circuit breaker.

**Fig. 8.58** Cutaway showing the configuration of a typical modern vacuum interrupter

**Fig. 8.59** Schematic of the typical configuration of a vacuum interrupter

The vacuum arc occurs at the cathode spots and carries a current with high-density plasma. The cathode spots supply the metal vapor and emit electrons that are accelerated in the arc plasma and ionize the other metal atoms through bombardment. The newly created ions move toward the cathode and collide with metal atoms. During the large current period, the vacuum arc also initiates from the anode spots, which are much larger than the cathode spots.

There are two vacuum arc modes: diffuse and constricted arcs (Fig. 8.60). A constricted arc is a single thick arc similar to a gaseous arc with a large current (typically larger than 10–15 kA) and high plasma den-

sity. It has a high atmospheric pressure due to excessive metal vapor (implying that the voltage of a constricted arc is higher than that of a diffuse arc).

As the current decreases, a constricted arc transforms into a diffuse arc, which consists of many arc columns with plasma cones directed from the small cathode spots to the anode during the small current period. These arc columns can move very quickly on the contact surface. The arc voltage across the contacts becomes very small (compared with that in gas circuit breakers)—about 20 V (irrespective of the electrode spacing)—before the current interruption, and does not present a prominent extinction peak (this is because the existence of fast-moving charged ions and electrons results in high conductivity).

Several measures have been applied to improve the interrupting performance of a vacuum interrupter by suppressing the creation of constricted arcs at higher current levels, which is also desirable because constricted arcs cause severe electrode erosion. One of the most well known of these measures involves moving the anode spots continuously by applying a transverse magnetic field (TMF) to the arc in order to reduce local electrode melting. Another method is to reduce the bombardment of the anode spots by the plasma by spreading the arc across the whole of the electrode while applying an axial magnetic field (AMF) between the electrodes.

Figure 8.61 shows some examples of the electrode configurations used in vacuum interrupters. A plane electrode is used for a vacuum interrupter with small interrupting currents. A spiral electrode has several spiral grooves, leading to a radially directed arc magnetic field. The magnetic field pushes the arc to the edge of the spiral fin, thus avoiding excessive local erosion due to the arc. An axial magnetic field electrode consists of several coils that can generate an axial arc magnetic

**Fig. 8.60** Interrupting process in a vacuum

**Fig. 8.61a–c** Electrode configurations for a vacuum interrupter. (a) Plane electrode, (b) spiral electrode, (c) axial magnetic field electrode

field. These specially designed contacts along with the radial and axial magnetic fields force the arc to keep moving on the electrode under the influence of its own magnetic field, which minimizes contact erosion and spreads it uniformly across the electrode.

Figure 8.62 shows a series of photographs showing the behavior of a traveling arc between the contacts, as driven by a transverse magnetic field.

A vacuum circuit breaker interrupts the current at current zero by establishing the dielectric strength between the contacts. It is very difficult for the arc plasma

to reestablish itself after current zero (after complete depletion of charged metal particles and electrons) because of the excellent dielectric strength of vacuum. Thermal interrupting failures are seldom observed. Since there is a very small amount of charged particles between the electrodes at current zero, a residual arc current flows when a recovery voltage is applied between the electrodes because the charged ions and electrons are removed by the small electric field after current zero. Even though the residual current tends to be larger than that in SF<sub>6</sub> gas circuit breakers, the presence of a large residual current after current interruption in a vacuum interrupter will not affect its thermal interrupting performance.

The interruption has been successfully completed when the dielectric strength across the contacts always surpasses the recovery voltage after current interruption. Some dielectric breakdown of a statistical nature may be observed, as the dielectric strength in a vacuum is strongly affected by the contact surface conditions and small metal particles can considerably modify the electrical field across the contacts.

The dielectric recovery characteristic during the dielectric recovering region is an important determinant of the success or failure of a circuit breaker, especially for low-current interruptions such as line-charging current switching and capacitor bank current switching.

**Fig. 8.62** Traveling arc behavior between the contacts, as driven by a transverse magnetic field

Fig. 8.63 Dielectric performance in a vacuum [8.21]

### 8.2.5 Comparison of the Dielectric Withstands of Various Interrupting Media

Figure 8.63 shows the dielectric recovery characteristics for various interrupting media with no load. The dielectric recovery characteristic is mainly determined

by the distance between the contacts, the density of the insulating medium if it is a gas, the opening speed, and the configuration of the electrodes. The dielectric strength increases linearly with the contact gap in a gaseous medium. In a vacuum, good dielectric strength is observed with a small gap but it gradually saturates as the gap increases.

On the other hand, the density of  $\text{SF}_6$  gas drops in some regions of the enclosure of an interrupter after a large current interruption due to the transfer of thermal energy from the arc plasma into the enclosure during the interruption process. This leads to the degradation of the dielectric recovery characteristic to some extent compared to that observed at no load and under small current switching conditions.

### 8.2.6 Summary

This section has described the interrupting phenomena encountered with different interrupting media. Circuit breakers play an important role in securing other substation equipment in power systems and have been a key component in the development of high-voltage and large-capacity transmission networks.

## 8.3 Switching Phenomena in Power Systems

A circuit breaker should be capable of making, carrying, and interrupting the current under both normal and abnormal conditions, especially in the case of a short circuit or fault. Various short-circuit conditions including single-phase grounded, three-phase grounded, and phase-to-phase ungrounded faults are expected to occur in power systems [8.35, 36]. When a circuit breaker interrupts a short-circuit current, different switching phenomena are observed depending on the conditions [8.37].

The short-circuit current is greatest for a three-phase grounded fault in most power systems. However, the short-circuit current for a single-phase grounded fault is larger than that of a three-phase grounded fault in a solidly earthed system where the zero sequence impedance ( $X_0$ ) is less than the positive sequence impedance ( $X_1$ ). The current ratio of a single-phase grounded fault to a three-phase grounded fault is given by  $3/(2 + X_0/X_1)$ , so the single-phase fault current is lower than the three-phase fault current when  $X_0 > X_1$ .

The short-circuit current after a fault occurrence comprises a decaying DC component superimposed on a symmetric AC current that also decays over time, as shown in Fig. 8.64. The decay of the AC component depends strongly on the reactance in the short circuit, including the generator reactance. The DC component

decays rapidly with the time constant of the power system ( $L/R$ ). The circuit breaker must withstand the electrical and mechanical stresses imposed by the short-circuit current.

A transient voltage is imposed between the contacts (the electrodes) of a circuit breaker when it interrupts a current. The TRV that appears immediately after interruption shows a damping oscillation around the prospective system voltage. After that, it approaches the system voltage (albeit with a slight shift caused

Fig. 8.64 DC component of a short-circuit current

Fig. 8.65 TRV and RV waveforms

by an imbalance in the short-circuit currents among the phases), which oscillates with the power frequency, as shown in Fig. 8.65. The TRV significantly affects the interrupting performance of the circuit breaker. The severity of the TRV strongly depends on the prospective system voltage, which varies with the system and the fault conditions, including the neutral connection. For example, the first-pole-to-clear factor is 1.3 for an effectively earthed neutral system and 1.5 for an isolated neutral system. The amplitude of the TRV also changes with the system and equipment conditions.

This section explores how the main switching phenomena of circuit breakers vary depending on the conditions and the fault location in power systems.

### 8.3.1 Fundamental Switching Phenomena

A circuit breaker is required to clear any faults that occur in a power system or to interrupt the currents stipulated in international standards such as IEC 62271-100 [8.38], even though, in order to ensure that circuit breakers are economical, the standards generally cover

Table 8.4 Switching duties in a power system

Switching duties	Fault location	Circuit breaker responsible
Bus terminal fault interruption	F1	CB1
Short line fault interruption	F2	CB2
Long line fault interruption	F3	CB2
Transformer limited fault interruption	F4	CB3
No-load line switching	–	CB4
Small capacitive current switching	–	CB5
Small inductive current switching	–	CB5

only 90% of the switching duties expected in existing power systems.

Figure 8.66 shows and Table 8.4 summarizes various switching duties imposed on a circuit breaker.

### 8.3.2 Bus Terminal Fault Interruption

A circuit breaker is normally located at both terminals of a transmission line. When a circuit breaker is required to clear a bus terminal fault that has occurred in the vicinity of a circuit breaker, another circuit breaker, located at the other end of the connected line, is required to clear a long line fault covered in the standards by terminal fault test duties T10 or T30.

The fault current and the TRV imposed on the circuit breaker after fault clearing vary depending on the location of the fault in the power system. The fault current increases with the amount of current flowing from the transmission lines and power transformers connected to power generators into a fault point.

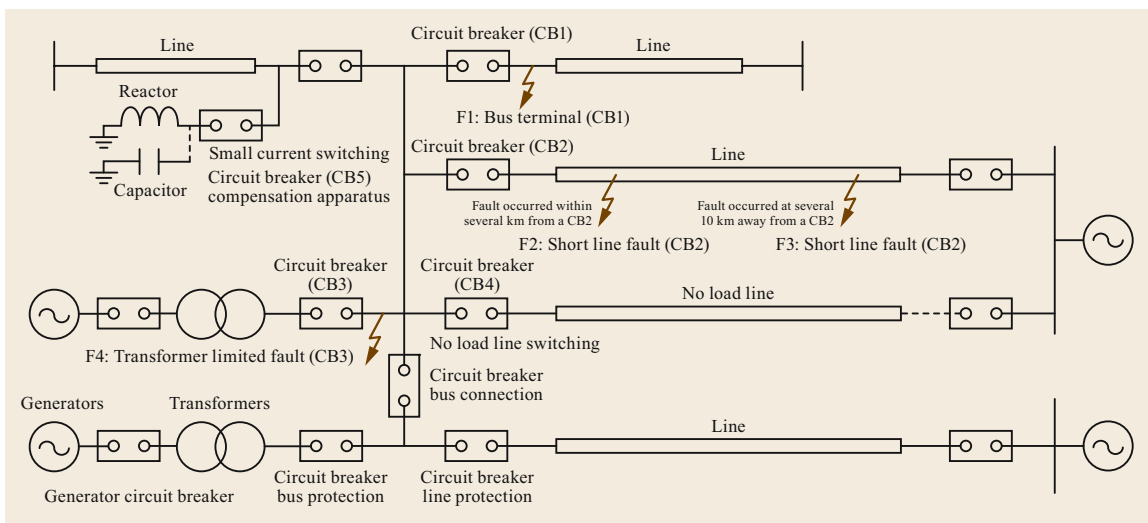

Fig. 8.66 Different switching duties depending on fault location in a power system

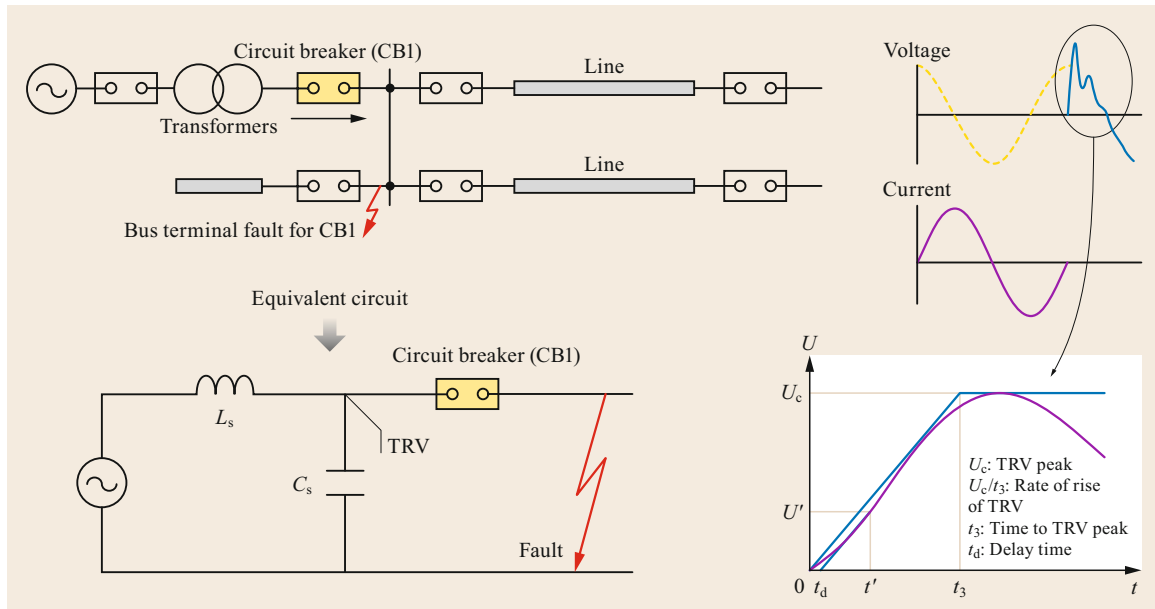

Fig. 8.67 TRV waveform of bus terminal fault corresponding to test duty T10

When only one current source (such as a load transmission line or a power transformer) supplies the current to a fault point, as shown in Fig. 8.67, the fault current is relatively small—normally less than 10% of the rated interrupting current (corresponding to test duty T10). The associated TRV generally shows a single frequency with a high TRV peak value that is determined by the amplitude factor in the related circuit. The TRV amplitude factor tends to be large due to the single frequency contributed by a single current source.

In particular, if a fault is generated immediately after a power transformer and there is no appreciable capacitance between the transformer and the circuit breaker, a severe TRV with a high TRV frequency may occur, which could exceed the standard RRRV values for test duty T10. This duty is often termed transformer limited fault interruption.

Even though a circuit breaker must be able to remove the arc energy generated in the interrupter during the arcing time after contact separation, the circuit breaker does not need to exhibit very strong interrupting performance during the thermal interrupting region because the rate of rise of the TRV (RRRV) is smaller than that for a short line fault (SLF) interruption. Therefore, the dielectric recovery capability of the circuit breaker, which must surpass the TRV at all times, is one of the main concerns if the circuit breaker is to clear a fault at test duty T10. The TRV presents a single frequency that is specified using a two-parameter reference line and a delay time in the standard when most of the current is supplied by a single power generator.

When several current sources from load transmission lines or power transformers supply the current to a fault point, as shown in Fig. 8.68, the fault current is relatively large—up to about 60% of the rated interrupting current (corresponding to test duty T60). The associated TRV shows multiple frequencies due to the different circuits for the various current sources. TRVs with multiple frequencies and different times to the peak due to the presence of multiple current sources tend to show reduced amplitude factors, resulting in lower TRV peaks for higher interrupting currents.

Figure 8.69 summarizes different bus terminal fault conditions for a power system configuration with several transmission lines, power transformers, and power generators. This figure shows that the amplitudes of the fault current and TRV waveforms depend on the fault location. When a fault is generated at F1, the circuit breaker (CB1) is required to clear a fault current that is about 10% of the rated interrupting current of CB1 and is mainly fed by one power transformer (the fault current flow is shown by a red arrow). After clearing the fault at F1, the TRV presents a high peak and a damping oscillation with a simple frequency determined by the circuit conditions of the single current source.

When a fault is generated at F2, the circuit breaker (CB2) is required to clear a fault current that is 30–60% of the rated interrupting current of the CB2 and is fed by several current sources through transmission lines and power transformers (the fault current flow is shown by a green arrow). After clearing the fault at F2, the TRV presents a lower peak than at F1 as well as multiple

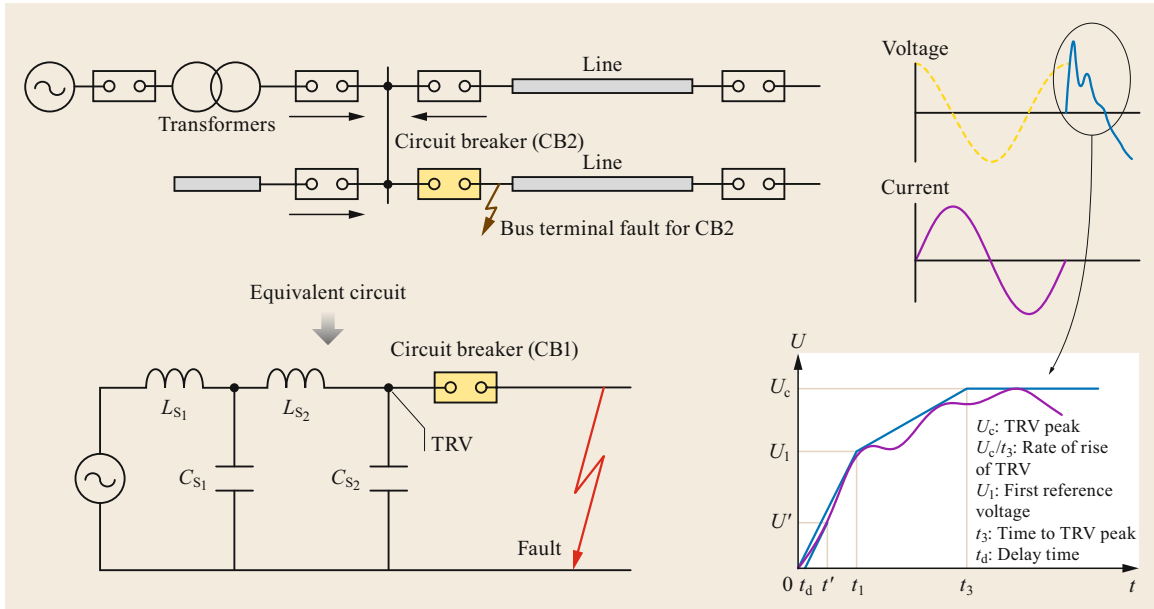

Fig. 8.68 TRV waveform of a bus terminal fault corresponding to test duty T60

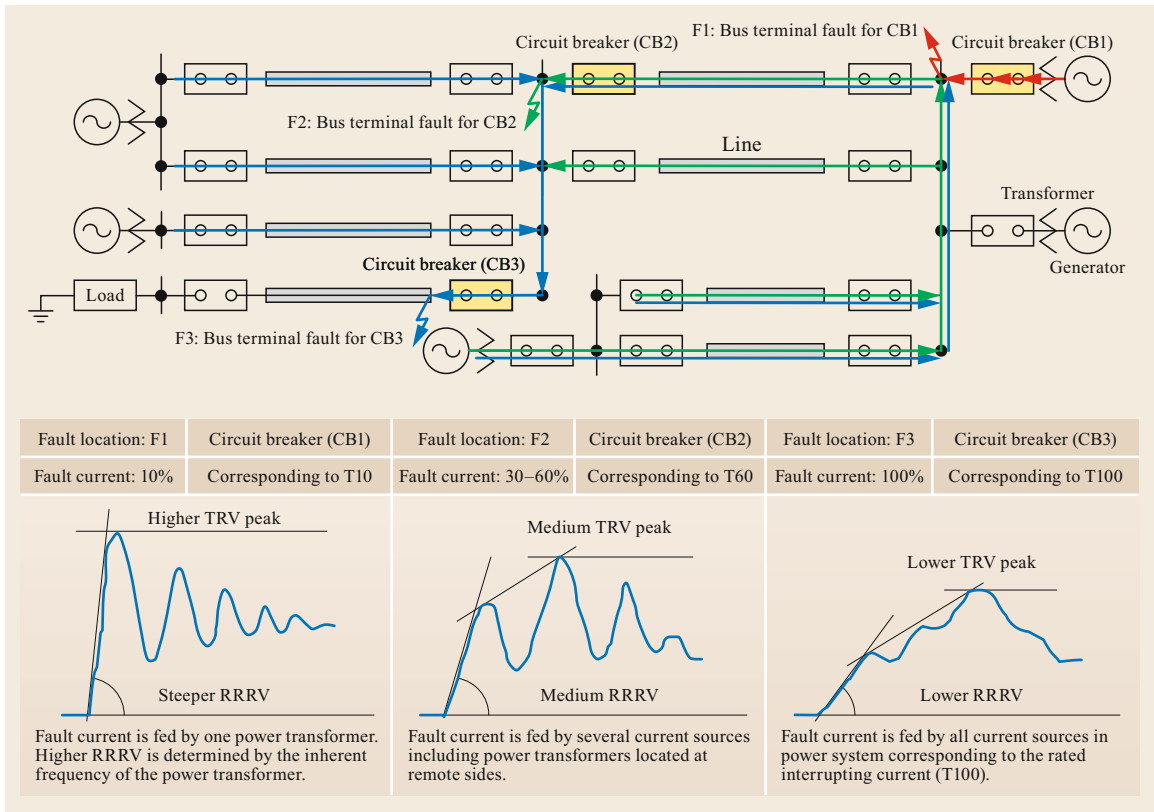

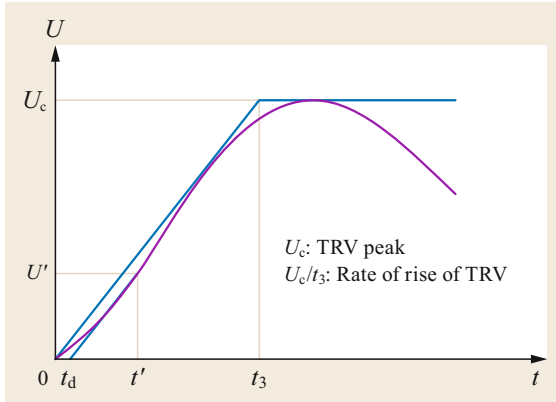

Fig. 8.69 Dependence of the TRV waveform of a bus terminal fault on the fault location

**Fig. 8.70** Specifying the TRV using a two-parameter reference line and a delay line

**Fig. 8.71** Specifying the TRV using a four-parameter reference line and a delay line

frequencies determined by the circuit conditions of the multiple current sources.

In the most severe case, when a fault is generated at F3 and all the transmission lines are loaded, the circuit breaker (CB3) is required to clear the fault current with the rated interrupting current of CB3, which is fed by all the current sources in the power system (the fault current flow is shown as a blue arrow). After clearing the fault at F3, the TRV presents a low peak as well as complex frequencies determined by the circuit conditions of all the current sources.

For bus terminal fault interruptions, the standard requires that the circuit breaker will interrupt symmetrical currents that are 10%, 30%, 60%, and 100% of the rated interrupting current as well as 100% of the current with the standard values of DC component (in asymmetrical current) with the corresponding TRV peaks and RRRVs shown in the standards, respectively. These test requirements correspond to test duties T10, T30, T60, T100s, and T100a.

For rated voltages equal to or higher than 100 kV, the TRV for terminal fault test duties is described by the two parameters shown in Fig. 8.70 for test duties T10 and T30 or the four parameters shown in Fig. 8.71 in the case of multiple TRV frequencies for test duties T60 and T100.

The peak value of the TRV ( $U_c$ ) applied to a circuit breaker during bus-terminal interruption is given by

$$U_c = U_r \sqrt{\frac{2}{3}} k_{pp} k_{af},$$

where:

$U_c$  is the TRV peak

$U_r$  is the rated voltage

$k_{pp}$  is the first-pole-to-clear factor

$k_{af}$  is the amplitude factor.

For a given rated voltage, both the first-pole-to-clear factor and the amplitude factor must be defined to determine the peak value of TRV. The power frequency recovery voltage ( $U$ ) is a function of the rated voltage and the first-pole-to-clear factor

$$U = \frac{U_r k_{pp}}{\sqrt{3}}.$$

IEC 62271-100 specifies a first-pole-to-clear factor of 1.3 for effectively earthed neutral systems at rated voltages of up to 800 kV. This value of  $k_{pp}$  is calculated from the zero-sequence reactance  $X_0$  and the positive-sequence reactance  $X_1$  using

$$k_{pp} = \frac{3}{2 + \frac{X_1}{X_0}}.$$

In a network with long transmission lines, the first-pole-to-clear factor tends to increase, because the ratio  $X_1/X_0$  of the lines decreases. On the other hand, in a network connected to large power transformers (a star connection with an earthed neutral or a delta connection), the first-pole-to-clear factor decreases and is occasionally less than 1.2 because the ratio  $X_1/X_0$  is equal to or larger than 0.5 ( $2X_1 > X_0$ ). In cases where most of the short-circuit currents are fed through large-capacity power transformers, the first-pole-to-clear factors are small because the zero-sequence impedance is reduced due to the delta connection of large-capacity power transformers ( $X_1/X_0$  approaches unity, or  $X_0$  approaches  $X_1$ ).

The impedance of overhead (OH) lines is almost inversely proportional to the square of the system operating voltage, so the ratio of the line impedance to the total transmission system impedance tends to be smaller for a system with higher voltages. This tendency reduces the zero-sequence impedance in UHV systems

**Table 8.5** Amplitude factors for terminal fault test duties

Test duty	Amplitude factor
T10	$1.7 \times 0.9(1.76)^a$
T30	1.54
T60	1.50
T100	1.40

<sup>a</sup> For UHV, the first-pole-to-clear factor of 1.2 is recommended instead of 1.3 for lower voltage ratings based on the large influence of a large capacity power transformer. The amplitude factor of 1.76 ( $1.7 \times 0.9 \times 1.5/1.3$ ) is stipulated for T10 duty to cover the TRV peak of long-line fault (LLF) interruption.

(at rated voltages of 1100 and 1200kV) due to the increasing influence of large-capacity power transformers, which have a smaller zero-sequence impedance  $X_0$  than transmission lines. Accordingly, the first-pole-to-clear factor in UHV systems is defined as 1.2 [8.37].

The amplitude factor of the TRV tends to decrease with the interrupting current because the superimposition of the TRVs (with multiple frequencies and different times to the TRV peak) originating from the various current sources (power generators) that contribute to the bus terminal fault reduces the amplitude factor.

Table 8.5 gives the amplitude factors in IEC 62271-100 for terminal fault interruption by circuit breakers with a rated voltage of 100kV and above. The amplitude factor is  $1.7 \times 0.9 = 1.53$  for test duty T10 at rated voltages of up to 800kV based on a first-pole-to-clear factor of 1.5 with a voltage reduction of 0.9 across the transformer. Note that the amplitude factor of the TRV tends to increase in UHV systems due to smaller losses from power transformers and transmission lines as well as reduced damping of traveling waves. It is therefore defined as 1.76 for UHV systems, keeping the same magnitude of the first-pole-to-clear factor times

**Table 8.6** RRRV values for terminal fault test duties

Test duty	RRRV (kV/ $\mu$ s)
T10	7
T30	5
T60	3
T100	2

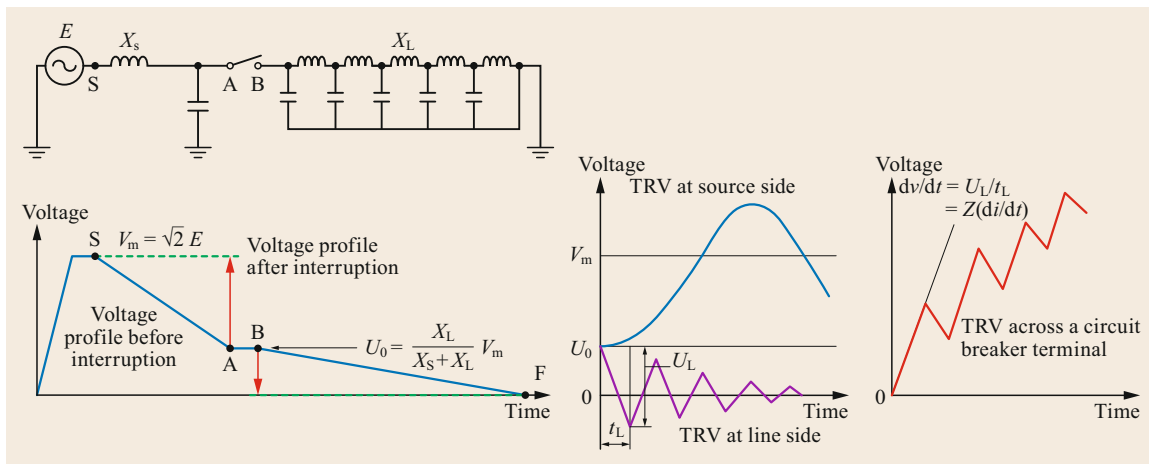

the amplitude factor based on the first-pole-to-clear factor of 1.3 stipulated for lower voltages.

Table 8.6 gives the rate of rise of TRV (RRRV) values in IEC 62271-100 for terminal fault interruption by circuit breakers with rated voltages of 100kV and above. Similarly, the RRRV tends to decrease with the interrupting current because the superimposition of the TRVs (with multiple frequencies and different times to the TRV peak) originating from the various current sources that contribute to the bus terminal fault reduces the RRRV.

### 8.3.3 Short Line Fault Interruption

When a fault occurs in a transmission line at a distance ranging from 100 m to a few kilometers down the line, a circuit breaker is required to clear this short line fault (SLF). When a circuit breaker clears the SLF generated on the line, a steeply rising TRV with a waveform similar to a sawtooth waveform is observed due to high-frequency oscillations generated by waves propagating along the line and reflecting between the circuit breaker terminal and the fault point.

Figure 8.72 shows an equivalent circuit and the associated voltage distribution when a SLF is generated on the line. The circuit breaker is connected to the generator through a power transformer at the source side and is connected to the transmission line at the line side, all of which can be modeled using a multiple lattice cir-

**Fig. 8.72** Equivalent circuit and TRV waveforms obtained under short line fault (SLF) conditions

circuit comprising a reactor and a capacitor, as shown in Fig. 8.72.

When the circuit breaker interrupts the fault current under SLF conditions, the voltage of the circuit breaker terminal at the source side is back to the system voltage at the transformer terminal, which causes an oscillation with a frequency corresponding to the power frequency in the source circuit. The source-side circuit can be approximated by a lumped circuit with constant concentrated parameters. The amplitude factor of the TRV is similar to that in the case of a terminal fault.

On the other side, the voltage of the circuit breaker terminal at the line side is dropped to the ground level, which creates another oscillation with a sawtooth (triangular) shape due to the propagation and reflection of waves along the line. The line-side circuit can be approximated by a small attenuated circuit with distributed parameters.

Figure 8.73 shows the TRV propagation at the line side without considering any attenuation of the traveling waves. After SLF interruption, the transients travel along the line in both directions. One propagates from the breaker terminal to the fault point and the other propagates from the fault point to the breaker terminal with a contact propagating velocity of  $c$ , which is about  $300 \text{ m}/\mu\text{s}$  through a transmission line.

The transient initiated from the breaker terminal (which has a voltage of  $U_0$  immediately after interruption) decreases with time and arrives at the fault point (where the voltage is always at the ground level) at  $t = L/c$ , where  $L$  is the line length. The transient is reflected at the fault point (discontinuity), travels back along the line, and returns to the breaker terminal at  $t = 2L/c$  with a voltage of  $-U_0$  (negative polarity), which corresponds to the first TRV peak ( $U_L$ ).

The transient continues to travel along the line in both directions at a constant velocity and reflects at the breaker terminal and the fault point, leading to the formation of a saw-tooth (triangular) waveform.

The waveform of the TRV across the circuit breaker terminals is a superimposition of those at both the source and the line sides, and the initial rate of rise of the TRV is given by  $dv/dt = Z(di/dt)$ , where  $Z$  is the line surge impedance. The TRV on the line side increases with increasing distance to the fault point, while the TRV on the source side decreases.

When a circuit breaker interrupts the SLF, the thermal interrupting performance is the main determinant of interruption success or failure given the severe energy input that occurs immediately after current interruption due to the high RRRV. When a circuit breaker cannot provide sufficient coolability for the energy

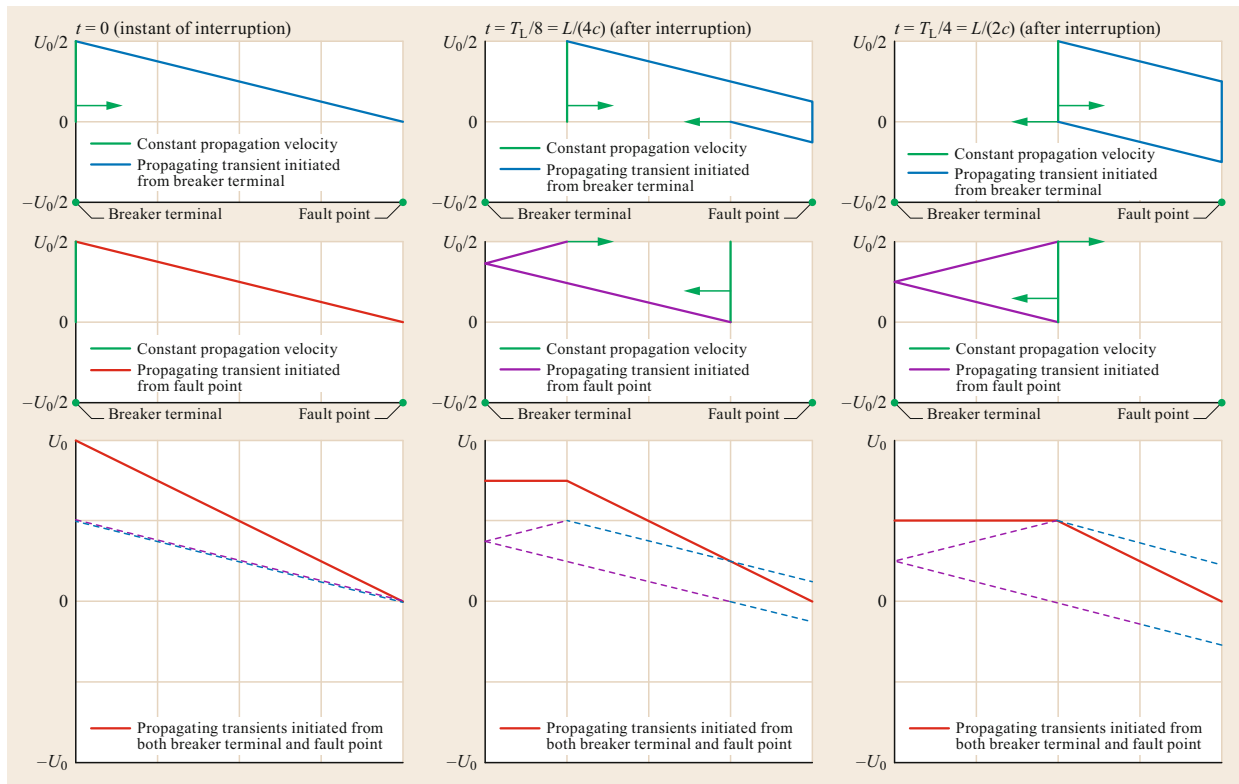

Fig. 8.73 TRV propagation under short line fault (SLF) conditions at the line side

Fig. 8.73 (continued)

**Fig. 8.74** Multibundle conductors under normal conditions and bundle collisions that occur under fault conditions

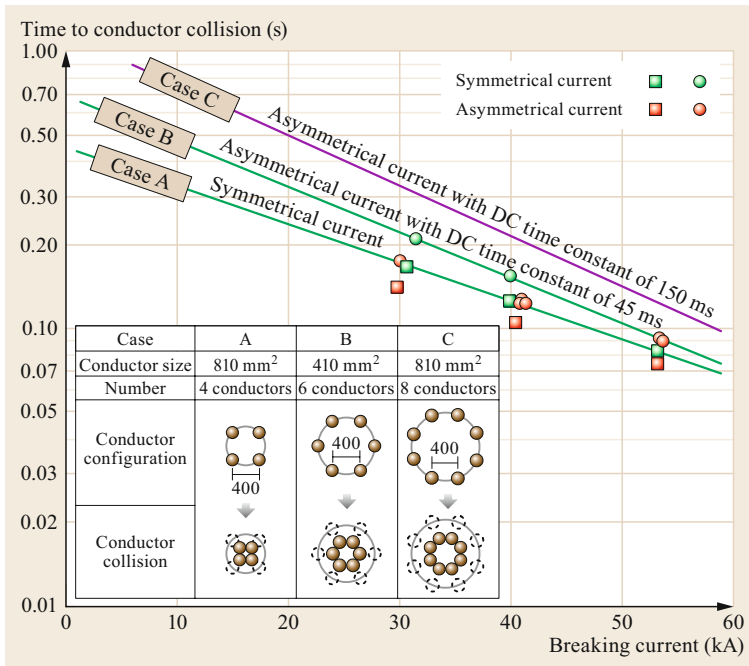

input during the thermal interrupting period, thermal reignition may happen.

The standardized value of  $Z$  in IEC 62271-100 and IEEE C37.04 is  $450 \Omega$ , which roughly corresponds to the surge impedance of a single conductor. In EHV and UHV systems, multibundle conductors are used, which give lower line surge impedances of  $250\text{--}400 \Omega$  under normal current carrying conditions, which can be found using  $\sqrt{L/C}$  with a large capacitance to ground. Here,  $L$  is the reactance of the line. The capacitance

of multi-bundle conductors to the ground is larger than that of a single conductor due to its higher equivalent cross-section to the ground. When a SLF is generated, the conductors in the multibundle conductors attract each other due to Lorentz forces that push the conductors together. Figure 8.74 shows a schematic of multibundle conductors under normal conditions and the bundle collision that occurs under fault conditions.

Besides the fault current, the line surge impedance depends on the multibundle conductor design (materials, cross-sections, span, and spacer size) and the mechanical tension applied to the conductors in the lines. Several studies, including those of CIGRE WG 13.01, have examined and reported the time required for a bundle collision. For example, twin conductors that were  $686 \text{ mm}^2$  in cross-section and carried  $40 \text{ kA}$  collided  $50 \text{ ms}$  after a fault occurrence, and quadruple conductors that were  $810 \text{ mm}^2$  in cross-section and carried  $30\text{--}50 \text{ kA}$  collided  $100\text{--}200 \text{ ms}$  after a fault occurrence, as shown in Fig. 8.75. A longer time to bundle contraction is expected for UHV lines, as they use more conductors and each conductor has a relatively large cross-section. A value of  $330 \Omega$  is standardized for the surge impedance of lines in UHV systems.

The severity of a SLF test duty depends mainly on the rate of rise of the recovery voltage, which is determined by the line surge impedance and slope of the fault current. The equivalent line surge impedance ( $Z$ ) for each pole-to-clear is given by the following equa-

**Fig. 8.75** Collision times of multi-bundle conductors

**Fig. 8.76** Comparison of the TRV waveforms obtained for interrupting currents corresponding to L90, L75, and L60

tions, where  $Z_0$  is the zero-sequence surge impedance and  $Z_1$  is the positive-sequence surge impedance

$$Z_{\text{first pole}} = \frac{3Z_1Z_0}{Z_1 + 2Z_0}, \quad (8.1)$$

$$Z_{\text{second pole}} = \frac{Z_1(Z_1 + 2Z_0)}{2Z_1 + Z_0}, \quad (8.2)$$

$$Z_{\text{third pole}} = \frac{2Z_1 + Z_0}{3}. \quad (8.3)$$

In an actual substation, a circuit breaker is connected to the bus terminal using a short line. The surge impedance of the short line is  $260 \Omega$  due to high capacitance to the ground because the short line is normally closer to the ground and is often connected to a capacitor voltage transformer. The surge impedance of the transmission line is  $450 \Omega$ . The short length of this line creates a similar triangular waveform with a high frequency and low amplitude that is termed the initial TRV (ITRV). The ITRV may exert severe thermal stress on the circuit breaker, depending on the conditions.

In the standards IEC 62271-100 and IEEE C37.04, L90 and L75 are the type test duties for short line fault (SLF) conditions. The fault current is equal to 90%, 75%, and 60% of the rated short-circuit breaking current, respectively. The requirements for a SLF at different current levels originated from the thermal interrupting capability of an air-blast circuit breaker, which generates a higher residual current after current interruption than a gas circuit breaker does.

Figure 8.76 shows TRV waveforms calculated for different current levels corresponding to L90, L75, and L60, assuming a 550 kV transmission line with

**Fig. 8.77** Comparison of the residual currents and TRVs obtained with an air-blast circuit breaker and a gas circuit breaker (the TRV curves are color-coded as in Fig. 8.76)

a rated interrupting current of 50 kA and a power frequency of 60 Hz. The line surge impedance is  $450 \Omega$ . The TRV presents a high RRRV, low TRV peak, and high TRV frequency at an interrupting current of 45 kA (L90, where a fault occurs 1.3 km from the circuit breaker). The RRRV gradually decreases, the TRV peak increases, and the TRV frequency decreases as the interrupting current is decreased from L75 (a fault occurs 3.8 km from the CB) to L60 (a fault occurs 7.5 km from the CB).

Figure 8.77 shows a comparison of the residual current and TRV waveforms obtained for different interrupting currents with an air-blast CB and a  $\text{SF}_6$  gas CB. The air-blast CB tends to conduct larger residual currents after current zero than the  $\text{SF}_6$  gas CB, and the peak residual current roughly corresponds to the TRV peak for test duty L60. In contrast, the smaller peak residual current obtained with the  $\text{SF}_6$  gas CB roughly corresponds to the TRV peak for test duty L90. Therefore, the energy input is highest for the TRV corresponding to L90 in the case of the  $\text{SF}_6$  gas CB, and for the TRV corresponding to L60 or L75 in the case of the air-blast CB. Accordingly, the thermal interruption duties represented by L60 or L75 may be more severe for an air-blast CB than the L90 duty.

Figure 8.78 shows the critical interrupting capabilities of an air-blast CB and a  $\text{SF}_6$  gas CB, respectively. Whereas L90 appears to be the most severe interrupting duty for the  $\text{SF}_6$  gas CB, L75 and L60 seem to be the most severe for the air-blast CB.

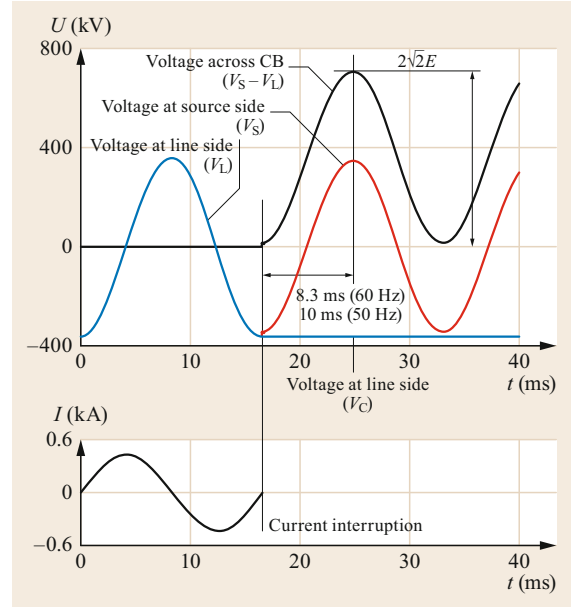

**Fig. 8.78** Thermal interrupting capabilities of an air-blast circuit breaker and gas circuit breaker for different currents

### 8.3.4 Capacitive Current Switching

When a circuit breaker connects or disconnects no-load transmission lines, no-load cables, and shunt capacitor banks (as shown in Fig. 8.79), it switches small capacitive currents of several tens to several hundreds of amperes that are 90° in advance of the voltage phase. After current interruption at the voltage peak of the load side with  $-E$  level (red line), the recovery voltage at the source side (black line) shows a  $1 - \cos$  waveform and is raised from  $-E$  to  $E$  level, while the voltage at the load side is kept as  $-E$  level. Therefore the voltage across CB is  $2E$  at maximum. The first reignition occurs at the voltage peak, the voltage at the load side is raised up to the voltage at the source side from  $-E$  to  $E$  level (the voltage across CB is dropped to zero), but it passes through  $E$  level and further up to  $3E$  level without attenuation. Thus, the voltage at the load side remains at  $3E$  level. Figure 8.80 shows the waveforms for the TRV across a circuit breaker, the TRV at the source side, and the TRV at the line side.

If a circuit breaker interrupts the current at this voltage peak ( $-5E$ ), again the recovery voltage at the source side shows an  $(1 - \cos)$  waveform and is raised from the  $-E$  to  $E$  level, while the voltage at the load side is kept as  $3E$  level. Therefore, the voltage across CB is

**Fig. 8.80** Recovery voltage (RV) waveforms after disconnecting a no-load line

$6E$  at maximum. The third reignition occurs at the voltage peak, the voltage at the load side is raised up to the voltage at the source side from the  $-5E$  to the  $E$  level (the voltage across CB is dropped to zero), but it passes through  $E$  level and further up to  $7E$  level without attenuation. Thus, the voltage at the load side attains  $7E$  level at this moment.

If a circuit breaker interrupts the current at this voltage peak ( $7E$ ), again the recovery voltage at the source side shows an  $(1 - \cos)$  waveform and is decreased from  $E$  to  $-E$  level, while the voltage at the load side is kept at  $7E$  level. Therefore, the voltage across CB is  $8E$  at maximum. The fourth reignition occurs at the voltage peak, the voltage at the load side is decreased to the voltage at the source side from  $7E$  to  $-E$  level (the voltage across CB is dropped to zero), but it passes the  $-E$  level and further down to the  $-9E$  level without attenuation. Thus, the voltage at the load side attains the  $-9E$  level at this moment, as shown in Fig. 8.81.

Since a circuit breaker can easily interrupt a small capacitive current, the dielectric interrupting performance

**Fig. 8.79** No-load transmission line switching

**Fig. 8.81a,b** Voltage escalation across CB caused by multiple reignitions, (a) voltage across CB, (b) voltage at line side

is the dominant influence on whether an interruption is successful for small capacitive current switching. The interruption is successfully completed when the dielectric strength across the contacts always surpasses the recovery voltage after current interruption.

When the TRV exceeds the dielectric recovery performance across the circuit breaker terminals, dielectric breakdown occurs. Dielectric breakdowns are categorized into reignitions and restrikes depending on when they occur. If the dielectric breakdown happens within an interval of less than a quarter cycle of the power frequency after an interruption at current zero, it is a restrike, which will not generate a severe overvoltage. However, if it happens with an interval of a quarter cycle of the power frequency or longer after an interruption at current zero, it is a reignition, which may generate a severe overvoltage.

Reignition at peak voltage with a load-side voltage (at the line side) of  $-E$  and a voltage across the circuit breaker of  $2E$  causes the load-side voltage to jump to  $3E$  (i.e.,  $E$  from the reverse polarity of the remaining DC plus  $2E$  from the TRV peak), as shown in Fig. 8.81. If the circuit breaker can interrupt the high-frequency current immediately after reignition, the load-side DC voltage at the line side remains  $3E$ . The recovery voltage across the circuit breaker presents a  $\cos - 1$  waveform that starts at  $-2E$  and reaches  $-4E$ . However, reignition

**Fig. 8.82** The severe inrush current and associated overvoltage generated when a circuit breaker makes the voltage peak during no-load line energization

at peak voltage with a load-side voltage (at the line side) of  $3E$  and a voltage across the circuit breaker of  $-4E$  causes the load-side voltage to jump to  $5E$  (i.e.,  $3E$  from the reverse polarity of the remaining DC plus  $2E$  from the TRV peak). In this case, if the circuit breaker can interrupt the high-frequency current immediately after reignition, the load-side DC voltage at the line side remains  $-5E$ . The recovery voltage across the circuit breaker presents a  $1 - \cos$  waveform that starts at  $4E$  and reaches  $6E$ . Finally, reignition at peak voltage with a load-side voltage (at the line side) of  $-5E$  and a voltage across the circuit breaker of  $6E$  causes the load-side voltage to jump to  $7E$  (i.e.,  $5E$  from the reverse polarity of the remaining DC plus  $2E$  from the TRV peak). The voltage escalation due to multiple high-frequency interruptions immediately after reignitions can impose serious stress on the equipment in the power system.

Energization of a no-load transmission line or a shunt capacitor bank may generate high inrush currents and associated overvoltages depending on the making instants of the voltage across a circuit breaker. Figure 8.82 shows the inrush current and associated overvoltage generated when a circuit breaker makes the voltage peak during no-load line energization, which may exert excessive mechanical and electrical stresses on the capacitor bank and other equipment in the power system and erode the circuit-breaker contact. Controlled switching can effectively reduce switching surges during no-load transmission line or shunt capacitor bank energization.

In a real substation, a circuit breaker is connected to the bus terminal using a short line. The short length

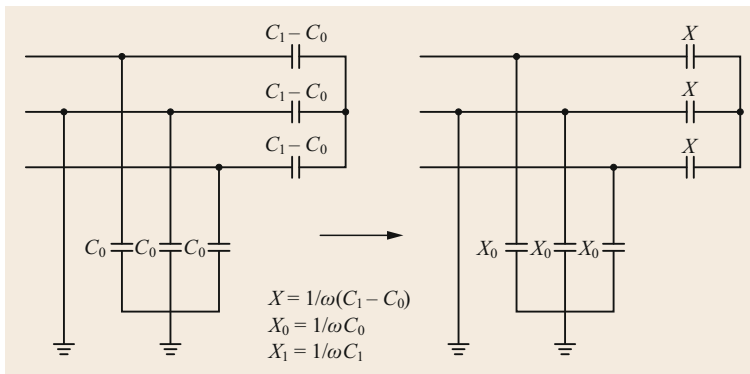

**Fig. 8.83** TRV and ITRV waveforms for no-load line disconnection

of this line creates an ITRV waveform with a high frequency and low amplitude. This waveform is called an ITRV, just as for SLF interruption. Figure 8.83 shows the TRV waveform that occurs when a circuit breaker disconnects a no-load transmission line.

The three-phase switching of no-load transmission lines and no-load cables is slightly more complex than that for shunt capacitor banks because the capacitance is distributed along the line rather than lumped and both line-to-earth and line-to-line capacitances are involved.

Figure 8.84 shows equivalent circuits of no-load transmission lines and cables characterized by a positive capacitance  $C_1$  and a negative capacitance  $C_0$ . Here  $C_1 = C_0$  corresponds to shunt capacitor bank switching with an earthed neutral. TRV will present a  $1 - \cos$  waveform similar to that for capacitor bank switching but with a different peak TRV that depends on the ratio  $C_0$  to  $C_1$ .

**Fig. 8.84** Equivalent circuits of no-load lines and cables

**Fig. 8.85** Peak TRV of the first-pole-to-clear for no-load line switching

When the load impedance  $X_L$  is  $1/\omega C_1$  for capacitor bank switching with an earthed neutral (where  $C_1 = C_0$ ), the peak TRV is  $2E$  (where  $E$  is the peak system voltage). The line impedance  $X_L$  for no-load transmission is given by

$$X_L = \frac{1.5X_0X}{1.5X + X_0}$$

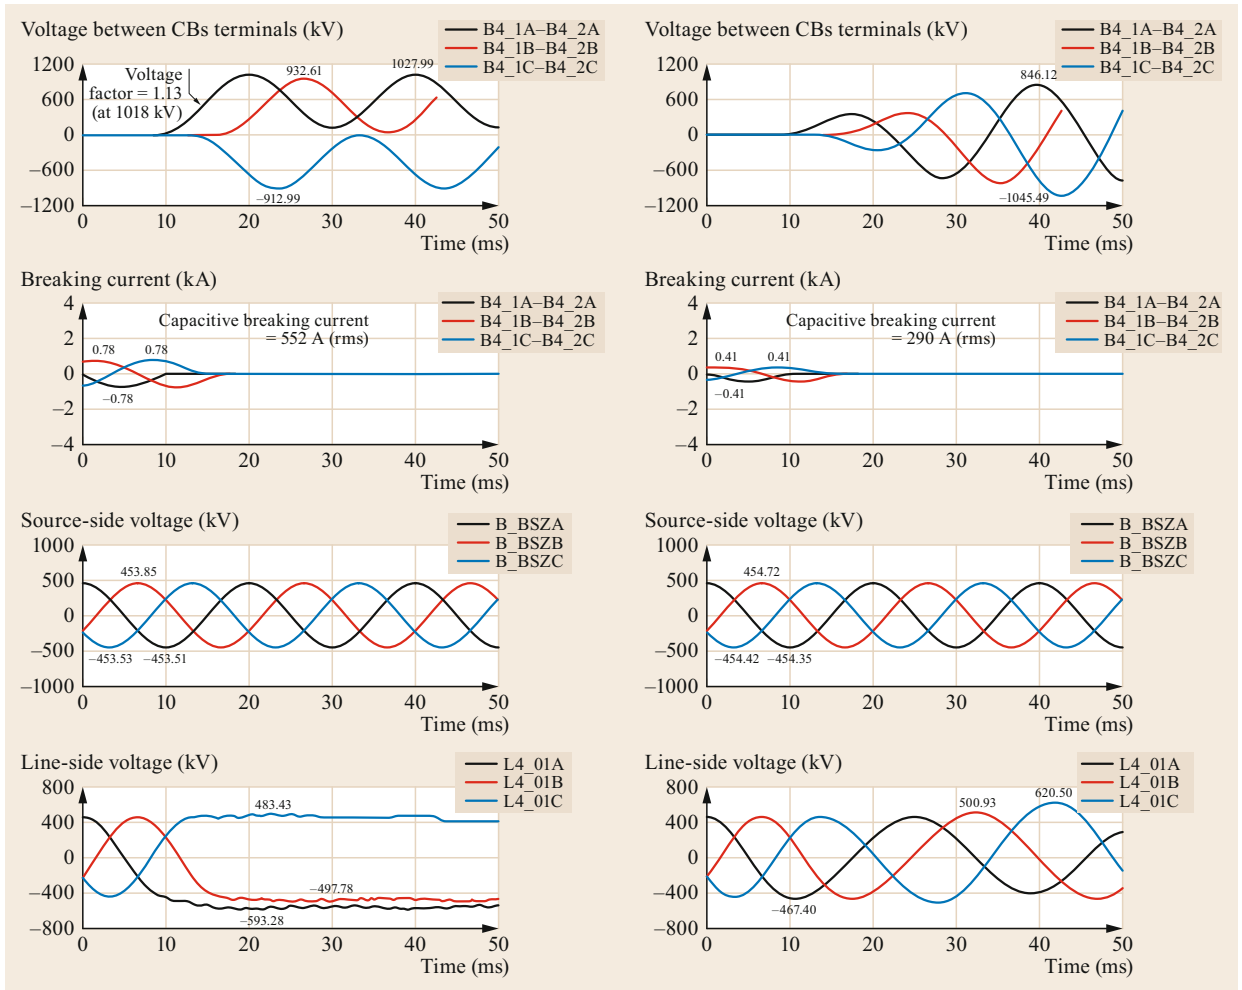

where  $X$  is  $1/\omega(C_1 - C_0)$  and  $X_0$  is  $1/\omega C_0$ . The peak TRV is given by

$$\text{Peak TRV} = \frac{6C_1/C_0}{1 + C_1/C_0}$$

Figure 8.85 shows the peak TRV as a function of  $C_1/C_0$ ; the peak TRV approaches a value of 3 with increasing  $C_1/C_0$ .

The peak TRV is  $2.4E$  when switching a no-load overhead transmission line (OHL), where  $C_1 = 2C_0$ , and it is  $3E$  when switching a no-load cable with an isolated neutral, where  $C_0 \approx 0$ .

**Fig. 8.86** Influence of a shunt reactor on the TRV for no-load line breaking in a 550 kV double-circuit network model with the system and equipment parameters employed in Thailand

In some cases the transmission line is equipped with shunt-reactor compensation, in order to absorb reactive power and keep the voltages along the line with desired margin by preventing from excessive voltage increase due to Ferranti effect under light load conditions or excessive renewable power generations. In case of a compensated line, the degree of line compensation (reactance) has a significant effect on the voltage at line side. The voltage across CB has a prominent beat especially in case of a high degree of compensation, because the line oscillation (TRV frequency) falls in the range of 30–50 Hz.

The influence of shunt reactors on the TRV during the switching of a 360 km no-load line was calculated for a 550 kV double-circuit transmission line. Figure 8.86 shows TRV waveforms obtained for no-load line switching with and without shunt reactors. The

TRV frequency is several tens of Hz and depends on the inductance of the reactor and the capacitance of the line, and the peak TRV in the network can be reduced considerably when a large shunt reactor is connected. For example, the peak TRV when a fault occurs at a remote distance of 360 km under line charging conditions in a 550 kV network is 1018 kV without a shunt reactor but less than 400 kV when a shunt reactor is connected. Therefore, shunt reactors can significantly reduce the first TRV peak obtained when disconnecting under no-load line charging conditions.

### 8.3.5 Small Inductive Current Switching

When a circuit breaker opens and closes a shunt reactor bank or unloaded power transformer, it switches small inductive currents of several tens of amperes with

Fig. 8.87 Equivalent circuit for small inductive switching

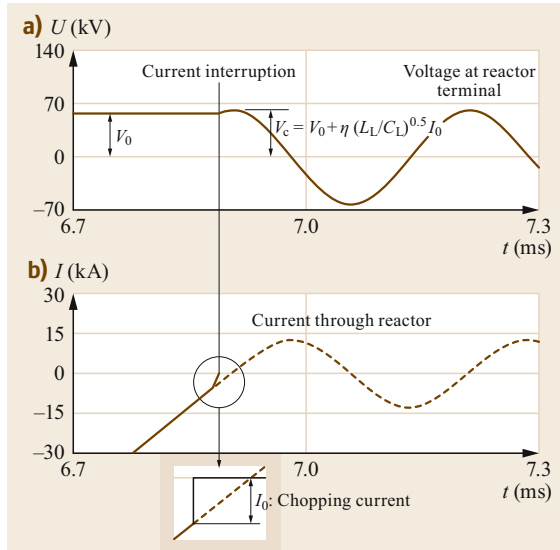

Fig. 8.88 (a) Voltage and (b) current behavior when current chopping occurs upon small inductive current interruption

a  $90^\circ$  lag with respect to the voltage phase. Figure 8.87 shows an equivalent circuit for small inductive current switching. Small inductive switching is generally not a significant test duty for a circuit breaker. However, a circuit breaker that presents high thermal interrupting performance may interrupt a small inductive current before an inherent current zero (current chopping), generating chopping overvoltage, which tends to increase with increasing chopping current.

Figure 8.88 shows the typical voltage and current behavior observed when current chopping occurs upon small inductive current interruption. The current chopping is sometimes accompanied by an expanding high-frequency current oscillation that leads to a sudden current zero. This is an arc instability phenomenon caused by the characteristics of the arc and the circuit conditions. The chopping current of a modern  $\text{SF}_6$  gas circuit breaker is no higher than 10 A, which does not generally lead to a severe chopping overvoltage.

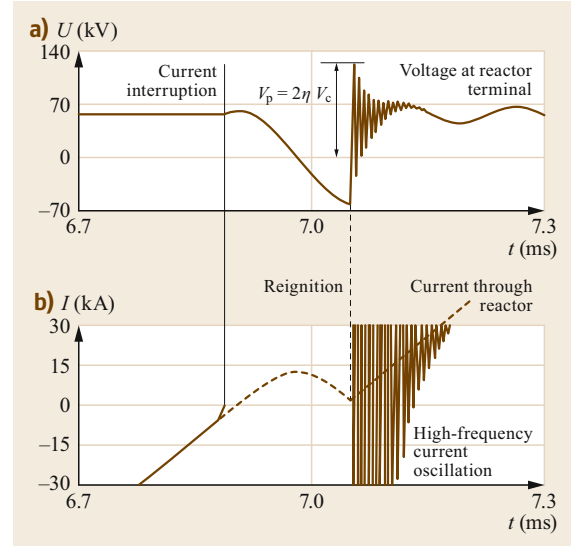

Fig. 8.89 (a) Voltage and (b) current behavior when reignition occurs upon small inductive current interruption

Another prominent phenomenon that is observed after small inductive current interruption is reignition. A circuit breaker can easily interrupt a small inductive current, even if the arcing time and contact gap are small. The dielectric withstand strength of a circuit breaker increases with the contact gap, so a small contact gap tends to generate voltage breakdown during the period when the TRV exceeds the dielectric withstand across the contact gap. Reignition provokes high-frequency current oscillations and associated overvoltages, as shown in Fig. 8.89. These reignition overvoltages may damage the nozzle and the contacts of the circuit breaker as well as the reactor insulation. Controlled switching is often applied to avoid reignitions during small inductive switching by increasing the arcing time.

Multiple reignitions and associated voltage disturbances may be observed, especially for vacuum interrupters (due to their excellent thermal interrupting capabilities), as shown in Fig. 8.90. If a high-frequency (HF) current generated after a reignition cannot be interrupted, the current will be interrupted at the next current zero in the power frequency. However, the high-frequency current may be interrupted immediately after a reignition if the circuit breaker has excellent thermal interrupting capabilities. Repeated reignition may occur if the dielectric strength is insufficient for the TRV withstand imposed immediately after current interruption. The overvoltage gradually increases in amplitude with multiple reignitions, and this overvoltage is repeatedly applied to substation equipment at the load side.

**Fig. 8.90** Multiple reignitions and high-frequency current interruptions

### 8.3.6 Transformer Limited Fault Clearing

One of the most severe fault current interruption duties of a circuit breaker is the clearing of a transformer limited fault (TLF). In Fig. 8.91 the two topology conditions of a TLF are given: the transformer-fed fault (TFF) and the transformer secondary fault (TSF). In both cases, the characteristics of the transformer are the dominant influences on the short-circuit current, its AC and DC components, the power frequency recovery voltage (the first-, second-, and third-pole-to-clear factors given by the neutral treatment of the system; the voltage drop), and the high-frequency TRV.

Due to the dominance of the transformer impedance, the TRV is largely dictated by the power-frequency voltage drop across the transformer. The higher the TLF current, the lower the voltage drop. A fault current of 6.3 kA will cause a voltage drop of roughly 90%, while a fault current of 12.5 kA will yield a voltage drop of around 70%. In practice, 12.5 kA corresponds to approximately 30% of the rated short-circuit current of the circuit breaker.

The ratio  $X_0/X_1$  varies considerably depending on the neutral treatment of the network and the transformer involved. However, for effectively earthed networks and transformers with an earthed neutral,  $X_0/X_1$  will be smaller than 1.0, leading to a reducing effect on the

first-pole-to-clear factor ( $k_{pp}$ ). However, under other conditions where transformer neutrals are not (always) connected to earth,  $k_{pp}$  may reach 1.5, although this is the exception rather than the rule, and it can be stated that at the transformer side, connected to networks of 100 kV and above, the first pole-to-clear factor for TLF will generally be close to 1.0 or even lower. The first-pole-to-clear factors as specified in the IEC standard for circuit breakers (1.2 for UHV and 1.3 for EHV) are therefore undoubtedly larger than those observed under service conditions. In cases where transformer neutrals are isolated from earth or connected by Petersen coils (resonance earthing),  $k_{pp}$  must be specified as 1.5.

Neglecting the contribution from the supply, which is at a much lower frequency, the peak TRV for a TLF is given by:

$$U_c = k_p k_{af} k_{vd} \frac{U_r \sqrt{2}}{\sqrt{3}}, \quad (8.4)$$

where:

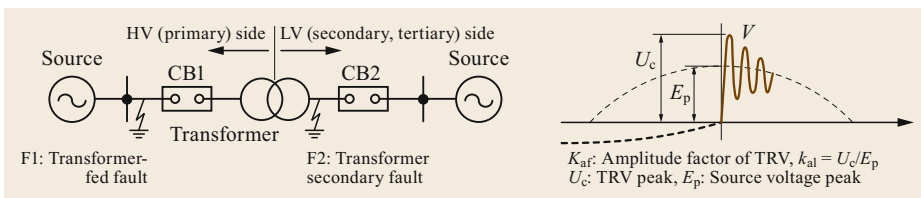

$U_c$  is the TRV peak

$k_p$  is the pole-to-clear factor ( $k_{pp}$  for the first-pole-to-clear)

$k_{af}$  is the amplitude factor

$k_{vd}$  is the voltage drop factor

$U_r$  is the rated voltage.

**Fig. 8.91** The transient recovery voltage (TRV) for transformer limited faults (TLFs)

**Fig. 8.92** Two-parameter TRV envelope for TLF conditions

When the capacitance to earth of the connection between the circuit breaker and transformer is large enough, the frequency response at the moment of fault current interruption (i.e., the TRV as a function of the frequency) will be dominated by this capacitance in parallel with the transformer short-circuit inductance. The TRV as a function of time will appear to be a rather simple single-frequency response: a damped  $1 - \cos$  function described by a two-parameter envelope, as defined in the IEC standard for high-voltage circuit breakers [8.38].

Figure 8.92 illustrates the TRV envelope for TLF conditions, which is covered by terminal fault test duties T10 and T30, corresponding to short-circuit currents of 10% and 30%, respectively, of the rated short-circuit current of the circuit breaker. The peak value  $U_c$  occurs at time  $T_2$  and  $t_3$  is the time taken for the line segments constituting the envelope to intersect. Figure 8.92 shows the steepness of the TRV expressed as the RRRV (rate of rise of TRV), which is immediately imposed after interruption as it is an important dielectric stress factor for the contact gap. Figure 8.93 presents the ratio of  $T_2$  to  $t_3$  as a function of the damping, which is expressed as the amplitude factor ( $k_{af}$ ). A factor of 2.0 means no damping, and an amplitude factor of 1.7 covers most real cases [8.39].

The corresponding RRRV can be then calculated from the peak TRV  $U_c$  and  $t_3$  as shown in Fig. 8.92 and below

$$\text{RRRV} = \frac{U_c}{t_3}, \quad (8.5)$$

where  $t_3$  can be derived from  $T_2$ , the time to peak TRV, as a function of the amplitude factor, as shown in Fig. 8.93.

When there is no external capacitance, the TRV is determined by a complicated transformer model. Several models that describe the transient behavior of

**Fig. 8.93** The ratios  $T_2/t_3$  and  $t_3/T_2$  as functions of  $k_{af}$

a transformer are available. However, it should be noted that the relevant range of frequencies for estimating the TRV waveform is between about 10 and 100 kHz. This range is much lower than most transient transformer models refer to, since they address the frequencies (up to tens of MHz) that accompany the internal stresses in the transformer's windings. Frequency response analysis (FRA) measurements are applied to study very-high-frequency models, but they are also useful for the low-frequency range and for determining the TRV waveform. They are used to obtain the frequency-dependent ratio of the output voltage to the input voltage in various configurations of shorted LV windings and excited HV phases of a power transformer.

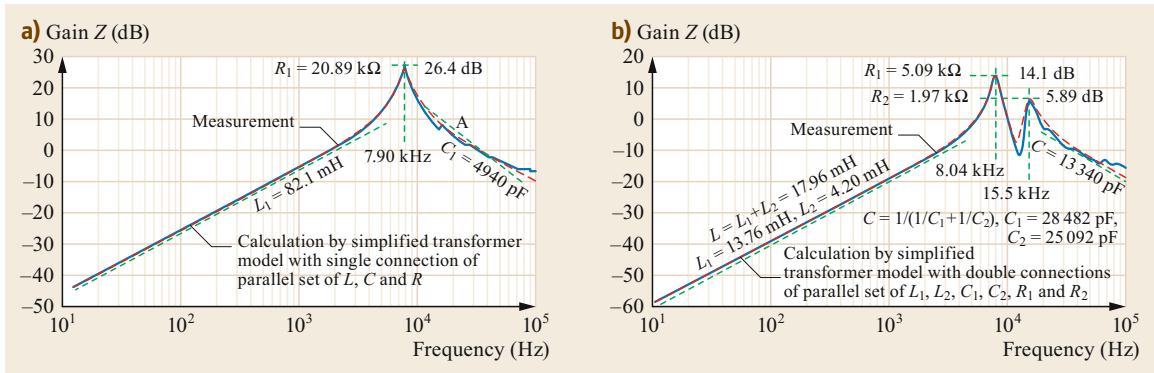

The impedance can also be measured directly using adequate measuring equipment. Figure 8.94 shows the magnitude and the argument (the phase angle shift) of the frequency-dependent transformer impedance.

FRA measurements indicate the transformer response in the frequency domain. Multiplying the transformer impedance in the frequency domain by the fault current function in the frequency domain gives the TRV in the frequency domain:  $\text{TRV}(\omega) = I_{sc}(\omega)Z(\omega)$ . Reverse Fourier transformation then yields  $\text{TRV}(t)$  in the time domain. Note that the fault current mentioned here is the so-called injected fault current, which has the opposite polarity to the actual fault current, meaning that the superposition of the actual and injected fault currents gives a net effect of zero current, i.e., fault clearing. During the relevant part of the TRV (a few ms), the injected fault current can be regarded as a ramp function:  $I(t) = St$ , or, in the frequency domain,  $I(\omega) = S/\omega^2$ . This reduces the effect of the higher-frequency part of  $Z(\omega)$  on  $\text{TRV}(\omega)$ .

Using the FRA measurements shown in Fig. 8.94, the short-circuit inductance can be obtained by fitting a straight line in the low-frequency range that increases in proportion to the frequency. It is also possible, albeit

**Fig. 8.94** FRA and TRV waveform obtained with a 400 kV, 80 MVA transformer. Transformer characteristics: 1U-1N tap5, 80 MV A, 3 $\Phi$ , HV = 400 kV, LV1 = 11.5 kV, LV2 = 11.5 kV,  $X_k$ @50 Hz = 309.3  $\Omega$ , estimated TRV parameters:  $k_{af} = 1.69$ ,  $t_3 = 61.1 \mu s$

**Fig. 8.95a,b** FRA measurements for a 525 kV, 1500 MVA transformer. (a) Primary side, (b) secondary side

less straightforward, to determine the surge capacitance by fitting a straight line in the upper frequency range that decreases in a manner inversely proportional to the frequency. This allows the surge capacitance to be determined in the relevant range of frequencies (tens of kHz to around 100 kHz).

Thus, a simple single-frequency model can be derived that is based on the short-circuit inductance  $L$  and the surge capacitance  $C$ . The parallel resistance  $R$  can

be estimated from the crest value of  $Z(\omega)$ . The damping of the single-frequency response can be calculated and the peak or amplitude factor  $k_{ap}$  can be derived from  $R/\sqrt{L/C} = R/Z$ . Multiple resonances can also be derived.

Typical responses obtained via FRA measurements with the first-pole-to-clear at the primary and secondary sides of a 1500 MVA shell-type transformer are shown in Fig. 8.95.

The TRV waveform can be reproduced using a simplified transformer model with a series connection of multiple parallel circuits of  $L$ ,  $C$ , and  $R$  based on the FRA measurements. Simplified transformer models for the primary and secondary sides can be obtained from the results of the FRA measurements, as shown in Fig. 8.96. Frequency responses were also calculated using these simplified transformer models, and are plotted in Fig. 8.95. The calculated responses show good agreement with the measured FRA characteristics.

Figure 8.97 shows the TRV waveforms reproduced by the simplified transformer models based on the FRA measurements. These calculated TRV waveforms also show good agreement with the measured TRVs. This confirms that a simplified transformer model that has a series connection of multiple parallel circuits of  $L$ ,  $C$ , and  $R$  and is based on FRA measurements can reproduce the TRV waveform obtained under TLF conditions very precisely [8.40].

The minimum amount of capacitance to earth between a circuit breaker and the power transformer has been investigated. The connection usually occurs through air-insulated conductors along distances ranging from tens of meters up to a hundred meters. Only limited high-voltage equipment is connected, and such equipment (current transformers, surge arresters, disconnectors, and earthing switches) may have a rather low capacitance to earth. Typical examples of the external capacitance of air-insulated substations give a minimum value that seems to be around 500–1000 pF almost independent of the rated voltage.

A substantial capacitance in comparison to the transformer capacitance will change the TRV waveform. When the external capacitance is included in the FRA measurement, it causes a shift in the total impedance to the left, i.e., to lower frequencies. In addition, the peak value of the transformer-frequency-dependent impedance increases, as the quality factor increases. Moreover, while the dominant frequency becomes more prominent, the other natural frequencies tend to diminish. Without external capacitance, the dominant frequencies tend to be between 10 and 20 kHz. When a minimal level of additional capacitance is added, the dominant frequency is around 10 kHz or less.

The given frequencies (around 10 kHz), the higher quality factors (leading to an amplitude factor of about 1.7), the low first-pole-to-clear factor (close to 1.0 but with a considerable margin; reaching up to 1.2 or 1.3), and the voltage drop factor (90% at a relatively low fault current, say 6 kA, and 70% at a relatively high fault current, say 12 kA) provide the basis to define the TRV parameters. Standardization for rated voltages from 100 kV up to and including 800 kV is underway.

### 8.3.7 Out-of-Phase Current Switching

A mandatory test duty for making and breaking out-of-phase currents is specified in the IEC and IEEE standards for high-voltage circuit breakers [8.40, 41]. These out-of-phase switching duties were established many decades ago for both standards. The out-of-phase current and TRV ratings are still based on the original

Fig. 8.96a,b Simplified transformer models for (a) the primary and (b) the secondary sides

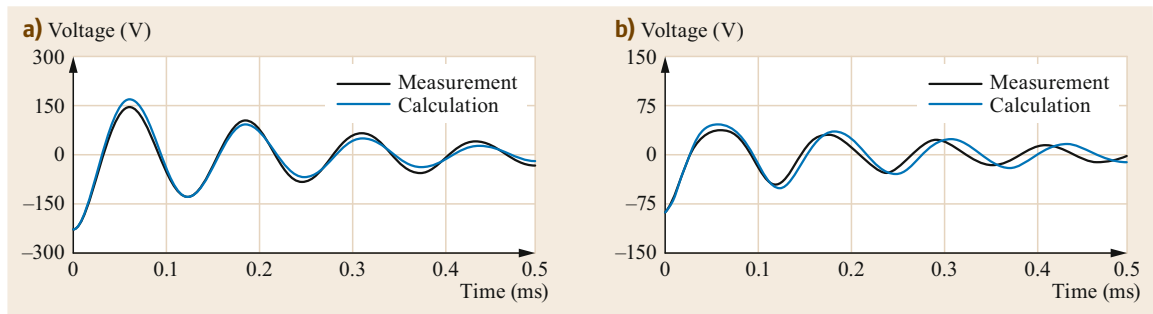

Fig. 8.97a,b TRVs on the (a) primary side and (b) secondary side, as reproduced by simplified transformer models

assumptions made when devising the duties. Although the ratings are still applicable for transmission systems, the background considerations must be adapted, since larger out-of-phase angles may be expected than those deduced from the specifications.

Power swing corresponds to a periodical lowering the amplitude of power frequency or the degradation of power quality, which is evoked by sudden changes like faults or switching operations, which may result in operation of a protective relay, due to the growing load flow in electrical power networks.

Power swing can be detected from 0.1 up to 10 Hz swing frequency, also during open-pole condition and during asymmetrical operation. The coordination of power swing detection, distance protection and out of step protection provides a reliable system protection.

There are always small power swings in a transmission network; these can be caused by small transients and the excitation of inherent oscillation conditions between parts of the power system. The actions of large power-plant controllers (for instance power system stabilizers) and HVDC controllers are typically sufficient to dampen the swings and prevent the escalation of such small power swings. In addition, larger but still stable power swings may occur due to larger excitations (sudden loss of a large power plant, a change in system impedances, a jump in system load). The actions of large power plant controllers (e.g., power system stabilizers) and HVDC controllers are typically sufficient to dampen the swings and prevent these small power swings from escalating. In addition, larger but still stable power swings may occur due to larger excitations (the sudden loss of a large power plant, a change in system impedances, a jump in the system load). When unstable power swings appear, they necessitate a serious intervention by protection and control equipment in the power system. Stable and unstable power swings are caused by an imbalance in active power (frequency instability), an imbalance in reactive power (voltage instability), a short circuit that has not been isolated quickly enough, or excessive power transfer through a generator or a transmission corridor (angular instability) (Fig. 8.98). Frequency, voltage, and angular instabilities often coincide. In this case, out-of-step conditions come into play and the system will be split due to automatic tripping by protective relays or special protection schemes.

Figure 8.98a shows a typical situation, where a fault between a power generation site and a load site leads to a sudden decrease of the voltage, while the power input to the system stays constant. The increase in (rotor) angle  $\delta$  is represented by the angle before up to after the short-circuit. After a fault clearance, the voltage returns to a value between the voltage before and the voltage

Fig. 8.98 (a) Angular stability and (b)  $P$ - $V$  curve (voltage stability)

during the fault. The power  $P$  that is transferred after short-circuit is larger than the power input and a deceleration takes place so that the angle returns to a new stable operating point. Beyond a certain combination of voltage drop during the fault and duration to clear the fault, it will no longer be possible to prevent a pole slip.

After a pole slip, the generator, the group of generators or the part of the power system may run again synchronously with the remaining part of the power system (this condition is not so common) or it may be separated from the remaining part. Power system instabilities can also be divided into short term phenomena (within seconds for voltage and frequency instability) and long-term phenomena (within tens of seconds to minutes). Rotor angle instability develops within seconds after a large disturbance and within tens of seconds after a small disturbance (leading to inter area oscillations).

A heavily loaded line requires reactive power in order to maintain the operational voltage limits at both line terminals. In addition to the active power to be transmitted, a larger amount of reactive power has to

be transferred as well. Figure 8.98b shows an example of a  $P$ - $V$  curve, which is presented with a transmission line circuit modelled by only a reactance and a resistance. The sending end voltage is kept constant, while the receiving end voltage is given as a function of the active power of the load. The ratio between reactive ( $Q$ ) and active power ( $P$ ) of the load is kept constant by a fixed power factor. Starting from the upper part and increasing the load, the receiving end voltage will drop until the critical point, the point of singularity, is reached and no more active power can be transferred. The critical point gives the voltage stability limit under these conditions.

An out-of-step condition is a power swing that causes a generator or group of generators to experience pole slipping for which some corrective action must be taken [8.42]. The term is synonymous with an unstable power swing [8.42] and a loss-of synchronism [8.43].

An out-of-phase condition is an abnormal circuit condition involving a loss or lack of synchronism between the parts of an electrical system on either side of a circuit breaker. In this condition, at the instant of operation of the circuit breaker, the phase angle between the rotating vectors representing the voltages generated on either side exceeds its normal value [8.42].

System separations and large disturbances occur more often than expected [8.44]. They are experienced in all parts of the world and are not restricted to certain types of networks (e.g., radial networks). Although the probability of system separation is smaller in dense meshed networks, cascading line tripping will change the topology into that of a radial network with identical effects. By definition, out-of-phase switching relates to the last line between the two parts of a power system to be separated. The risk of an out-of-step or out-of-phase condition should not be ignored; it should be taken into account by protection experts as well as circuit-breaker experts.

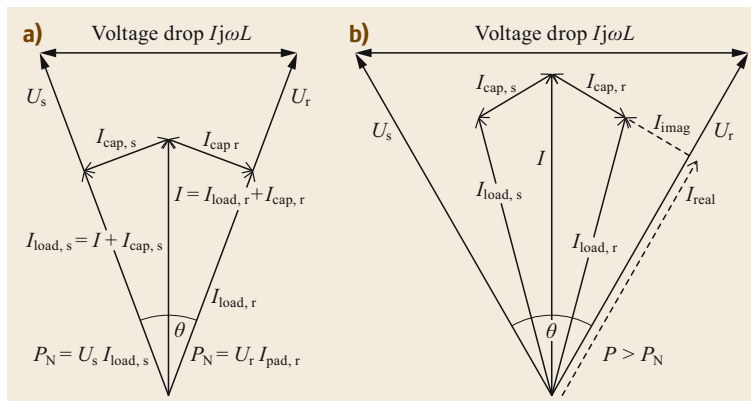

It should be noted that the amplitude of the out-of-phase current is an important stress factor during the

current interruption process, at it directly influences the amount of energy to be absorbed by the arc between the circuit breaker contacts. The larger the amount of energy, the more difficult it is to withstand the transient recovery voltage immediately after current zero. For transmission circuit breakers, an out-of-phase angle of  $180^\circ$  gives a 40% larger out-of-phase current than an out-of-phase angle of  $90^\circ$  and a 40% increase in the steepness of the TRV (RRRV); for generator circuit breakers, an out-of-phase angle of  $180^\circ$  might give a much higher current—up to 80% larger than that which occurs for an out-of-phase angle of  $90^\circ$ . In the standards, the rated (i.e., maximum) out-of-phase current is defined as a percentage of the rated short-circuit current.

System separation proceeds with a cascade of tripping connections, and thus with an increase in the impedance between the representative voltages on both sides of the circuit breaker. Therefore, specified amplitudes of the out-of-phase current as large as 5 and 25% of the rated short-circuit current of the circuit breaker involved are quite reasonable for high-voltage circuit breakers.

Also, the larger the out-of-phase angle, the larger and the faster the recovery voltage and the transient recovery voltage. The rate of rise of the recovery voltage can be considered to be covered by T30 or by a transformer limited fault test duty when a transformer represents the dominant impedance. However, a high-amplitude  $U_c$  representing the largest of all test duties is typical of out-of-phase TRVs. As such, this also serves as a reference for special cases such as long line fault clearing and the clearing of faults on series-compensated OH-lines.

Shortly before the moment of system separation, both parts of the network are connected by a contracted corridor of just one circuit. This condition is similar to a radial network, and the out-of-phase angle is determined by the power flow and the reactance of the connecting circuit or circuits in series (Fig. 8.99). The

**Fig. 8.99a,b** The out-of-phase angle  $\theta$  can be determined by the power flow, the reactance of the connecting circuit. The larger angle (b) is required to transfer a larger amount of active power and it will be further increased in case of larger impedance of the line

**Fig. 8.100** Out-of-phase recovery voltage at 81.8% of the rated voltage as a function of the out-of-phase angle for  $k_{pp} = 1.3$  (blue) and  $k_{pp} = 1.5$  (brown)

larger the impedance  $\omega L$  and the power flow, the larger the angle along the line.

When detailed information on large disturbances has been published, out-of-phase angles of far greater than  $90^\circ$  have been reported. For instance, during the large disturbances in India on July 30th and 31st, 2012, the angle between the involved regions jumped from  $60^\circ$  to  $260^\circ$  (for system separation at 02:33:15.4 on July 30th) and from  $90^\circ$  to  $190^\circ$  (for system separation at 13:00:18 on July 31st) [8.44, 45].

Report [8.45] is one of the few to give detailed information about the development of the difference in angle between two regions to be separated. Obviously, these angles become large and consequently the amplitude of the system voltage near the center of oscillation is low. In addition, large disturbances in the system come with voltage instability problems. Large voltage dips, depressed voltages, and dramatic voltage drops have been reported to occur at the moment of system separation, together with large power flows. For instance, when the Italian grid separated from the European continental grid in 2003 [8.46], the voltage fell below 80% of the nominal value. This phenomenon is also mentioned in [8.47]. The cascading tripping of overhead lines and other components led to a sudden increase in reactive power consumption and consequently to system voltage depression and eventually collapse.

For high-voltage circuit breakers, this means that large out-of-phase angles most probably coincide with voltage levels far lower than the rated voltage of the

circuit breaker—even below the minimum voltage level acceptable to grid codes, which is normally 20% below the rated value. To be precise, the maximum operating voltage acceptable to grid codes is usually 110% of the nominal voltage, and the minimum voltage is 90% of the nominal voltage (although the minimum voltage under extreme conditions is normally specified to be 85% for a certain amount of time, and an even lower value may be permitted for a very short time). As the rated voltage of the circuit breaker should be at least the maximum operating voltage of the system, the minimum operating voltage is the rated voltage divided by at least 1.1 and multiplied by 0.9 ( $\leq 81.8\%$ ). For the grid codes, the maximum operating voltage is usually 110% of the nominal voltage and the minimum voltage 90% of the nominal voltage (the minimum voltage in extreme conditions is normally specified to be 85% for a certain amount of time and even lower could be indicated for very short time).

As the rated voltage of the circuit breaker should be at least the maximum operating voltage in the system, the minimum operating voltage is the rated voltage divided by at least 1.1 and multiplied by 0.9 ( $> 81.8\%$ ). Figure 8.100 shows the actual out-of-phase recovery voltage at the minimum operating voltage as a function of the out-of-phase angle. It is compared with the out-of-phase recovery voltage stipulated in the standard for high-voltage circuit breakers [8.49] based on the rated voltage and a first-pole-to-clear factor of 1.3 (effectively earthed networks: blue) and a first pole to-clear factor of 1.5 (non-effectively earthed networks: brown). From the standard values, it can be deduced that these correspond to out-of-phase angles of  $105^\circ$  (first-pole-to-clear factor: 1.3) and  $115^\circ$  (first-pole-to-clear factor: 1.5). These angles are explained in Fig. 8.101, together with those for other first-pole-to-clear conditions.

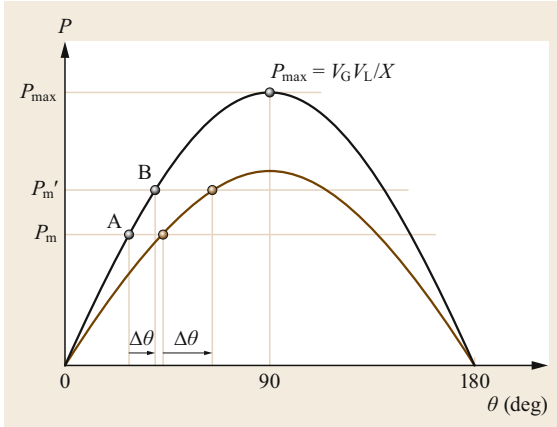

At the minimum operating voltage acceptable to grid codes (which is larger than the system voltages reported during large disturbances), the out-of-phase recovery voltage is found to be (far) less than or equal to the value used for type testing, even for the largest out-of-phase angles. As such, actual cases seem to be covered for smaller out-of-phase angles (up to  $90^\circ$ ) up to the rated voltage and for larger angles and large power flows (up to  $180^\circ$ ) up to the minimum operating voltages [8.44].

### 8.3.8 Mechanical Model of Power System Stability

Equipment requirements are identified by studying the phenomena in power systems. The engineers involved in equipment design, testing, application, and assessment often need to understand various switching behaviors observed in power systems. The use of a mechanical model as an analogy for a power transmission system is introduced in this section in order to explore system stability during an out-of-phase condition.

Figure 8.102 shows a simple transmission system with a generator and a load, where the voltage at the generator ( $V_G$ ) and the voltage at the load center ( $V_L$ ) are both considered to remain constant. The AC power transmission capacity increases with the system voltage and decreases with the line reactance ( $X$ ). The transmission capacity ( $P$ ) also depends on the difference in voltage phase angle ( $\theta = \theta_1 - \theta_2$ ) between the generator terminal and the transmission line end.

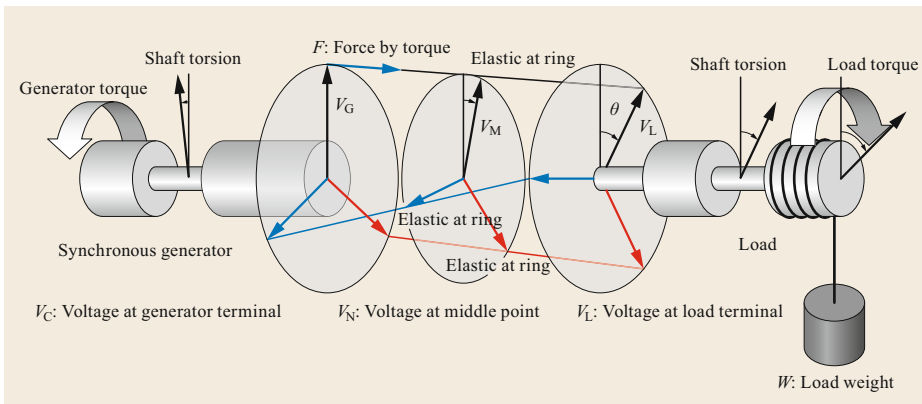

The transmission capacity is given by

$$P = V_G V_L \sin \frac{\theta}{X}, \quad (8.6)$$

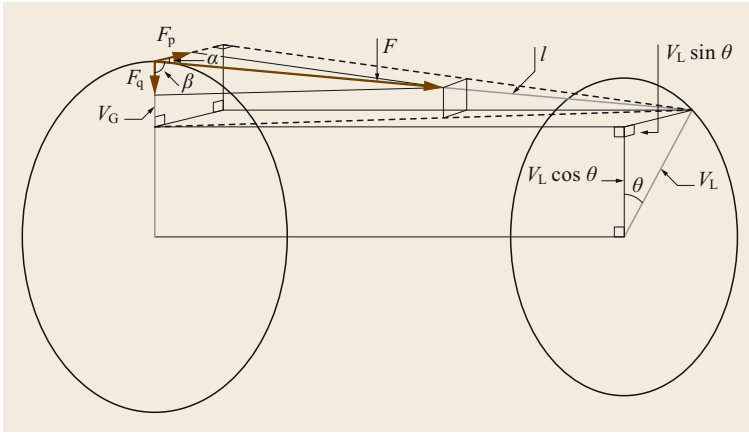

where  $V_G$  and  $\theta_1$  are the voltage and its phase angle at the generator terminal, and  $V_L$  and  $\theta_2$  are the voltage and its phase angle at the line end. The transmission capacity is highest when the difference in voltage phase angle is  $90^\circ$ . Figure 8.103 shows the transmission capacities for different power generation values. A small increase in the phase angle (less than  $90^\circ$ ) can increase the transmission power from  $P_m$  (point A) to  $P'_m$  (point B) in the case of a large power generator.

From Fig. 8.103, it is clear that the power system is more stable when the system is operated in the small phase angle difference region (less than  $90^\circ$ ) because the transmission capacity can increase if demand increases or in a contingency case, such as the loss of a circuit due to a fault (blue line).

Figure 8.104 shows a mechanical analogy for a power transmission system called a Noda model [8.50]. In this model, the generator is represented by a rotary torque handle and the load is shown as a hoist loaded with a weight ( $W$ ). The radii  $V_G$ ,  $V_M$ , and  $V_L$  of the three disks correspond to the system voltages at the generator terminal, the midpoint of the transmission system, and the load terminal, respectively. The three disks are connected by three elastic strings (e.g., rubber wire).

**Fig. 8.104** Mechanical model of power transmission with a generator and a load

**Fig. 8.105** Resolution of the elastic force into circumferential and radial components

The torque power ( $F$ ) generated by turning the handle at the generator side is transmitted through the elastic strings and winds up the weight on the load side.

If  $F$  and  $F_0$  are the tensions of the elastic strings of length  $l$  (the angular difference between the disk at the generator terminal and the disk at the load terminal is  $\theta$ ) and  $l_0$  (the angular difference is zero), respectively, the tension can be expressed as follows, where  $1/X$  is the elastic constant of the string:

$$F - F_0 = \frac{1}{X} (l - l_0), \quad F \cong \frac{l}{X}.$$

If  $F_p$  is the circumferential component of the tension  $F$ , and  $P$  is the angular moment of the force (as shown in Fig. 8.105), the following equation (analogous to the transmission capacity) is obtained

$$F_p = F \cos \alpha = F \frac{V_L \sin \theta}{l} = \frac{V_L \sin \theta}{X},$$

$$P = F_p V_G = \frac{V_G V_L \sin \theta}{X}.$$

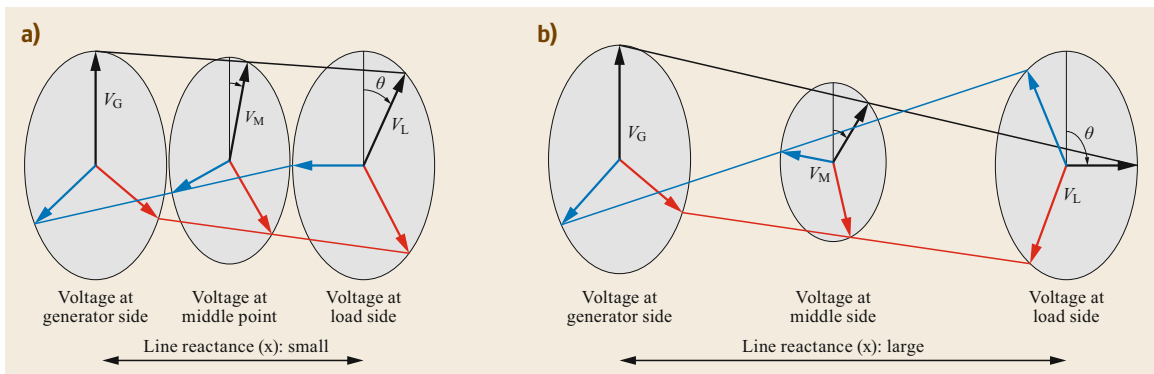

Also, if  $F_q$  is the radial component of the tension  $F$  and  $Q$  is the radial component of the force, the following equation is obtained:

$$F_q = F \cos \beta = F \frac{V_G - V_L \cos \theta}{l} = \frac{V_G - V_L \cos \theta}{X},$$

$$Q = F_q V_G = V_G \frac{V_G - V_L \cos \theta}{X}.$$

If the weight (which corresponds to the power load  $P$ ) is increased, the mechanical angular difference ( $\theta$ ) also needs to increase, resulting in the expansion of the three elastic strings and a decrease in the radius (i.e., the voltage) at the midpoint  $V_M$ . The mechanical force ( $Q$ ) compresses the radius  $V_G$  (which corresponds to the reactive power).

Figure 8.106 shows a schematic of three disks and the elastic strings connected to these disks, which correspond to small and large line reactances. The system stability is enhanced when the voltage is high and the line reactance is small, which results in the operation of the power system at a small phase angle difference.

**Fig. 8.106a,b** Two schematics of three disks: (a) small line reactance and phase angle; (b) large line reactance and phase angle

**Fig. 8.107** Twisted elastic strings corresponding to power system breakdown due to a large phase angle difference (out-of-phase condition)

**Fig. 8.108** Photograph of a Noda model

When the phase angle exceeds the critical condition, the elastic strings are eventually twisted at the midpoint (as shown in Fig. 8.107), which corresponds to an out-of-phase condition or breakdown at the midpoint of the power system.

Figure 8.108 shows an actual demonstration model proposed by Noda.

Flexible alternating current transmission systems (FACTSs) and series capacitor compensation are often used for reactive power compensation in a long transmission line. The relevant Noda model can explain the impact of positioning these compensation devices in the middle of the transmission line by increasing the voltage at the midpoint. This results in more stable power transmission and a larger transmission capacity, as shown in Fig. 8.109.

### 8.3.9 Comparison of the Switching Phenomena Obtained at 50 and 60 Hz

#### (A) Power Frequency

Even though power systems are operated at 50 Hz in most countries, some countries and regions, such as the United States and west Japan, use a power frequency of 60 Hz, as shown in Fig. 8.110. Both frequencies coexist

**Fig. 8.109a,b** Noda model illustrating reactive power compensation. Voltage at middle point: (a) low, (b) reactive power compensation; out-of-phase angle  $\theta$ : (c) large, (d) small

and there is presently no push for worldwide standardization in this regard.

Some electric appliances may not operate efficiently or even safely if used on anything other than the intended power frequency. However, most substation equipment, especially circuit breakers, can be operated at both power frequencies (50 and 60 Hz).

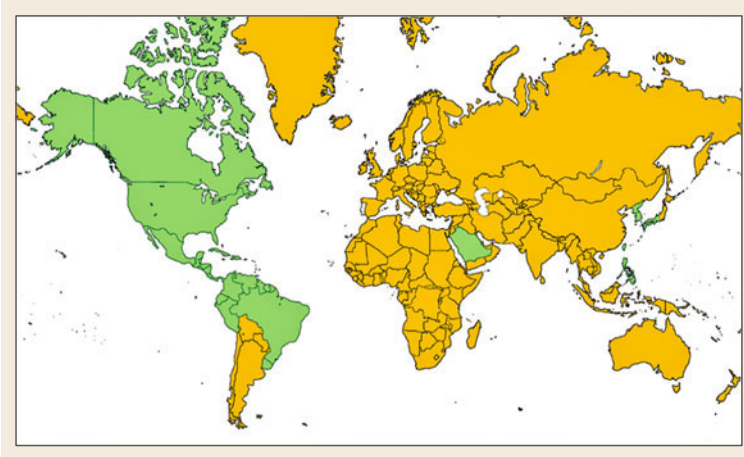

Strictly speaking, changing the power frequency will affect the performance of substation equipment. For instance, if we consider a power transformer with a particular capacity, a more compact transformer can be used with a higher power frequency than with a lower power frequency. The effects of the power frequency on the interrupting performance for various switching duties are given below.

#### (B) Thermal Interrupting Capability

When a circuit breaker interrupts the same current under SLF conditions, better cooling performance (higher thermal interrupting) is needed when the power frequency is 60 Hz as shown in Fig. 8.111, because the current and voltage slopes ( $di/dt$ ,  $dv/dt$ ) at current zero are 1.2 times higher than those obtained when the power frequency is 50 Hz, resulting in higher ohmic heat input around the current zero. Some circuit breaker designs employ a larger grading capacitor for 60 Hz than for 50 Hz because it enhances the thermal interrupting capability by reducing the current slope at the current zero.

#### (C) Dielectric Interrupting Capability

A circuit breaker is required to interrupt the short-circuit current under bus terminal fault (BTF) conditions

**Fig. 8.110** World map showing the use of different power frequencies (50 Hz in yellow and 60 Hz in green) in different regions and countries

at any current zero when the minimum arcing time after the contact separation has elapsed. This means that the circuit breaker should have an interrupting window a half-cycle wide at minimum (for symmetrical current). The intervals between current zeros are 10 ms at 50 Hz and 8.3 ms at 60 Hz as shown in Fig. 8.112. Therefore, the circuit breaker must have a longer interrupting window, resulting in a longer effective gas flow period, if 50 Hz is used.

#### (D) Capacitive Switching Capability

TRV peaks appear half a cycle after interrupting the current under capacitive switching conditions, which corresponds to 10 and 8.3 ms from current interruption at 50 and 60 Hz, respectively, Fig. 8.113. Therefore, the circuit breaker must have a better dielectric withstand strength recovery between the contacts in case of 60 Hz,

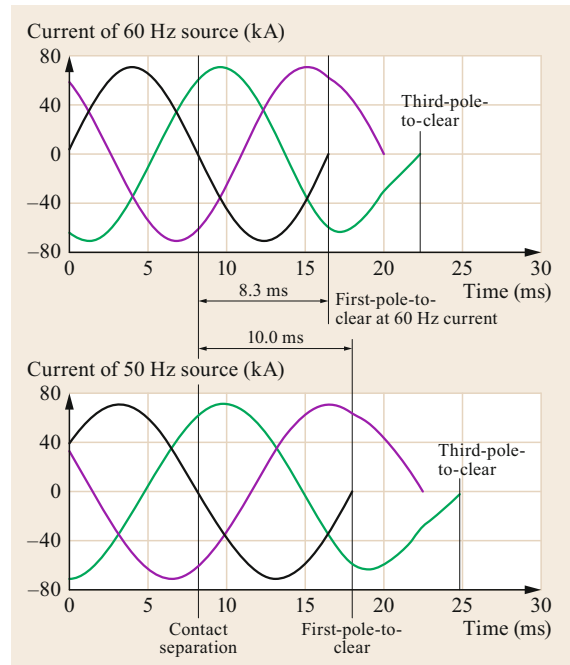

**Fig. 8.111** Comparison of  $(di/dt)$  at current zero and TRV obtained for power frequencies of 50 and 60 Hz

which is normally attained by increasing the contact opening speed.

#### (E) Inductive Switching Capability

There is no significant difference in switching performance between 50 and 60 Hz under inductive switching conditions because the TRV is determined by the circuit conditions at the load side (not the power-frequency source side). In addition, the amplitude and the fre-

**Fig. 8.112** Comparison of the interval between current zeros in a three-phase current for power frequencies of 50 and 60 Hz

**Fig. 8.113** Recovery voltage after capacitive current interruption for power frequencies of 50 and 60 Hz

quency of high-frequency current oscillations and associated overvoltages associated with reignitions do not show any dependence on whether the power frequency is 50 or 60 Hz. Therefore, the standard IEC 62271-100 permits inductive switching tests to be performed at either 50 or 60 Hz.

#### (F) Current-Carrying Capability

The short time current withstand test can also be performed at either 50 or 60 Hz, because the energy and mechanical stresses imposed on an interrupter do not vary significantly depending on whether the power frequency is 50 or 60 Hz considering the current-carrying duration of 1 s, even though the current at the first peak is 2.5 times and 2.6 times the root-mean square of the current for 50 and 60 Hz, respectively. Therefore, the standard IEC 62271-100 allows the short time current withstand test to be performed at either 50 or 60 Hz.

In general, manufacturers provide circuit breakers that are applicable for use with both power frequencies (50 and 60 Hz) even though the power frequency impacts the switching performance.

#### (G) Continuous Current-Carrying Capability

IEC 62271-1 states that the performance of switching devices of the open type with no ferrous components adjacent to the current-carrying parts at 60 Hz can be deemed to be the same as their performance in tests carried out at 50 Hz provided that the temperature rise recorded during the test at 50 Hz does not exceed 95% of the maximum permissible value. This recognizes the fact that the temperature rise is generally slightly higher when carrying a continuous current at 60 Hz.

### 8.3.10 Switching Requirements for UHV Transmission

The first commercial UHV transmission system with a rated voltage of 1100 kV AC commenced operation

on January 6th, 2009 following on-site commissioning tests during December 2008 in China. Since then, UHV AC (up to 1200 kV) and UHV DC (up to 1000 kV) networks have steadily expanded in some countries such as China and India.

In October 2006, CIGRE SC A3 published WG A3.22 on the technical requirements for substation equipment exceeding 800 kV as well as some technical documents summarizing the specifications for substation equipment ( $\geq 800$  kV) based on investigations performed for various UHV and EHV projects [8.49, 51–53].

In order to minimize the costs and visual impact of UHV transmission lines and substations, advanced technological solutions and analytical optimization techniques were introduced. Furthermore, the results of studies relating to reduced insulation coordination requirements and the requirements for some system transients (e.g., TRVs, ITRVs, very fast transient overvoltages (VFTOs)) at UHV levels have an impact on the insulation coordination requirements (distances, dimensions, insulation thickness) for EHV voltages (800, 550, 420 kV).

In the 1970s and 1980s, some utilities around the world started pilot schemes for AC power systems with voltages above 1000 kV. The former USSR (Union of Soviet Socialist Republics) performed long-term testing of a plant with a rated voltage of 1200 kV, while in the USA, Bonneville Power Administration (BPA) and American Electric Power (AEP) ran pilot schemes that operated at 1200 and 1500 kV, respectively. During the 1980s, the former USSR even had a pilot plant with a rated voltage of 1800 kV, and they operated a commercial 1200 kV transmission system that included 1900 km of OH lines (although only half of that network was actually operated at 1200 kV) from 1985 until 1991. In the 1990s, a 1050 kV pilot plant was operated in Italy for two years. Also, in Japan, a 1100 kV pilot scheme has been in operation since 1996, together with 430 km of UHV OH lines (which are operated at 550 kV) [8.51].

Table 8.7 shows various issues specifically associated with UHV AC power systems that could have a considerable impact on substation equipment. In particular, the use of multibundle conductors with large-diameter, large-capacity power transformers leads to distinctive phenomena for UHV power systems. In addition, the application of high-performance surge arresters (MOSAs) with low protection voltages to effectively limit overvoltages is integral to the design of some UHV systems. The impact of this design approach and its influence on specifications are briefly described in this section.

The technical and economic consequences of insulation levels are becoming increasingly important, especially for UHV systems. Optimal insulation coordination can be achieved using high-performance

**Table 8.7** Issues specifically associated with UHV AC power systems

Equipment	Phenomena specific to UHV systems	CIGRE investigations
Substation equipment	Increased insulation levels (reduced LIWV/LIPL)	Various mitigation schemes are applied to suppress the SIWV levels as much as possible
Four-legged reactor HSGS	Prolonged secondary arc extinction time due to higher coupled voltage and induced current	Four-legged shunt reactor can facilitate successful autoreclosing under the 1LG condition for a single circuit
Surge arrester shunt reactor	Prominent Ferranti effect and TOV due to high capacitance of overhead lines	Severe voltage factor and breaking current are not seen for capacitive current switching
Circuit breaker GIS, transformer	Severe VFTO due to geometry and topology of UHV substation	Resistor-fitted DS can effectively suppress VFTO for GIS substation
Circuit breaker	Large time constant of DC component in fault current due to low losses from transformers and lines	Time constants in UHV systems are 100 ms for India, 120 ms for China, and 150 ms for Japan
Circuit breaker	Reduced first-pole-to-clear factor due to small zero-sequence impedance in UHV systems	First-pole-to-clear factors are 1.1 for Japan, 1.2 for India, and 1.0–1.23 for China
Circuit breaker surge arrester	High amplitude factor in TRVs due to low losses from power transformers and transmission lines	RRRV for TLF exceeds the existing standard value; MOSA can suppress the TRV peak for terminal faults
Circuit breaker surge arrester	High TRV peak value corresponding to out-of-phase duty due to low damping of traveling waves	Further investigations are expected to provide some solutions for out-of-phase phenomena
Circuit breaker	Reduced line surge impedances due to multibundle conductors with large diameters	Line surge impedance is suggested to be 330 Ω for 8-bundle conductors designed for UHV OH lines
Line substation (AIS)	Possibility of a reduced corona onset voltage with increased corona losses and audible noise	UHV lines employ 8 conductors with a cross-sectional area of 400–810 mm <sup>2</sup> depending on the allowable level of corona noise

MOSAs [8.54] with the *I*–*V* characteristic shown in Fig. 8.114.

Studies of the insulation coordination using accurate computer-aided simulations are common in such projects. Another important aspect of insulation coordination is the utility’s policy regarding withstand margins for severe lightning impulse or switching impulse conditions with a very low probability of occurrence.

As lightning overvoltages dominate the nonself-restoring internal insulation design of substation equip-

ment, it is important to rationalize lightning overvoltages by positioning a sufficient number of MOSAs at appropriate locations, such as at line entrances, busbars, and transformers. Table 8.8 lists examples of several MOSA arrangements along with the corresponding costs and lightning impulse withstand voltages (LIWVs) at UHV substation equipment. The arrangement that includes two surge arresters per circuit at the line entrance, two per quarter bus, and one per transformer bank is one of the most favored for UHV transmission in Japan.

**Fig. 8.114** Typical *I*–*V* characteristic of a high-performance MOSA

Layout of surge arrester						
Transformer overvoltage LIWV (kV)	1950	1943	1895	1943	1938	1896
GIS overvoltage LIWV (kV)	2898	2854	2730	2628	2506	2208
Cost (%)	102	105	109	103	103	100

**Table 8.8**  
Relationship between LIWVs and MOSA layouts

**Fig. 8.115** LIWV specifications for transformers and substation equipment

VFTO levels are reduced to 1.3 pu or below through the application of a resistor-fitted disconnecting switch with a 500 Ω resistor [8.55, 56]. This scheme also effectively suppresses electromagnetic interference in the secondary circuits of CTs, VTs, and protection and control equipment.

Utilities generally use both analytical and simplified IEC approaches to evaluate LIWV levels. The specified LIWVs of UHV switchgear for 1050, 1100, and 1200 kV systems range from 1.25 to 1.49 times the lightning impulse protection level (LIPL) value, as shown in Fig. 8.115.

In addition, it is important to suppress switching overvoltages as much as possible because it allows air clearances to insulation to be reduced, which in turn allows the heights of transmission towers and the dimensions of open-air parts in substations to be suppressed. Therefore, as well as MOSAs, switching equipment

equipped with preinsertion closing/opening resistors are applied to limit switching overvoltages. Additional MOSAs along OH lines and controlled switching are other options that can be employed to reduce switching overvoltages even further. The application of mitigation schemes can markedly change the switching impulse withstand voltage (SIWV) level, so simulations are useful to evaluate their effects. Figure 8.116 shows that the UHV system in Japan takes full advantage of these schemes.

Tables 8.9 and 8.10 show examples of the processes used to determine the LIWV and SIWV in China and Korea. Note that the calculated maximum overvoltage is found to be similar to the switching impulse protection level (SIPL) for each system.

The short-circuit current observed in an UHV system also shows some remarkable features. The use of large-capacity power generators and large-capacity

**Fig. 8.116** SIWV specifications for transformers and substation equipment

**Table 8.9** Examples of processes used to determine the LIWV

Country	Korea 800 kV	China 1100 kV (pilot)
LIPL	1310 kV (2.00 pu) at 20 kA	1620 kV (1.80 pu) at 20 kA
MOSA layout	1 unit for line entrance 1 unit for busbar 1 unit for transformer	1 unit for line entrance 2 units for busbar 1 unit for transformer
Maximum LIWV analysis		1796 kV for transformer 2040 kV for GIS
Acceptable failure rate	0.4 faults/100 km-year-line	0.112 faults/100 km-year-line
Safety factor	-	1.15 for internal insulation
LIWV for transformer	2050 kV (3.14 pu)	2400 kV (2.67 pu)
LIWV for other equipment	2250 kV (3.44 pu)	2250 kV (2.51 pu)
LIWV/LIPL	1.72	1.48

Country	Korea 800 kV	China 1100 kV (pilot)
SIPL	1200 kV (1.85 pu) at 2 kA	1460 kV (1.63 pu) at 2 kA
Resistance for GCB	1000 Ω for closing	600 Ω for closing
Maximum overvoltages	1124 kV for grounding fault 999 kV for closing 1186 kV for opening	1472 kV for opening
Maximum line length	160 km	420 km (tentative)
Flashover probability	0.1%/1 flashover per 1000 operations	0.1%/1 flashover per 1000 operations
Safety factor	-	1.15 for internal insulation
SIWV for transformer	1500 kV (2.30 pu)	1800 kV (2.0 pu)
SIWV for other equipment	1425 kV (2.18 pu)	1800 kV (2.0 pu)

power transformers result in a high  $X/R$  ratio, which leads to an increased DC time constant in fault currents. EHV and UHV transmission lines employ multibundle conductors with large diameters in order to reduce corona noise as well as to increase the transmission capacity.

Table 8.11 summarizes the analytical results for DC time constants calculated based on various tower

designs and multibundle conductors used in different projects. In IEC62271-100, a special case time constant of 75 ms for rated voltages of 550 kV and above, which corresponds to the medium value of the constants surveyed for 800 kV lines, is indicated. Since the DC time constant in an UHV system must be larger than this, a standard time constant of 120 ms is stipulated for UHV.

**Table 8.11** Conductor sizes and DC time constants of short-circuit currents in EHV and UHV transmission lines

Maximum voltage	Conductor size (mm <sup>2</sup> )	Bundle	DC time constant (ms)
765 kV (Canada)	686	4	75
800 kV (USA)	572	6	89
800 kV (South Africa)	428	6	67
800 kV (Brazil)	603	4	88
800 kV (China)	400	6	75
1200 kV (Russia)	400	8	91
1050 kV (Italy)	520	8	100
1100 kV (Japan)	810	8	150
1100 kV (China)	500	8	120

TRVs with high amplitude factors are expected in UHV systems due to the use of low-loss UHV power transformers and UHV transmission lines. An important parameter to consider when defining the TRV envelope of UHV circuit breakers is the first-pole-to-clear factor, which is specified to be 1.3 for lower-voltage systems with an effectively earthed neutral in IEC standard 62271-100. The first-pole-to-clear factor depends on the ratio  $X_0/X_1$  of the system at the location of the circuit breaker. OH lines give a  $X_0/X_1$  of around 3, while large transformers tend to have a ratio of less than or close to 1. In UHV substations, the short-circuit current will be determined to a large extent

by the contribution from the transformers rather than the contribution from the OH lines, so the first-pole-to-clear factor tends to be lower than 1.3. The standard value for UHV systems is stipulated to be 1.2.

Another characteristic that should not be overlooked is the equivalent surge impedance of the OH lines, which is especially important for short line faults. The standards cover the interruption of a single fault to earth and therefore require the equivalent surge impedance of the last clearing pole. The interruption of short line faults is associated with frequencies in the kHz range, and large eight-bundle conductors will not contract completely during the first 100–200 ms. Under these conditions, the equivalent surge impedance will be much lower than 450  $\Omega$ , as shown in Table 8.12 and Fig. 8.117. Therefore, the equivalent surge impedance of UHV OH lines is reduced from 450 to 330  $\Omega$ .

Equivalent surge impedances also play a role when clearing long line faults (LLF) and out-of-phase (OP) currents. MOSAs can reduce peak TRV values to a certain extent, but MOSAs have a much greater effect during breaker terminal faults (test duties T100 and T60) and the interruption of transformer limited faults (TLFs: test duty T10).

Figure 8.118 shows how the TRV waveform can be expressed using four parameters—an approach that is used for test duties T60 and T100 (60% and 100% of the rated interrupting current of a circuit breaker). The curve for the four-parameter TRV consists of three parts: an interval where the voltage rises at the rate  $U_1/t_1$  until the first reference voltage ( $U_1$ ) is attained, another interval where the voltage rises at the rate  $U_c/t_2$  until peak TRV ( $U_c$ ) is reached, and then the period after peak TRV.

**Table 8.12** Surge impedance of transmission lines

Highest voltage (kV)	Conductor size (mm <sup>2</sup> )	Number of conductor	Conditions (TRV frequency)	$Z_0$ ( $\Omega$ )	$Z_1$ ( $\Omega$ )	Equivalent surge impedance ( $\Omega$ )		
						1st pole	2nd pole	3rd pole
550 (Japan)	410	6	Normal conduction (60 kHz)	444	226	270	281	299
			Bundle contraction (60 kHz)	580	355	408	417	430
800 (South Africa)	428	6	Normal conduction (27.5 kHz)	403	254	290	296	304
			Bundle contraction (27.5 kHz)	509	359	398	403	409
1050 (Italy)	520	8	Normal conduction (26.2 kHz)	406	210	250	260	275
			Bundle contraction (26.2 kHz)	532	343	389	396	406
1100 (Japan)	810	8	Normal conduction (25 kHz)	476	228	276	289	311
			Bundle contraction (25 kHz)	595	339	396	407	424

**Fig. 8.117a–c** UHV line configurations used in different countries (see also Table 8.12): (a) South Africa (800 kV), (b) Italy (1050 kV), (c) Japan (1100 kV)

**Fig. 8.118** Plot showing the TRV waveform expressed using four parameters

Table 8.13 summarizes the standard TRV values for an UHV circuit breaker and compares them with the corresponding values for lower voltages, including EHV (up to 800 kV). The values for UHV systems may be considered also for the requirements of EHV systems.

Using the proposed impedance of  $330 \Omega$  and information available on the minimum equivalent surge impedance in an UHV substation, it was concluded that the RRRV,  $U_1$ ,  $t_d$ , and  $t_{dL}$  for UHV can be kept the same as those specified for the test duties T100, T60, T30, T10, and SLF at lower rated voltages. For the ITRV, the value for the busbar surge impedance is proposed to be the same as that for 800 kV ( $325 \Omega$  instead of  $260 \Omega$  for the lower rated voltages), but the time  $t_i$  is proposed to be  $1.5 \mu\text{s}$ , as the dimensions of UHV air insulated

switchgear (AIS) are considerably larger than those of the AIS for lower rated voltages. However, the conditions under which such a long  $t_i$  may occur may also be applicable to 800 kV.

Based on the information collected so far, it has been proposed that the same amplitude factors should be used as those employed for lower voltages, with the exception of  $k_{af}$  for T100, where it is recommended that this factor should be increased from 1.4 to 1.5. The reasons for doing so are, on the one hand, the results of system studies, mainly for the proposed UHV system in Japan, and on the other hand, the fact that  $(k_{pp}k_{af})$  gives the same peak value with both the existing IEC parameters and the proposed values. This peak value for T100 and T60 happens to be about 5% above the MOSA clipping level; the margin of 5% above SIPL accounts for differences in design.

From simulations, it is clear that MOSAs have a reducing effect on the peak TRV, as can be seen in Fig. 8.119.

Based on the equivalent surge impedance seen by the circuit breaker's clearing pole and the number of MOSAs connected at the source side of the circuit breaker (present at the substation), it is possible to determine the intersection point with the  $I-V$  characteristic(s) of the surge arrester, which gives the clipping level (Fig. 8.120).

The ratings for disconnecting switches and earthing switches applied in UHV systems are higher than those applied at lower voltages. The specified currents and related voltages for bus transfer duty and bus charging current switching duty are relatively high. Figure 8.121

**Table 8.13** TRV parameters of UHV circuit breakers

UHV	First-pole-to-clear factor	Amplitude factor	1100 kV	1200 kV	Rate of rise of TRV	Time to TRV peak	Time to TRV peak
Duty	$k_{pp}$	$k_{af}$	TRV peak (kV)	TRV peak (kV)	RRRV (kV/ $\mu$ s)	$t_2$	$t_3$
T100	1.2 (1.3)	1.5 (1.4)	1617	1764	2	3.0 $t_1$ (4 $t_1$ )	
T60	1.2 (1.3)	1.5	1617	1764	3	4.5 $t_1$ (6 $t_1$ )	
T30	1.2 (1.3)	1.54	1660	1811	5		$t_3$ ( $t_3$ )
T10	1.2 (1.3)	1.76	1897	2076	7		$t_3$ ( $t_3$ )
TLF	1.2 (1.5)	0.9*1.7	1649	1799	( <sup>a</sup> )		( <sup>a</sup> )
Out-of-phase	2.0	1.25	2245	2450		1.38 $t_1$ (2 $t_1$ )	

Values in parentheses are standards for systems with voltages of 800 kV and below.

$t_1$  and  $t_3$  are based on  $k_{pp} = 1.2$

(<sup>a</sup>) RRRV =  $U_c/t_3$  with  $t_3 = 6U_T/I^{0.21}$ , as shown in ANSI C37.06.1-2000 for transformers up to 550 kV.

For UHV transformers, RRRV and  $t_3$  are determined by the transformer impedance and its equivalent surge capacitance (specified as 9 nF)

**Fig. 8.119a,b** Effect of a MOSA on the TRV waveform [8.57]: (a) T60, breaking current 26.2 kA; (b) T100, breaking current 33.8 kA

shows the load capacitance and equivalent length of the GIS for different voltage levels and bus charging currents. The bus charging currents evaluated for several existing UHV substation layouts can reach 0.4 A. Schemes for future UHV substations with maximum busbar lengths of up to 200 m suggest that a bus charging current of 2 A should also be sufficient for future applications [8.57].

Bus transfer currents must be defined according to the actual current rating, the type of substation involved, and the maximum loop length. As Fig. 8.122 shows, for the GIS, bus transfer voltages of 80 and 300 V correspond to currents of 1600 and 8000 A, respectively, while for AIS and MTS (mixed technology switchgear),

a bus transfer voltage of 400 V corresponds to 1600 A as well as 4000 A, respectively [8.59].

In Annex C of IEC 62271-102 [8.60], electromagnetically and electrostatically induced currents and voltages are standardized for 550 and 800 kV earthing switches, which are designated for use in circuits with relatively long lines or high coupling to an adjacent energized circuit (class B earthing switches).

One special topic in this context is the occurrence of VFTO due to the charging and discharging of busbar sections by disconnecting switches in GIS. Such switching causes a large number of restrikes and pre-strikes with high-frequency responses of the traveling waves in the GIS. These high-frequency voltages may

**Fig. 8.120** Intersection of the system response line with the  $I-V$  characteristic of the MOSA

reach amplitudes that could endanger the insulation of the GIS equipment as well as directly connected equipment, such as transformers and shunt reactors. As shown in Fig. 8.123, this phenomenon is a more serious problem at UHV than at 800 kV. When necessary, one countermeasure is to apply a preinsertion resistor to disconnecting switches [8.57, 59].

Other dedicated switching equipment in EHV and UHV systems is used to stimulate secondary arc extinction. When an arc grounding fault occurs in one phase, a circuit breaker separates the faulty phase to clear this single phase fault; the secondary arc is induced by electrostatic and electromagnetic induction by healthy or non-faulted lines with the system voltage. It does not disappear at the same instant of fault interruption but will continue a certain time until insulation recovery where the grounding fault was generated.

**Fig. 8.121a,b** Rated voltage dependence of the (a) bus charging current and load capacitance and (b) bus charging current and equivalent busbar length, as per IEC 62271-203 [8.58]

**Fig. 8.122a,b** Bus transfer voltage as a function of the length of (a) the current-carrying loop with GIS and (b) the current-carrying loop with AIS (including MTS)

**Fig. 8.123** Dependence of VFTO and LIWL of the GIS on the rated voltage [8.59]

Since a single-phase or multi-phase auto reclosing can be completed successfully the arc (fault) extinction, it is important to comprehend a typical time of secondary arc extinction in UHV and EHV systems.

When single phase auto reclosure (SPAR) is used, most utilities apply four-leg shunt reactors to limit the secondary arc current, so that it will extinguish within a reasonably short time (mostly within 1 s), but some utilities apply a special scheme to switch off the shunt reactor(s) of a healthy phase [8.59] or apply three-phase high-speed reclosure TPHSR or apply high speed grounding switch (HSGS) to bypass the secondary arc by a short duration (typically 0.5 s) short-circuit, in order to extinguish it. Such solutions are used for UHV, 800 kV and lower rated voltages. Specifications for the HSGS are now within IEC in the process of standardization. Switchgear for the special switching scheme of a healthy phase shunt reactor is yet to be addressed.

HSGSs have been applied to both ends of 550 kV transmission lines in the United States and have shown the ability to successful extinguish secondary arcs in the field. This corresponds to inductive current switching with 700 A for the first switch to open and capacitive current switching with 120 A for the second switch [8.61, 62].

## 8.4 Controlled Switching

Controlled switching systems (CSSs) have become an economical way to reduce switching surges in various switching applications [8.64–67]. Recent developments in transformer switching that account for the residual flux can provide an effective means of mitigating severe inrush currents and temporary overvoltages that could lead to the inappropriate operation of protective relays and power quality degradation [8.68–70]. The

**Table 8.14** HSGS requirements

	USA	Korea	Japan	Japan <sup>a</sup>
Highest voltage (kV)	550	800	1100	1100
Interrupting current (kA)	700	8000	7000	7830
TRV peak (kV)	260	700	900	570
RRRV (kV/ $\mu$ s)	0.1	1.3	1.15	0.46

<sup>a</sup> Duty for delayed current zero interruption with an arcing time of 80 ms + minimum arcing time

In Korea, HSGSs are installed at both ends of 800 kV double-circuit transmission lines with line lengths exceeding 80 km, and they implemented 22 successful high-speed multiphase reclosures with HSGS in the period 2003–2007.

UHV systems in Japan with vertically configured double-circuit OH lines decided to employ HSGSs to achieve high-speed single-phase and multiphase reclosing for all fault modes (e.g., 1LG, 2LG, 3LG, and 4LG).

Table 8.14 summarizes the technical requirements for HSGSs intended for the UHV and EHV systems in the US, Korea, and Japan.

### 8.3.11 Summary

Various switching phenomena are observed in power systems. Generally speaking, a circuit breaker must be able to cope with all switching duties expected for a power system, in accordance with the standards.

There is a well-known rule that, to avoid imposing excessively severe requirements, the standards cover 90% of current network conditions, implying that there are special requirements are not covered by the existing standards. For example, a circuit breaker may not comply with some of the excessive interrupting requirements for transformer limited faults, some reactor switching requirements, and some excessive TRV requirements for series-capacitor bank switching. Special care must be taken when applying circuit breakers for those requirements.

use of CSSs applied to lines of combination with metal oxide surge arresters can reduce undesirable overvoltages caused by the energization of a long transmission line in order to comply with the insulation coordination [8.71, 72]. Real-world examples of the application of line switching are limited, which may be due to initial difficulties resulting from insufficient consideration of technical aspects, including idle time compensation.

**Table 8.15** Testing requirements for the components of a CSS and an integrated CSS system [8.63]

Components and system	Test items	Characteristics/remarks
Type test for circuit breakers	Electrical performance	Rate of rise of dielectric strength (RRDS) Rate of decrease of dielectric strength (RDDS) Maximum making voltage for voltage zero target Minimum arcing time to avoid a reignition or restrike
	Mechanical performance	Scatter in the operating time Variation in the operating time under operational conditions Delay in the operating time after idle time
Type tests for controllers and sensors	Functional test	Scatter in the timing of open/close commands All compensation functions Self-check function, etc.
	Electromagnetic, mechanical, environmental	Dielectric withstand, EMI Vibration, shock, seismic activity Cold, dry heat, temperature/humidity, etc.
Commissioning tests for the integrated system	Controlled switching test	Distribution of switching instants Distribution of making voltage Verification of restrike-free or reignition-free interruptions

The CIGRE guide emphasizes the importance of compensating for variations in the operating time because a CSS requires high operational consistency during the circuit breaker lifetime. Compensation for operating time variations due to external variables such as the ambient temperature, control voltage, and mechanical energy of the drives can be performed by the controller based on the dependence of the variations on the variables, evaluated according to the testing requirements listed in Table 8.15 [8.63].

### 8.4.1 Principle of Controlled Switching

Controlled switching is a term that is commonly used to describe the application of electronic control equipment (a controller) to facilitate the operation of the contacts of a switching device at a predetermined point in relation to an electrical reference signal in order to reduce switching surges.

The components used in CSSs are normally tested in the factory during routine and type tests. For circuit breakers, factory tests include electrical performance tests of, say, dielectric characteristics such as the rate of decrease of dielectric strength (RDDS), the rate of rise of dielectric strength (RRDS), and the minimum arcing time to avoid a reignition, as well as mechanical performance tests of variations in the operating time due to operating conditions and the delay in the operating time after idle time. The controller and the related sensors are tested to verify their functions and their electromagnetic, seismic, and environmental compatibilities. Finally, the controlled switching performance of the integrated system is assessed [8.63].

The term *controlled opening* (deenergization) refers to the technique of adjusting the contact separation of

each pole of a circuit breaker with respect to the phase angle of the current and thereby controlling the arcing time in order to minimize stresses on the components of the power system.

Figure 8.124 shows typical timing sequences for controlled opening or deenergization.

To achieve controlled opening, the current through the circuit breaker or a reference voltage is monitored; for example, the controller often detects periodic current zeros for the reference signal. The arcing time for each pole is controlled by setting the instant of contact separation with respect to the current waveform.

The initial opening command is issued randomly with respect to the reference signal. This command is delayed in order to separate the contact of each phase independently when the circuit breaker can secure an optimum arcing time. This can substantially reduce the restrike probability during consecutive capacitor deenergization or avoid reignition in the case of reactor deenergization.

Similarly, the term *controlled closing* (energization) refers to the technique of controlling the instant of making (current initiation) with respect to the system voltage waveform (phase angle). Typical timing sequences for controlled closing (energization) at voltage zero are given in Fig. 8.125.

In controlled closing, the source voltage is monitored by the controller. Again, the closing command is issued randomly with respect to the reference signal. The command is delayed in order to achieve the optimum phase angle of each voltage independently. This example relates to a capacitive load, where the optimum making instant is the voltage zero, which can be attained with an ideal circuit breaker with infinite RDDS and no mechanical scatter. Pre-arcing before the con-

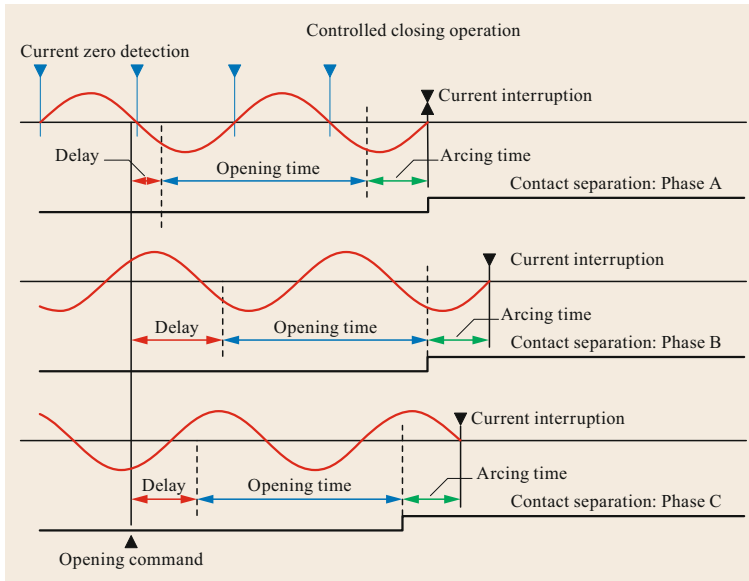

Fig. 8.124 Controlled deenergization

Fig. 8.125 Controlled energization at voltage zero

tacts touch is not considered. A practical case in which voltage zero is targeted is described in the next section.

In the case of an inductive load, the optimum making instant is the voltage peak, as shown in Fig. 8.126, where the pre-arcing time between prestrike and the instant at which the contacts touch is assumed to be a quarter of a cycle. The dependence of the opening time on the operating conditions and the prestrike behavior is particular to each type of circuit breaker.

The optimum targets for different applications are summarized in Table 8.16.

The voltage peak energization strategy is suitable for a transformer with a large parallel capacitance, as it will result in a significant reduction in the residual flux after deenergization. The optimum making instant for a practical transformer is when the prospective normal core flux at energization is identical to the residual flux (see Sect. 8.4.4).

Modern SF<sub>6</sub> circuit breakers generally present very low restriking probabilities for capacitive current interruption, meaning that restriking-induced problems are rare. Nevertheless, the restriking probability can be fur-

**Fig. 8.126** Controlled energization at peak voltage

ther reduced via controlled switching, which is employed to ensure long arcing times and hence larger contact gaps at current interruption.

When controlled switching is applied to reactor deenergization, the optimum opening instant is often selected so as to achieve the maximum arcing time. Even though the use of controlled switching may increase chopping overvoltages due to an increased prearcing time, reignition overvoltages are normally more severe than chopping overvoltages (especially for a modern SF<sub>6</sub> circuit breakers).

All circuit breakers exhibit a high probability of reignition for arcing times of less than the minimum arcing time, and reignition may damage the nozzle and contacts of the circuit breaker. In contrast, depending on the number of series-connected breaking units (the interrupting performance) and the capacitance across the circuit breaker, chopping overvoltages may be prominent when the arcing time is maximized, especially for air-blast circuit breakers. Thus, the approach adopted should depend upon the relative importance of reignition versus current chopping. However, users must

decide upon the relative importance of reignition versus current chopping.

#### 8.4.2 Capacitor Switching Applications

Controlled switching of shunt capacitor banks is used to minimize stresses on the power system and its components. Controlled closing reduces the magnitudes of inrush currents and the associated overvoltages and provides an alternative to the use of fixed inductors. Controlled opening leads to a further reduction in the restrike probability for the circuit breaker. Single capacitor bank switching leads to higher local and remote overvoltages, whereas back-to-back switching generates large inrush currents.

Shunt capacitor bank energization causes local effects in the substation and remote effects at the receiving ends of transmission lines connected to the substation. Local effects include inrush currents and overvoltages, mechanical and dielectric stresses in the capacitor bank and other equipment in the substation, erosion of the circuit breaker contacts, transient po-

**Table 8.16** Optimum instants for controlled switching [8.64]

Switching application	Optimum instant for controlled switching	Benefits
No-load transformer energization	Voltage peak with no residual flux or prospective core flux identical to the residual flux	Reduction of inrush current and associated overvoltage
No-load line energization	Voltage zero across the circuit breaker	Reduction of overvoltage and elimination of need for closing resistor
Shunt capacitor energization	Voltage zero across the circuit breaker	Voltage zero across the circuit breaker
Shunt capacitor deenergization	Maximum arcing time	Minimization of restrike probability
Shunt reactor deenergization	Maximum arcing time (to avoid reignition)	Reduction of overvoltage and elimination of reignition

**Fig. 8.127** Example of the analysis of inrush currents obtained when energizing 145 kV capacitor banks

tential rises in the substation earthing mesh, and the coupling of transient surges to control and protection wiring. Remote effects include overvoltages at the far ends of radially connected transmission lines as well as overvoltages in MV and LV networks connected to the secondary side of transformers at the end of these lines. The optimum making instant for wye-connected, earthed-neutral shunt capacitor banks should be a voltage zero across the circuit breaker in each phase.

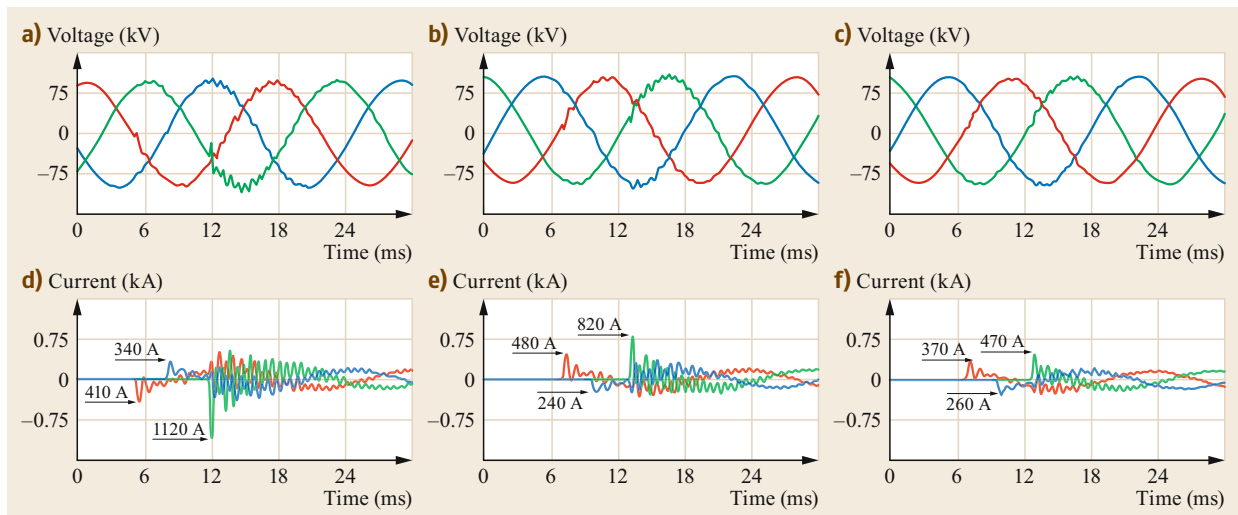

Figure 8.127 shows an example of the analysis of inrush currents obtained when energizing 145 kV capacitor banks. The maximum inrush current is 4.9 pu of the nominal current. This can be suppressed to less than 2.4 pu with a CSS. The energization target is set to make a  $13^\circ$  electrical angle with the voltage waveform.

After calibration on site, controlled switching tests were performed at the system voltage of 121 kV using a target for the closing operation of 8 electrical degrees, as determined by the RDDS and mechanical scatter plus a slight safety factor. The target for the opening operation was set to give the maximum arcing time before the current zero.

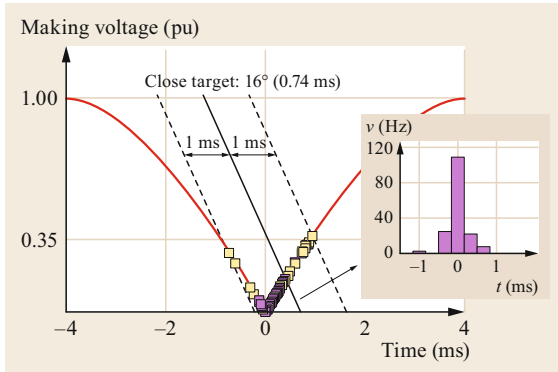

Figure 8.128 shows the voltage and current waveforms obtained during the second, third, and sixth of ten controlled energization tests conducted during the commissioning tests. For the first making test, the making instant of the third phase shows a slight delay, even though the inrush current of 1290 A is within the permissible tolerance. This delay is probably caused by a difference of the actual RDDS due to design tolerances of the interrupter dimensions or closing velocity scatter because of individual properties of the components. The controller applied to this circuit breaker can compensate for this difference through adaptive control.

A circuit breaker with a normalized RDDS of less than 1 can be applied for capacitor switching because the inrush current can be sufficiently suppressed if the making voltage is less than half of the maximum pre-strike voltage. Idle time compensation is recommended for drives with operating times that have an idle time dependence. Adaptive control is also required to compensate for any operating time drift that persists over a number of consecutive operations.

Controlled switching tests were performed at a system voltage of 145 kV using a target closing instant of 16 electrical degrees, as determined by the measured RDDS and mechanical scatter. The circuit breaker

**Fig. 8.128a-f** Voltage waveforms obtained in the second (a), third (b), and sixth (c) energization tests and current waveforms obtained in the second (d), third (e), and sixth (f) energization tests performed using a 121 kV CSS in the field (ten tests were performed in total)

**Fig. 8.129** Making-voltage distribution and closing-instant distribution

has been operated daily in the field since the commissioning tests. Figure 8.129 shows the distribution of closing instants measured by the controller along with the distribution of making voltages calculated from the data. The closing instants present a normal distribution around the closing target of 16 electrical degrees, with a small standard deviation of less than 0.3 ms, which corresponds to the maximum making voltage of 0.35 pu.

### 8.4.3 Reactor Switching Applications

Shunt reactor switching is a known source of current and voltage transients. Overvoltages due to current chopping and reignition can damage any high-voltage equipment. High asymmetrical inrush currents may be generated by performing shunt reactor energization at an unfavorable instant. These inrush currents can provoke electromechanical stress or a high-magnitude zero-sequence current of an extended duration. Controlled switching can be applied in both cases to reduce the expected transients.

During shunt reactor deenergization, overvoltages can be generated in two ways: by current chopping and by reignition.

Chopping overvoltages are a consequence of the forced interruption of the inductive current before its natural zero. They mainly depend on the number of series-connected breaking units present, the chopping number of the circuit breaker, the capacity (in MVA) of the reactor, the capacitance in parallel with the circuit breaker, and (in certain cases) the arcing time. For modern SF<sub>6</sub> circuit breakers, chopping overvoltages are not very high (they typically reach up to 1.5 pu), but they increase with arcing time.

Reignition overvoltages are generated by reignitions following the initial interruption. Reignitions are provoked when the voltage between the contacts ex-

**Fig. 8.130** Definition of the minimum arcing time for reactor deenergization

ceeds the dielectric withstand of the contact gap. The rate of rise of voltage during a reignition ranges between lightning and fast-front transients, depending on the length of the busbar between circuit breaker and reactor, while chopping overvoltages are similar to slow-front transients (switching surges). Reignition may affect circuit breaker elements such as the nozzle and contacts and the reactor insulation. For example, perforation of an insulating nozzle, signs of arcs occurring away from the arcing contacts, and metal particles in the interrupter have been reported. The CIGRE international reliability survey for the years 2004–2007 shows that the major failure frequencies for circuit breakers operating on shunt reactors are around an order of magnitude higher than those for line and transformer breakers. Even though not all types of circuit breakers are damaged in the same way, it is desirable to eliminate reignitions.

All circuit breakers exhibit a high probability of reignition for arcing times that are less than the minimum arcing time ( $T_{a\min}$ ). Figure 8.130 shows a schematic of the voltage withstand characteristic of a circuit breaker along with the transient recovery voltage across the circuit breaker for reactor deenergization. Since the main criterion for eliminating reignition is to avoid the reignition window, the optimum instant for contact separation is when the expected arcing time exceeds  $T_{a\min}$ . When promoting increased arcing times in this way, it should also be noted that chopping overvoltages can increase with arcing time.

Since reignition overvoltages are normally more severe than chopping overvoltages, controlled switching is commonly used to increase the arcing time. It is important to determine the relative importance of reig-

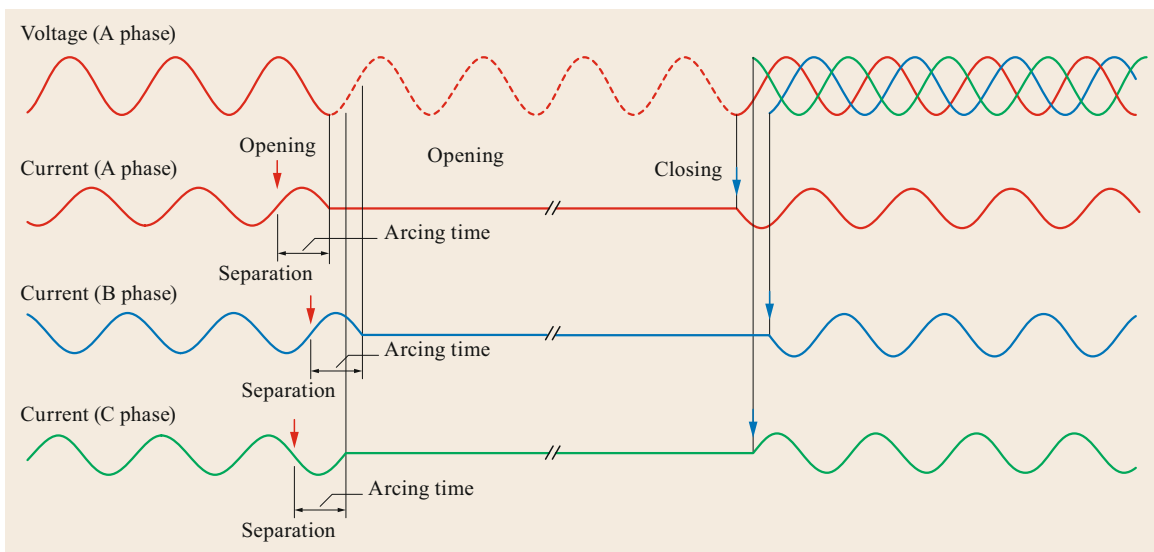

**Fig. 8.131** Distribution of opening instants during controlled reactor opening

nition and current chopping according to the circuit breaker design.

In this section, we have extolled the benefits of controlled opening. However, there are certain cases where controlled opening provides little or no advantage. For example, tests in which controlled reactor opening was applied to a minimum oil circuit breaker were not successful due to the occurrence of reignitions regardless of the arcing time. In this case, controlled switching cannot avoid reignitions.

Figure 8.131 shows an excellent reignition-free performance with CSS demonstrating the deviation of de-energization instants within only 0.21 ms.

Figure 8.132 shows voltage and current oscillograms for the deenergization and energization of a 245 kV controlled shunt reactor in the field. The maximum inrush current of 1270 A observed upon random closing was suppressed to below 50 A.

**Fig. 8.132** Voltage and current behavior during controlled shunt reactor switching

#### 8.4.4 Transformer Energization

The energization of an unloaded transformer can generate high-amplitude inrush currents, which stress the windings and can cause maloperation of protection relays and prolonged temporary harmonic voltages, which can in turn degrade the quality of the electricity supply. High inrush currents also impose severe mechanical stresses on the transformer windings and may reduce the life expectancy of a transformer exposed to frequent energization. For example, step-up transformers in hydroelectric power plants are frequently switched to adapt to daily load variations. These risks can be ameliorated through the use of a closing resistor (or by controlling the making instant of simultaneously operated three-phase circuit breakers).

The interruption of no-load transformer currents is similar in nature to the interruption of shunt reactor currents. However, the natural frequencies are much lower and the damping is very high, meaning that the overvoltages generated at deenergization have extremely low amplitudes. Breaking instant control is similar to that applied for shunt reactors when the residual flux in the transformer cores is negligible.

The magnetic circuits of transformers have magnetization curves with a pronounced bend from the nonsaturation region to the saturation region. For economic reasons, power transformers are designed to have an operational peak flux value as close as possible to the saturation value. The flux in a transformer energized by a steady-state alternating voltage varies from a negative peak value to an equivalent positive value during one half cycle of the voltage waveform. The change in flux of twice the maximum flux value is proportional to the

time integral of the voltage waveform between two successive zero points. If the circuit breaker is closed at a voltage zero, the full change in flux is required during the first half cycle. When the flux is initially at zero, the maximum flux developed will be twice the normal operational peak value. Since the operational peak flux is already close to the saturation value, an increase in flux to double this value corresponds to extreme core saturation. Consequently, the inductance drops and the current rapidly rises to a very high value.

At the making instant, residual flux from the previous opening may be present in the transformer. If this residual flux is of the same polarity as the change in flux, the combination of the change in flux with the residual flux will lead to even greater saturation of the magnetization circuit.

The processes that occur when a three-phase transformer is energized are more complex because the three phases are linked both magnetically and galvanically. The structure of the winding connection and the neutral point treatment influence the value of the inrush current.

It is possible to propose a general principle for reducing inrush currents during controlled closing by adopting the hypothesis that there is no residual flux and that the flux in all cores is nil prior to closing. Closing must first be performed on either one phase (if the neutral of the primary winding is earthed) or two phases (if the primary winding is isolated). The making target

is the maximum line-to-earth voltage (earthed neutral) or the maximum phase-to-phase voltage (isolated neutral) so that fluxes are generated without transients. The making instant of the remaining phase(s) must be chosen such that the flux that circulates in the corresponding cores following the initial closing is the same as the flux that circulates in these cores under steady-state conditions. This stops flux transients from being created in the cores [8.68].

Figure 8.133 shows the energization strategy for a three-core transformer with a wye (star) connection and an isolated neutral. Energizing a single phase has no effect, since there is no flow path for magnetizing current due to the isolated neutral point. The phase-to-phase voltage  $U_{13}$  is switched on when its maximum value occurs at time  $t_1$ . The corresponding stationary core fluxes  $\phi(F)_1$  and  $\phi(F)_3$  have instantaneous values of zero at that instant ( $t_1$ ). They attain their maximum values 90 electrical degrees later, at time  $t_2$ , when the fluxes are identical to the steady-state core flux values. This means that voltage  $U_2$  can be switched without any transient reaction at time  $t_2$ .

On the other hand, Fig. 8.134 shows the energization strategy for a three-core transformer with a wye (star) connection and a solidly earthed neutral. Phase  $L_2$  is energized when the phase voltage  $U_2$  is at its peak at time  $t_1$ . The magnetizing current  $J_2$  is able to flow through the earthed neutral point. The magnetizing

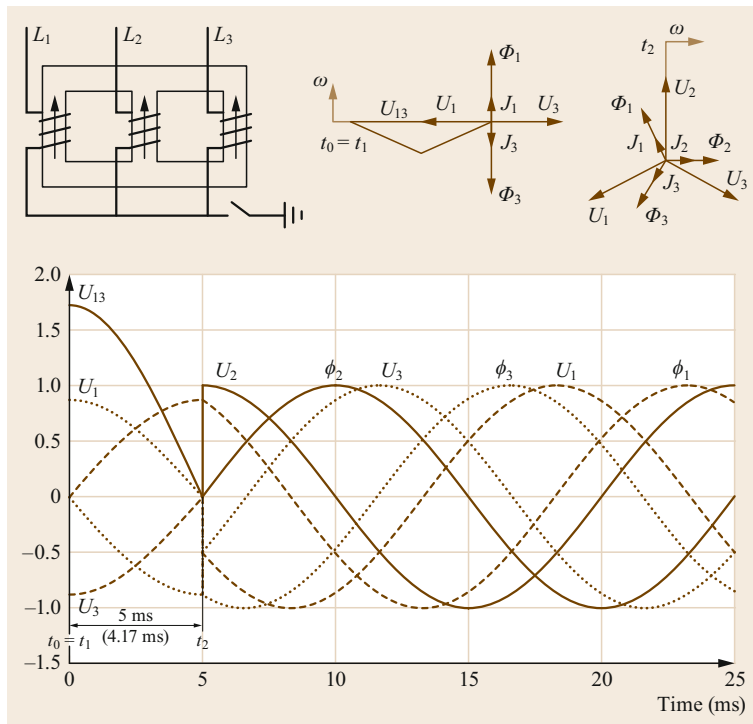

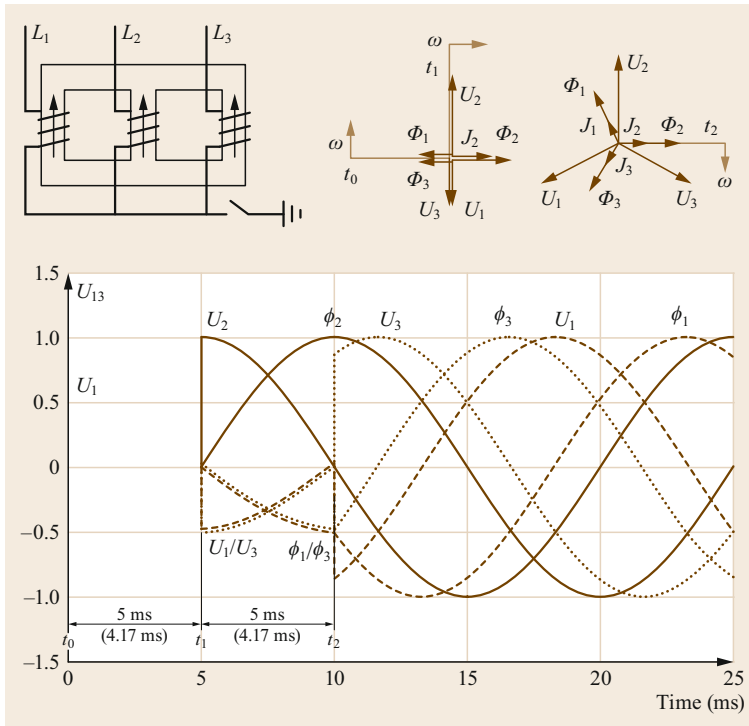

Fig. 8.133 Closing strategy for an isolated neutral transformer

**Fig. 8.134** Closing strategy for a solidly earthed transformer

field  $\phi(F)_2$  begins without any transient. The associated magnetizing current  $J_2$  must also allow for the excitation of the other two phases, each of which has half the flux during this stage. Consequently, this current is 1.5 times its three-phase steady-state value.

By  $t_2$ , the fluxes  $\phi_1$  and  $\phi_3$  have reached levels corresponding to their three-phase steady-state values. Phases  $L_1$  and  $L_3$  may therefore be energized without transients at time  $t_2$ .

The optimal making instants for the different phases to minimize the inrush current (based on the hypothesis that there is no residual flux in the cores) are summarized in Table 8.17. Phase  $L_2$  is wound around the middle core in three- or five-leg (core) power transformers. The voltages of the different phases can be written as

$$U_1 = U \sin\left(\frac{\omega t + 2\pi}{3}\right),$$

$$U_2 = U \sin(\omega t),$$

$$U_3 = U \sin\left(\frac{\omega t - 2\pi}{3}\right).$$

The making instant is given in relation to the zero-voltage instant of  $U_2$ ; see Figs. 8.133 and 8.134.

For any practical application of a CSS to transformer energization, the residual fluxes in the transformer cores should be considered when determining

the optimal energization instants, especially when the capacitance between the windings and the ground is small. Therefore, the inrush currents will depend on the following characteristics:

- The magnetic characteristics of the transformer cores
- The making instants of the circuit breaker
- The electrical connections of the power transformer
- The residual flux
- The electrical characteristics of the source system [8.68–70].
