Keywords: dermatophytes, survey, United States, humans, 1982/84

Abstract

A survey of dermatophytes isolated from patients seeking medical advice was made from 1982 to 1984 in the United States. The survey included 59 locations with data from 49 cities and one state. Listing of the isolated dermatophytes and the frequency given by percentage of total follows: Trichophyton rubrum 46.8%, T. tonsurans 33.3%, T. mentagrophytes 10.1%, Microsporum canis 4.5%, Epidermophyton floccosum 3,5%, M. gypseum and T. verrucosum both 0.7%, M. audouinii and T. terrestre both 0.1%, and T. violaceum 0.06%. No isolations of M. ferrugineum or T. schoenleinii were reported.

Temporal increases were observed for frequencies of *T. mentagrophytes, T. tonsurans* and *M. canis,* and decreases occurred for frequencies of *E. floccosum* and *T. rubrum* when the data from this survey were compared by the goodness of fit test to data of the 1979 to 1981 survey. The percent of dermatophyte isolations identified as *T. tonsurans* correlated significantly with the percentage of blacks in cities of 100000 or more people.

Introduction

This second survey of dermatophytes isolated from human patients in the United States from 1982 to 1984 was again an investigation by the Dermatophyte Survey Committee. This is a committee of the Medical Mycological Society of the Americas. As in the first survey (4), the nomenclature to be used for the survey was that used by Rebell & Taplin (2). Only the taxa of dermatophytes were requested from respondents and not the site infected on the body.

Materials and methods

Those individuals or laboratories that supplied data for the first survey were asked to supply infor-

mation for this second survey. The College of American Pathologists, through their Laboratory Improvement Office, consented to include a dermatophyte survey form with their mycology unknowns. The number of isolations of dermatophytes was principally requested, but if these were not available, an indication of the taxa isolated by means of a check mark was requested secondarily.

Results

The results were tabulated by city or state. These results are listed in Table 1.

For a summary table, only those numerical results given were used. Table 2 gives the summary of dermatophytes isolated from 1982 to 1984 and the percentage each contributed to the total. The

Adress for offprints: James T. Sinski, University Department of Microbiology and Immunology, University of Arizona, Tucson, AZ 85721, USA.

Table 2. Totals of dermatophytes isolated from human patients in the United States from 1979 to 1984.

table also gives the results of the 1979 to 1981 survey with the percentage each contributed to the total.

Frequencies of reported isolations were tabulated for nine of the dermatophytes having frequencies of 5 or more for each of the two three-year periods (Table 2). Application of a goodness of fit test (5) resulted in a G statistic of 128.17 which is highly significant (p < 0.001) when compared to 2 with 8 degrees of freedom. This implies that frequencies of one or more of the nine dermatophytes have changed over these two time periods beyond that which could be attributed to chance. Temporal increases were observed for frequencies of T. mentagrophytes, T. tonsurans and M. canis, whereas decreases occurred for frequencies of E. floccosum and T. rubrum.

Similar results were obtained when the goodness of fit test was applied to each of the six annual frequencies for six of the dermatophytes which had 5 or more reported isolations each year.

Rippon has stated that the vast majority of infections by T. tonsurans is in black children (3). The percentage of blacks in cities over 100000 population, obtained from the U.S. Bureau of Census Statistical Abstract (6), positively correlated with the percentage of infections caused by T. tonsurans reported for 29 cities (r=0.525, p<0.01).

Two respondents supplying data also reported isolation of a strain of *M. canis* that had very little yellow reverse pigmentation to no pigmentation at all and the absence of macrospores upon initial isolation on Sabouraud's medium plus antimicrobials. These isolations were made in Detroit, Michigan, Site 2 and Tucson, Arizona. Modified corn meal medium was used to develop few typical macrospores for identification. This strain caused cases of tinea that were very difficult to treat. Physicians treating individuals infected with this strain reported that the dosage of griseofulvin had to be increased threefold from that ordinarily recommended to obtain a cure.
