Patterns of seagrass (*Posidonia oceanica*) flowering in the Western Mediterranean

Received: 22 April 2005 / Accepted: 20 September 2005 / Published online: 10 November 2005
© Springer-Verlag 2005

Abstract The intensive reconstructive sampling (1957–2004, 39 localities), a systematic direct observation (1992–2004, 1 locality) and particular direct observations (66 localities) of *Posidonia oceanica* meadows were analysed together with temporal series of flowering available in the literature (19 localities). This allowed the examination of temporal and spatial variability in annual flowering prevalence (FP, the fraction of meadows flowering in a given year) and of annual meadow flowering intensity (FI, number of inflorescences per shoot) for the period 1979–2004 across the Western Mediterranean, as well as spatial variability of flowering frequency (FF, the fraction of years that a given meadow has flowered) and shoot flowering probability (Pf, fraction of flowering stalks appeared per annual segment). Each year, on an average 17% of the investigated meadows flowered, ranging from 3 to 86% of meadows among the years. The highest annual FP and FI values were obtained in 2003 (FP=0.86 and mean FI=0.23±0.03 inflorescences shoot⁻¹). A secondary peak of FP and mean FI occurred 9 years earlier, in 1994 (FP=0.44 and mean FI=0.08±0.02). Both peaks of flowering occurred after hot summers. Flowering synchrony in particular years

across the Western Mediterranean and clines of increased meadow flowering frequency towards the North and East, suggests the existence of large-scale environmental mechanisms controlling the floral induction. On the other hand, meadow FF and Pf were highly heterogeneous among and within the meadows, indicating that local factors also may play a significant role in flowering induction. When flowering, the Western Mediterranean meadows showed an average 0.11±0.02 inflorescences shoot⁻¹, but FI greatly varied among and along the series (from 0.002 to 0.54 inflorescences shoot⁻¹) and decreased significantly with depth but was independent of meadow shoot density and meadow latitude or longitude. The shoot flowering probability was quite low (0.007±0.002 inflorescences shoot⁻¹ year⁻¹) and exponentially increased with shoot age.

Introduction

Seagrasses are clonal plants for which sexual reproduction is believed to play a modest role, compared to clonal reproduction (Hemminga and Duarte 2000). This is the case for *Posidonia oceanica* (L.) Delile (e.g. Marbà et al. 1996a), the dominant seagrass in the Mediterranean (occupying between 2.5 and 5×10¹⁰ m², Bethoux and Copin-Monteagut 1986; Pasqualini et al. 1998), where it is endemic (den Hartog 1970). This statement has been supported by the observation of low genetic diversity in most *P. oceanica* meadows (Procaccini and Mazzella 1996; Procaccini et al. 1998, 2000), and, specially, by the paucity of flowering observations (Giraud 1977; Pergent et al. 1989). Nevertheless, reports of *P. oceanica* flowering have greatly increased in the past two decades, parallel to the observational effort (e.g. Thelin and Boudouresque 1985; Buia and Mazzella 1991; Balestri 2004), and reports of seedling recruitment have also become more frequent (Gambi et al. 1996; Buia and Peirano 1988; Balestri et al. 1998). Moreover, high clonal diversity has been reported in many meadows, as

more powerful molecular markers have been discovered (Alberto et al. 2003; Jover et al. 2003; Arnaud-Haond et al. 2005). These recent developments suggest that sexual reproduction may play a more important role, at least in the long-term population dynamics of the species, than it is believed so far.

Flowering is a first bottleneck on the sexual reproduction of *P. oceanica*. Flowering is an irregular phenomenon both spatially and temporally, but the potential patterns of this variability, which may suggest factors that influence the flowering, remain largely unexplored. Pergent et al. (1989) suggested, on the basis of reconstructive analyses of *P. oceanica* flowering, that meadows may flower about once in a decade, but more recent studies have reported meadow flowerings in consecutive years (Buia and Mazzella 1991; Semroud 1993; Balestri and Cinelli 2003). Patchiness in flowering intensity is often high, even at small spatial scales of a few metres (Gambi et al. 1984; Balestri 2004), as also reported for other species of the same genus (Inglis and Smith 1998; Campey et al. 2002). Furthermore, some reports indicate that flowering occurrence and intensity may vary with depth (Gambi et al. 1984; Semroud 1993).

The multiple observations of intensive and widespread flowering events especially after warm summers (Jahandiez 1914 in Giraud 1977; Mazzella et al. 1983; Pergent et al. 1989; Stoppelli and Peirano 1996; Balestri and Vallerini 2003) have provided evidence that flowering could be induced by high seawater temperature. This evidence, as well as some observations of the consecutive flowerings in Southern meadows, led to the speculations that *P. oceanica* would flower only after warm summers in their northern range of distribution, while the meadows in the southern distributional limit of the species would flower almost annually (Molinier and Picard 1953). The hypothesis of the floral induction by temperature has been recently challenged on the basis that it seems to occur 7 months before anthesis and could be limited by resource availability instead (Gobert et al. 2001, 2005), and because of the high variability in flowering occurrence observed in neighbouring meadows, which probably experience comparable temperature regimes (Semroud 1993; Balestri 2004).

Despite the accumulation of flowering reports in the Mediterranean (e.g. Thelin and Boudouresque 1985; Panayotidis and Liapi 1990) and systematic studies over time (Pergent et al. 1989; Buia and Mazzella 1991; Bussotti and Guidetti 1996; Balestri and Vallerini 2003; Balestri 2004), the broad-scale spatial and temporal patterns of *P. oceanica* flowering which could help to define the factors influencing flowering occurrence and intensity, remain poorly understood because the information is fragmented.

In the present study, we aim at identifying temporal and regional patterns in *P. oceanica* flowering occurrence and intensity in the Western Mediterranean. To evaluate this purpose we used reconstructions of meadow flowering and systematic inter-annual observations in 40 meadows, as well as particular observations in 66

additional localities, most of them distributed along the Spanish and Italian Mediterranean coasts. The analysis of flowering geographic variability has been amended with published reports also derived from reconstructive or systematic surveys for 19 more localities along the Western Mediterranean. Finally, the power of a possible dependence of flowering on meadow latitude, longitude, depth, shoot age and shoot density has been tested using regression analysis.

Materials and methods

Flowering temporal series

A total of 47 flowering temporal series have been obtained both from reconstructive techniques and systematic direct observations in 40 *P. oceanica* meadows (Table 1, Fig. 1).

In Spain, we sampled a total of 36 meadows from the Balearic Islands ($N=19$, Table 1) and the Iberian coasts ($N=17$, Table 1) by SCUBA diving. Between 66 and 501 vertical shoots attached to 15 to 200 horizontal rhizome pieces (allowing the calculation of shoot age at flowering) were haphazardly harvested in the inner part of each meadow, in areas of around 50 m² in July 1992, October 2000, and May 2001. In all the meadows, shoot density was measured within 3–20 quadrats of (0.25 m²) haphazardly deployed in the meadows. In Santa Maria and Es Castel meadows from Cabrera Island (Balearic Islands), sampling has been repeated in several stations following a depth gradient (four stations at 7, 13, 18 and 28 m and five stations at 5, 10, 15, 20 and 25 m, respectively). In some of these stations sampling has been repeated in September 2004 (69 shoots per station), in order to complete the series until that year.

In Northern Italy, 150 shoots from three meadows (Table 1) have been harvested in a hierarchical sampling design (see Balestri 2004), in which the station level had an area of 50 m². Additionally, one meadow (Antignano) in the Ligurian Sea (North-Western Italy) has been examined systematically over 13 years, obtaining a temporal series from direct observations (Table 1). The complete data set of temporal series obtained (inflorescences per shoots examined per year) is available in Appendix (Tables 4, 5, 6, 7, 8, 9).

Reconstructive techniques

Past flowerings of a *P. oceanica* shoot can be detected because of the base of inflorescences stalks that remain attached to the shoots decades after flowering (Pergent and Pergent-Martini 1990). Annual cycles of rhizome vertical growth, which are detected by measuring the leaf sheaths thickness (Pergent and Pergent-Martini 1990, method used in Italian samples) or the rhizome internodal lengths (Duarte et al. 1994, method used in Spanish samples), allowed the past flowerings to be da-

ted. Both techniques have been shown to release equivalent results (Guidetti 2000).

Particular flowering observations

In the Ligurian Sea (NW Italy) nine meadows were checked over 1–3 years for the presence/absence of inflorescences between 1992 and 1994, allowing quantitative estimates of flowering intensity (FI, number of inflorescences per shoot). Quantitative measures of

flowering intensity have been performed at 2–4 m depth, by counting the number of shoots and inflorescences within ten quadrats (0.25 m²) randomly placed in an area of 100×100 m².

In the Balearic Islands and Spanish mainland, all the meadows visited between autumn 2001 and autumn 2004 have been surveyed for the presence/absence of inflorescences, obtaining qualitative records of flowering/no flowering during these years from an additional of 51 meadows. In some meadows of the Balearic islands, FI estimations have been obtained by direct count

Fig. 1 Distribution of the *Posidonia oceanica* meadows sampled (dark circles) and obtained from the literature (triangles) for flowering data, along the Western Mediterranean. Broken lines identify the groups formed for the analysis of variability of flowering among regions

of shoots and inflorescences within 7–20 quadrats (0.25 m^2) randomly deployed along 40–60 m transect, at a uniform depth, parallel to the coastline. Additionally, an extensive measurement of FI has been performed in Magalluf Bay (Mallorca, Balearic Islands), at 7 m depth, where inflorescences and shoot densities (i.e. inflorescences or shoots per m^2) have been measured in 66 quadrats (0.25 m^2) randomly established in an area of $40 \times 80 \text{ m}^2$. Direct observations in five meadows of the Balearic Islands, for which reconstructive series have been carried out (Magalluf, in Mallorca island, Es Port Bay, Es Castel and Sta. Maria bay, in Cabrera island), allowed the extension of these time series (Table 1).

In the meadows from Murcia (8), the shoot coverage (i.e. percentage of area covered by alive rhizomes) and the inflorescences density were measured along four depth transects of $50 \times 1 \text{ m}^2$, using 12 randomly placed quadrats (0.16 m^2), while shoot density was measured haphazardly within 6 quadrats (0.04 m^2) in areas of the meadows with 100% coverage. shoot density in each quadrat was estimated as the product of the fractional

cover and the average shoot density within dense (100% cover) areas of the meadow. Flowering intensity was then calculated for each quadrat.

Additional qualitative flowering records have been obtained for six meadows from Spanish (5) and French (1) Mediterranean coasts through personal communications from other authors. The resulting flowering (and non-flowering) citations, sources and estimates of flowering intensity from particular observations are shown in Appendix (Table 10), available as electronic supplementary material.

Data analysis

The minimum number of shoots examined from reconstructive analysis to retain a positive or negative flowering citation as reliable for any 1 year, has been arbitrarily set at 20 shoots, equivalent to a detection limit of $0.05 \text{ inflorescences shoot}^{-1}$.

FF Flowering frequency; FI flowering intensity; Pf shoot flowering probability

^aThe FF estimate from this locality (0.82) has been considered outstanding and has not been included in the analysis

Mediterranean was estimated both from time series and scattered flowering (and non-flowering) records.

Meadow flowering frequency (FF) was estimated as the fraction of years that a particular meadow has flowered, for meadows in which direct or reconstructive records were available for at least 4 consecutive years. When several series of flowering occurrence were available for the same locality (different stations or depths within less than 1 km distance), a unique FF local value was obtained for global analysis by averaging the FF estimates from the different stations. This strategy was selected in order to minimize the possible effects of the increase in sampling area in these localities with respect to localities with a unique sampling station. Only when shoots sampled within each station were not sufficient to yield long-enough series (minimum 20 shoots year⁻¹, minimum 4 years), a unique series of flowering occurrence was obtained by compounding the shoots sampled in the different stations, and a local FF value was calculated from it.

Meadow flowering intensity for each year was estimated from direct and reconstructive data as the fraction of shoots presenting inflorescences or stalks within a particular year. Meadow FI from reconstructive data was estimated only for years where a minimum of 50 shoots could be examined. Mean annual FI was estimated as the average of positive FI records obtained from different meadows within the same year. Mean local FI was calculated as the average of all positive annual FI recorded within a meadow. For localities with several stations, a mean local FI value was obtained for the global analyses by averaging positive annual flowering intensity estimates obtained from all stations, unless there were not enough shoots available for FI estimation from reconstructive data. In those cases, meadow FI was estimated by compounding shoots from different stations in a unique series.

The shoot flowering probability, Pf, defined as the probability that any one shoot will flower in any 1 year (Gallegos et al. 1992) was estimated in each meadow from reconstructive data, as the fraction of stalks appeared per the total number of shoot annual segments examined in each locality.

The shoot flowering probability for shoots of a particular age was estimated from Spanish reconstructive data as the fraction of flowering shoots in each age class per the total number of shoots that reached or surpassed this age class. We performed correlation and regression analyses between shoot flowering probability and shoot age.

In order to fill the geographic gaps in the analysis of geographic variability in flowering frequency and intensity, additional reconstructive and direct observation data series (19 localities) of flowering in the Western Mediterranean were obtained from published reports (see Table 2, Fig. 1). The detection thresholds for FI and FF calculations as well as integrative rules (several stations in one locality) defined for original data from this study have been equally applied to bibliographic data.

Latitude and longitude of each meadow (from this study or from bibliography) have been recorded in situ, using GPS technology, recorded from literature or indirectly estimated from an Atlas.

The variability in flowering intensity among regions and years was estimated for the 1989–1999 decade (represented in 26 data series), using the (χ^2) replicated goodness of fit test (GENMOD proc. of SAS v. 6.12, SAS Institute Inc.), as the data did not fulfil the assumption of normality of residuals necessary to perform analysis of variance. Region (Western Italy, Balearic Islands and Eastern Iberian coasts, Fig. 1) was included as a fixed factor, year as a within-subject (i.e. repeated measures) fixed factor and locality as a random factor (subject). We used a binomial distribution and logit link function (0: non-flowering shoot, 1: flowering shoot).

The same analysis was applied to test the homogeneity of annual FI between decades 1981–1989 and 1990–1999 in nine meadows where flowering time series extended over both decades. Decade was included as a within-subject (i.e. repeated measures) fixed factor and locality as a random factor (subject). We used a binomial distribution and logit link function (0: non-flowering shoot, 1: flowering shoot). Years were considered as replicates within decades. This analysis was performed to test the existence of decadal differences and to decide if FF, Pf and average FI from different series, which overlapped but did not cover exactly the same years, could be compared directly or if the spatial variability in those variables should be performed only on estimates from the same period. As no significant difference was found between decades in the nine longest time series, we compared FF, shoot flowering probability and average flowering intensity (of flowering years) estimated from the whole data series.

Spatial variability of FF, Pf and average FI was analysed among and within the regions (Western Italy, Balearic Islands, Eastern Iberian coasts, France and Maghreb), using Kruskal-Wallis non-parametric test. Variability of these parameters among and within regions was estimated using the maximum likelihood method (Variance components procedure in Generalized Linear Models of STATISTICA 6.0TM). The relationship of meadow FF, Pf, mean FI (of positive FI annual values) and FI in 2003 (when flowering was prevalent in the regions studied) with meadow latitude and longitude was examined using correlation and regression analyses. FF, Pf and mean FI of series (not grouped in localities) were directly used to explore possible relationships with depth and shoot density, also through correlation and regression analyses.

Results

Temporal variability

The shoots collected and direct observations allowed us to obtain 150 new records of flowerings and 367 of

non-flowering, spanning from 1977 to 2004, along the Western Mediterranean (Table 1 and Appendix tables).

The time series of annual FI showed synchronous flowering in distant meadows across the Western Mediterranean in years 1992–1994 and in 2003 (Table 1), when the highest FI values were recorded. FI in the decade 1989–1999 showed large and significant variability among years ($P < 0.001$) and regions ($P < 0.001$).

Flowering was most prevalent in 1982, 1994, 2001 and 2003 (Fig. 2a). The annual inter-meadow average FI

also showed high temporal variability, with maxima in 1993 and 2003 (Fig. 2b, Table 3). FI and FP were not significantly correlated after removing the outstanding values of year 2003 ($P = 0.125$; Fig. 2c). No significant monotonous trends in FP or mean annual FI were detected over time, although both FP and mean FI were maximal in the year 2003. Moreover, annual FI did not differ significantly ($P = 0.34$) between the decades of 1980–1989 and 1990–1999 in the nine temporal series encompassing the entire period.

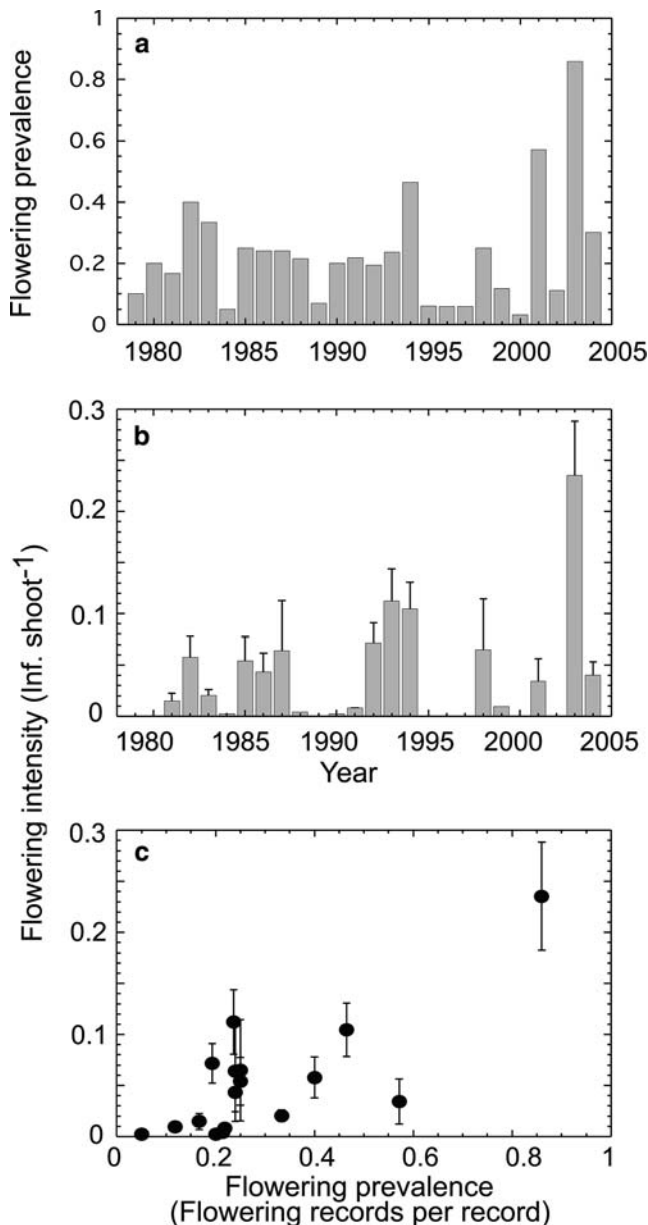

Fig. 2 Time series of **a** *Posidonia oceanica* flowering prevalence (FP annual fraction of flowering meadows per total meadows studied) and **b** the average annual flowering intensity (FI number of inflorescences per shoot) in the Western Mediterranean. **c** Flowering intensity with respect to flowering prevalence. Correlation ($R^2 = 0.56$; $P < 0.001$) is only significant with the values of 2003 (without 2003: $R^2 = 0.1$; $P = 0.13$)

Meadow flowering frequency

The FF in the 54 meadows, where such data were available (40 from this work plus 14 out of the 19 localities from literature), showed significant heterogeneity among regions (39.2% of the variance), although most of the variability was due to the differences between localities within the regions (60.8% of the variance). No flowering was detected in almost half of the meadows, while flowering frequency was distributed normally in the rest (Fig. 3a).

The mean global FF was estimated at 0.17 ± 0.02 (SE, Table 3), and FF differed significantly ($P < 0.01$) among regions (Italy, Balearic Islands, Eastern Iberia, France and Maghreb). FF significantly and positively correlated with latitude ($R^2 = 0.17$; $P < 0.002$; Fig. 4a) across the Western Mediterranean. The strength of the correlation increased when the meadows were grouped by bins of 3° latitude ($R^2 = 0.78$; $P > 0.06$). Meadow FF also increased significantly towards the East, both when examining individual meadows ($R^2 = 0.35$; $P < 2 \cdot 10^{-6}$; Fig. 4b) and meadows grouped by bins of 3° longitude ($R^2 = 0.84$; $P < 0.007$). FF along the Spanish coast was significantly higher in the Balearic meadows than in the meadows along the Eastern Iberian Coasts (Kruskal-Wallis test; $P < 0.03$, Table 3).

Within two meadows in the Cabrera Island, Sta. María and Es Castel, for which several sampling stations were available at increasing depths, all the variability in flowering frequency was significantly correlated with depth ($P < 0.04$) and was independent of shoot density (Fig. 5). But no significant correlations were found between FF and depth or FF and shoot density when adding the rest of series of the Western Mediterranean ($P > 0.5$), suggesting that the correlation with depth observed may help to explain FF variability within meadows, but not across the region.

Flowering intensity

When meadows flowered, the mean FI in the Western Mediterranean (only European coasts) was 0.11 ± 0.02 inflorescence shoot⁻¹. Nevertheless, FI differed greatly among the regions for a given year. In the Balearic Islands, flowering in 2003 was outstanding (on an average 0.37 ± 0.12 inflorescence shoot⁻¹), and more

Table 3 Average (\pm SE) meadow flowering frequency (FF, flowering years per year), flowering intensity (inflorescences Shoot⁻¹, calculated from meadows FI means), maximum and minimum of

annual FI means, and average shoot flowering probability (Pf, inflorescence. shoot⁻¹ year⁻¹) of *Posidonia oceanica* in different regions of the Western Mediterranean

than 20 times higher (Kruskal-Wallis: $P < 0.001$) than in the coasts of Murcia in the same year (0.02 ± 0.01 inflorescence Shoot⁻¹), while the only FI value available for Italy in 2003 (Antignano: 0.27 ± 0.06 inflorescence Shoot⁻¹) was comparable to those observed in the Balearic Islands. In autumn 2003, 64.3% of the heterogeneity in FI was associated with differences between the Balearic Islands and the Eastern Iberian coasts, while differences among meadows within a region and patchiness within a meadow accounted for 18.2 and 17.4% of the variability in FI, respectively.

Flowering intensity in 1994 was on an average six times higher in Italian meadows (0.107 ± 0.027 inflorescence shoot⁻¹) than in Spanish meadows (0.018 ± 0.002 inflorescence shoot⁻¹). An intensive flowering event was observed in 2004 in the meadows of Murcia, where 20 out of 35 meadows visited had flowered (FI = 0.05 ± 0.01 inflorescence shoot⁻¹, J. M. Ruiz, unpublished data) while in the Balearic Islands only two single inflorescences, in two meadows out of 15 surveyed, were found. Despite those annual differences among regions, all the heterogeneity in mean local FI occurred among localities and no significant differences among the regions were found (Table 3; $P = 0.17$). The variability in mean local FI did not depend on latitude or longitude ($P > 0.05$, $N = 24$).

Flowering intensity in 2003 decreased slightly with depth in Murcia ($R^2 = 0.08$; $P < 0.05$; Fig. 6b) and in the Balearic Islands ($R^2 = 0.21$; $P < 0.05$; Fig. 6c). FI in 2003 in Murcia was also significantly but weakly correlated with meadow shoot density ($R^2 = 0.1$; $P < 0.03$). But this correlation could be spurious, derived from the negative correlation of shoot density with depth ($R^2 = 0.14$; $P < 0.04$). Moreover, FI in 2003 was independent of shoot density in the Balearic Islands (where shoot density also decreased with depth: $R^2 = 0.46$; $P < 0.008$). In Magalluf, FI was found to be independent of shoot

density ($P > 0.05$) in an intensive survey at constant depth (7 m) in autumn 2003.

The variability in the averages of FI series was also negatively correlated with meadow depth ($R^2 = 0.14$; $P < 0.04$, Fig. 6a).

Flowering probability and shoot age

Only 2.4% of the shoots examined had flowered at least once. The flowering probability per shoot and per year (Pf) was quite low (0.007 ± 0.002 (SE) inflorescence shoot⁻¹ year⁻¹, Table 3), ranging between 0 and 0.068 across the Western Mediterranean, with an exponentially decreasing frequency distribution (Fig. 3b). Pf showed significant heterogeneity among regions (14%, $P < 0.001$, 5 regions, Table 3), although most heterogeneity occurred among localities within regions (86%). Pf was not correlated with latitude, but increased towards the East (0.18; $P < 0.001$). There was also a very slight, although significant negative correlation between Pf and depth across sites and stations ($P < 0.001$).

Within the Spanish samples, the distribution of shoots that reached or surpassed a certain age decreased exponentially with shoot age (Fig. 7a). The frequency distribution of shoot ages at flowering also seemed to decrease with age, although there was a peak at the 9 years-age class (Fig. 7b). Despite of this decrease and of this particular peak, the shoot flowering probability increased exponentially with shoot age (Fig. 7c), as described by the fitted regression Eq. 1 ($R^2 = 0.78$; $P < 10^{-6}$):

$$\ln(\text{Pfa}) = 1.36 \cdot \ln(a) - 8.94 \quad (1)$$

where “ a ” represents the shoot age, expressed in years and “Pfa” represents the shoot flowering probability at age “ a ”.

Discussion

The described results support the notion of a high inter-annual flowering variability in *P. oceanica* meadows along the Western Mediterranean (Giraud 1977; Pergent et al. 1989; Balestri 2004). In years with high flowering prevalence (e.g. 2003), inflorescences can be found, on an average in four out of the five meadows visited in this basin, while in other years only 3% of meadows would bear inflorescences. Years with widespread flowering along the Western Mediterranean, as observed in 1994 and 2003, coincide with peaks of meadow flowering intensity. In particular, the flowering prevalence and flowering intensities registered in 2003 are the highest ever reported in the Mediterranean ($FP_{2003} = 0.86$, $FI_{2003} = 0.45 \pm 0.04$ (SE) inflorescences shoot⁻¹ in Magalluf Bay, Mallorca). The values observed were twice as high as those in the year with the second highest annual mean FI, observed in 1993, and four times above the global mean FI (0.11 ± 0.02 inflorescences shoot⁻¹) of flowering meadows. This outstanding flowering occurred following the hottest summer registered in Europe over the past 500 years (Luterbacher et al. 2004). This year extensive flowering was also detected in some meadows of the Eastern Mediterranean, along the Ionian Sea (M.

Open squares correspond to average values of data grouped by 3° bins and horizontal and vertical bars on the binned data indicate standard errors for the geographic position and FF, respectively. The dashed line represents the fitted regression line for the data ungrouped

Salomidi, personal communication) and in the Cretan coast (O. Invers, personal communication). As reported by several authors (Stoppelli and Peirano 1996; Balestri and Vallerini 2003), the high flowering prevalence of 1993 and 1994 also coincided with summer temperatures above the normal values. The observations of simultaneous flowering events across and within the regions indicate that large-scale factors (e.g. seawater temperature, Giraud 1977; Boyer et al. 1996) could play an important role in the induction of *P. oceanica* flowering. Synchronous widespread flowerings have been linked to seawater temperature variability in some Australian (Inglis and Smith 1998) and Philippine seagrasses (Rollón et al.

Fig. 5 Relationships between **a** FF (flowering years per year recorded) and depth (m) in the stations of Cabrera ($FF = -0.017 (\pm 0.007) \times \text{depth (m)} + 0.418 (\pm 0.111)$; $R^2 = 0.37$; $P < 0.04$); **solid circles** correspond to stations in Sta. 2003). In addition to years of consistent, abundant flowering throughout the Western Mediterranean, there were years of relatively high flowering prevalence in particular regions, such as in autumn 1993 in the Ligurian Sea (Italy), 2001 in the Balearic islands (Spain), or 2004 in the coast of Murcia (Spain).

More evidence of large-scale control of flowering is the presence of significant regional differences in the meadow FF and shoot flowering probability, as well as FI in particular years. Similarly, Inglis and Smith (1998) reported that the highest variability in flowering intensity of *Posidonia australis* occurred both at the intra-meadow scale of tens of metres and at the regional scale (hundreds of kilometres).

The regional variability in the meadow FF and flowering probability appears to follow a geographic pattern, as meadows located towards the northeast of the Western Mediterranean basin seem to flower more frequently. Meadow FF apparently increases towards the north, while shoot flowering probability is not correlated with latitude. Such results are not consistent with earlier reports of more frequent *P. oceanica* flowering in the Southern Mediterranean coast (Molinier and Picard 1953; Semroud 1993), at least in the Western Mediterranean. These authors hypothesized that warmer South Mediterranean waters could be a better environment for *P. oceanica* meadow development and flowering. The results of the present study suggest that the hypothetical link between *P. oceanica* flowering and temperature may involve temperature variations as triggers of flowering, rather than absolute values. The latitudinal cline of the flowering season, slightly delayed towards the north as reported by Sandmeier et al. (1999), reinforce this idea. The reported delay in flowering by 1 month in the deep meadows compared to shallow ones, parallel to a delay in maximum temperature (Buia and Mazzella 1991) also supports the notion of temperature changes as triggers of flowering.

The significant increase in meadow FF and Pf towards the eastern range of the Western Mediterranean

basin coincides with a greater genetic diversity of *P. oceanica* meadows as observed in the Central Mediterranean (Procaccini et al. 2000; Arnaud-Haond et al, submitted). The level of genetic diversity among aquatic species has been linked to the importance of sexual reproduction in their life histories (Barret et al. 1993; Eckert and Barrett 1993). Sexual reproduction is expected and has been shown (Gavino et al. 2000) to increase genetic diversity of populations. It could be the case for *P. oceanica* meadows if higher FF implies higher sexual reproduction. Conversely, low genetic diversity can potentially reduce flower production and seed set in clonal aquatic plants (Dorken and Eckert 2001). Both possibilities are not mutually exclusive.

Nevertheless, latitude and longitude are not linked to the meadow FI and only account for a modest fraction of the variance in FF and probability. Most of the variability of FF and Pf and all of the variability in mean local FI occur among localities within the regions. Thus, local factors like nutrient availability (Gobert et al. 2001) should also play an important role in flower induction and abundance. The local factors explored in this study (shoot density and depth) do not appear to influence meadow FF. Yet, the fraction of inflorescences per shoot seems to decrease with depth, but is independent of shoot density at a given depth. Hence, the lack of relationship between FI and shoot density previously reported for two Italian meadows by Balestri (2004) appears to be a general pattern in the Western Mediterranean.

Light availability and mean and maximum water temperature decline with depth, inducing important adaptations of *P. oceanica* meadows (Pirc 1984). The reduced *P. oceanica* FI and Pf with depth suggest a role for these variables, similar to their demonstrated role in flowering induction in many terrestrial species (e.g. Heide 1994; Roussopoulos et al. 1998). If a seasonal change in water temperature is the signal inducing *P. oceanica* inflorescences development, as suggested by Buia and Mazzella (1991), then the lower temperature amplitude

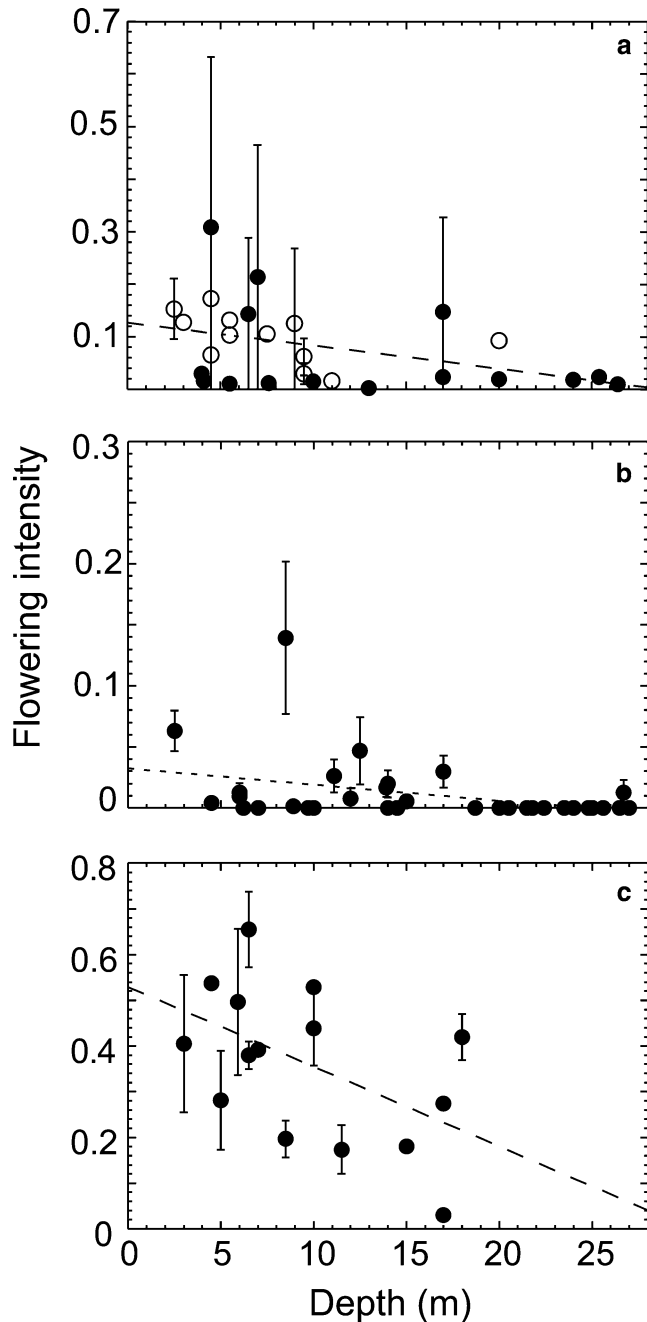

Fig. 6 Relationships between depth (m) and **a** the average FI (mean series FI, inflorescences per shoot, excluding no flowering years; $FI = -0.004 (\pm 0.002) \times \text{Depth (m)} + 0.127 (\pm 0.024)$; $R^2 = 0.14$; $P < 0.04$), **b** the FI in 2003 in meadows from Murcia (Spain); $FI = -0.0011 (\pm 0.0005) \times \text{Depth (m)} + 0.028 (\pm 0.009)$; $R^2 = 0.08$; $P \leq 0.05$), **c** The FI in 2003 in meadows in the Balearic Islands (Spain); $FI = -0.018 (\pm 0.008) \times \text{Depth (m)} + 0.53 (\pm 0.09)$; $R^2 = 0.21$; $P \leq 0.05$). *Dashed lines* represent the fitted linear regressions

in deep meadows would represent a weaker trigger of flowering, which could be reflected on a reduced FI.

The shoot flowering probability was extremely low, and the fraction of shoots examined that flowered at least once during their lives (less than 2.4%) was lower

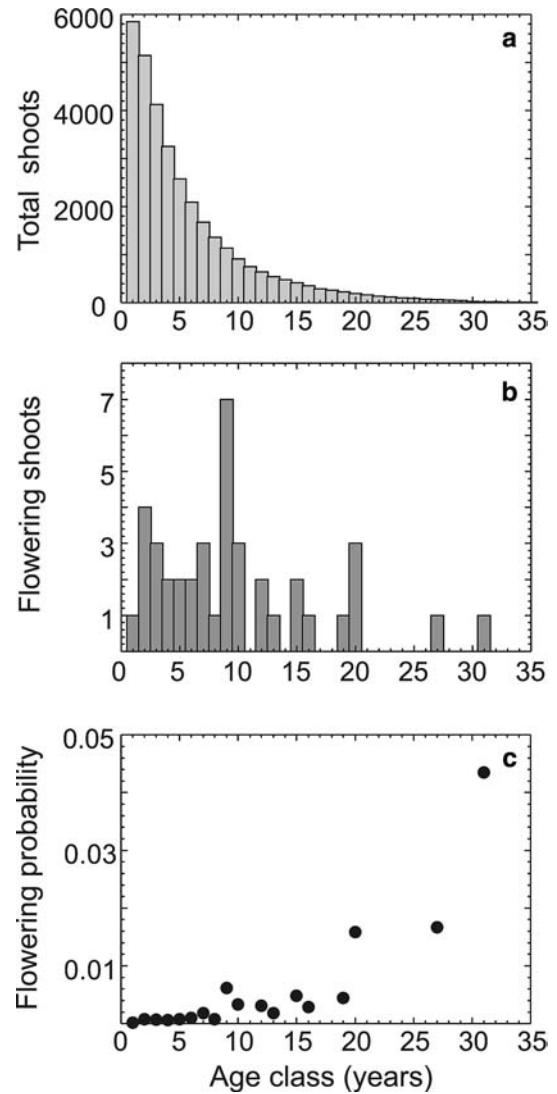

Fig. 7 **a** Frequency distribution of shoots that reached or surpassed a certain age (in years), **b** Frequency distribution of shoot flowering ages. **c** The relationship between the flowering probability (P_f) of *Posidonia oceanica* shoots and shoot age

than in most seagrasses for which it has been reported, as *Thalassia testudinum* (14%; Gallegos et al. 1992, *T. hemprichii* (17%), *Cymodocea rotundata* (5.6%) and *Enhalus acoroides* (97.7%) (Duarte et al. 1997), despite the long shoot lifespan of this species, which can reach 50 years, as reported by Marbà et al. (1996b).

We observed the shoot flowering probability to increase exponentially with shoot age. This observation is in contrast with the reported pattern of flowering probability reaching a maximum at 6-year-old shoots in two Ligurian *P. oceanica* meadows (Balestri and Vallerini 2003). The latter observation may be anomalous, as the shoots sampled in that work were relatively young (maximum 16 years), compared to the lifespan of *P. oceanica* shoots in most meadows (Marbà et al. 1996b). In addition, the frequency distribution of shoots that reached or surpassed a certain

age was constant in age classes 1–6 years old, instead of exponentially declining, as observed in most meadows (Duarte et al. 1994).

An increase in the shoot flowering probability with an increasing shoot age has been reported for other sea-grass species (Gallegos 1992; Vantussenbroek 1994; Duarte et al. 1997). As in many terrestrial plants, the increase in flowering probability with plant age or size may be related to the need of a certain amount of reserves accumulated, in order to provide or compensate for reproductive costs.

In summary, the results presented here provide an evidence of clear temporal and regional patterns in flowering of *P. oceanica* meadows in the Western Mediterranean. FF and flowering probability of the meadows showed a tendency to increase towards the eastern and/or northern regions of the Western Mediterranean. Extensive flowering events were relatively synchronous across the regions, with the most intense flowering event yet reported occurring in 2003, the warmest year in the past centuries across Europe. There was a high variance in the FI and frequency within and among meadows, with a tendency towards a reduced FI with depth and patchiness possibly related to the age structure of the meadow, as the probability to flower increased exponentially with increasing shoot age. The patterns in

P. oceanica flowering, reported here suggest that temperature changes or other large-scale factors co-varying with latitude and longitude may act as important drivers, explaining a significant part of both spatial and temporal heterogeneity in meadow FF and shoot flowering probability in the Western Mediterranean, although the high flowering variability among localities point to local factors as exerting a strong control on flowering.

Acknowledgements We are grateful to Rocío Santiago, Regino Martínez and Catalina Arrondo for their participation in field and lab work and to Amparo Lázaro and Javier Rodríguez for instructive discussions and suggestions for data analysis. This research has been funded by the EU projects M&M's (EVK3-CT-2000-00044 and REN-2000-3091-CE/MAR) and LIFE-Posidonia (LIFE 2000/NAT/E/7303) and by the Spanish National Programme of Research in Protected Areas (MAM/2484/0055/2002).
