Abstract Bone loss and the resulting skeletal fragility is induced by several pathological or natural conditions, the most prominent of which being aging as well as the decreased levels of circulating estrogens in post-menopausal females. To date, most treatments against bone loss aim at preventing excess bone resorption. We here summarize data indicating that the estrogen-related receptors (ERRs) α and γ prevent bone formation. Inhibiting these receptors may thus constitute an anabolic approach by increasing bone formation.

Keywords Nuclear receptors · Bone · ERR · Osteoblasts · Menopause

Introduction

Bone is a highly dynamic tissue that is under constant remodeling, a phenomenon that comprises two complementary processes: bone formation and bone resorption (reviewed in Frenkel et al. [1]). Two main cell types participate to these features. Osteoclasts are cells of the hematopoietic lineage that resorb bone, whereas osteoblasts are cells of mesenchymal origin that mineralize the bone matrix. The equilibrium between these two processes is tightly controlled under “normal” conditions. However,

this equilibrium can be disrupted under pathological conditions but also under naturally occurring ones. Indeed aging, affecting both males and females, reduces bone formation by decreasing the capacities of pre-osteoblasts to differentiate into mature cells (reviewed in Khosla [2]). In addition, the cessation of the ovarian functions at menopause, leading to reduced circulating levels of estrogens, results in increased osteoclast differentiation and thus enhanced bone resorption (reviewed in Manolagas et al. [3]). This leads to osteoporosis, a bone fragility syndrome that includes an increased fracture risk particularly in aging females, due to the combination of both processes. To date most treatments against osteoporosis are anti-catabolic, i.e. aim at reducing excess bone resorption by osteoclasts. However, anabolic treatments (aiming at enhancing bone formation) are starting to emerge (reviewed in Marie and Kassem [4]). Here we review data that indicate that negatively targeting the estrogen-related receptors (ERR) α and/or γ may constitute a promising approach to design anabolic treatments.

The estrogen-related receptors: ligand-independent nuclear receptors

The nuclear receptor (NR) superfamily comprises 48 members in the human that are generally defined as ligand-dependent transcription factors [5, 6]. With few exceptions, these factors all share a similar protein organization. A centrally located DNA-binding domain (DBD) composed of two zinc finger modules mediates a direct interaction with cognate response elements on the promoters of their target genes. A hinge region links the DBD to the C-terminally located ligand-binding domain (LBD). The latter is a globular structure comprising several alpha-helices and

undergoes a conformational change upon interaction with a specific ligand. This results in the production of an interaction surface that allows the recruitment of transcriptional co-activators. In turn these co-activators, directly or indirectly, induce chromatin modifications and the recruitment of the transcriptional machinery at the promoters, leading to increased expression of target genes. In addition, some but not all, receptors possess an N-terminally located domain that can mediate ligand-independent transcriptional activation.

Ligands (such as 17 β -estradiol or the thyroid hormone) had been described well before the first characterization of their cognate receptors (estrogen receptor [ER] and thyroid hormone receptor [TR]) in the mid-eighties [6]. Using newly cloned receptor sequences as probes, several other nuclear receptors have been isolated starting in the late eighties and have been referred to as “orphans” in the initial absence of an identified natural ligand. Although specific ligands have been identified for some of these receptors, a number of receptors remain orphan. This is for instance the case of the estrogen-related receptors (ERR) α and β , the first orphan receptors identified in 1988 [7]. Together with the more recently isolated ERR γ [8], they form a distinct sub-family, and display a strong level of sequence identity with each other, in particular within their DBD and LBD (Fig. 1).

Determination of the 3D structure of the LBDs of ERR α and γ has shown that these receptors display an “active” conformation, allowing to contact co-activators in the absence of any ligand in their putative ligand-binding pocket [9, 10]. Although the crystal structure of ERR β has not been published, it seems thus likely that all ERRs act as ligand-independent transcription factors, although clearly belonging to the NR superfamily (reviewed in Horard and Vanacker [11]). Several publications indicate that the transcriptional activities of the ERRs can be regulated by various processes, such as sub-cellular localization or post-translational modifications (see examples in [12–17]). One key point is, however, the capacity to interact with specific

co-modulators that can be viewed as protein ligands and may be available or not in a given cellular context (see examples in [18–20]).

Despite the capacity of the ERRs to act in a ligand-independent manner, several synthetic compounds have been identified that [positively (agonists) or negatively (inverse agonists)] modulate their transcriptional activities, more or less specifically. For instance, 4-hydroxy-tamoxifene [OHT; a selective estrogen receptor modulator (SERM) which is broadly used in breast cancer therapy] or its analog GSK5182 reduce the activities of both ERR β and γ [21–23] whereas GSK4716 and DY131 act as agonists for both receptors [24, 25]. Published literature suggests that it is difficult to identify modulators that clearly discriminate between ERR β and γ , likely because of the particularly high level of sequence identity in their LBDs. To date, one exception is bisphenol A (BPA), which counteracts the effects of inverse agonists on ERR γ in a seemingly specific manner both in vitro and in vivo [26–28]. In contrast, compounds have been isolated that specifically target ERR α , and not β or γ . This is the case of pyrido[1,2- α]pyrimidine-4-ones derivatives that act as agonists [29]. Conversely for instance XCT790 and C29 act as inverse agonists and, at least for the former, promote proteasome-dependent degradation of the receptor [30]. However, data are often lacking that could indicate whether these compounds indeed act in vivo, although this has been shown for instance for C29, GSK5182 and BPA (see [28, 31, 32]). Whether the effects of a given drug strictly depend on a given ERR species is also often an open question. Despite these restrictions, these compounds can be viewed as useful tools to study the functions of the ERRs, and may suggest promising approaches to modulate the activities of the ERRs in given pathological processes.

Physiopathological functions of the ERRs

In vitro and in vivo studies have contributed to identify several physiopathological functions played by the ERRs. ERR β is mainly expressed in embryonic tissues in the mouse and regulates placental development [33] as well as the maintenance of self-renewal in both embryonic and trophoblast stem cells [34–38]. The role played by ERR β in human embryonic tissues is unknown. It should be noted that the receptor is not expressed in human embryonic stem cells, in contrast to mouse ones, but an expression in other human embryonic tissues has not been documented to date [39]. ERR β is also involved in the specification of epithelial cells in the mouse inner ear [40]. Consistently, mutations in the human ESRRB gene (encoding ERR β) result in a form of hearing impairment [41]. It has also been shown that maintenance of the number of rod

Fig. 1 Organization of the estrogen-related receptors. The ERRs comprise two conserved domains, the centrally located DNA-binding domain (DBD) and the C-terminally located ligand-binding domain (LBD). The percentage of sequence identity within these domains is indicated relative to ERR α on the receptors, and between ERR β and ERR γ , above and below the brackets

photoreceptor cells during mouse aging depends on $ERR\beta$ but no data are available concerning the impact of the receptor on human retina [42].

$ERR\alpha$ and γ are strongly expressed in tissues with high energy demand (for instance heart, muscle, liver and fat) where they control various metabolic processes such as mitochondrial biogenesis and function, lipid uptake and oxidation, tricarboxylic acid cycle and neoglucogenesis (reviewed in [43–46]). These activities of $ERR\alpha$ and γ are exerted not only in conventional metabolic tissues but also have a considerable impact on pathological processes such as cancer (reviewed in [47–49]). For instance both receptors are at the heart of the metabolic switch referred to as the Warburg effect in which cancer cells shift from oxidative to glycolytic metabolism [20, 50, 51]). Interestingly, these receptors display opposite functions in this process as well as in the establishment of other traits of cancer progression such as proliferation and epithelial–mesenchymal transition (EMT) [52–56]. All these features are promoted by $ERR\alpha$ while repressed by $ERR\gamma$. This is consistent with $ERR\alpha$ and γ being factors of unfavorable and favorable prognosis (respectively), as described in several cancer types (review in [47, 57]). In this line, additional works have also shown that $ERR\alpha$ promotes cell migration, invasion and the establishment of metastasis [58–60].

$ERR\alpha$ is also a critical component of innate immune response, regulating the production of mitochondrial reactive oxygen species in response to γ -interferon as well as attenuating toll-like receptor inflammatory response in macrophages [61, 62].

Functions of the ERRs in mineralized tissues

$ERR\alpha$ is highly expressed in the ossification zones (long as well as flat bones) during mouse embryonic development [63] suggesting a contribution to endochondral as well as intramembranous ossification. However, examination of $ERR\alpha$ knock-out ($ERR\alpha$ KO) animals has shown that the receptor is not required for bone morphogenesis or ossification in young animals, i.e. up to 14 weeks of age, at which peak bone mass is reached [64, 65]. This was estimated by measuring both trabecular and cortical bone parameters that do not significantly vary between mutant and wild type littermates. However, $ERR\alpha$ KO animals do not lose bone with aging (i.e. between 14 and 24 weeks of age), in contrast to wild type counterparts. The latter also dramatically lose bone upon ovariectomy (which mimicks menopause in mice). In striking opposition, $ERR\alpha$ KO animals are resistant to this bone loss. As evidenced by the analysis of dynamic bone parameters, osteoclasts number and activity is unchanged whereas bone formation rate (i.e., osteoblast activity) is increased in $ERR\alpha$ KO animals

relative to wild types. Consistently, pre-osteoblasts originating from mutant animals are more prone to differentiate, express enhanced levels of osteoblast molecular markers (including those of $Runx2$, the master gene of osteoblast differentiation) and display increased mineralizing activity *ex vivo*. Taken together with the decreased capacity displayed by $ERR\alpha$ KO mesenchymal cells to differentiate, at least *in vivo*, into the adipocyte lineage [64, 66, 67], this suggests that $ERR\alpha$ affects the early determination of mesenchymal stem cells, promoting their commitment into the adipocyte lineage at the detriment of the osteoblast one (Fig. 2a). This is in contradiction with earlier results showing that overexpression of $ERR\alpha$ in pre-osteoblasts *in vitro* promotes rather than decreases osteoblast differentiation [68]. One possible explanation to reconcile these discrepant results comes from the data published by Kammerer et al. [69] who showed a complex effect of $ERR\alpha$ on $Runx2$ expression in cell culture. Indeed the receptor can stimulate or repress $Runx2$ expression in the presence of PGC-1 α or PGC-1 β , respectively. In contrast

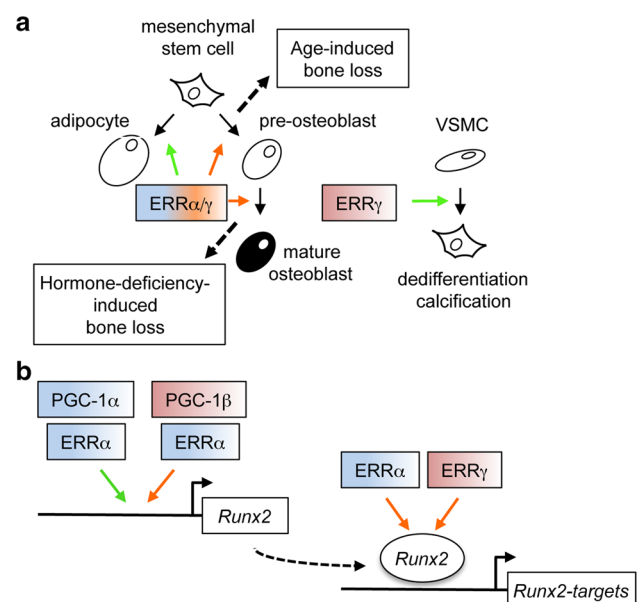

Fig. 2 Functions of $ERR\alpha$ and γ in mineralizing cells. **a** Effects of $ERR\alpha$ and $ERR\gamma$ on mineralizing cells. $ERR\alpha$ exerts early effects on mesenchymal cells inducing commitment to the adipocyte lineage (green arrow), while repressing commitment to the osteoblast one (red arrow). $ERR\alpha$ also acts later in this lineage, inhibiting osteoblast maturation, an activity shared by $ERR\gamma$. The two repressive effects of $ERR\alpha$ on osteoblast differentiation contribute to bone loss during aging and hormonal deficiency, respectively. Furthermore $ERR\gamma$ decreases trabecular bone mass but promotes calcification in vascular smooth muscle cell (VSMC). Note that the effect of $ERR\gamma$ on hormone deficiency-induced bone loss has not been investigated so far. **b** Effects of $ERR\alpha$ and γ on $Runx2$ expression and activity. $ERR\alpha$ activates (green arrow) or repress (red arrow) $Runx2$ expression in the presence of PGC-1 α or β , respectively. Both $ERR\alpha$ and γ inhibit the transcriptional activities of the $Runx2$ protein. See text for details and references

ER α activates Runx2 expression in the presence of PGC-1 β (Fig. 2b). This suggests that ER α may also indirectly promote the positive activities of ERR α by competing for PGC-1 β binding. It could be hypothesized that the expression of all these factors varies with age, hormonal status and/or pre-osteoblast differentiation state. For example, it has been shown that 17 β -estradiol regulates ER α mRNA expression and protein stability (reviewed in [70]) as well as PGC-1 α expression [71]. Taking these data together, it is thus possible that ERR α is a fine-tuning modulator of Runx2 expression and thus of osteoblast differentiation in vivo. The consequences of these subtle regulations may be cumulative and therefore would only be obvious in terms of bone mass after a given amount of time, i.e., after the occurrence of peak bone mass.

On another hand, the increased capacity of ERR α KO pre-osteoblast to differentiate ex vivo can be rescued by reintroduction of the receptor after the onset of differentiation, suggesting a later effect of ERR α , i.e., rather on osteoblast maturation [65]. It is, thus, possible that the receptor exerts two independent effects on osteoblast differentiation (early at the commitment level, late at the maturation level). In this line, it is worth noting that when ERR α is inactivated during osteoblast maturation (using conditional knock-out mice), Runx2 expression is not modulated, in contrast to that of its target genes. This suggested that the receptor also impacts on Runx2 activity, a hypothesis which has been confirmed [72]. In addition ERR α positively and directly modulates the expression of osteopontin (opn), a late marker of osteoblast maturation which inhibits mineralization [64, 65, 73–76]. Interestingly ERR α conditional knock-out animals resist to ovariectomy-induced but not to age-induced bone loss.

Altogether this shows that ERR α exerts at least two independent effects on osteoblast differentiation, resulting in two independent phenotypes in vivo. In other terms, the repressive effects of ERR α on osteoblast commitment contribute to bone aging, whereas the negative action of the receptor on osteoblast maturation participates to bone loss induced by hormone withdrawal. Although additional research is needed to determine the precise molecular mechanisms through which ERR α exerts these effects, this suggests that deactivating the receptor could increase bone formation in vivo. Targeting ERR α could thus be a promising strategy to prevent bone loss during aging and after menopause. In support to this statement, inactivating the receptor in human pre-osteoblast also leads to increased differentiation in cell culture [64]. However, it should be noted that all the above data have been obtained using a genetic inactivation of ERR α . Obviously a pharmacological approach would be preferred but, to date, no report has been published concerning the effect of ERR α -deactivating compounds on osteoblast in vitro and bone in vivo.

The complete inactivation of ERR γ in mice leads to perinatal death [77], preventing the study of the bone status of mutant animals. Cardelli and Aubin [78] recently reported that ERR γ ^{+/-} animals displayed increased trabecular bone as compared to wild type counterparts. Intriguingly this phenotype only affects males, but not females, suggesting an undocumented cross-talk of ERR γ with hormone signaling. ERR γ ^{+/-} bone phenotype can be observed as early as after 8 weeks after birth, aggravates with age and correlates with increased osteoblast number and activity in vivo. As for ERR α , inactivation of ERR γ leads enhanced pre-osteoblast differentiation ex vivo [78] as well as reduced adipocyte differentiation in vitro [79]. The former effect is thought to rely on unchecked Runx2 activity in the absence of ERR γ [80], as is again the case for ERR α [72]. A second level of ERR γ activity has been suggested with the receptor inducing the expression of miR-433, which targets Runx2 mRNA for degradation [81]. These studies suggest that ERR γ is anti-osteogenic and that its inhibition could lead to increased mineral density. Intriguingly, however, a recent report [82] shows that ERR γ promotes vascular calcification, a major component of morbidity and mortality in patients with such diseases as atherosclerosis. In cultures of vascular smooth muscle cells ERR γ expression is induced by calcification medium and in turn directly and indirectly induces the expression of BMP2. Importantly, in vivo treatment with an ERR γ specific inverse agonist reduces vascular calcification in the mouse. ERR γ is therefore anti-osteogenic in bone and pro-osteogenic in the vasculature. The mechanisms that accounts for these antagonistic activities is not clear but a recent report proposes that in liver cells, the transcriptional activation of Cyp2E1 by ERR γ can be switched off by interaction with the ROR α nuclear receptor [83]. Whether such a type of interference mechanism is at work in mineralizing cells is presently unknown. Since ERR α and ERR γ display rather similar effects on bone cells (i.e., anti-osteogenic), it will be interesting to determine whether the former also displays anti-mineralizing activities in the vasculature.

The effects of ERRs on the other major cellular component of bone (i.e., osteoclasts) have also been addressed. Study of ERR γ ^{+/-} has shown that osteoclast number and activities do not vary comparing to wild type animals [78]. Analysis of ERR α KO mice in terms of osteoclast number and activities has raised contradictory results, ranging from no variation [64, 65] or decreased parameters [84]. Noteworthy it had previously been shown that ERR α promotes osteoclast spreading and migration in cell culture [85] raising the possibility that the absence of the receptor in knock-out animals may be compensated for by unidentified factor(s). In addition an indirect effect of ERR α on osteoclasts has also been reported. Overexpression of the

receptor in xenografted breast cancer cells results in increased production of osteoprotegerin, an inhibitor of osteoclastogenesis, leading to decreased osteoclast differentiation by recipient immunodeficient mice and reduced capacity of tumor cells to metastasize in the bone [59].

Possible future directions

Both $ERR\alpha$ and γ exert anti-osteogenic effects in bone, through both overlapping and divergent mechanisms. This suggests that deactivating these receptors could be a promising approach to reduce bone loss, possibly whatever its cause, since inhibiting these receptors leads to increased bone formation. However it should be reminded that most of the results obtained to date originate from mouse models and care should be taken concerning translation to human. The activities of $ERR\alpha$ and $ERR\gamma$ appear convergent on bone, yet the receptors strikingly differ concerning their impact on cancer. $ERR\alpha$ is a factor of poor prognosis and promotes traits of cancer aggressiveness whereas $ERR\gamma$ is a factor of favorable prognosis and likely decreases cancer aggressiveness. It can therefore be hypothesized that deactivating $ERR\alpha$, in contrast to $ERR\gamma$, may reduce the risk of cancer-related side effects. The recent discovery of a pro-osteogenic effect of $ERR\gamma$ on vasculature is, however, intriguing in that it, in particular, also questions the effect of $ERR\alpha$ on this process. Whether both receptors there behave in a similar (as in bone) or divergent manner (as in cancer) is an important question to solve.

Although it is difficult to definitely exclude the possibility of a natural ligand in vivo, it is highly likely that the ERRs act as ligand-independent manner. However the activity of these receptors can be modulated by synthetic compound that impact on their protein stability and/or transcriptional activities. This renders them attractive targets to tackle pathophysiological processes in which they are involved. The ability of these specific compounds to modulate the activities of the ERRs in vivo is only starting to be studied and there is no doubt that efforts will be developed in this direction.
