Nucleotide Sequence of the Genomic Region Encoding Alcohol Dehydrogenase in *Drosophila affinidisjuncta*

Robert G. Rowan and W.J. Dickinson

Department of Biology, University of Utah, Salt Lake City, Utah 84112, USA

Summary. The DNA sequence of a 3886-bp genomic region containing the alcohol dehydrogenase (Adh) gene from Drosophila affinidisjuncta, and the RNA sequences of the D. affinidisjuncta Adh transcripts, are presented. These data support the conclusion that two Adh promoters generate distinct, developmentally regulated Adh transcripts. Correlations between these sequences and the transcription map are discussed. Comparisons between these and equivalent data from D. melanogaster are also presented. We note the following observations: (1) Except at the extreme 3' end, the two genes are identically organized. (2) Drosophila Adh protein accumulates amino acid replacements at the rate of approximately 0.5 per million years. (3) Among the non-protein-coding DNA sequences, putative homologies occur in the two promoter regions.

Key words: Alcohol dehydrogenase – Hawaiian picture-winged *Drosophila* – Gene promoters – DNA sequence evolution

Introduction

Drosophila alcohol dehydrogenase (ADH) provides an interesting model system for the analysis of gene regulation (e.g., Dickinson and Carson 1979; Maroni et al. 1982; Batterham et al. 1983; Goldberg et al. 1983; Fischer and Maniatis 1986) and also for studies on gene organization (Benyajati et al. 1983; Fischer and Maniatis 1985; Rowan et al. 1986), gene evolution (Kreitman 1983; Bodmer and Ashburner 1984), and ecological genetics (e.g., McKenzie and

Offprint requests to: W.J. Dickinson

Parsons 1972; McKenzie 1980; David and Van Herrewege 1983). In particular, the developmental expression (Ursprung et al. 1970; Savakis et al. 1985) and the molecular organization (Benyajati et al. 1981, 1983) of the Drosophila melanogaster ADH gene (Adh) have been well characterized. Previous work from this laboratory has analyzed the expression of ADH activity in many members of the Hawaiian picture-winged group of Drosophila (Dickinson 1980a), and the Adh gene from one of these, Drosophila affinidisjuncta, has also been studied at the molecular level (Brennan et al. 1984a; Rowan et al. 1986). Although they are distantly related, D. affinidisjuncta and D. melanogaster exhibit similar patterns of ADH expression (Rowan et al. 1986). In contrast, ADH is expressed with different developmental specificities in some other Hawaiian picture-winged species (Dickinson 1980a; Rowan and Dickinson 1986).

Several data imply that DNA sequences near the Adh structural gene are important for the developmental regulation of ADH activity. Interspecific differences in ADH expression patterns within the Hawaiian Drosophila are cis-dominant in species hybrids, suggesting that regulatory elements are closely linked to the enzyme locus (Dickinson and Carson 1979; Dickinson 1980b). In D. melanogaster, gene transformation experiments have show that correct expression can be obtained with an 11,800bp fragment of cloned Adh genomic DNA (Goldberg et al. 1983). Also, similar experiments show that a 5400-bp D. affinidisjuncta genomic Adh clone is expressed with very nearly correct accuracy in transgenic D. melanogaster (Brennan and Dickinson 1988). Here we present the DNA sequence of the D. affinidisjuncta Adh genomic region and the corresponding mRNA and ADH amino acid sequences. We then compare these sequences with those of D. melanogaster. These data demonstrate the similarity of these Drosophila genes and identify genomic sequences that may regulate Adh expression. The evolution of the Adh locus is also discussed.

Materials and Methods

DNA Sequencing. The molecular cloning (Brennan et al. 1984a) and characterization (Rowan et al. 1986) of the D. affinidisjuncta Adh genomic region have been reported. A total of 3886 contiguous base pairs of DNA from the Adh-containing bacteriophage lambda clone S36G1-11B (Brennan et al. 1984a) was subcloned as fragments from restriction enzyme digestions into the vectors m13mp8 and/or m13mp9 (Messing and Vieira 1982). These clones were sequenced by the dideoxynucleoside chain termination procedure (Sanger et al. 1977) according to the map presented in Fig. 1. In all but two locations, both DNA strands were sequenced. For the two exceptions, the data obtained by the chain termination method were confirmed by chemical cleavage sequencing (Maxam and Gilbert 1980) of DNA subcloned into the vector pUC8 (Vieira and Messing 1982). Enzymes and oligonucleotide primers were purchased from New England Biolabs. Deoxynucleoside triphosphates and dideoxynucleoside triphosphates were purchased from Boehringer Mannheim Biochemicals and from P.L. Biochemicals, respectively. Radiolabeled nucleoside triphosphates were purchased from New England Nuclear.

Denaturing polyacrylamide gels for DNA sequencing were prepared and used according to Maxam and Gilbert (1980), except that gels were bound to one glass plate of the gel former and processed for autoradiography according to Garoff and Ansorge (1981).

RNA Sequencing. RNA sequencing by chain termination (Hamlyn et al. 1978) was performed as follows. ³²P-end-labeled DNA fragments (primers) were obtained from genomic Adh clones and annealed to Adh RNA at 49°C as previously described (Rowan et al. 1986). Positions of the DNA primers are given in Fig. 1 (open arrows) and in the Results section. Each annealing contained either 20 μ g of poly(A)-selected RNA from adult flies (for sequencing around intron 1) or 10 μ g of poly(A)-selected RNA from larvae (for sequencing around introns 2 and 3). Annealed nucleic acids were purified by ethanol precipitation and resuspended in 125 mM NaCl, 25 mM Tris-HCl (pH 8.3), 10 mM MgCl₂, and 5 mM dithiothreitol, which contained 100 μ M each of dATP, dGTP, dTTP, and dCTP (120 µl total volume). The four corresponding dideoxynucleoside triphosphates were added separately to four 30-µl aliquots of the above reaction mixture, to a final concentration of 10 μ M (Fig. 3A) or 40 μ M (Fig. 3B and C). Reactions with 10 units of reverse transcriptase (Seikagaku America) were incubated at 42°C for 10 min and terminated by phenol extraction. After recovery by ethanol precipitation, the nucleic acids were resuspended in formamide, heated to 65°C for 10 min, and analyzed on sequencing polyacrylamide gels.

The isolation of *D. affinidisjuncta* RNA from whole organisms (Brennan et al. 1984a) and from larval or fly tissues (Rowan and Dickinson 1986) has been described. Feeding third-instar larvae or adults aged 1–3 weeks posteclosion were used in this study.

Primer Extension Analysis. DNA fragments (primers) were ³²Pend-labeled with DNA polymerase large fragment (Maniatis et al. 1982) using α -[³²P]dATP or α -[³²P]dCTP (New England Nuclear) and purified by polyacrylamide gel electrophoresis. Primers were extended on RNA templates with reverse transcriptase as

described above, with the omission of dideoxynucleoside triphosphates. Polyadenylated RNA (0.5 µg) from larvae (Fig. 4A) or adults (Fig. 4B) and the total RNA from the equivalent of two adult abdominal fat body samples, two adult heads, and the Malpighian tubules from 25 adults (Fig. 4C) were analyzed. The same primers were also extended on complementary DNA (cDNA) templates (m13 genomic subclones) in typical DNA sequencing reactions to yield markers for the relevant genomic regions. For the analysis of larval Adh transcripts, a 608-bp EcoRI-HindIII fragment of cloned genomic DNA (coordinates 1986-2594 in Fig. 2) was used. Synthesis of adult Adh cDNA was primed with a 1522-bp SalI-HindIII genomic DNA fragment (coordinates 1432-2594 in Fig. 2). These large primers were more easily prepared and more efficiently extended than smaller DNA fragments (unpublished observations), but are too large for accurate sizing by gel electrophoresis. Therefore, the labeled extension products were cleaved from the primer sequences by restriction enzyme digestion as described by Rowan et al. (1986). Only extended primers contain a regenerated restriction enzyme recognition site at their 3' end, and the radiolabel is cleaved from the primer and retained by the extension as a result of digestion. In the present instance, cleavage of adult Adh cDNA with SalI and of larval Adh cDNA with EcoRI results in appropriately sized ³²P-labeled cDNAs (Fig. 4). DNA template-directed sequencing reactions were phenol extracted, ethanol precipitated, and digested with either SalI or EcoRI. Digested DNAs were ethanol precipitated, resuspended in formamide, heated to 65°C for 10 min, and analyzed by electrophoresis on sequencing gels.

Data Analysis. An unpublished sequence of the D. melanogaster Adh locus was provided by M. Ashburner. This is a composite sequence derived from two sources: 2540 bp, inclusive from 473 bp 5' to the distal Adh mRNA sequence to 211 bp 3' to the polyadenylation site, was determined from the Canton-S clone psAC1 (Goldberg 1980) by H. Haymerle and M. Ashburner (unpublished). Contiguous with this sequence is an additional 4293 bp of 5'-flanking and 590 bp of 3'-flanking sequence (M. Aguade and M. Kreitman, unpublished; Kreitman 1983) of an African isolate contained in the clone Af-S (Kreitman 1983). All of this composite sequence was compared to the D. affinidisjuncta sequence presented in Fig. 2. The similarity of the D. affinidisjuncta protein coding region to the corresponding D. melanogaster sequence was obvious (see Results). Flanking DNA sequences were analyzed for similarity as follows. A computer program was used to locate many short blocks of intersequence similarity, which were then evaluated manually. In general, the acceptable alignments were those that, when taken together, produced a larger alignment with the individual members occurring in the same relative order in each species' genome (i.e., only apparent deletions/insertions, and not transpositions, were tolerated; no relative inversions were indicated). This parsimonious approach might have neglected some biologically meaningful similarities, but did remove many similarities that are probably fortuitous.

Results

The D. affinidisjuncta Adh transcription map is stagespecific (Fig. 1). Most of the Adh RNA from adult flies contains a small 5' exon (exon 1) that is separated from the rest of the transcript by a relatively large intron (intron 1). Larval Adh transcripts lack exon 1 sequences, and intron 1 sequences contribute to the 5' end of larval Adh RNA (see Fig. 1). These two RNA 5' end structures account for all of the

Fig. 1. Transcription map of the *D. affinidisjuncta Adh* gene (Rowan et al. 1986) and DNA sequencing strategy. The polarity with reference to *Adh* mRNA (5'-3') and size scale (bar = 150 bp) are shown. Solid bars represent the genomic locations of the exons in adult (1, 2A, 3, 4) and in larval (2L, 3, 4) *Adh* mRNA. Shaded bars show the adult and larval *Adh* mRNA structures, referred to as the "distal" and "proximal," respectively, transcripts. Dashed lines locate the 5' end of each mRNA to its genomic position. The positions of introns [(1), (2), and (3)] are indicated. Open arrows mark the priming sites used in *Adh* RNA sequencing (see Fig. 3). For simplicity, only one of several polyadenylation sites (AAA) is shown. Below the transcript map, solid arrows designate individual sequences obtained by the Sanger method from m13 genomic subclones. Dashed arrows designate sequences obtained by the Maxam and Gilbert method.

detectable postembryonic Adh transcripts in D. affinidisjuncta (Rowan et al. 1986). Introns 2 and 3 (Fig. 1) are common to all detectable Adh transcripts in both larvae and adults. For brevity, the transcripts are referred to as "distal" (containing the distal exon 1) or "proximal" (lacking exon 1) in this report.

The nucleotide sequence of the D. affinidisjuncta Adh region is presented in Fig. 2. Adh RNA transcripts, previously located relative to restriction enzyme recognition sites (Rowan et al. 1986; Fig. 1), are more accurately mapped to the genomic DNA sequence by the following data. Adh RNA sequences for the regions interrupted by introns 1 and 2 were obtained using a 121-bp HincII-TaqI DNA fragment (coordinates 2231-2352 in Fig. 2; open arrow over exon 3 in Fig. 1) as the sequencing primer. The alignment of these sequences (Fig. 3A and B) with the genomic DNA sequence is obscured by a dinucleotide reiteration in the donor and acceptor splice sequences of both intron 1 (GT reiterated) and intron 2 (AG reiterated). In each case, however, only one of the two possible alignments will yield donor and acceptor sequences that obey the well-established consensus rules (Mount 1982). These define coordinates for intron 1 (1473-2003) and for intron 2 (2126-2206) as indicated in Fig. 2. Intron 3 was located by sequencing Adh RNA using a 132-bp AvaI-Bg/II DNA fragment (coordinates 2728-2860 in Fig. 2; open arrow over exon 4 in Fig. 1). The implied sequence of intron 3, indicated by the RNA sequence (Fig. 3C), is unambiguous (coordinates 2612-2685 in Fig. 2) and shows donor and acceptor splice sequences that obey consensus rules.

The 5' ends of *D. affinidisjuncta Adh* RNAs were located by primer extension experiments as shown in Fig. 4. Both transcript types map as expected (Rowan et al. 1986), but appear heterogeneous over

several nucleotides. The 5' terminal nucleotides of proximal transcripts (Fig. 4A; "p"s in Fig. 2) are the same in each larval tissue that expresses Adh RNA (data not shown). Distal Adh transcripts occur in the adult head, fat body, and Malphigian tubules (Rowan and Dickinson 1986). There are four apparent 5' distal cap sites (Fig. 4B; "d"s in Fig. 2), the most distal of which is not utilized in the adult head (Fig. 4C).

Features of the D. affinidisjuncta Adh Region

Available data indicate that distal and proximal Adh transcripts are produced from a single copy gene (Brennan et al. 1984a; Rowan et al. 1986). Transcription of this gene has not been studied directly, but aspects of the Adh DNA sequence argue that these two RNAs arise from different transcriptional events, rather than from differential processing of a single primary transcript. First, genomic "TATA box" sequences, centered at 1387 and at 1945 (Fig. 2, "box"), are located just upstream from the apparent 5' end of each transcript. Also, donor and acceptor intron splicing sequences (Mount 1982) in the predicted distal RNA primary transcript accurately predict the 5' end structure of the observed transcript. Thus, like the D. melanogaster Adh gene (Benyajati et al. 1983), the D. affinidisjuncta Adh gene appears to be expressed from two distinct promoters.

Drosophila affinidisjuncta Adh RNA 3' ends are polyadenylated and map to several locations within a 250-bp genomic region. The observed 3' ends in larval RNA (Fig. 2, "lv." and "+") and in adult RNA (Fig. 2, "ad." and "+") differ from each other at some positions (Rowan et al. 1986). The more proximal of these termini are not correlated with the presence of generally recognized polyadenyla-

Fig. 2. Nucleotide sequence of the mRNA-like strand in the 5' to 3' orientation of the *D. affinidisjuncta Adh* genomic region. A *Hind*III recognition sequence (AAGCTT) at position 2590 identifies the center (position 0) of the published restriction enzyme map (Brennan et al. 1984a; Rowan et al. 1986). The sequence of the distal *Adh* mRNA, extending from the most distal 5' cap site to the most highly expressed polyadenylation site (see Rowan et al. 1986), is underlined. Notations above the sequence: "box" indicates TATA sequences; "d" and "p" identify the cap sites of distal and proximal, respectively, *Adh* mRNAs; the locations of introns 1, 2, and 3; asterisks identify the translational start and stop codons; "lv." and "ad." identify polyadenylation sites unique to larvae and adults, respectively; "+" indicates a polyadenylation site common to both larvae and adults. Below the sequence, "polyA?" and "polyA" indicate possible and known, respectively, polyadenylation signal sequences; two overlapping signals are indicated by "polyAs." The sequence from 3127 to 3652 is presented in an alignment with the sequence from 1501 to 2031, the latter in lowercase letters. Within this alignment, a blank space in either sequence indicates the absence of a nucleotide at that position, sequence identity is indicated by the dashed line, and sequence differences are explicitly indicated.

tion signal sequences (reviewed by Birnstiel et al. 1985). Other A/T-containing hexanucleotide sequences (Fig. 2, "polyA?") do occur at appropriate positions, and might therefore be functional signals for this gene. Distal 3' termini follow recognizable polyadenylation signals (Fig. 2, "polyA") by 5-41 nucleotides. For comparison, the consensus value for this distance has been given as a range of 10-30 nucleotides (Birnstiel et al. 1985).

Interestingly, 525 bp of DNA on the 3' side of the ADH coding region is apparently a direct, imperfect duplication of the sequence immediately 5' to the coding region. Most of intron 1 and all of the (proximal) mRNA leader sequence, but none of the ADH codons, are duplicated. Blot hybridization data (Brennan et al. 1984a and unpublished) also indicate that the entire *Adh* region is not duplicated. This duplication is displayed in Fig. 2 by aligning the

Fig. 2. Continued.

Fig. 3. Drosophila affinidisjuncta Adh mRNA sequences. Sequences covering the regions interrupted by introns 1, 2, and 3 are given in A, B, and C, respectively. See text for methods. Arrows mark the location of intervening sequences.

sequence in the 3' region (numbered 3127-3652) with the 5' sequence (numbered 1501-2031). The divergence between these sequences is similar to the divergence of the 3' Adh region within the picturewinged species group (R.G. Rowan and J.A. Hunt, unpublished), suggesting that the duplication is about as ancient as this taxonomic group. Several of the observed Adh mRNA polyadenylation sites, including the most abundant site at position 3238 (Fig. 2), are in the duplicated region. Consequently, it is tempting to speculate that the unusually large number of 3' ends in D. affinidisjuncta Adh mRNA is a result of the disruption, by the duplication event, of an ancestral gene organization that was more conventional.

There is no suggestion that different *D. affinidisjuncta Adh* transcripts encode different proteins. Proximal and distal RNAs utilize the same putative initiation (position 2033, Fig. 2) and termination (position 2950) codons, and no data imply heterogeneity in the central portion of the *Adh* transcription map (Rowan et al. 1986).

Comparison of the D. affinidisjuncta and D. melanogaster Adh regions

Conceptual translation of the DNA sequence encoding the ADH protein from *D. affinidisjuncta* yields an amino acid sequence that is very similar to that from *D. melanogaster* (Fig. 5). At the DNA level (data not presented), the two species' *Adh* protein coding sequences are 75% identical, with 54 nonsynonymous and 86 synonymous codon changes. *Adh* introns 2 and 3 are not large and interrupt the protein coding sequence at the same positions (Fig. 5, arrows) in each species.

Flanking the protein coding sequence, very limited similarities are observed between the D. affinidisjuncta and D. melanogaster Adh sequences. Accordingly, subjective methods contributed significantly to the detection of similarity in these regions. An evaluation of the similarity between the D. affinidisjuncta and D. melanogaster genomic DNA sequences around the distal Adh promoter is given in Fig. 6A. The alignment extends continuously through the D. affinidisjuncta sequence for 357 bp upstream (-357) and for 78 bp downstream (+78)from the predominant distal Adh RNA 5' end position (+1). Possibly homologous D. melanogaster DNA sequences occur in two large blocks (-620 to)-466 and -185 to +108), separated by approximately 280 bp of DNA that could not be assigned to the same genomic location in the D. affinidisjuncta sequence. Interestingly, 23 bp of this "deleted/inserted" D. melanogaster DNA (position -302 to -280) is very similar to a 28-bp D. affinidisjuncta sequence that occurs just outside of the long alignment (position -357 to -329; see Fig. 6A). The TATA sequence occupies position -31 to -25 in the DNA sequence of both species.

The D. melanogaster DNA region -86 to -46(region D1) contributes to the activity of the distal Adh promoter in vitro, and a putative Adh transcription factor can be specifically bound to this region in vitro (Heberlein et al. 1985). This region is not well conserved in D. affinidisjuncta, and over one-half of region D1 has been excluded from the alignment in Fig. 6A. However, D. affinidisjuncta sequences with similarity to parts of this D. melanogaster region do occur at their homologous location (-60 to -53, Fig. 6D and E) and also in relatively upstream (Fig. 6B and C) locations. The upstream similarity contains one copy of the sequence CTGC, which is repeated four times, and also twice in reverse, in the D. melanogaster D1 region. Overlapping the D. affinidisjuncta CTGC is GCAGC (Fig. 6B); the related sequence GCTGC overlaps the D. melanogaster CTGC repeats. The single D. affinidisjuncta CTGC aligns with one other of the four D. melanogaster CTGC repeats (Fig. 6C). Relatively downstream similarities to region D1 emphasize a different sequence repeat, TCGAC (Fig. 6D and E). This sequence and the related TCAAC in the D. affinidisjuncta sequence form a conserved tandem repeat that aligns with the D. melanogaster sequence in two ways. The two species' promoter sequences are slightly displaced, relative to each other and the TATA sequences, in these instances.

A comparison of the exon 1 sequences (Fig. 6A, D. affinidisjuncta +1 to +58) shows a reduction in size for D. affinidisjuncta, but appreciable sequence conservation. As presented (Fig. 6A), the size difference is accounted for in two similarly sized blocks of D. melanogaster DNA (+42 to +57 and +72 to +86) located in the 3' half of exon 1. In all, the alignment produces a sequence similarity of 67% (39 out of 58 D. affinidisjuncta nucleotides matched) for exon 1. For comparison, the first 92 bp of Adh protein-coding sequence (from exon 2) correspond one to one with a 68% sequence similarity (not presented).

Proximal Adh promoter regions are compared in Fig. 7. This alignment includes a sequence from intron 1 and includes the untranslated 5' leader sequence of proximal RNA. Identical TATA sequences occur at -31 to -24 in the D. affinidisjuncta and at -32 to -25 in the D. melanogaster sequences. The most upstream similarity in the alignment is an A-rich sequence that includes lesser amounts of T and C (Fig. 7, boxed).

The *D. affinidisjuncta* sequence between -95 and -72 aligns with the homologous *D. melanogaster* sequence (Fig. 7). The latter (designated P0) binds a possible transcription factor in vitro (Heberlein et

Fig. 4. Primer extension mapping of the 5' ends of proximal (A) and distal (B and C) Adh transcripts from D. affinidisjuncta. See text for methods. Asterisks mark the alignment of cDNA termini (lane X in A and B) with the genomic DNA sequence (A and B, lanes G, A, T, C). The 5' ends of distal Adh transcripts from separate adult tissues (FB, abdominal fat body; H, head; MT, Malpighian tubules) are identified in C.

al. 1985). A second upstream region of the *D. melanogaster* sequence (-150 to -104, designated P1) possesses a binding activity that is related to that of the distal promoter region D1 (Heberlein et al. 1985; see above). Recall that the *D. melanogaster* D1 sequence is not well represented in *D. affinidisjuncta* (Fig. 6A), and note from Fig. 7 (see asterisks) that the related region P1 is also not similar to the *D. affinidisjuncta* sequence. A third protein-binding region of the *D. melanogaster* proximal *Adh* promoter (P2; Heberlein et al. 1985) is not apparent in the *D. affinidisjuncta* sequence, and is also not present in the *D. melanogaster* sequence that is used in the present analysis.

The two species' proximal Adh RNA 5' leaders are of similar size, and the conserved DNA sequence is clustered around the intron 1 splice acceptor sequence (+28 to +42 in D. affinidisjuncta; Fig. 7). In all, the proximal 5' leader sequences are 45% similar (28 of 62 D. affinidisjuncta nucleotides matched). For comparison, the distal leader similarity is 55%. A fraction of both of these values can be attributed to the conservation of intron 1 splicing sequences. Downstream (3') to the Adh protein-coding region, D. affinidisjuncta and D. melanogaster DNA sequences are not similar (not presented). Only two polyadenylation signal sequences occur in the D. melanogaster sequence, and only one of these (122 nucleotides from the translation termination codon) is used in vivo (Benyajati et al. 1983). This organization contrasts sharply with the multiple occurrences of apparently functional polyadenylation signals in the D. affinidisjuncta Adh gene sequence (Fig. 2).

Discussion

Previous reports have stressed the apparent similarity between *D. affinidisjuncta* and *D. melanogaster Adh.* Distal and proximal *Adh* mRNAs occur in both species, and the two transcipt types show the same developmental restriction in both species (Rowan et al. 1986). Also, the two species' ADH activities are biochemically similar (Dickinson and Carson 1979; Dickinson 1980a). The present com-

parison shows the correlates of this similarity at the DNA sequence level.

Drosophila melanogaster and D. affinidisjuncta are not closely related. One measure of the evolutionary distance between these species is the disparity of their ADH amino acid sequences (Fig. 5): of the 254 positions in the D. affinidisjuncta sequence, 54 are different in D. melanogaster. Historical and biogeographical data (Throckmorton 1975) and immunological distance measurements (Beverley and Wilson 1982, 1985) indicate that the subgenera Drosophila (which includes D. affinidisjuncta) and Sophophora (which includes D. melanogaster) diverged approximately 40-60 million years (Myr) ago. Accordingly, the amino acid replacement rate for Drosophila ADH appears to be approximately 0.5/Myr. Amino acid replacement rates in Adh genes from closely related members of the *melanogaster* species group, e.g., 2 per approximately 2 Myr in D. simulans/D. melanogaster and 3 per approximately 1 Myr in D. simulans/D. mauritiana (Bodmer and Ashburner 1984), are similar to this value.

It is commonly observed that a given protein evolves at a uniform rate in separate lineages (Dickerson 1971; Kimura 1983). For *Drosophila* ADH,

a relative rate test (Sarich and Wilson 1967) may be performed using the published D. mulleri ADH-1 sequence (Fischer and Maniatis 1985). Drosophila mulleri and D. affinidisjuncta are members of different radiations within the subgenus Drosophila (Throckmorton 1975), and are therefore equally removed from the sophophoran species D. melanogaster. The pairwise comparisons D. affinidisjuncta/ D. melanogaster (54 amino acid replacements; see above), D. mulleri/D. melanogaster (47 replacements; not presented), and D. affinidisjuncta/D. mulleri (27 replacements; not presented) indicate a uniform rate of ADH protein evolution, and provide an estimate of the time of divergence between members of the virilis-repleta (D. mulleri) and the immigrans-Hirtodrosophila (D. affinidisjuncta) radiations (see Throckmorton 1975).

Benyajati et al. (1981) previously discussed physical properties of the *D. melanogaster* ADH enzyme as inferred from its amino acid sequence; their conclusions are germane to the present analysis. Briefly, the first 140 amino acid residues of *D. melanogaster* ADH probably include the cofactor (NAD+)-binding domain, and catalytic activity therefore resides in the remaining sequence (Benyajati et al. 1981). Four *Drosophila* ADH amino acids, which are in-

Fig. 5. Comparison of the ADH amino acid sequences from D. affinidisjuncta (aff) and D. melanogaster (mel), obtained by a conceptual translation of the Adh mRNA sequences. Amino acids are numbered in the D. affinidisjuncta sequence beginning with the initiating methionine at position 1. Asterisks mark the charged residues in each sequence, and sequence differences are underlined. Arrowpoints mark conserved residues implicated in cofactor binding (Benyajati et al. 1981). Arrows show the locations of Adh introns 2 (position 31/32) and 3 (position 166/167).

Fig. 6. Comparison of the distal Adh promoters from D. affinidisjuncta (a) and D. melanogaster (m). Sequences are negatively numbered proceeding upstream, and positively numbered proceeding downstream, from the 5' end of Adh mRNA at +1. Only the most abundant of four D. affinidisjuncta RNA 5' ends (see Fig. 4B) is considered. The TATA sequences at -25 are boxed. Underlined sequences exhibit the indicated identity (percentage of nucleotide positions matched), and these occur in the same relative order in each species' genome. An overlined sequence occurs in a different position in the two species. The D. affinidisjuncta sequence GTGTTCC at -137 is given in parentheses in two alternate alignments with the D. melanogaster sequence. Asterisks indicate conserved repeats of (G)CAG(A/T). The vertical arrow at D. affinidisjuncta position +58/+59 marks the boundary between exon 1 and intron 1 (see Fig. 1). B, C, D, E Alignment of distal Adh promoter sequences from D. affinidisjuncta (lower sequence) with those from D. melanogaster region D1 (see text). Numbering of sequences as in A.

variantly positioned in the coenzyme binding domains of all dehydrogenases (Benyajati et al. 1981), are indicated by arrowpoints in Fig. 5. Also, amino acid replacements that appear in *D. affinidisjuncta* ADH are "conservative" (Zuckerkandl and Pauling 1965; Miyata et al. 1979), and are equally partitioned between both putative domains (28 changes in the first 138 residues and 26 changes in the remaining 116 residues).

Functions other than protein coding are not easily recognized from DNA or RNA sequence data alone, but molecular genetic analyses do suggest consensus properties for sequences that regulate gene expression (Davidson et al. 1983). Because some regulatory sequences appear as similarities in the DNA sequences of homologous or similarly regulated genes (e.g., Pelham 1982; McKnight et al. 1984; Parslow et al. 1984), we have compared the Adh promoter sequences from D. affinidisjuncta to those from D. melanogaster.

As aligned in Fig. 6A, distal Adh promoter sequences contain 10 areas of limited interspecific similarity (underlined; average size 17 bp, average identity 79%). Proximal promoter sequences contain three such areas (Fig. 7, underlined; average size 13 bp, average identity 80%). The biological significance of these similarities remains untested, but more thorough studies of other genes (e.g., Davidson et al. 1983; Donahue et al. 1983; Dynan and Tjian 1985; Karin et al. 1984; McKnight et al. 1984; Stuart et al. 1984; Johnson and Herskowitz 1985; Osborne et al. 1985; Simon et al. 1985) show that the sizes, percentage similarities, and organization of these Adh sequences are appropriate for sequences that encode regulatory function(s). P element-mediated gene transfer methods (Rubin and

Spradling 1982) are being developed to test this hypothesis directly (Brennan et al. 1984b; Brennan and Dickinson 1988).

52

Nontranslated leader sequences (in exon 1) of the two species' distal Adh transcripts are similar to each other (Fig. 6A, sequence +1 to +56, and asterisks). In contrast, similarities between the nontranslated leaders of the proximal Adh transcripts are limited, and these probably reflect the conservation of intron 1 splice recognition sequences (Fig. 7, sequence +1 to +61). Distal, more than proximal, mRNA leader sequences might be important for Adh translational control (e.g., Klemenz et al. 1985; see Kozak 1983), or perhaps exon 1 sequences regulate the abundance of Adh transcripts. In principle, these too are testable hypotheses.

Functional tests of the *D. affinidisjuncta Adh* gene, placed into the *D. melanogaster* genome by P element-mediated transformation, show that *D. affinidisjuncta Adh* does indeed contain regulatory information that is accurately expressed in the *D. melanogaster* milieu (Brennan and Dickinson 1988). With the reservation that the introduced *D. affinidisjuncta Adh* clone was larger (by about 900 bp at the 5' and about 600 bp at the 3' end) than the *Adh* sequence reported here, these data do strengthen the inference that observed DNA sequence similarities are functionally significant.

The present study found a partial duplication of an *Adh* sequence immediately following the complete *Adh* gene. This duplication is in turn followed closely by a sequence that is repeated several times within the *D. affinidisjuncta* genome. This repetitive element has not been characterized, but blot hybridizations show that at least part of its sequence Fig. 7. Comparison of the proximal Adh promoters from D. affinidisjuncta (a) and D. melanogaster (m). The sequence is numbered relative to the 5' end of the proximal Adh transcript at +1. TATA sequences, conserved A-rich upstream regions, and the translation initiation codon (ATG) are boxed. Underlined sequences exhibit the indicated identity (percentage of nucleotide positions matched). Sequences in parentheses, D. affinidisjuncta -139 and D. melanogaster -144, show an 86% identity, but are differently located within the A-rich region. Asterisks indicate sequences within the D. melanogaster region P1 (Heberlein et al. 1985) and similar sequences in D. affinidisjuncta. The vertical arrow marks the intron 1-exon 2A boundary (see Fig. 1).

is included in Fig. 2 (Brennan et al. 1984a and unpublished). These and other data distinguish the *D*. *affinidisjuncta Adh* duplication from duplications of the *Adh* region in other *Drosophila* species.

A probable tandem duplication of Adh has been preserved in *D. melanogaster* and in *Drosophila pseudoobscura* as a gene encoding a protein now only vaguely similar to ADH (Schaeffer and Aquadro 1987). This putative gene is directly 3' to the single *Adh* gene in these two species; related sequences have been cloned from *D. affinidisjuncta* and mapped (by in situ hybridization) to a chromosome location unlinked to *Adh* (Brennan et al. 1984a and unpublished).

The Drosophila mulleri genome contains three tandem copies of Adh, two of which encode ADH (Fischer and Maniatis 1985). Unlike the duplication of Adh intron 1 in D. affinidisjuncta, sequences that flank the duplicated ADH coding regions in D. mulleri have diverged greatly from each other and are not recognizably similar (Fischer and Maniatis 1985).

Thus, three unique tandem duplications of *Adh* DNA have now been described. At the least, these kinds of data should be valuable for phylogenetic analyses.

Acknowledgments. Our colleague Mark Brennan provided valuable insights, encouragement, and technical advice during this study. M. Ashburner provided an unpublished Adh sequence from D. melanogaster. We are grateful to L. Bossi and D. Smith for technical advice on m13 cloning and sequencing, and to P. Keim for help with Maxam and Gilbert sequencing. E. Kofoid made computer programs available, and patiently taught computer methods for DNA sequence analysis to R.G.R. Glenn Herrick critically reviewed an earlier draft of the manuscript. This work was supported by grant HD 10723 from the National Institutes of Health (NIH). R.G.R. was supported by an NIH predoctoral service award trainee grant (5-T32-GM7464).
