

# A MATHEMATICAL MODEL TO PREDICT $\delta$ -FERRITE CONTENT IN AUSTENITIC STAINLESS STEEL WELD METALS

M.A. Valiente Bermejo

Dr. María Asunción VALIENTE BERMEJO (valiente.asun@gmail.com)  
is an independent consultant and researcher, Barcelona (Spain).

ABSTRACT

This paper presents a mathematical model to forecast the level of residual  $\delta$  ferrite in terms of FN in austenitic stainless steel welds at cooling rates between 10 °C/s up to 10<sup>3</sup> °C/s. With this aim, two series of austenitic steel specimens were prepared using an electric arc remelt furnace. Whilst the alloying level was kept constant at  $[Cr_{eq} + Ni_{eq}] = 30\%$  and  $[Cr_{eq} + Ni_{eq}] = 40\%$ , the  $Cr_{eq}/Ni_{eq}$  ratio was gradually increased from 1.22 up to 2.00 in each series. For each alloying level, a highly correlated polynomial function (FN vs.  $Cr_{eq}/Ni_{eq}$ ), was found, being  $Cr_{eq}$  and  $Ni_{eq}$  Hammar and Svensson's equivalents. These experimental results have led to the importance of  $[Cr_{eq} + Ni_{eq}]$  and  $(Cr_{eq}/Ni_{eq})$  variables in the forecast of the residual ferrite content and a general expression including both variables is proposed.

$$FN = 54.22 - 126.26(Cr_{eq} + Ni_{eq}) + [-48.11 + 37.14(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right) + [-0.23 + 61.95(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right)^2$$

The proposed model is able to forecast the level of  $\delta$  ferrite with a mean error of +1.01 FN within a deviation of +/- 2.12 FN with 95 % probability by just considering the chemical composition of the alloy. This level of error has been proved to be lower than DeLong's and WRC-1988 diagrams errors. Moreover, the proposed model has also been compared with WRC-1992 diagram and FNN-1999 neural network and it provides a more accurate FN forecast within the range of compositions and cooling rates considered.

## 1 Introduction

Controlling the  $\delta$ -ferrite content in stainless steels is of utmost importance, as its content will influence the material properties and its on-site behaviour in terms of weldability, corrosion resistance, toughness and thermal stability. Hot cracking phenomenon and low temperature toughness have been extensively studied [1-17] and it is commonly agreed that the absence or low  $\delta$ -ferrite levels, which are the result of austenitic [A] or austenitic-ferritic [AF] solidification modes, leads to hot cracking phenomena during arc welding solidification and also that values over 5 FN are detrimental to low temperature toughness. Therefore, it is vital to control  $\delta$ -ferrite in those welding consumables which are intended for cryogenic applications. On the other hand, high levels of  $\delta$ -ferrite coupled with long-time high-temperature cycles may cause embrittlement phenomena due to the spinodal decomposition of  $\delta$ -ferrite, or the formation of undesirable  $\delta$ -sigma phase.

The  $\delta$ -ferrite level can be controlled by taking real measurements, in most cases by using magnetic determination or in the minority by quantitative metallographic determination, or alternatively by using well-recognised forecast methods like the WRC-1992 diagram or the FNN-1999 artificial neural network which are derived from the chemical composition of the weld deposit. These forecast methods are essential during the design stage of a project when the weld pad is not available or when different options of welding consumables are being considered in order to have a good approach of the  $\delta$ -ferrite level that will be achieved.

Historically, different methods have been used for the forecast of  $\delta$ -ferrite in stainless steels. In 1985, Olson [18] contributed to the literature with a comprehensive compilation of them. A summarised chronology of the most important events in the  $\delta$ -ferrite prediction is presented in Table 1.

The current paper presents a new contribution to  $\delta$ -ferrite prediction in austenitic stainless steel arc-welded metals.

Table 1 – Summarised chronology of methods for  $\delta$ -ferrite forecast

Researchers	Year	Event	Significance
Strauss & Maurer [19]	1920	Ni vs. Cr diagram to forecast the metallographic phases in rolled stainless steels.	First diagram to predict metallographic phases in relation to chemical composition in rolled stainless steels.
Newell & Fleischman [20]	1938	First mathematical equation to describe the boundary between austenitic and ( $\gamma+\delta$ ) mixed microstructure in wrought stainless steels.	Mathematical expressions defining $\delta$ -ferrite and $\gamma$ -austenite phases' stability as a function of the chemical composition of the alloy.
Feild, Bloom & Linnert [21]	1943	Mathematical equation to predict austenitic weld metal microstructure when welding armour steels with austenitic stainless steel consumables.	
Binder, Brown & Franks [22]	1949	Austenite stability versus ferrite stability as a mathematical expression.	
Campbell & Thomas [23]	1946	Microstructure and mechanical properties of welded 25Cr20Ni alloy correlated to chemical composition.	First time proposing the concept of "equivalent", by grouping in the same arm of the expression all the alloying elements promoting the same microstructural phase.
Schaeffler [24-26]	1947-1949	Development of 3 diagrams in which the author gradually refined the Cr equivalent expression. Second and third versions also included iso-ferrite lines expressed as % volume ferrite.	First time of a diagram including Cr equivalent and Ni equivalent on the axes and weld metal microstructural phases plotted, together with ferrite content determined by quantitative metallography.
DeLong & Reid [27, 28]	1956	Diagram focused on the austenite-ferrite transition of Schaeffler's diagram. The influence of the N on the reduction of $\delta$ -ferrite content in the weld metal is quantified in the expression of Ni equivalent	Increased the number of austenitic alloys analysed to improve the precision of Schaeffler's diagram. Instead of quantitative metallography, magnetic determination of $\delta$ -ferrite was carried out and expressed as % volume ferrite.
Long & DeLong [29-31]	1973	Revision of former diagram including experimental data of alloys with higher $\delta$ -ferrite contents than 8 FN to replace previous extrapolations in his former diagram	First time using the new standardised Ferrite Number (FN) scale proposed by the Welding Research Council (WRC) and the International Institute of Welding (IIW)
Between 1973 and 1988 some studies were carried out in relation to the effect of alloying elements on the $\delta$ -ferrite content, resulting in new expressions for chromium and nickel equivalents. During that period Suutala <i>et al.</i> [2, 3, 6-8] proposed the solidification modes [A, AF, FA, F] and Kotecki [32, 33] found a solution to extend the measurement of $\delta$ -ferrite content to the duplex stainless steels			
Siewert, McCowan & Olson [34]	1988	WRC-1988 diagram based on multivariable linear regressions from the WRC database [35] which included the chemical composition and the experimental FN value of 923 stainless steels.	Differently from previous ones, the diagram included duplex and highly alloyed stainless steels data, increasing the forecast to 100 FN and it is the first one in stating the solidification modes and its transition lines instead of the metallographic phases
Kotecki & Siewert [36, 37]	1992	WRC-1992 diagram improved WRC-1988 diagram by adding the Cu contribution to the nickel equivalent in order to extend the diagram to those duplex containing around 2% Cu in their composition.	The diagram was designed with extended axis-similarly to Schaeffler's diagram- in order to make possible the forecast of the chemical composition and the $\delta$ -ferrite content of dissimilar welds. This WRC-1992 diagram is still valid in ASME III code
Kotecki [38, 39]	1999	WRC-1992 diagram including the martensite limit formation for 1 %, 4 % and 10 % Mn claddings on it.	Increased the applicability of the WRC-1992 diagram for claddings.
Balmforth & Lippold [40]	2000	Diagram for ferritic and martensitic stainless steels	It depicts microstructures and $\delta$ -ferrite (as % ferrite) determined by quantitative metallography (as both martensite and ferrite have magnetic response).
Since the end of the 90's until today, the most significant advance in the prediction of FN has been the development of artificial neural networks. Vasudevan <i>et al.</i> [41] and Vitek <i>et al.</i> [42-45] based their models on multivariable non-linear regressions between the chemical composition, the solidification mode, the cooling rate - which in turn controls the solid state transformation $\delta \rightarrow \gamma$ and the FN value. Vitek developed two neural networks, the FNN-1999 considering only the chemical composition as input variable and the ORFN in 2003 including the cooling rate as an additional parameter. Both researchers took the WRC database [35] as input data.			

## 2 Experimental procedure

Two series of austenitic steel specimens were designed and prepared; the first one consisted of 45 samples with a constant alloying level of  $[Cr_{eq} + Ni_{eq}] = 40\%$  and the second one consisted of 42 samples with a constant alloying level of  $[Cr_{eq} + Ni_{eq}] = 30\%$ . Whilst the alloying level was kept constant, the  $Cr_{eq}/Ni_{eq}$  ratio was gradually increased from 1.22 up to 2.00 in steps between 0.01 and 0.03. Chromium and Nickel equivalents ( $Cr_{eq}$ ,  $Ni_{eq}$ ) were calculated using the equations established by Hammar and Svensson [46] [Equations 1. a), b)]. Suutala *et al.* [3, 6-8], who established the solidification modes, also stated that these equivalents gave a better correlation between composition and solidification modes than Schaeffler's or DeLong's ones. Moreover, as it will be shown later in this paper, the use of Hammar and Svensson's equivalents compared with WRC equivalents [36], results in a mathematical model with lower error in the FN prediction.

$$Cr_{eq} = Cr + 1.37 Mo \quad (1.a)$$

$$Ni_{eq} = Ni + 0.31 Mn + 22 C + 14.2 N \quad (1.b)$$

The base materials used for sample preparation were three grades of solid wires for Gas Tungsten Arc Welding (GTAW), including one mild steel grade and two austenitic grades whose designations and chemical compositions are shown in Table 2. Except for the molybdenum content which was analysed by OES at the author's laboratory, the wires' analyses were conducted by an external and independent laboratory. According to their test report, silicon, manganese, phosphorous, chromium and nickel were analysed by wet process defined in BS Handbook no. 19, BS 6200. Carbon and sulphur were analysed by combustion IR ABS whilst nitrogen and oxygen were analysed by inert gas fusion process.

The pre-cleaned wires were cut into segments between 10-18 mm in length and mixed in required proportions as per Appendixes 1 and 2, so that the designed arc melted samples (buttons) be in accordance with desired levels of  $[Cr_{eq} + Ni_{eq}]$  and  $Cr_{eq}/Ni_{eq}$  ratios. Later on, in Section 3, these designed compositions will be compared with the experimental compositions determined by Optical Emission Spectroscopy (OES). The total weight of each batch of the samples was 50 g which were melted in a pure argon atmosphere using the electric arc remelt furnace, based on GTAW process which is recommended by the ASTM E1306-94 standard [47] and depicted in Figure 1. In a previous detailed research on the standard

by the current author [48], evidences of compositional heterogeneity were found and some modifications were recommended to the ASTM in order to ensure homogeneous samples. Consequently, ASTM issued a new revision to the standard, ASTM E1306-07 [49]. The same work demonstrated that, for a satisfactory sample, the optimum parameters for the remelting process were; -current 550 A, voltage 30 V, holding duration 60 s and then followed by 3 min cooling inside the furnace. Accordingly, these settings were applied to all sample preparation of the current work.

The solid and homogeneous sample obtained was then cut in two halves (see Figure 2) by a cooled and lubricated sawblade and the transversal cross-section (Figure 3), which is considered for  $\delta$ -ferrite measurements, was slightly ground by using P400 silicon carbide abrasive paper.

As depicted in Figure 3, the transversal cross-section is geometrically characterised by a rectangle of 30 mm length and 7 mm height together with a circular segment of a 30 mm chord and 3 mm height, giving a resulting grid of 12 columns and 5 rows with a minimum of 50 squares each one of an approximate surface of 6 mm<sup>2</sup>. The overall surface was divided into three zones containing 12 squares each, as shown in Figure 4: the upper one (coloured in yellow) which was in contact with the inert gas, the lower one (coloured in green) which was in contact with the copper crucible and the central one (coloured in rose) which was considered representative of an as-welded GTAW deposit in terms of cooling rate [48] and therefore was specifically investigated.

An M10B-FE Fischer feritscope was used for the  $\delta$ -ferrite measurements in terms of Ferrite Number (FN). It was calibrated against a set of IIW (International Institute of Welding) secondary calibration standards according to the international standard EN ISO 8249:2000 [50]. The procedure for the use of the feritscope includes the list of tolerances of the equipment for the different FN bands, and the higher the FN the less stringent the tolerance. Tolerances are as follow: +/- 1FN for (0-14) FN, +/-2 FN for (14-24) FN, +/-3 FN for (24-40) FN and +/-4 FN for (40-70) FN.

Five individual FN measurements were taken at each of the 12 central squares of the transversal cross-section (rose zone in Figure 4); therefore each sample is described by 60 individual readings and its average value.

Figure 1 – Schematic illustration of the furnace

To provide with information about variability in these experimental FN measurements, sample A22R ( $Cr_{eq}/Ni_{eq} = 1.30$ ,  $[Cr_{eq}+Ni_{eq}] = 40\%$ ) as representative of low ferrite samples and sample A731 ( $Cr_{eq}/Ni_{eq} = 2.00$ ,  $[Cr_{eq}+Ni_{eq}] = 40\%$ ) as representative of high ferrite samples were considered. Table 3 shows the results obtained when recording the average FN value and the standard deviation in three specific cells of the central column and also in each zone of the transversal cross-section (Figure 4). In all these cases, the standard deviations of the average values are lower than the feritscope tolerances for the specific FN band, as stated above.

In order to compare the results under a higher cooling rate, the central cross-sections of 6 selected samples for their different solidification modes were additionally remelted, as shown in Figure 5, using a conventional GTAW process with the following parameters: 60 A, 11 V and holding

time 15 s, 8 l/min argon gas flow, 14 °C room temperature, 2 % thoriated tungsten diameter 2.4 mm. Twenty FN measurements were taken in the remelted area and the average FN value was calculated.

As has been previously referred, with the aim to check possible variations in the chemical composition caused by vaporization or by segregations during the melting process, samples were analysed by using Optical Emission Spectroscopy with a Spectrolab equipment. One analysis per sample was conducted at the centre of the transversal cross-section.

### 3 Results and discussion

The individual FN measurements taken on each square of the 87 samples are available in a previous research document by the current author [48]; however Tables 4 and 5 show the average FN value obtained at the central zone of the transversal cross-section for each sample series.

Figure 6 illustrates the relationship between the average FN and the Cr<sub>eq</sub>/Ni<sub>eq</sub> ratio shown in Tables 4 and 5. The data are fitted using minimum squares according to a second degree polynomial and the results are depicted graphically on the same Figure 6 and numerically on

Table 6. Only those data with FN > 0 have been considered for mathematical fitting. It is clearly shown that the experimental data and the second degree polynomial functions are strongly correlated, as it is demonstrated by the R-square values.

These results demonstrate that for every alloying level  $[Cr_{eq} + Ni_{eq}]$  there is a highly correlated polynomial function to fit the experimental FN values and the  $Cr_{eq}/Ni_{eq}$  ratio. Therefore, these results lead to the conclusion that FN depends on both variables: the alloying level  $[Cr_{eq} + Ni_{eq}]$  and the  $Cr_{eq}/Ni_{eq}$  ratio. Taking this point into consideration, a general expression for the FN forecast in the austenitic stainless steels under arc electric solidification conditions is proposed herein.

Variables are defined according to Equation (2) and a general expression is proposed considering the fact that the relationship between variables FN and  $Cr_{eq}/Ni_{eq}$  is described by a second degree polynomial function according to Equation (3).

$$\begin{cases} FN = y \\ Cr_{eq}/Ni_{eq} = x \\ Cr_{eq} + Ni_{eq} = z \end{cases} \quad (2)$$

$$\begin{cases} y = a + bx + cx^2 \\ \text{(being } a = f(z), b = g(z), c = h(z)) \end{cases} \quad (3)$$

Boundary conditions are:

Table 6 – Resulting coefficients for the second degree polynomial regression

Series	a	b	c	R-square
30 %	16.34	-36.97	18.35	0.97
40 %	3.72	-33.25	24.55	0.99

$y = a + b \cdot x + c \cdot x^2$ , being  $y = FN$  and  $x = Cr_{eq}/Ni_{eq}$

$y > 0$  : the amounts of  $\delta$ -ferrite are enough to be detected by the feritscope,

$1.22 < x < 2.00$  : austenitic stainless steels condition,

$0.2 < z < 0.5$  : austenitic stainless steels condition.

The main problem lies in finding the functions  $f(z)$ ,  $g(z)$  and  $h(z)$  that correlate the variation of the polynomial expression versus the variable  $z$ . As the coefficient values are known for  $z = 0.3$  (30 % series) and  $z = 0.4$  (40 % series) (see Table 6), a linear variation of the coefficients is initially assumed (see Equations 4, 5 and 6)

$$f(z) = a = \alpha + \beta z \quad (4)$$

$$g(z) = b = \alpha' + \beta' z \quad (5)$$

$$h(z) = c = \alpha'' + \beta'' z \quad (6)$$

Replacing the pair of known values  $(a, z)$  of Table 6 in Equation (4), it leads to a determined 2-equation system which can be solved and as a result, the 2 unknown values  $(\alpha, \beta)$  are calculated. Repeating the same process with the pair of known numbers  $(b, z)$  in Equation (5) and  $(c, z)$  in Equation (6) it is possible to calculate the remaining unknown values  $(\alpha', \beta')$  and  $(\alpha'', \beta'')$ .

Equations (7-9) are the result of rewriting Equations (4-6) but introducing the calculated coefficients obtained.

$$f(z) = a = 54.22 - 126.26z \quad (7)$$

$$g(z) = b = - 48.11 + 37.14z \quad (8)$$

$$h(z) = c = - 0.23 + 61.95z \quad (9)$$

Replacing the above mentioned expressions in the general expression of Equation (3), it is possible to obtain  $y$  as

a dependent function of the variables x and z, as it can be seen in Equation (10).

$$y = 54.22 - 126.26z + (-48.11 + 37.14z)x + (-0.23 + 61.95z)x^2 \quad (10)$$

Rewriting Equation (10) but using the physical variables, the general function for predicting the FN in austenitic stainless steels by means of its chemical composition is expressed as Equation (11).

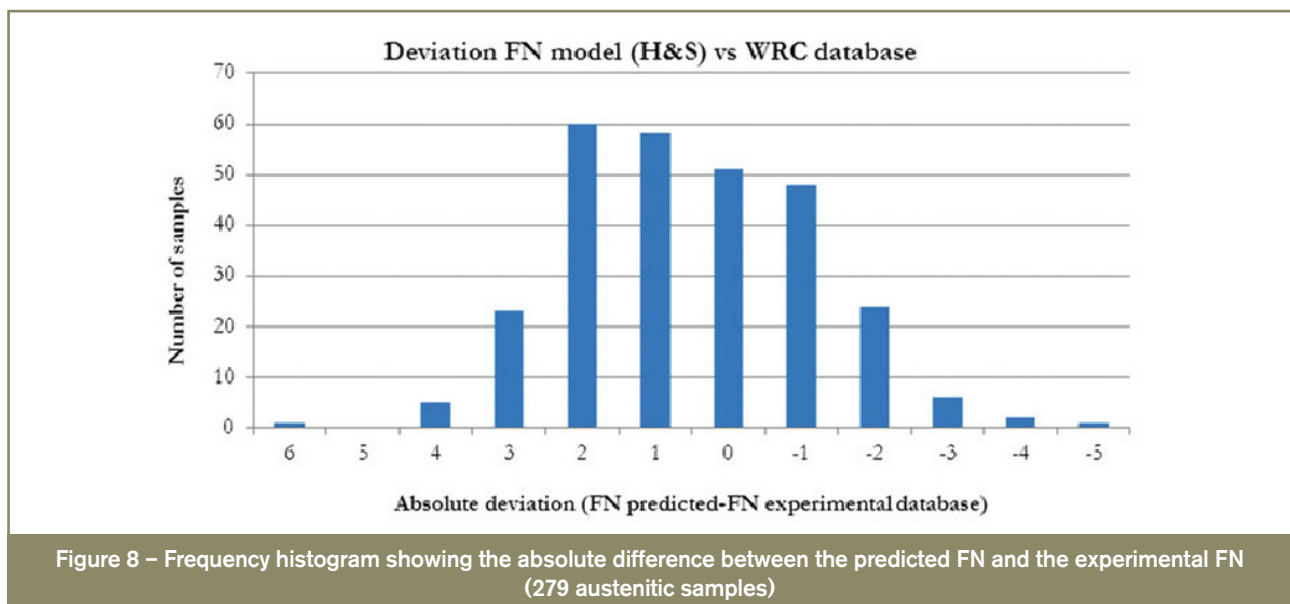

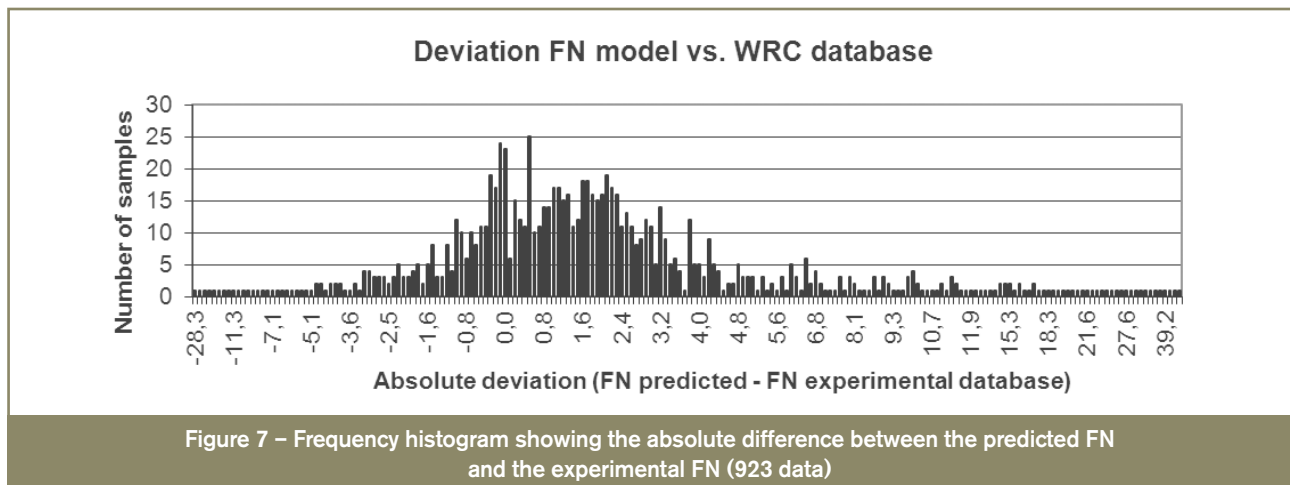

In order to validate the general expression obtained, the WRC database [35] is used. It contains the chemical composition and the FN experimental measurements of 923 different stainless steels, therefore, the  $Cr_{eq}$  and  $Ni_{eq}$  were calculated from the chemical composition provided by the database and then the  $[Cr_{eq} + Ni_{eq}]$  and  $(Cr_{eq}/Ni_{eq})$  values were calculated for each sample and introduced in the Equation (11) in order to obtain a predicted FN value.

Each predicted FN value was then compared with the experimental FN provided by the database and the absolute difference between both values is shown in Figure 7 for the complete set of data.

The statistical processing of the 923 results leads to conclude that the error or absolute difference follows a normal distribution where the expected error is + 2.47 FN with a +/- 5.75 FN confidence interval for 68 % of cases. Considering that the 923 data include all sort of stainless steels (martensitic, ferritic duplex and superaustenitic), and not only the austenitics which are the aim of the current research, it can be concluded that the dispersion between the predicted FN by the Equation (11) and the experimental FN stated by the WRC is acceptable.

However, as depicted in Figure 8, if the comparison is done but only considering the 279 samples of the database whose chemical compositions are within the range of the

$$FN = 54.22 - 126.26(Cr_{eq} + Ni_{eq}) + [-48.11 + 37.14(Cr_{eq} + Ni_{eq})] \left( \frac{Cr_{eq}}{Ni_{eq}} \right) + [-0.23 + 61.95(Cr_{eq} + Ni_{eq})] \left( \frac{Cr_{eq}}{Ni_{eq}} \right)^2 \quad (11)$$

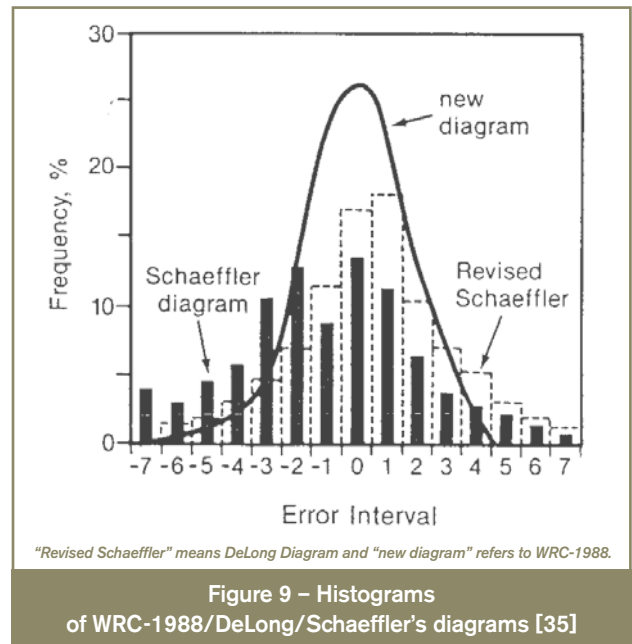

austenitics [Cr: 19-27 %, Ni: 6.6-20 %, Mn: 1-2 %, C: 0.02-0.08 %, Mo: 0-2 %, N < 0.15 %], then the statistical processing confirms that the expected error is **+ 1.01 FN** with a **+/- 1.06 FN interval confidence for 68 % of cases** and a **+/- 2.12 FN interval confidence for a probability of 95 %**. Therefore, the general expression provides for 95 % of samples an error better than 1.01 FN +/- 2.12 FN.

This level of error given by the general expression has been compared with DeLong Diagram's error and with WRC-1988 Diagram's error [34, 35, 51]. As it is shown in Figure 9, for the FN range between (0-18), DeLong's histogram is claimed to be centred in an error of +2 FN with a +/-8 FN interval confidence, and for the same FN range, the WRC-1988 is claimed to be centred in -1 FN with a +/-4 FN for an interval confidence of 95 %. These are higher errors than the obtained with the general expression proposed here.

The author recognises that the proposed mathematical model is based on the measurements taken by one single feritscope and on the chemical analysis of one single laboratory, and that although these equipments are properly calibrated, they could be subjected to a degree of uncertainty compared to the results given by a different equipment or laboratory. However, the fact that the mathematical model has been successfully contrasted with the experimental values given by the WRC database, which contains data from very different sources, it contributes to validate the mathematical model proposed herein.

It is well known that nowadays the most accurate methods for the FN forecast in arc welding are the WRC-1992 Diagram and the FNN-1999 neural network, therefore, in order to compare the accuracy and goodness between the above mentioned methods and the general expression found in this research, the chemical composition of 87 samples

prepared in this research were used as input data for the three methods and results are depicted in Figure 10. The dotted red line represents the ideal method, where the experimental and the calculated FN values match. The rose circles represent the correlation between the experimental FN and the predicted FN by the WRC-1992 diagram, whilst the orange triangles refer to the FNN-1999 neural network and the green squares represent the correlation of the general expression proposed here. It is shown that the WRC-1992 underestimates the FN value throughout all the compositions range whilst the FNN-1999 makes an accurate forecast for samples with FN < 10 and that similarly to WRC-1992, the method also underestimates the values for samples with FN > 15. It is clear that the general expression (Equation 11) provides better matching than WRC-1992 and FNN-1999 for these 87 samples.

Figure 10 – Comparison between forecast methods: General expression, WRC-1992 Diagram and FNN-1999 neural network

In a previous research work by the current author [48], it was determined by DAS (Dendrite Arm Spacing) that these samples prepared using the electric arc furnace were cooled at 10°C/s whilst the central area remelted using conventional GTAW was cooled at 10<sup>2</sup>-10<sup>3</sup> °C/s. Cooling rates in the orders of magnitude between 10-10<sup>3</sup> °C/s are considered typical for the arc welding processes [52-54]. Table 7 shows the experimental FN measurements taken in both cooling conditions and also the FN values obtained using the general expression [Equation (11)]. It is clearly shown that the general expression provides an excellent forecast for the FN value under both cooling conditions. The only case where the forecast differs from the experimental measurements is in the specific case of the sample with primary ferritic solidification mode [F], which is more related to the duplex stainless steels than to the austenitics. The cooling rate highly influences the presence of residual  $\delta$ -ferrite at room temperature in primary ferritic modes [F] because high cooling rates limit the diffusion and the solid state transformation  $\delta \rightarrow \gamma$ , therefore it is logical to observe higher FN values at higher cooling rates as long as the working conditions will be in the order of magnitude of the arc electric cooling rates. However, under extremely high cooling conditions (10<sup>4</sup>-10<sup>7</sup> °C/s) usually related to Laser Beam Welding or Electron Beam Welding, researchers found that those samples which would present [F] solidification mode under arc welding cooling rates, turn to present  $\gamma$ -austenite as stable phase at room temperature. Elmer *et al.* [53, 55], Anderson *et al.* [56] and Inoue *et al.* [57] propose that samples with ferritic primary solidification mode [F] under high cooling conditions could experience  $\delta \rightarrow \gamma$  massive transformation, whilst other researchers [58] also explain the lack of  $\delta$ -ferrite at room temperature by a shift from [F] to [A] solidification mode caused by the dendrite tip undercooling phenomenon.

A thorough mathematical development of Equation (11) has been carried out in previous research work [48], and other practical and additional results related to the design

of austenitic alloys have been proposed, for example it is possible to know for whatever alloying level  $[Cr_{eq} + Ni_{eq}]$  which would be the minimum  $Cr_{eq}/Ni_{eq}$  ratio to detect  $\delta$ -ferrite (see Equation (12)), or inversely for a fixed  $Cr_{eq}/Ni_{eq}$  ratio, it would be possible to find the linear expression which defines the FN value versus the alloying level.

In order to check any possible influence of the arc melting process on the chemical composition of the samples, a comparison has been established between the designed compositions, which were calculated from the experimental composition of the initial wires (see Table 2 and Appendices 3 and 4), and the buttons' compositions which were determined by Optical Emission Spectroscopy (see Appendices 5 and 6). One analysis per sample was conducted at the centre of the transversal cross-section.

With this aim, a deviation ratio ( $\epsilon$ ) was defined as the quotient between the experimental composition and the designed composition. Therefore, elements with  $\epsilon = 1$  indicate that there is no deviation between their initially designed composition and the experimental one in the area analysed, whilst  $\epsilon > 1$  and  $\epsilon < 1$  indicate a local increase or loss respectively. Figure 11 summarises the results obtained.

The experimental values for nitrogen and oxygen obtained by OES are abnormally high (Appendices 5 and 6), giving  $\epsilon$  values up to 8, so they cannot be considered for any further discussion and this also prevents the calculation of experimental  $Ni_{eq}$  values and their possible comparison with the initially designed  $Ni_{eq}$  values. When plotting the nitrogen and oxygen deviations, it was found that both elements present the same trend in the same samples, and from metallographic inspection nor oxides nor nitrides are observed in the samples, therefore, these facts seem to indicate that the difference in dimensions between the sample and the spectrometer fixture has allowed some air to enter into the analysis chamber, giving these abnormally high values for nitrogen and oxygen.

$$Cr_{eq}/Ni_{eq} = \frac{48.11 - 37.14 (Cr_{eq} + Ni_{eq}) + \sqrt{2364.45 - 17125.49 (Cr_{eq} + Ni_{eq}) + 32666.61 (Cr_{eq} + Ni_{eq})^2}}{123.90 (Cr_{eq} + Ni_{eq}) - 0.46} \quad (12)$$

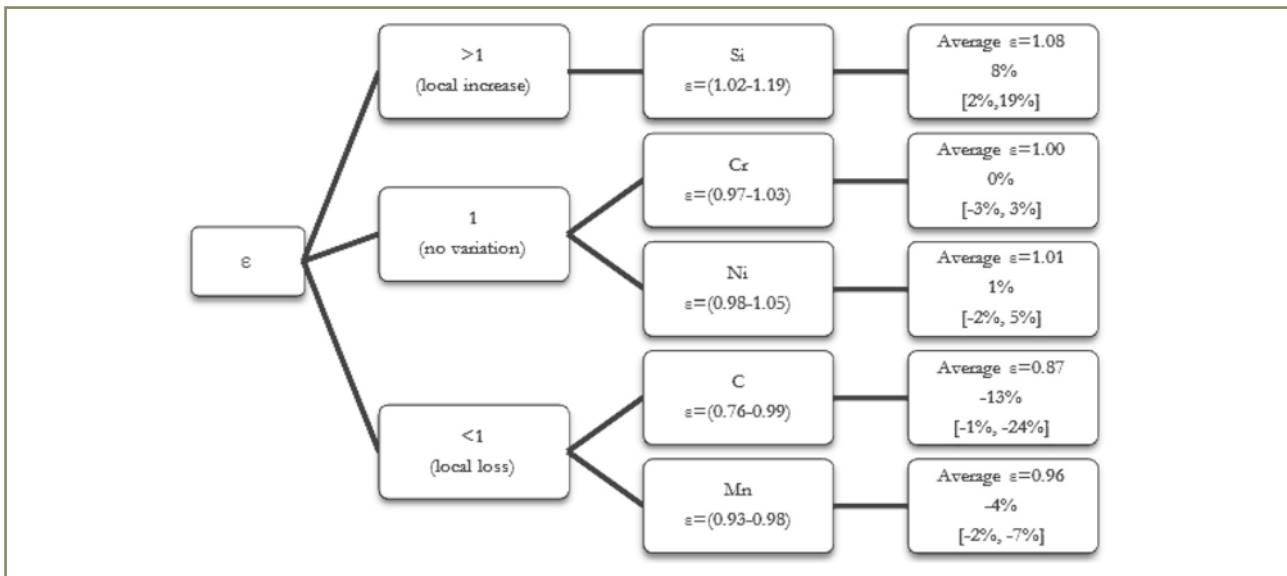

Figure 11 – Deviation ratios for the chemical composition of the samples

Regarding silicon, it does not have a specific weight in the Hammar & Svensson's equivalents, but a local increase was evident. By using SEM microscopy and EDS microanalysis, the current author [48] found clear evidences of spherical particles of one micrometre diameter which were mainly enriched in silicon and in minor contribution included sulphur and traces of aluminium. From 2 to 3 particles were found in an area of 40 x 60 μm. Therefore, it seems very possible that OES analysis shows a local increase in silicon due to this segregation phenomenon.

Carbon and manganese experience a loss during the melting process which has been previously related to vaporization by some authors [59-62], however, considering the relative weight that carbon and manganese have in the calculation of the Hammar & Svensson's nickel equivalent and considering also the low initial contents of these

elements, it is possible to demonstrate that a reduction of 13 % in carbon and of a 4 % in manganese do not influence on the initially designed value of nickel equivalent.

Chromium and nickel, which are the main responsible elements for the  $\delta$ -ferrite content and which have the most important contribution to the calculation of the equivalents, do not experience a significant variation in their chemical composition (average  $\epsilon_{Cr} = 1.00$  and  $\epsilon_{Ni} = 1.01$ ) due to the arc melting process. From the above mentioned results, it is possible to conclude that the initially designed  $Cr_{eq} / Ni_{eq}$  ratios remain unchanged despite the melting process.

The currently developed mathematical model uses the Hammar & Svensson's equivalents. Below, the same mathematical procedure was applied again, but this time using three different equivalents as input data and

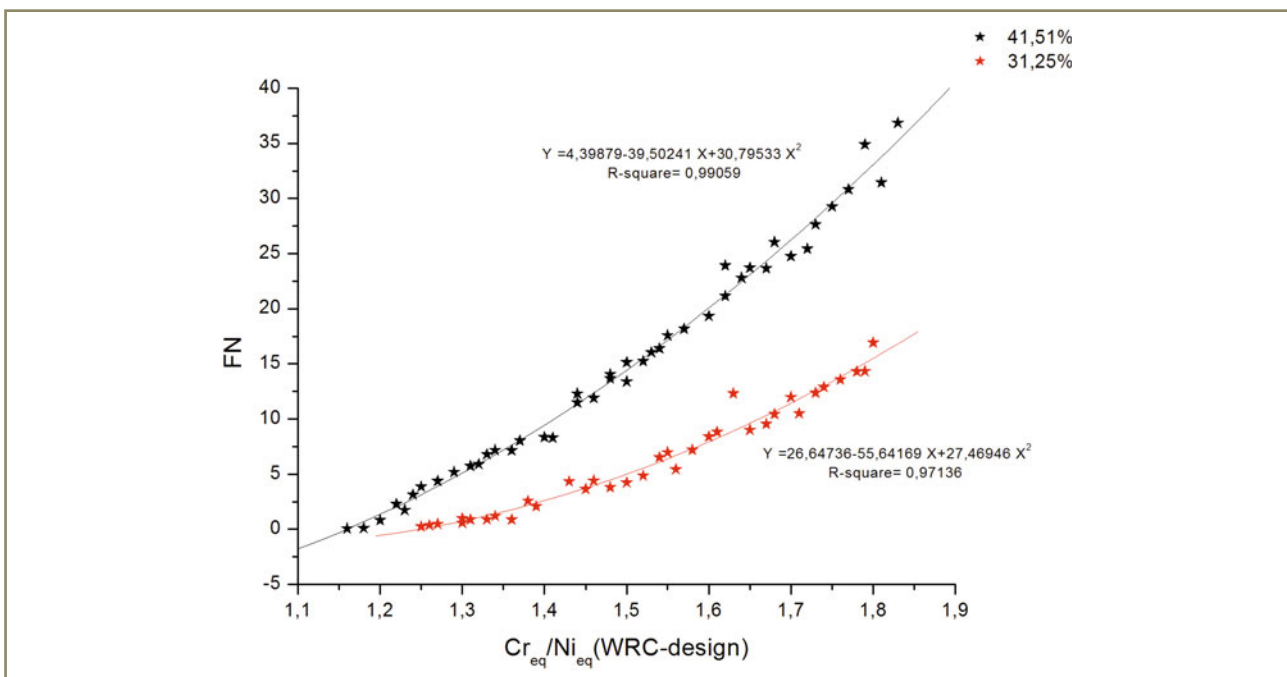

Figure 12 – FN vs.  $Cr_{eq} / Ni_{eq}$  (WRC)

consequently obtaining three new mathematical expressions. Therefore, firstly experimental FN vs. each different  $Cr_{eq}X/Ni_{eq}X$  were plotted and second degree polynomial fit were interpolated, secondly the general second degree polynomial function was calculated and finally, the general function obtained was validated by comparison between the predicted FN and the WRC experimental database.

The equivalents used as input data were: the current WRC equivalents [36], the chromium and nickel values obtained from OES analysis of the samples and finally, the chromium and nickel values designed from weight combination of the initial wires. Figures 12, 13 and 14 illustrate the relationship between the experimental FN values and the above mentioned equivalent ratios. As

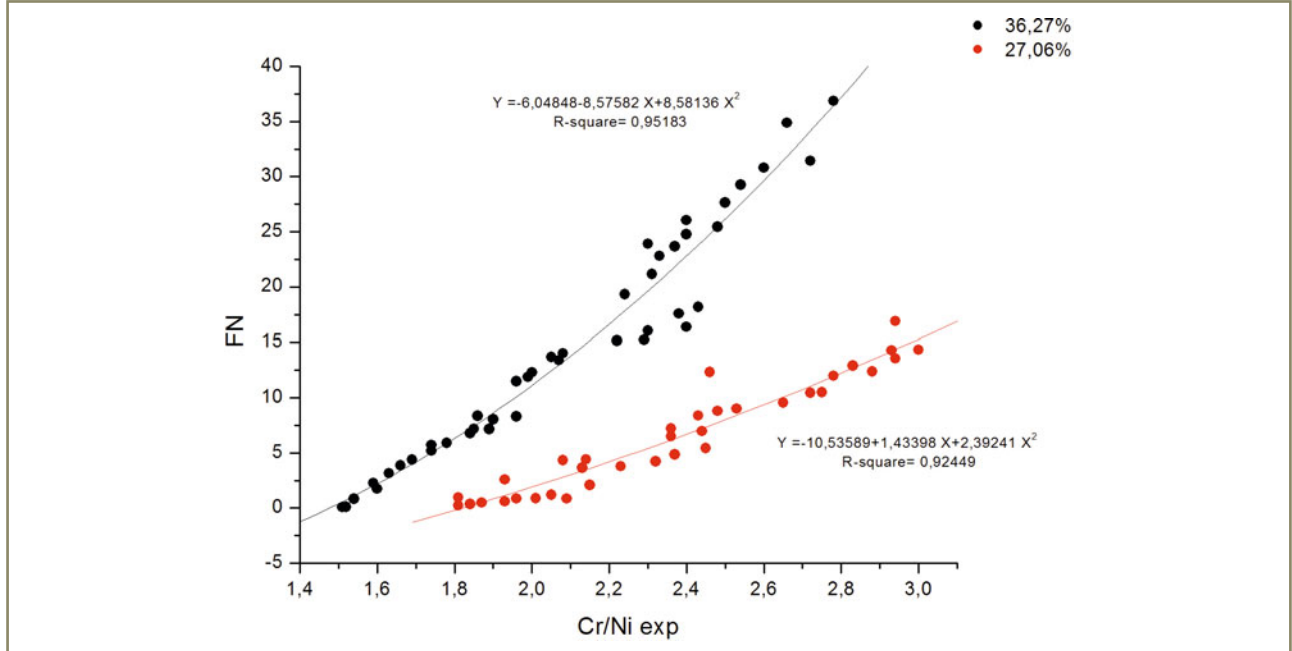

Figure 13 – FN vs. Cr/Ni (OES)

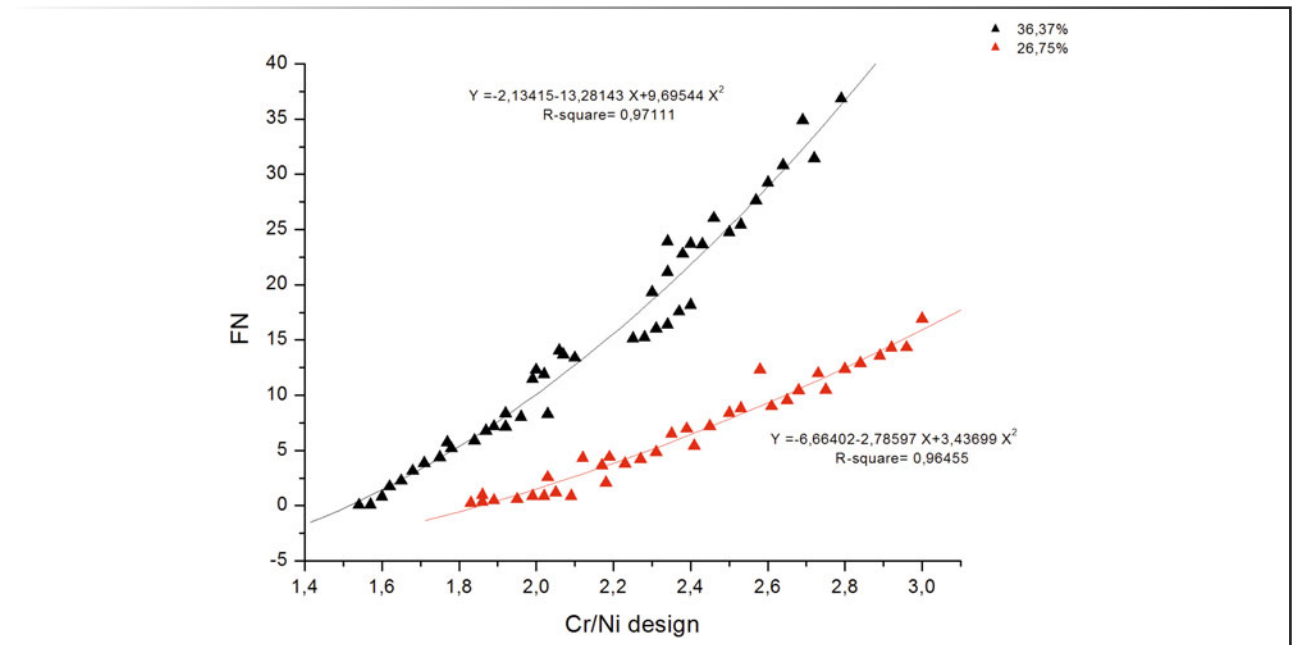

Figure 14 – FN vs. Cr/Ni (Designed)

Table 8 – Error comparison with different models

Equivalents	Expected error (Average error)	Confidence interval for a probability of 68 %	Confidence interval for a probability of 95 %
WRC	<b>2.45 FN</b>	<b>+/- 1.00 FN</b>	<b>+/- 2.00 FN</b>
OES Cr, Ni	-1.29 FN	+/- 2.38 FN	+/- 4.76 FN
Designed Cr, Ni	-1.96 FN	+/- 3.07 FN	+/- 6.14 FN

depicted, data were fitted using minimum squares to second degree polynomial functions and similarly to Figure 6 with Hammar and Svensson's equivalents, a strong correlation (R-square) was found in all the cases, independently of the equivalents used.

It is worthy to note that the best correlations are found when using Hammar and Svensson's and WRC equivalents, even with the same R-square values. Therefore, as it was foreseeable, the use of equivalents rather than only Cr and Ni compositions confirms the influence of the alloying elements –ferrite promoters and austenite promoters- on the FN values.

The general second degree polynomial functions found for each of the three above mentioned cases are Equation (13) for WRC equivalents, Equation (14) for OES (Cr, Ni) compositions and Equation (15) for designed (Cr, Ni) compositions.

$$FN = 94.41 - 216.85(Cr_{eq} + Ni_{eq}) + [-104.80 + 157.30(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right) + [17.34 + 32.42(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right)^2 \quad (13)$$

$$FN = -23.72 + 48.72(Cr + Ni) + [30.84 - 108.68(Cr + Ni)] \left(\frac{Cr}{Ni}\right) + [-15.79 + 67.20(Cr + Ni)] \left(\frac{Cr}{Ni}\right)^2 \quad (14)$$

$$FN = -19.26 + 47.09(Cr + Ni) + [26.40 - 109.10(Cr + Ni)] \left(\frac{Cr}{Ni}\right) + [-13.97 + 65.06(Cr + Ni)] \left(\frac{Cr}{Ni}\right)^2 \quad (15)$$

## 4 Conclusion

It has been found that the  $\delta$ -ferrite content (expressed as FN) versus the  $Cr_{eq}/Ni_{eq}$  ratio can be mathematically fitted by a highly correlated second degree polynomial for each constant alloying level  $[Cr_{eq} + Ni_{eq}]$ :

$$FN = 16.34 - 36.97(Cr_{eq}/Ni_{eq}) + 18.35(Cr_{eq}/Ni_{eq})^2$$

for  $[Cr_{eq} + Ni_{eq}] = 30\%$

$$FN = 3.72 - 33.25(Cr_{eq}/Ni_{eq}) + 24.55(Cr_{eq}/Ni_{eq})^2$$

for  $[Cr_{eq} + Ni_{eq}] = 40\%$

Based on these results, a general expression has been developed in order to propose a new tool to forecast the level of  $\delta$ -ferrite in the austenitic stainless steels (from FN = 0 up to FN = 37) under arc electric solidification conditions (cooling rates from 10°C/s up to 10<sup>3</sup> °C/s), just by using the chemical composition as input data.

$$FN = 54.22 - 126.26(Cr_{eq} + Ni_{eq}) + [-48.11 + 37.14(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right) + [-0.23 + 61.95(Cr_{eq} + Ni_{eq})] \left(\frac{Cr_{eq}}{Ni_{eq}}\right)^2$$

Being  $Cr_{eq}$  and  $Ni_{eq}$  Hammar & Svensson's equivalents.

In order to validate these expressions, the predicted FN values were compared against the 279 austenitic samples of the WRC experimental database [35]. Results are summarised in Table 8 and from the three different equivalents evaluated, it seems clear that the model with the WRC ones presents the best ones with the lowest confidence interval. However, as it was noted previously, the currently developed model with Hammar and Svensson's equivalents has an expected error of **+1.01 FN, a +/-1.06 FN interval confidence for 68 % cases and a +/- 2.12 FN interval confidence for 95 % cases**. When comparing it with the model obtained with WRC equivalents, it is clear that there is no significant difference in terms of confidence intervals, but there is a higher expected error (+2.45 FN) in the model with WRC equivalents. Therefore, it could be concluded that the mathematical expression with Hammar and Svensson's equivalents results in the lower error for FN prediction.

It has been demonstrated that the expression gives a forecasted FN value which could differ from the experimental value between -1.11 and +3.13 with 95 % confidence interval. This is an excellent level of error taking into consideration that other highly recognised methods like DeLong Diagram claimed to present an error of +/-8 FN or WRC-1988 Diagram which claimed to present a deviation of +/-4 FN for the same confidence level. On the other hand, the FN values predicted by the expression found in this research present less deviation than the predictions made for the same samples using the currently international methods WRC-1992 Diagram and FNN-1999 neural network, and moreover its use only needs the input of the  $Cr_{eq}$  and the  $Ni_{eq}$  in the general expression, which is simpler than using a diagram or running a neural network in a computer.

It has been found that the model with Hammar and Svensson's equivalents results in the lower error for FN predictions in comparison with WRC equivalents and in comparison with equivalents considering only Cr and Ni compositions (even if they are designed compositions or determined by OES). It is also worthy to notice that FN versus  $Cr_{eq}/Ni_{eq}$  follows second degree polynomial functions for a constant level of alloy  $[Cr_{eq} + Ni_{eq}]$  independently from the equivalents used.

The mathematical processing of the general expression has led to find other mathematical expressions of interest in the austenitic stainless steel design, for example in the

cryogenic field where  $\delta$ -ferrite needs to be carefully controlled. Therefore, it is possible to calculate the chemical composition boundaries for base materials and welding consumables in order to achieve low levels of  $\delta$ -ferrite.

The general expression proposed in this work also provides an excellent forecast for FN in austenitic stainless steels in the range of cooling rates of  $10^2$ - $10^3$  °C/s. The only case where the forecast differs from the experimental measurements is in the specific case of the sample with primary ferritic solidification mode [F], which is more related to the duplex stainless steels than to the austenitics.

## Acknowledgements

The author gratefully acknowledges the support of Metrode Products Ltd and is especially indebted to Dr. Zhuyao Zhang and Mr. Adam W. Marshall for providing the materials and facilities in order to carry out this research. The current research is part of the Doctoral Degree Thesis entitled "Modelització del nivell de ferrita  $\delta$  als acers inoxidable austenítics sotmesos a fusió per arc elèctric", which was submitted for the Degree of Doctor in Chemistry by the author at the University of Barcelona the 29th of June 2010. It is also gratefully acknowledged the supervision of Dr. Pere Molera and Dr. Núria Llorca from the Department of Materials Science and Metallurgical Engineering at the University of Barcelona. It is gratefully acknowledged the sponsorship by ESAB for the author's attendance to the IIW 64th Annual Assembly in Chennai and is especially grateful to Dr. Leif Karlsson for his invaluable commitment.
