Abstract To date, only three types of full-length *mariner* elements have been described in ants, each one in a different genus of the Myrmicinae subfamily: *Sinvmar* was isolated from various *Solenopsis* species, *Myrmar* from *Myrmica ruginodis*, and *Mboumar* from *Messor bouvieri*. In this study, we report the coexistence of three *mariner* elements (*Tnigmar-Si*, *Tnigmar-Mr*, and *Tnigmar-Mb*) in the genome of a single species, *Tapinoma nigerrimum* (subfamily Dolichoderinae). Molecular evolutionary analyses of the nucleotide sequence data revealed a general agreement between the evolutionary history of most the elements and the ant species that harbour them, and suggest that they are at the vertical inactivation stage of the so-called *Mariner* Life Cycle. In contrast, significantly reduced levels of synonymous divergence between *Mboumar* and *Tnigmar-Mb* and between *Myrmar* and *Botmar* (a *mariner* element isolated from *Bombus terrestris*), relative to those observed between their hosts, suggest that these elements arrived to the species

that host them by horizontal transfer, long after the species' split. The horizontal transfer events for the two pairs of elements could be roughly dated within the last 2 million years and about 14 million years, respectively. As would be expected under this scenario, the coding sequences of the youngest elements, *Tnigmar-Mb* and *Mboumar*, are intact and, thus, potentially functional. Each *mariner* element has a different chromosomal distribution pattern according to their stage within the *Mariner* Life Cycle. Finally, a new defective transposable element (*Azteca*) has also been found inserted into the *Tnigmar-Mr* sequences showing that the ant genomes have been invaded by at least four different types of *mariner* elements.

Keywords Transposon · *Mariner* elements · *Tapinoma nigerrimum* · Hymenoptera · Formicidae

Introduction

Transposable elements (TEs) are repeated DNA segments able to change from one locus to another within the genome of their hosts. They fall into two main categories, class I and class II, according to their structure and transposition mechanism involving RNA or DNA molecules as intermediates for their mobility (Wicker et al. 2007).

Mariner elements are class II TEs. *Mos1*, isolated from *Drosophila mauritiana*, was the first *mariner* element discovered (Jacobson et al. 1986). Elements with similar motifs or *mariner*-like elements (MLEs) belong to a large and varied superfamily named *IS630-Tc1-mariner* (*ITm*), which is widespread and abundant in eukaryotic genomes (Bouuaert and Chalmers 2010; Zhou et al. 2011; Diao et al. 2011, among others). The *ITm* superfamily is further divided into several families based on the characteristics of their catalytic triad, D(Asp)DE(Glu) or DDD (Shao and Tu 2001; Diao et al. 2011). The catalytic motif of the *mariner*

family is DD(34)D (three aspartic acid residues in conserved positions, the last two separated by 34 residues)(Robertson 1996; Lohe et al. 1997). MLEs are about 1.3 kb in length and have one intronless open reading frame (ORF) which encodes a transposase. They are flanked by inverted terminal repeats (ITRs), usually about 28–30 bp long, although they can be considerably larger (Leroy et al. 2003) and generally show the 5'-YYAGRT consensus at their outer ends (Langin et al. 1995). The conservation of two regions at positions 3–8 and 14–18 of the ITRs with sequence logos AGGTBK and WARRK, respectively, has also been reported (Lampe et al. 2001). MLE transposases have two domains, the N-terminal ITR-binding domain containing a helix–turn–helix (HTH) motif, and a C-terminal catalytic domain with the conserved catalytic triad. The conservation of the bipartite nuclear location signal (NLS), flanked by phosphorylation target sites of casein kinase II, has also been suggested (Lohe et al. 1997; Plasterk et al. 1999). The amino-acid sequences WVPHEL and YSPDLAP (I/S/T) separated by about 150 amino-acid residues, are also conserved motifs (Robertson and MacLeod 1993; Augé-Gouillou et al. 2005).

Most MLEs described to date, carry mutations that disrupt their ORFs (generate early stop codons and/or frame-shifts) as well as degenerated ITRs, which cause a reduction or complete loss of their ability to transpose. The so-called *Mariner* Life Cycle includes three stages: the invasion of a new host by horizontal transfer (HT), proliferation in the host genome, and vertical inactivation as a result of the accumulation of mutations (Robertson and Asplund 1996; Hartl 2001).

Three criteria have been used to infer the existence of HT processes: (1) high sequence similarity between the TEs from phylogenetically distant hosts, (2) incongruence between the phylogenies of host and TEs, and (3) discontinuous distribution (patchy distribution) across a group of taxa (reviewed by Loreto et al. 2008). At present, the comparison between the nucleotide divergences at synonymous sites (K_S) observed in TEs and in the nuclear genes of the hosts is considered the best method to infer HT processes. The rationale is that the time to the most recent common ancestor of horizontally transferred transposons might be significantly shorter than that between the species that host them, so that they have had less time to accumulate mutations than the nuclear genes of their hosts (Sánchez-Gracia et al. 2005; Bartolomé et al. 2009; reviewed by Schaack et al. 2010).

Hitherto, only three full-length *mariner* elements have been described in ants, each one in a different genus. They belong to the *mauritaniana* subfamily, included in the *mariner* family (Lampe et al. 2003; Silva et al. 2005; Rouault et al. 2009). *Sinvmar* has been isolated from *Solenopsis invicta* and from other species from the *Solenopsis* genus (Krieger and Ross 2003), *Myrmar* from *Myrmica ruginodis* (Bigot et al. 1994;

Rouleux-Bonnin et al. 2005), and *Mboumar* that has been isolated from *Messor bouvieri* (Palomeque et al. 2006). Previously, partial *mariner* elements had been isolated in the *Tapinoma sessile* and *Crematogaster cerasi* genomes (Robertson and MacLeod 1993). Among all ant MLEs, only *Mboumar* was found to codify a full-length active transposase (Palomeque et al. 2006; Muñoz-López et al. 2008). Until now, only three active transposons had been found: *Mos1* (Medhora et al. 1991; Hartl 2001), *Famar1* from the European earwig, *Forficula auricularia* (Barry et al. 2004) and *Mboumar-9* (Muñoz-López et al. 2008). In ants, the three types of *mariner* elements described have been studied only in the ant genera indicated, except the *Myrmar* element, which has also been found in the bumblebee *Bombus terrestris* (Hymenoptera, Apidae), a species also included in the order Hymenoptera but phylogenetically far from the ants (Rouleux-Bonnin et al. 2005).

The genetic system of the host species is a significant factor on the dynamics of the MLEs and other TEs (reviewed by Hua-Van et al. 2011). The ants (Hymenoptera, Formicidae) are haplodiploid with haploid males. In haploid males TEs with recessive deleterious effects will be unmasked and they will be exposed to selection. For this reason, they would be expected to be readily eliminated from the haplodiploid genomes (Hurst and Werren 2001), so that the incidence of TEs should be relatively low in these genomes. Bigot et al. (1994) found MLEs on different Hymenopteran species of wasps, bees and on the ant *Myrmica ruginodis*, as previously mentioned. The authors suggested that this wide distribution of MLEs could be explained by the lack of deleterious effects of these elements on the viability of insects due to their preferential insertion in a specific and conserved sequences where its insertion may be selectively neutral (Bigot et al. 1994; Rouleux-Bonnin et al. 2005). However, other authors have suggested that the conservation of these sequences may simply be the result of the ancient insertion of a *mariner* element before the divergence of the host species (Haine et al. 2007). Despite the fact that ant males do not undergo meiotic recombination, a high recombination rate has been found in the ants *Acromyrmex echinator* and *Pogonomyrmex rugosus* and in several species of honeybees and wasps (Meznar et al. 2010; Niehuis et al. 2010; Sirviö et al. 2011). Different hypotheses have been proposed to explain this high recombination rate; generally it has been considered as evolutionarily selected among Hymenopteran insects, although the role of selection has not been demonstrated (Sirviö et al. 2006; Niehuis et al. 2010; Sirviö et al. 2011). Overall, the existence of a low or high genetic variability in ants is still a matter of debate (Viginier et al. 2004; Wilfert et al. 2007; Wysocka et al. 2011). Few studies have been made so far on the variability and incidence of MLEs in ant genomes.

This study aims to determine whether on the genome of the ant *Tapinoma nigerrimum*, coexist the three different

MLEs described in other ant species, and to provide an estimate of their genetic diversity, chromosome location and life cycle stage. We conducted this study in *T. nigerrimum* because the genus *Tapinoma* belongs to the Dolichoderinae subfamily (Hymenoptera, Formicidae) whereas the genera *Myrmica*, *Solenopsis* and *Messor* belong to the Myrmicinae subfamily (Hymenoptera, Formicidae). The divergence between both subfamilies seems to have occurred about 110 million years ago (Moreau et al. 2006). If any of the three full-length *mariner* element described in ants were present on *Tapinoma*, the comparison of the phylogenies of *mariners* and their host species might provide interesting data on the life cycle of these *mariner* elements. To amplify the *mariner* sequences, primers complementary to conserved regions of the transposons were used. A given species may contain several types of *mariner* in its genome if it has suffered multiple invasion events. Consequently, the lack of congruence between phylogenies may be due to the comparison of non-orthologous sequences. For this reason and in agreement with other authors (Krieger and Ross 2003) we have used specific primers enabling the amplification of a single type of element. The chromosomal localization of TEs is another important feature. TEs are not distributed at random throughout the chromosomes. They are frequently located in constitutive heterochromatin, especially centromeres and telomeres, where their potential deleterious effect is limited (Charlesworth et al. 1994; Bartolomé et al. 2002; Fontanillas et al. 2007). It has also been suggested that TEs could be involved in centromere and telomere function (reviewed by Hua-Van et al. 2011). Detailed cytogenetic studies are very limited in ants (Lorite and Palomeque 2010) being *T. nigerrimum* one of the few exceptions, a fact that allows the present study.

Material and methods

Material, DNA extraction, PCR amplification and cloning

Tapinoma nigerrimum and *Messor bouvieri* adult workers were sampled in the province of Jaén (Spain). *Solenopsis invicta* was collected in the Louisiana University Campus (Louisiana, USA) and *Myrmica ruginodis* in Tours (France). Genomic DNA was extracted from pools of 10–15 ants from each sample, following Heinze et al. (1994).

Specific primers were designed in order to amplify the different *mariner* elements. For *Myrmar*-like insertions a unique primer was designed using the ITR sequence of the published *Myrmar mariners* (Bigot et al. 1994; Rouleux-Bonnin et al. 2005) (Mrug-MAR 5'-CCAGGTCTGTAATATGAAACCGGAAT). Only one primer was necessary since the 5'-ITRs and the 3'-ITRs of these elements are highly conserved. Also, only a unique primer was necessary

for amplification of the *Mboumar*-like *mariners*. This primer (ITR-MAR 5'-CCAGGTGTGTCGGTAATTCCTTTCCGG) was based on the ITR sequences of *Mboumar mariner* (Palomeque et al. 2006). On the contrary, since 5'-ITRs and 3'-ITRs of *Sinvmar* are known to be different (Krieger and Ross 2003), two primers were used for *Sinvmar*-like *mariner* amplification (Sinv-mar-1 5'-TTAGGTGTTAACTTAATTCCTGCCGCT and Sinv-mar-2 5'-AATTGAAGGTA ACTTAATTCCTGCCGTT).

PCR amplifications were initially denatured at 92 °C for 2 min and performed using the following cycling profile: 30 cycles at 92 °C (30 s), 50 °C (30 s), 72 °C (2 min), with a final elongation step of 72 °C for 5 min. Reactions were set up in a 50- μ l mixture containing 100 ng of genomic DNA, 0.5 mM dNTPs, 50 pmol of the primer and 1 U of *Taq* polymerase. The amplified fragments were analyzed by electrophoresis in agarose gels, eluted from agarose gel and cloned into the pGEM-T Easy vector (Promega). For all PCRs, only the most intense and clear fragments were studied. Recombinant plasmids were sequenced on both strands by the dideoxy sequencing method.

Three nuclear gene fragments were amplified in the ant species; *wingless* (*wnt-1*), *abdominal-A* (*abdA*) and *long-wavelength rhodopsin* (*lw Rh*). The *wnt-1* fragment was amplified using the primers Wg578F (5'-TGCACNGTGAARACYTGCTGGATGCG) and Wg1032R (5'-ACYTCGCAGCACCARTGGAA) (Abouheif and Wray 2002; Ward and Downie 2005). For the *abdA* gene the primers ant-M (5'-CGGCACCGCGATATGAGTACGAAATTC) and ant-J (5'-GGGTTGTTGGCAGGATGTCAAAGGATG) (De Menten et al. 2003) were used. The *lw Rh* gene fragment was amplified using the primers LR143F (5'-GACAAAGTKCCACCRGARATGCT) and LR639ER (5'-YTTACCGRTTCCATCCRAACA) (Ward and Downie 2005). PCR reactions were initially denatured at 94 °C for 2 min and then subjected to 35 cycles at 94 °C (60 s), 45–56 °C (60 s), 72 °C (2 min), with a final elongation step of 72 °C for 5 min. Reactions were set up in a 50- μ l mixture containing 100 ng of genomic DNA, 0.5 mM dNTPs, 50 pmol of the primer and 1 U of *Taq* polymerase. The amplified fragments were analyzed by electrophoresis in agarose gels. Eluted fragments were directly sequenced on both strands using the same primers used for PCR amplification.

Sequence analyses

Multiple-sequence alignments were initially performed using CLUSTALW (Larkin et al. 2007) and MUSCLE (Edgar 2004), and corrected by hand in order to maintain the open reading frame of the coding sequences. Sequence comparisons, ORF search, and other sequence analyses were performed using the available online programs from NCBI

(<http://www.ncbi.nlm.nih.gov/guide/>). The NSP@Network Protein Sequence Analysis program was used for the prediction of helix–turn–helix motifs (http://npsa-pbil.ibcp.fr/cgi-bin/npsa_automat.pl?page=npsa_hth.html). The putative TATA box and polyadenylation signals were determined using the programs HCtata (Hamming Clustering Method for TATA Signal Prediction in Eukaryotic Genes) and HC polyA (Hamming Clustering Poly-A Prediction in Eukaryotic Genes). The phosphorylation target sites at casein kinase II were determined using the Motif Finder program (<http://motif.genome.jp/>). Searches of repetitive element-related sequences were performed using RepeatMasker Web Server (<http://www.repeatmasker.org/cgi-bin/WEBRepeatMasker>).

Molecular evolutionary analyses

The level of genetic diversity among groups of sequences was estimated by means of π (Nei 1987), which measures the average number of nucleotide differences per site between pairs of sequences, using the Jukes and Cantor correction. Standard errors were estimated by bootstrap (1,000 replications).

Evolutionary distances between groups of sequences were measured as the average number of pairwise nucleotide differences per site. Estimates of nucleotide divergence at all sites were obtained using the Maximum Composite Likelihood method (Tamura et al. 2004), and at synonymous sites (K_s) using the Kumar model (Nei and Kumar 2000). Standard errors of these estimates were calculated by bootstrap (1,000 replicates). These calculations were made with the aid of MEGA 5.0 (Tamura et al. 2011).

Phylogenetic relationships among the *mariner* sequences we explored using neighbor-joining (NJ) and maximum likelihood (ML). The nucleotide substitution models were evaluated using MEGA 5.0, the models with the lowest BIC scores (Bayesian Information Criterion) were considered better to describe the substitution pattern (Tamura et al. 2011). Using this criterion the best model chosen was Tamura 3-parameter assuming a fraction of sites evolutionarily invariable (T92+I). NJ and ML trees were constructed using MEGA 5.0 (Tamura et al. 2011). Bootstrap values for each branch were assessed from 1000 replicates in both cases. The *mariner Ammar1* (Genbank accession no. AY154751) from *Apis mellifera* was used as an out-group in the phylogenetic analyses. This *mariner* belongs to the *mellifera* subfamily (Lampe et al. 2003).

In order to determinate the phylogenetic relationships of the *mariners* described in this report with other *mariner* elements, phylogenetic analyses were also performed using transposase amino acid sequences from several representative *mariner* subfamilies (Lampe et al. 2003; Krieger and Ross 2003; Bui et al. 2008) (Table S1). In the phylogenetic

analyses, the *Fusarium oxysporum impala* transposase (GenBank accession no. AAB33090) was used as an out-group as Krieger and Ross (2003). For *Mboumar* and *Tnigmar-Mb mariner* their putative transposase sequences were used. For the *Solenopsis* species *mariner*, *Tnigmar-Si*, *Myrmar* and *Tnigmar-Mr* the transposase of the more likely ancestral active *mariner* was built using the consensus sequences. The best amino acid substitution model was evaluated using MEGA 5.0 (Tamura et al. 2011). Results showed that the best-fit amino acid substitution model was the WAG model with a proportion of invariant sites (WAG+I). ML trees were built using MEGA 5.0 and support values were determined by bootstrap analyses with 1,000 replicates.

In situ hybridization procedures

Chromosome spreads were obtained from adult male gonads. In situ hybridization was carried out as described previously (Lorite et al. 2002; Palomeque et al. 2005). The *mariner* probes (*Tnigmar-Si-16*, *Tnigmar-Mr-3*, and *Tnigmar-Mb-1*) were labeled with biotin-16-dUTP using a biotin nick translation kit (Roche). Fluorescence immunological detection was performed using the avidin–FICT/anti–avidin–biotin system with three rounds of amplification. The preparations were counterstained with propidium iodide and DAPI. FISH was carried out in high-stringency conditions to avoid co-hybridization among different *mariner* types (Palomeque et al. 2005). The temperature used for hybridization was 37 °C and post-hybridization washes were performed at 42 °C in 50 % formamide. These stringency conditions allow hybridization between DNA–DNA duplex sharing approximately 80–85 % sequence homology (McClellan 1998).

Results

Isolation and sequence analyses of *mariner* elements

Three independent PCR amplification assays were performed using *T. nigerrimum* DNA as a template and specific primers for the ITR sequences of *Sinvmar* (Krieger and Ross 2003), *Myrmar* (Bigot et al. 1994; Rouleux-Bonnin et al. 2005) and *Mboumar* (Palomeque et al. 2006) *mariner* TEs. A thin band of about 1.3 kb, three clear amplification bands with different sizes (about 2,200, 900, and 400 bp) and an intense band of about 1.3 kb, were obtained with each primer set, respectively (Fig. S1).

BLAST analyses from the cloned PCR products revealed that the sequences were highly homologous to the elements used to design the primers. Following the nomenclature proposed by Robertson and Asplund (1996) with our own

modification, the *mariner* elements were named *Tnigmar-Si*, *Tnigmar-Mr*, and *Tnigmar-Mb* (*T. nigerrimum mariner* similar to the *S. invicta mariner*, *M. ruginodis mariner* and *M. bouvieri mariner*, respectively). In addition, a new defective MLE sequence was found in *Tapinoma nigerrimum*. It was inserted into *Tnigmar-Mr*. BLAST analyses showed that it displays high homology with a sequence present in the *Azteca instabilis* ant genome and we named it *Tnigmar-Az*. The features of this MLE will be exposed later.

Six *Tnigmar-Si* sequences were obtained (*Tnigmar-Si*-1, -3, -5, -16, -17 and -20; Fig. S2, GenBank accession no. HE577153 to HE577158). They are very similar, with just six segregating variants ($\pi=0.001\pm 0.0006$). The ORF of all sequences are interrupted by stop codons and frameshift mutations which are likely to render them inactive. *Tnigmar-Si* displays little divergence from other *mariner* elements described in *Solenopsis invicta* (*Sinvmar*) as well as in other species from the same genus, such as *S. macdonaghi* (*Smacmar*), *S. richteri* (*Sricmar*), and *S. saevissima* (*Ssaemar*) (Krieger and Ross 2003), with an average synonymous divergence of the order of 0.23 (Table 1). The consensus sequence of *Tnigmar-Si* is shown in Fig. 1. Conceptual translation and their phylogenetic analyses showed that these elements belong to the *mauritiana* subfamily of the *mariner* elements (Fig. 3 and Fig. S3). From here on, they will be referred to as the *Solenopsis mariner* group.

In a second set of experiments using the primers specific for *Myrmar*, we obtained sequences from ten different clones. Six of them were 2,174–2,175 bp long (*Tnigmar-Mr*-1, -2, -4, -5, -6, and -7. GenBank accession no. HE577159 to HE577164) and were interrupted by the insertion of a 901- to 902-bp fragment of another MLE at position 967 of the alignment (Fig. 2), which we have named *Tnigmar-Az* (see above). The six *Tnigmar-Mr* sequences display little sequence diversity, with just seven singleton variants in the remaining 1,279 nucleotides ($\pi=0.003\pm 0.002$). The phylogenetic analysis of *Tnigmar-Mr* revealed that they were closely related to

Myrmar, and also to *Botmar* of *Bombus terrestris* (Rouleux-Bonnin et al. 2005) and as shown in Fig. 3. The consensus of *Tnigmar-Mr* sequences is shown in Fig. 1. The putative ORFs of the *Tnigmar-Mr* sequences were interrupted by several mutations causing frameshifts and early stop codons. Conceptual translation of *Myrmar*, *Botmar* and *Tnigmar-Mr* elements and their phylogenetic study suggest that they also belong to the *mauritiana* subfamily of the *mariner* element and from here on they will be referred to as the *Myrmica mariner* group (Fig. 3 and Fig. S3). The other four clones (*Tnigmar-Mr*-3, -8, -9, and -11) corresponded to internally deleted forms of *Tnigmar-Mr* sequences (Fig. 2 and Fig. S4) (GenBank accession no. HE5771657, HE577165, HE577166, and HE577168).

Four sequences, *Tnigmar-Mb*-1, -2, -3 and -5, were obtained with the primers specific for *Mbourmar* (GenBank accession no. HE577149 to HE577152). Again, the sequences displayed reduced genetic diversity ($\pi=0.004\pm 0.0011$). The *Tnigmar-Mb* consensus sequence (Fig. 1) included a full-length ORF. This element is nearly identical ($K_S=0$; Table 1) to *Mbourmar* previously described in *M. bouvieri* (Palomeque et al. 2006). A phylogenetic analysis suggests that these two elements belong to the *mauritiana* subfamily of the *mariner* elements, and from here on they will be named the *Messor mariner* group (Fig. 3 and Fig. S3).

Figure 4 shows the alignment between *Mbourmar-9* and the sequences isolated from *T. nigerrimum*. These sequences showed a high nucleotide identity. The ITRs of *Tnigmar-Mb* elements showed conservation of the consensus 5'-YYAGRT motif (Langin et al. 1995) and the other nucleotide positions considered important in the transposition processes (Lampe et al. 2001). The two ITRs from *Tnigmar-Mb* were perfect inverted repeat sequences as a result of the amplification technique used, showing two nucleotide differences at 3'-ITR in relation to *Mbourmar-9* and only one in relation to other *Mbourmar* elements. *Tnigmar-Mb* also had a putative TATA box (position 57), except on *Tnigmar-Mb*-5, and a polyadenylation signal (position

Fig. 1 Alignment of the consensus sequences of the three full length different types of isolated *mariner* elements: *Tnigmar-Si*, *Tnigmar-Mr*, and *Tnigmar-Mb*. The corresponding ITRs are shaded

1206) like *Mboumar-9*. A conceptual translation and search for ORF showed that *Tnigmar-Mb-5* has a stop codon (Fig. 4). However, *Tnigmar-Mb-1*, -2, and -3 contained a full-length open reading frame which codified a putative

protein with a very strong similarity to the active Mboumar transposase (Muñoz-López et al. 2008). The putative transposase codified by *Tnigmar-Mb* contains the conserved DD (34)D motif and all the characteristic motifs of an active

Fig. 2 Schematic representation of the clones obtained using as a primer the ITRs of the *mariner* transposable element *Myrmar* isolated from the ant *Myrmica ruginodis* (Bigot et al. 1994; Rouleux-Bonnin et al. 2005), showing the *Azteca* element (*Tnigmar-Az*) inserted into a *Tnigmar-Mr mariner* (a and b). The duplication of TA dinucleotide

and the nucleotide insertion site are also represented. The nucleotide positions of the internal deletions shown by clones of 900–901 bp (c) and 392 bp (d) are also indicated. Only clones marked with an asterisk have been obtained by PCR amplification techniques

transposase (Fig. 4.) All together, the data suggest that *Tnigmar-Mb* is an active TE.

Phylogenetic analyses

The three full-length *mariner* elements isolated from *Tapi-noma nigerrimum* belong to the *mauritiana* subfamily although they were clearly different as revealed by the large levels of synonymous nucleotide divergence between them. K_S between *Tnigmar-Mr* and *Tnigmar-Mb* is 0.76 ± 0.100 , and between them and *Tnigmar-Si* slightly exceeds 1.00 in both cases (Table 1).

The evolutionary relationships among the MLEs found in *T. nigerrimum* and those from other ants and the bumblebee are depicted in Fig. 3. The phylogenetic tree shows three

highly supported clades that correspond to the *Solenopsis*, *Messor* and *Myrmica mariner* groups previously described. *Tnigmar-Si* and *Tnigmar-Mr* are well differentiated from the other members of their respective groups, which is consistent with the expected phylogenies of their hosts and supports the hypothesis that these elements have been vertically transmitted (Fig. 3). The phylogenetic analyses using all sequences of each type of *mariner* also showed the same results (Fig. S5). Contrastingly, *Myrmar* is more closely related to *Botmar* than to *Tnigmar-Mr* which seems at odds with the host’s phylogeny, since *Botmar* was isolated from *Bombus terrestris*, a bumblebee from a different Hymenoptera family. Furthermore, *Mboumar* and *Tnigmar-Mb* clustered together in a single monophyletic group and they are nearly identical (see above). Such high similarity is

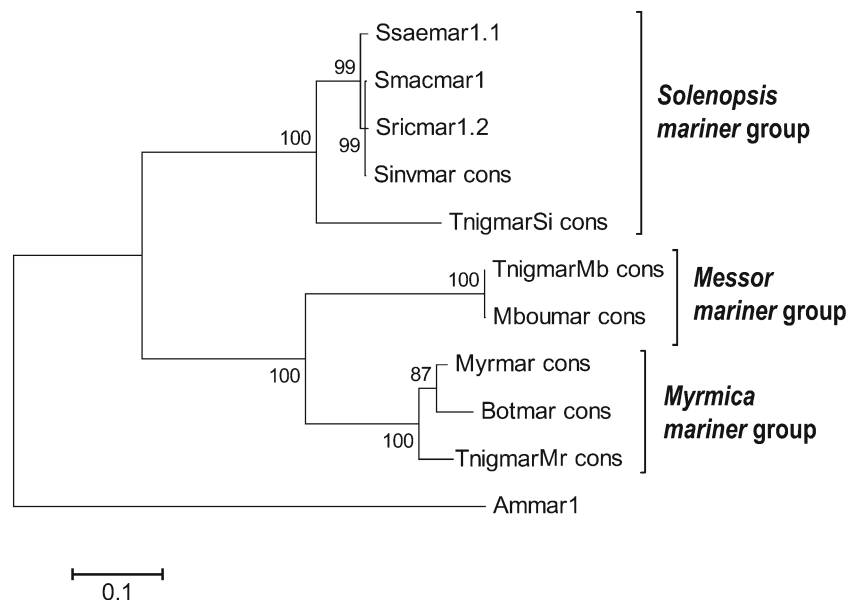

Fig. 3 Maximum-likelihood tree depicting the phylogenetic relationships of the *mariner* elements. The sequences of four elements were retrieved from GenBank: *Ssaemar1.1* (*Solenopsis saevissima*, AF518177; *Sricmar1.2* (*Solenopsis richteri*), AF518176; *Smacmar1* (*Solenopsis macdonaghi*), AF518174 and *Ammar1* (AY155490). *Ammar1* a *mariner* element from *Apis mellifera* was used as outgroup. When several sequences for the same *mariner* were available consensus

sequences were used: *Botmar* (*Bombus terrestris*, AJ312716, AJ312717, AJ312720, AJ312722); *Sinvmar* (*Solenopsis invicta*, AF518169 to AF518173), and *Myrmar* (*Myrmica ruginodis*, AY652423 to AY652426). Branches with bootstrap support values greater than 80 % are indicated. The scale bar represents the number of substitutions per site units. Neighbor-joining (NJ) methods produced similar topologies

Fig. 4 Alignment of the *Mboumar-9* sequence (Palomeque et al. 2006) and all *Tnigmar-Mb* sequences. The ITRs are shaded. The putative proteins codified by *Mboumar-9* and *Tnigmar-Mb* sequences are also shown as well as the TATA box, the bipartite nuclear location signal (NLS), the conserved D,D(34)D motif and other important features. An asterisk indicates the stop codon in the ORF on *Tnigmar-Mb-5* sequence

unexpected as their host species belong to different ant subfamilies (Myrmicinae and Dolichoderinae, respectively), whose split has been dated about 110 mya (Moreau et al. 2006).

Estimates of K_S between the *mariner* element and same data from nuclear genes are shown in Tables 1 and 2, respectively. We obtained the nucleotide sequences of three single-copy nuclear genes, *abdominal-A* (*abdA*), *long wavelength rhodopsine* (*lw Rh*) and *wingless* (*wnt-1*) from *T. nigerrimum*, and of *lw Rh* and *wnt-1* from *M. bouvieri* and *M. ruginodis* (GenBank accession no. HE963096 to HE963102). We also retrieved from GenBank sequences of these same loci from *S. invicta*, *B. terrestris* and other species of all genera (Table S2). Although we were unable to obtain the *abdA* sequence from *M. bouvieri* samples after repeated attempts, this locus has been sequenced in other *Messor* species (*M. julianus*, *M. denticornis* and *M. andrei*; Brady et al. 2006; Table S2). The synonymous differentiation between *T. nigerrimum* and *M. bouvieri* at *lw Rh* and *wnt-1* were 0.28 ± 0.083 and 0.40 ± 0.080 , respectively. Mean K_S at *abdA* locus between different *Messor* species (Table S2) and *T. nigerrimum* was of the order of 0.42, which was not significantly different from that observed at the other two loci between *T. nigerrimum* and *M. bouvieri*. These values are in good agreement with our estimate of average $K_S = 0.36 \pm 0.010$ across the three loci between various species of these two genera (Table 2).

Chromosomal location of *mariner* elements

The chromosome number of *T. nigerrimum* is $n=9$. All chromosomes showed heterochromatin on pericentromeric regions according to standard C-banding technique results

Table 2 Estimates of mean synonymous divergence at *abdA*, *lw-Rh* and *wnt-1* between ant and bumblebee genera

	<i>Tapinoma</i>	<i>Myrmica</i>	<i>Messor</i>	<i>Solenopsis</i>	<i>Bombus</i>

<i>Myrmica</i>	0.31		0.015	0.017	0.099
<i>Messor</i>	0.36	0.25		0.009	0.005
<i>Solenopsis</i>	0.31	0.22	0.21		0.037
<i>Bombus</i>	0.80	1.05	0.88	0.91	

Mean K_S values and standard errors are indicated below and above the diagonal, respectively. These values were obtained using the sequences of the three loci from several species of each genus (see Table S2 for details)

(Palomeque et al. 1988). The results showed that each type of *mariner* element has a different hybridization pattern (Fig. 5). Only one or two positive hybridization signals in some chromosomes were found when *Tnigmar-Si* sequence was used as probe. In addition, the positive signals were not located in the pericentromeric regions (Fig. 5a). On the contrary, *Tnigmar-Mr* and specially *Tnigmar-Mb* were more widespread in the genome of *T. nigerrimum* and numerous hybridization signals were visible in all chromosomes (Fig. 5b, and c). These signals appeared both in pericentromeric regions as in the euchromatic chromosome arms. In this species the rDNA genes are located in the proximal region of short arm of chromosome 6 (Lorite et al. 1997). This region presented hybridization signals when *Tnigmar-Mr* or *Tnigmar-Mb* was used as a probe (Fig. 5c and b). However, the distribution patterns of both types of *mariner* were not the same. First and overall, positive hybridization signals were more numerous when *Tnigmar-Mb* was used as a probe. In addition there were regions with numerous copies of the *Tnigmar-Mb* but few or none of the *Tnigmar-Mr* (e.g., the long arm of chromosome 2), with the opposite pattern (e.g., the long arm of chromosome 4) or with a similar hybridization patterns (e.g., chromosome 5) (Fig. 5b3 and c3).

Analysis of new transposable elements-related sequences

Inserted into *Tnigmar-Mr* sequences, we found a sequence related to the TE, as mentioned above. *Tnigmar-Az* was inserted into a TA dinucleotide, as usual for *mariner* elements (Fig. 2 and Fig. S4). All sequences were very similar, with 901–902 bp in length and with perfect ITRs of 29–30 bp (Fig. S6). They could codify a polypeptide (208 aa) according to the results obtained using the ORF Finder program from NCBI. DELTA-BLAST (Boratyn et al. 2012) analysis showed that the conceptual translated nucleotide presented a possible motif HTH and part of the catalytic motif of the MLEs transposase. The comparison between the 208-aa polypeptide and the transposases of other MLEs suggested that the *Tnigmar-Az* sequences might have been generated by an internal deletion from a full length *mariner* which would include part of the catalytic motif, consequently the polypeptide would not active (Fig. S7). On the insertion into *Tnigmar-Mr* could be involved an active *Tnigmar-Az* in which the internal deletion took place quickly or a deleted sequence and a trans-acting transposase generated by a functional transposon. The phylogenetic analyses indicated that *Tnigmar-Az* was near to the *marmoratus mariner* subfamily (Fig. S3), defined by Bui et al. (2008).

This element was also present in the *Azteca instabilis* ant genome and we named it *Ainsmar-Az*. *Ainsmar-Az* was found inserted into the TA dinucleotide (position 507) from the carbomoylphosphate synthase (CAD) gene (Ward et al. 2010; GenBank accession no. FJ939902). It was inserted

Fig. 5 Chromosomal location of the three types of *mariner* elements. Metaphase plates of *T. nigerrimum* with chromosomes stained with DAPI fluorochrome (**a**, **d**, and **g**) and in situ hybridization with

Tnigmar-Si (**b**), *Tnigmar-Mr* (**e**), and *Tnigmar-Mb* (**h**) as probes. Karyotypes showing the different hybridization pattern obtained with *Tnigmar-Si* (**c**), *Tnigmar-Mr* (**f**), and *Tnigmar-Mb* (**i**). Bar=5 μ m

into the first intron of the gene sequence according to the study of corresponding protein (GenBank accession no. ADD13205.1) (Fig. S8). A similar sequence was found in a BAC clone from the butterfly *Heliconius melpomene* (Lepidoptera, Nymphalidae) (GenBank accession no. CU856076) (Fig. S9). It was also inserted into a TA dinucleotide (position 15.872). In addition, the *Ainsmar-Az* sequence was present only in the gene of *A. instabilis*, but not in the same gene from related species (Ward et al. 2010, GenBank accession no. FJ939903 and FJ939904). This fact suggests that at some point in time it had to be active. Similar results have been reported in the study of *Bmmar2*, a type of *mariner* element isolated from the silkworm *Bombyx mori* (Lepidoptera, Bombycidae) and in other related species (Kumaresan and Mathavan 2004), with incomplete versions of the transposon inserted in non-coding regions of some genes.

Discussion

In this study, we report the coexistence of three *mariner* elements (*Tnigmar-Si*, *Tnigmar-Mr*, and *Tnigmar-Mb*) in the genome of a single species, *Tapinoma nigerrimum* (subfamily Dolichoderinae). They belong to the *mauritiana* subfamily of MLEs and are closely related to the three different types of *mariner* TEs that have been described in three ant genera of the Myrmicinae subfamily: *Solenopsis*, *Myrmica*, and *Messor*.

Tnigmar-Si sequences showed high similarity and they were predictably inactive. Similar results have been reported by Krieger and Ross (2003) from other *mariner* elements described in *Solenopsis invicta* (*Sinvmar*) and in other species of the same genus (Krieger and Ross 2003). The high similarity between *Tnigmar-Si* sequences could be explained by biological processes such as their recent non-

autonomous mobilization by transposases coded by other active transposons, or a high rate of gene conversion among insertions. However, the facts that all the substitutions are found just in a single sequence of the samples (singletons) and that a similar scenario was obtained for most other elements in this, as well as other studies (Krieger and Ross 2003; Bigot et al. 1994; Rouleux-Bonnin et al. 2005; Palomeque et al. 2006), mean that we cannot discard the possibility that these singletons substitutions correspond to nucleotide miss-incorporations during the PCR amplification procedure.

The *Tnigmar-Mr* elements were closely related to *Myrmar* of *M. ruginodis*, and also to *Botmar* of *Bombus terrestris* (Rouleux-Bonnin et al. 2005). The *Tnigmar-Mr* sequences also were predictably inactive sequences. A similar situation occurred with the *mariner* sequences from *M. ruginodis* and *B. terrestris* (Bigot et al. 1994; Rouleux-Bonnin et al. 2005). Elements corresponding to internally deleted forms of *Tnigmar-Mr* were also found. Deletion derivatives have also been isolated in *M. ruginodis* and *B. terrestris* by Bigot et al. (1994) and Rouleux-Bonnin et al. (2005) as well as other organisms (Rezende-Teixeira et al. 2010, among others). The transposition mechanism of “cut-and-paste” of these elements requires the repair of the gaps left in the excision process; incorrect repairs may give rise to the observed deletions, as suggested by other authors (Brunet et al. 2002).

A new defective MLE sequence *Tnigmar-Az* was inserted into *Tnigmar-Mr*. It showed the structure of a *mariner* element with an internal deletion. *Tnigmar-Az* was inserted always in the same position into *Tnigmar-Mr* sequences suggesting a single transposition event, followed by the subsequent transposition of the surrounding element. A similar sequence was found inserted into an intron of a gene from *Azteca instabilis* ant. It is the first time in Hymenoptera that a *mariner* has been described inserted into an intron of a gene. This situation is very common in mammalian genomes (Sironi et al. 2006) and probably also in non-mammalian vertebrates and invertebrates genomes (Sela et al. 2010).

Evidence for horizontal transfer events of MLEs

The patterns of genetic divergence and the phylogenetic relationships of *Tnigmar-Mb* and *Mbourmar*, as well as those between *Myrmar*, *Botmar* and *Tnigmar-Mr* do not seem to be consistent with the expectations assuming vertical transmission. In principle, the discrepancies between the phylogenetic relationships of the elements and those of their hosts could have two explanations. One is that the *mariner* elements described in this study splitted from a common ancestor, before the divergence of the ants and the bumblebees, and have been transmitted vertically ever since; only

one of them, more closely related to *Myrmar*, has been found in *B. terrestris* (*Botmar*). However, the identity between *Tnigmar-Mb* and *Mbourmar* could not be explained under this scenario. Alternatively, the closer relationships observed between *Botmar* and *Myrmar* and between *Tnigmar-Mb* and *Mbourmar* could be explained by recent HT events of these elements to their current hosts. One way to address this problem is to compare the phylogenies of the elements and the species that harbor them. As a proxy for the patterns of neutral divergence among the host species we estimated K_S and compared them with analogous estimates from the elements. With this purpose we estimated K_S of three single-copy nuclear genes between the host's species and the analogous estimates from the *mariner* elements. We have estimated an average $K_S=0.36\pm 0.010$ (Table 2) across the three loci between various species of *Tapinoma* and *Messor* genera. Under the assumption that coding sequences of TEs and host genes experience a similar mutation rate (this is discussed at length in Bartolomé et al. 2009), the fact that the elements isolated from *T. nigerrimum* and *M. bouvieri* are nearly identical, suggests that they have not been inherited by vertical transmission, and that recent HT processes were involved in the evolution of these *mariners*. The observed K_S between *Botmar* and *Myrmar* (0.04 ± 0.010 from Table 1) was nearly 20 times smaller than that found between the two host species they were described in (mean $K_S=1.05\pm 0.099$ from Table 2). Again, the most parsimonious explanation is that a common ancestor of *Botmar* and *Myrmar* entered the genomes of one (or both) of these species long after their split. However, the greater divergence between the two elements, together with the fact that none of the sequenced insertions contained an intact coding sequence suggests that this HT event took place a long time ago.

If we consider that the divergence time for the Myrmicinae and Dolichoderinae subfamilies is of around 110 mya (Moreau et al. 2006), and that the mean K_S for *abdA*, *lw Rh* and *wnt-1* between several species representative of the genera *Messor*, *Solenopsis* and *Myrmica* from Myrmicinae, and four species of *Tapinoma* (Dolichoderinae) is 0.33 ± 0.015 (from Table 2), the mean divergence rate would be of $0.0014\pm 6.5\times 10^{-5}$ substitutions per nucleotide per mya (the rate of neutral divergence equals the observed divergence divided by the time to the most recent common ancestor of the species compared multiplied by two; Li 1997). Thus, the HT of the element could be roughly dated around 14.3 ± 3.57 mya. Contrastingly, the neutral divergence rate estimated for other model insect species such as *Drosophila* is significantly larger (0.011; Tamura et al. 2004). Using this estimate, the HT event would be dated about 1.8 ± 0.455 mya. Given that molecular clock rates are known to vary across organisms and over time (Li 1997; Nei and Kumar 2000), we are inclined to trust the dating from

the molecular rate obtained from the ant data, although it was estimated using fewer nuclear loci.

On the other hand, the full identity of the consensus coding sequences of *Tnigmar-Mb* and *Mboumar* suggests that the time since the HT event approximates zero. If we assume that neutral mutations follow a Poisson distribution, the probability of observing exactly zero changes is e^{-m} , where m is the expected number of changes. If we allow for the probability of zero to be 0.05, $m=2.996$. The upper limit for the time since the HT event can then be estimated as $(2.996/512)/(2 \times 0.0014) = 2$ million years, where 512 is the total number of synonymous sites analyzed. However, caution is recommended when interpreting these results. It should also be noted that the HT hypothesis is further supported by the fact that the consensus sequence of the four *Tnigmar-Mb* elements have a full length intact ORF, which means that they are or have recently been potentially active, as demonstrated *in vitro* for *Mboumar* (Muñoz-López et al. 2008). It is likely that TE activity is needed for HT, as extrachromosomal copies of the elements produced during transposition are expected to be more easily transported to new hosts, and new copies need to be integrated into their genomes.

Chromosome distribution and *Mariner* Life Cycle

The chromosome localization of *Tnigmar-Si*, *Tnigmar-Mr*, and *Tnigmar-Mb mariner* TEs showed that each type of *mariner* element has a different hybridization pattern, which could reflect that these elements are at different stages of the *Mariner* Life Cycle in the host genomes. When a young and active transposon invades a new host by horizontal transmission, it has to multiply within the genome and colonize the germ line to expand within the species and population. At the same time mutations may be accumulated giving rise to inactive or partially inactive copies (reviewed by Miskey et al. 2005). At this stage the transposon copies should be numerous and scattered all over the genome. Consequently, widespread hybridization signals should be detected on the host's chromosomes. The hybridization patterns obtained in the study of *Tnigmar-Mb* element suggest that it could be at this stage of the *mariner* cycle. Mutation accumulation causes the vertical inactivation of the elements, which eventually determines their stochastic loss from the genomes. Thus, the transposon to survive could be horizontally transferred to new host and the cycle would begin again (reviewed by Miskey et al. 2005). MLEs, especially in an inactive state, may persist in a genome through evolutionary time including speciation processes (Hartl et al. 1997). Although we cannot discard the possibility that other intact copies may still exist undetected in the ants' genomes, the fact that all *Tnigmar-Si* and *Tnigmar-Mr* copies were defective due to accumulation

of null mutations suggest that these two families could be in the decaying phase of their cycle, with comparatively reduced copy numbers, approaching their stochastic loss from their host genomes.

Acknowledgements We thank Dr. Dale K. Pollet (Louisiana State University Agricultural Center, Baton Rouge, LA, USA) for providing us samples of *Solenopsis invicta*. We are also grateful to Alain Lenoir (Université François Rabelais, Tours, France) for providing us samples of *Myrmica ruginodis*. This work was supported by the Spanish Junta de Andalucía (through the programs “Ayudas a Grupos de Investigación”, Group BIO220 and “Incentivos a proyectos de investigación de excelencia”, project CVI-6807, co-funded by the European Regional Development Fund), by the Spanish Ministerio de Educación e Innovación (through project CGL2011-23841, co-funded by the European Regional Development Fund) and by the University of Jaén (through the program “Programa propio de ayudas para la realización de proyectos de investigación”, UJA-08-16-03).
