# Effective patient prioritization in mass casualty incidents using hyperheuristics and the pilot method

**Carlos Cotta** 

Published online: 13 February 2011 © Springer-Verlag 2011

**Abstract** Whenever a mass casualty disaster takes place, the medical infrastructure available has to deal with a surge in the number or patients severely ill or injured. Using triage methods casualties have to be prioritized to receive health care in a limited-resource scenario. Aiming to do the greatest good to the greatest number of people, it has to be determined how to make the best use of these resources. This constitutes a very complex task that has to consider issues such as the current number of casualties, their lifetime expectancy, their resource consumption, etc. We approach this task within the framework of the pilot method and hyperheuristics. We show how these metaheuristics can effectively manage a number of simpler heuristics, providing improved results on an ample set of simulated problem scenarios. An exhaustive empirical evaluation analyzes the influence on performance of factors such as the total number of casualties, the severity of their medical condition, the treatment time, the number of resources available, or the number of triage classes.

Keywords Mass casualty incident · Triage · Hyperheuristics · Pilot method

## 1 Introduction

A disaster is a catastrophic event that seriously disrupts the normal functioning of society at a scale which may vary depending of its magnitude (Koenig et al. 1996). In the aftermath of a disaster, society has to cope with the damage infringed, both from

the material and the humanitarian perspective. The latter is actually one of the most tragic aspects of a disaster, and dealing with it can undoubtedly constitute a major challenge: a quick response is needed to deliver humanitarian relief and appropriate medical care to the victims of the disaster, in a scenario in which basic infrastructures for communication and transportation may be greatly affected. Needless to say, this involves being able to manage adequately all available resources (van Veelen et al. 2006), in particular when these are scarce with respect to the number of casualties and the severeness of their injuries.

Among the numerous problems arising in a situation as described—involving transportation logistics (Doerner and Hartl 2008), medical routing (Tatomir and Rothkrantz 2006), facility location (Lee et al. 2009), etc.—we will focus on the decision-making underlying the distribution of medical care to casualties. In this sense, mass casualty disasters require a paradigm change from the standard approaches to emergency room care in which available medical resources are not overwhelmed by the sporadic arrival of casualties (Frykberg 2004). Quite on the contrary, in a mass casualty scenario health care demand typically exceeds hospital resources (e.g., imaging devices, life-support systems, operating rooms, etc.). It is thus crucial to make the most effective use of these limited resources.

The term *triage* is used to denote the mentioned decision-making process for distributing medical resources among patients (Iserson and Moskop 2007; Kennedy et al. 1996; Robertson-Steel 2006). Roughly speaking, triage involves sorting patients in different categories according to their medical condition and prioritizing treatment among them. A more detailed overview on triage methods will be provided in Sect. 2. A recurrent theme in triage systems is ensuring the maximal benefit from the limited medical resources (Bostick et al. 2008). We approach this problem from an utilitarian perspective in which the goal is attaining the greatest good for the greatest number of people (Bar-Joseph et al. 2003; Roccaforte and Cushman 2007). More precisely, we consider the problem of prioritizing patients in order to maximize the expected number of survivors. This is done on the basis of available information on survival probabilities and how these change over time for each patient category. This problem will be formalized in Sect. 3.1.

We approach this patient prioritization problem via metaheuristics. To the best or our knowledge, this constitutes a novel application domain for these techniques: to be precise, we consider hyperheuristics (Cowling et al. 2000; Burke et al. 2003; Chakhlevitch and Cowling 2008; Özcan et al. 2008) and the pilot method (Duin and Voß 1994, 1999; Voß et al. 2005). These techniques will exploit heuristics recently defined for scheduling impatient jobs (Argon et al. 2008), and will be described in Sect. 3.3. We have conducted an extensive experimental evaluation of these techniques on a large number of simulation scenarios intended to capture mass-casualty incidents of different severity. Given the nature of the problem, any gain that can be attained even if small—is very valuable. As it will be shown in Sect. 4, this is generally the case for metaheuristics, which compare favorably in general to existing heuristic policies. The results also provide some insights into the sensitivity of these heuristics to different features of the disaster scenarios (e.g., number of resources available, severity of patient conditions, overall number of patients, etc.). This information yields useful hints on the strengths and limitations of each technique.

#### 2 Background and related work

As mentioned in Sect. 1, when a mass casualty incident (MCI) takes place there is a sudden and serious disproportion between the resources required by the casualties and the resources that are available. Focusing on critically ill or injured patients, a surge in their number in the aftermath of a MCI will overwhelm the capacity of hospitals and critical care units, decreasing their response capability (Rubinson et al. 2005). In this context, the notion of surge capacity is precisely defined as the ability to cope with a sudden, unexpected increase in patient volume beyond the present capacity of the facility (Hick et al. 2009).

Even though most medical facilities have a certain surge capacity, peak demand of limited resources (X-ray devices, mechanical ventilators, operating rooms, etc.) will lead to dramatic situations in which these resources must be rationed and directed to patients who will benefit most from them (Roccaforte and Cushman 2007). In this scenario, the needs of the community as a whole stand above those of individuals considered in isolation. The implications of this change of paradigm are manifold and include the temporary adjustment of the standard of care for all patients (Challen et al. 2007), directing resources to patients to whom these will be most effective. The process of sorting and prioritizing patients is termed triage.

Leaving aside the profound ethical issues surrounding triage in the aftermath of a MCI (Daniels 2000; Good 2008; Larkin and Arnold 2003), its actual technical implementation is complex. Currently, there are about a dozen mass-casualty triage systems in use around the world (Cone and MacMillan 2005). These triage methods sort patients into groups according to a certain number of medical indicators (pulse rate, breath status, etc.). For example, one of the most commonly used systems is the Simple Triage And Rapid Treatment (START) system (Super 1984). This system is aimed at providing rescuers with the ability of classifying patients in less than 60 seconds into four classes: green (delayed care), yellow (urgent care), red (immediate care), black ('expectant' or dead). Other triage systems may differ in the set of medical variables considered, or in the resulting patient groups (e.g., adding a blue/violet class for likely expectant patients). For a comparative of triage methods, the reader is referred to (Garner et al. 2001).

Triage does not end with the classification of patients into groups as sketched above. Actually, that is just the first step of the process, which can be described as field triage or primary triage. Further re-examination and prioritization can take place at different points of the medical care chain, such as at hospital arrival or at the intensive care unit level. With the goal of distributive justice in mind, patient prioritization may not necessarily equate to the severeness of their medical condition though. Certainly, less severely injured patients can better tolerate delays and/or some degree of suboptimal care (Hirshberg 2004) [the principle of 'minimal acceptable care' (Stein and Hirshberg 1999)]. Likewise, START expectant category is meant to leave out of further consideration those patients who will not survive even with maximal resuscitative effort (Cone and MacMillan 2005) (of course, such patients are entitled to receive palliative treatment and comforting measures to preserve their dignity). However, in some cases it has been suggested that priority should be given to moderate severity patients rather than to those of the greatest severity (Frykberg 2004). Such a decision is motivated by

the different profile of resource consumption by patients in different groups—check, (e.g., Peleg et al. 2004).

Health care officials thus face complex decisions that need to be addressed not just considering the criticality of patient conditions, but also the number of patients-and their corresponding health status—in need of using the same medical resources (Saffle et al. 2005; Challen et al. 2007). This issue has been recently addressed by (Argon et al. 2008), by analyzing the conditions in which a state-independent policy (i.e., a policy that does not take into account the number of patients in each triage class) can be optimal. They consider a single-server system (that is, one single resource used in mutual exclusion and non-preemptively by waiting patients, e.g., an operating room). It is shown that if patients can be ordered such that those in a most urgent life-threatening situation also require less time to be serviced, then the optimal policy will give priority to these. However, in a most typical scenario in which patients of greatest severity also require longer use of the server, the optimal policy has a complex structure that depends on the system state. In a scenario in which both lifetimes and operation times are exponentially distributed the system is memoryless. Hence, the optimal policy is time-independent and only needs to consider the number of patients in each triage class. In a more general (and realistic) situation in which lifetimes follow a different distribution (e.g., Weibull 1951), time is, however, a defining characteristic of the system state as well, thus greatly increasing the complexity of the problem. This can be further aggravated if there are more than one shared resource—e.g., multiple operating rooms—as we will consider here. In this context, we pose the use of two metaheuristic approaches-hyperheuristics and the pilot method-to approach this prioritization problem. These metaheuristics will use as internal lower level heuristics both state-independent and state-dependent heuristics defined in the literature (Glazebrook et al. 2004; Argon et al. 2008).

#### **3** Solving the patient prioritization problem

In order to tackle the problem outlined before, let us first formulate it in a more precise way. Subsequently, we will describe some heuristics for the problem that will pave the way to define our metaheuristic approaches.

## 3.1 Problem formulation

As mentioned in Sect. 2, field triage methods classify casualties into one of several groups on the basis of a quick assessment of several health variables. We assume this classification clusters patients into tiers  $c_1, \ldots, c_k$ , such that  $c_i$  patients have a more critical condition than those of  $c_j$ , j > i. Such criticality is modeled by means of a lifetime expectancy, which we assume to be Weibull-distributed. The Weibull distribution is commonly used in survival analysis to model the lifetime of individuals or the time-to-failure in mechanical devices (Lee and Wang 2003). One of the most salient features of the Weibull distribution is the fact that it allows generalizing the exponential distribution: while the latter corresponds to a constant hazard rate (hence the memoryless property), the Weibull distribution can model an increasing,

constant, or decreasing hazard rate depending on a certain shape parameter  $\alpha_i$ . We consider  $\alpha_i > 1$  and therefore the hazard rate increases with time, in accordance with the aggravated state of casualties pending medical treatment. In this case, the mean lifetime is given by  $\beta_i \Gamma(1 + 1/\alpha_i)$ , where  $\Gamma(\cdot)$  is the gamma function and  $\beta_i$  is the scale parameter. As to service times, which we will refer to as operation times henceforth, we consider two scenarios. We will initially consider patients in each class  $c_i$  require a deterministic time  $\tau_i$  to be treated. While simplified, this assumption is, however, consistent with a 'damage control' situation, in which rapid and abbreviated care is given in the operating room until the MCI overload recedes (Frykberg 2004). In such a situation, operation times may not greatly fluctuate. In any case, we also analyze a second scenario in which operation times are stochastic. To be precise, our model considers that any operation needs a minimum time  $\tau_i$ , and can have an excess time which for simplicity is assumed to be exponentially distributed with parameter  $1/(\eta_i \tau_i)$ , where  $\eta_i$  is an additional class parameter.

Given the above parameters, the objective is to take decisions online to determine from which class the next patient to be operated will be taken, so as to finally maximize the number of patients treated—or equivalently, to minimize the number of patients that die while waiting for treatment. We assume that there are  $\rho$  identical operating rooms available, and therefore decisions are taken any time one of these operating rooms becomes available.

#### 3.2 Basic heuristics

Heuristics for patient prioritization can be classified as state-dependent and state-independent. The latter are arguably simpler, since they only consider the lifetime estimates and operation times, but not the number of patients in each class. Among these, we have considered the following:

• Time Critical First (TCF): each time t a decision has to be taken, classes are sorted according to decreasing values of their updated abandonment rates  $r_i(t)$  (the abandonment rate being the reciprocal of the mean remaining lifetime). Subsequently, a patient of the first non-empty class is taken. Following (Argon et al. 2008), updated abandonment rates are computed as follows:

$$r_i(t) = \frac{\alpha_i e^{-t'}}{\beta_i \Gamma(1/\alpha_i, t')} \tag{1}$$

where  $t' = (t/\beta_i)^{\alpha_i}$ , and  $\Gamma(a, b) = \int_b^\infty u^{a-1} e^{-u} du$  is the incomplete gamma function.

• The  $r\mu$  heuristic: this heuristic is due to (Glazebrook et al. 2004), and sorts classes by decreasing values of  $r_i\mu_i$ , where  $r_i$  is the updated abandonment rate computed at time *t* as before, and  $\mu_i$  is the service rate (the reciprocal of  $\tau_i$ ).

In addition to these heuristics, two state-dependent policies defined in Argon et al. (2008) are considered:

 Triangular heuristic (T): considering a two-class problem, the T heuristic gives priority to class c<sub>1</sub> if

$$\frac{(x_1-1)r_1+x_2r_2}{\mu_1} \leqslant \frac{x_1r_1+(x_2-1)r_2}{\mu_2} \tag{2}$$

where  $r_i$ ,  $\mu_i$  are defined as above, and  $x_i$  is the number of patients in  $c_i$ . This heuristic is termed triangular because Eq. (2)—along with  $x_1, x_2 > 0$  (otherwise no heuristic decision is required)—defines a right triangle in  $(x_1, x_2)$ -space. Note that this heuristic can be regarded as a greedy selection procedure picking the class that minimizes the mean number of impatient deaths during operation. We have therefore generalized it to scenarios with more than two classes as selecting the class *i* that minimizes  $d_i$  given by

$$d_i = \frac{1}{\mu_i} \left( -r_i + \sum_j x_j r_j \right) \,. \tag{3}$$

This quantity can be actually seen as the mean number of impatient deaths in all classes when a patient from class i is taken to the operation room.

- Rectangular heuristic (R): related to the previous heuristic, this policy assumes  $r_1 > r_2$  and  $\mu_1 < \mu_2$ , and defines two threshold values:

$$T_1 = \frac{\mu_2(r_1 - r_2)}{r_1(\mu_2 - \mu_1)}$$
 and  $T_2 = \frac{\mu_1(r_1 - r_2)}{r_2(\mu_2 - \mu_1)}$ . (4)

 $T_1$  (resp.  $T_2$ ) is obtained by plugging  $x_1 = T_1$  and  $x_2 = 1$  (resp.  $x_1 = 1, x_2 = T_2$ ) in Eq. (2) and solving it as an equality, hence obtaining the coordinates of the endpoints of the triangle hypotenuse. Class  $c_1$  patients are selected if, and only if,  $1 \le x_1 \le T_1$  and  $1 \le x_2 \le T_2$  (thus defining a rectangle in  $(x_1, x_2)$ -space by doubling the triangle defined by the T heuristic; this simple structure is an advantage of this heuristic). Note that unlike the T heuristic, the R heuristic is not directly generalizable to more than two patient classes.

These heuristics have been used as low-level heuristics (LLH) in the metaheuristic approaches defined next.

#### 3.3 Metaheuristics approaches

The basic heuristics defined in the previous section provide fast yet in general myopic decision procedures. In order to alleviate the 'locality' of the decision-making procedure and obtain globally better solutions, we need to add a metaheuristic layer to provide higher-level guidance and escape from greedy traps. We have approached this using both hyperheuristics (Cowling et al. 2000; Burke et al. 2003; Chakhlevitch and Cowling 2008; Özcan et al. 2008) and the pilot method (Duin and Voß 1994, 1999; Voß et al. 2005).

Starting with the latter, the pilot method can be defined as a tempered greedy method (Duin and Voß 1999; Voß et al. 2005) that looks ahead by using a LLH as *pilot*, that is, to obtain an objective-value test of the goodness of each possible choice. To describe the deployment of this method on the prioritization problem, let us consider any prioritization policy  $\Xi$  (such as any of those described in the previous subsection) be defined as a function CHOICE- $\Xi(\mathbf{x}, \mathbf{P}, \mathbf{t})$ . This function takes as parameters the whole system state: the number of patients  $\mathbf{x}$  in each class, the distribution parameters  $\mathbf{P}$  defining each class, and the times  $\mathbf{t}$  at which each of the operating rooms will be available. Regarding the latter, these times are known in advance in the first scenario in which operation times are deterministic; in the second scenario in which these times are stochastic, an approximation can be used (we consider the minimum operating time  $\tau_i$  as an optimistic estimation in this case). This function returns the class index from which a patient must be picked, given the system state that is passed as input.

Now, let UPDATE(**x**, **P**, **t**, *j*) be a procedure that assumes that at time  $t_{\gamma}$ , where  $\gamma = \arg\min\{t_i \mid 1 \le i \le \varrho\}$  a patient from class *j* is taken to the operating room, and updates the system state accordingly. This involves updating the time the corresponding operating room will be available again  $(t_{\gamma} \leftarrow t_{\gamma} + \tau_j)$ , decreasing by one the number of patients in class *j*, and recomputing the expected number of survivors in each patient class by the time *t'* the next operating room becomes available. For Weibull-distributed survival times, the probability of a patient surviving up to time  $t_1$  given that he survived up to time  $t_0$  is

$$p(t_0, t_1, \alpha, \beta) = e^{-\left[(t_1/\beta)^{\alpha} - (t_0/\beta)^{\alpha}\right]}$$
(5)

where  $\alpha$  and  $\beta$  are, respectively, the shape and scale parameters as mentioned in the previous section. The expected number of survivors is then computed by multiplying the actual number of patients in each class by their survival probability (calculated using  $t_0 = t_{\gamma}$ ,  $t_1 = t'$ , and the corresponding distribution parameters), rounding to the nearest integer.

Finally, let CONSTRUCT- $\mathcal{Z}(\mathbf{x}, \mathbf{P}, \mathbf{t})$  be a function that takes as input the system state, simulates it to completion using CHOICE- $\mathcal{Z}$  as decision-making procedure, and returns the total number of patients operated:

```
1 function CONSTRUCT – \Xi(\mathbf{x}, \mathbf{P}, \mathbf{t}) : \mathbb{N};
 2 begin
 3
            \omega \leftarrow 0;
            while \sum_i x_i > 0 do
 4
 5
                   j \leftarrow \text{CHOICE} - \Xi(\mathbf{x}, \mathbf{P}, \mathbf{t});
 6
                  \omega \leftarrow \omega + 1;
 7
                  UPDATE(\mathbf{x}, \mathbf{P}, \mathbf{t}, j);
 8
            endw
 9
           return \omega;
10 end
```

Now, given a certain heuristic  $\Xi$ , let us define policy PILOT( $\Xi$ ) as given by the following choice function:

```
1 function Choice-Pilot(\Xi)(\mathbf{x}, \mathbf{P}, \mathbf{t}) : \mathbb{N};
 2 begin
 3
            \sigma \leftarrow \{i \mid x_i > 0\};
            for i \in \sigma do
 4
                  x' \leftarrow x; t' \leftarrow t;
 5
                   UPDATE(\mathbf{x}', \mathbf{P}, \mathbf{t}', i);
 6
 7
                   \zeta_i \leftarrow \text{CONSTRUCT} - \Xi(\mathbf{x}', \mathbf{P}, \mathbf{t}');
 8
            endfor
  0
            return arg max{\zeta_i \mid i \in \sigma};
10 end
```

As it can be seen, CHOICE-PILOT( $\Xi$ )(·) is a higher-order function that uses CON-STRUCT- $\Xi$  to obtain an indication of the goodness of making each of the possible choices at a given instant (i.e., a projection of the number of patients treated; in case of ties, the most critical class is taken). This way, choices are more informed since they rest on actual objective values rather than on myopic measures. The quality of the pilot  $\Xi$  is crucial for the performance of the algorithm though. This will be empirically analyzed in the next section.

The second metaheuristic approach considered is based on hyperheuristics. These can be defined as higher level heuristics that manage a set of LLHs (of cardinality greater than one), using only limited problem information (Chakhlevitch and Cowling 2008). Basically, the hyperheuristic decides at each instant which of the available LLHs will be used. The underlying idea is thus making combined use of several LLHs, so that by making appropriate choices it is possible to exploit their strengths and compensate their weaknesses (Burke et al. 2003). Such choices can be done in a variety of ways: at random, using some greedy measure, using some kind of machine learning mechanism, or even using a full-fledged metaheuristic to optimize the sequence of LLHs invocations. In this case, the mechanism that best suits the needs of fast online decision-making is a greedy selection method. More precisely, let  $\Xi = \{\Xi_1, \ldots, \Xi_h\}$  be a set of LLHs defined in Sect. 3.2. Then, let us define CHOICE-HYPER( $\Xi$ )(·) as follows:

```
1 function CHOICE-HYPER(\Xi)(\mathbf{x}, \mathbf{P}, \mathbf{t}) : \mathbb{N};
 2 begin
 3
          \sigma \leftarrow \{\text{CHOICE} - \Xi_i(\mathbf{x}, \mathbf{P}, \mathbf{t}) \mid \Xi_i \in \Xi\};
           if |\sigma| = 1 then
 4
 5
                return [\sigma]; //returns the only element in \sigma.
 6
           else
                 for i \in \{1, ..., |\Xi|\} do
 7
 8
                   \zeta_i \leftarrow \text{CONSTRUCT} - \Xi_i(\mathbf{x}, \mathbf{P}, \mathbf{t});
  9
                 endfor
10
                 return arg max{\zeta_i \mid i \in \sigma};
11
          endif
12 end
```

As it can be seen, the hyperheuristic first checks whether there is agreement among the available LLHs on which patient class to pick. If there is, no further computation is required and the unanimous decision is returned. If this is not the case, each of the associated construction heuristics is run to determine which selection is more beneficial. Note that even though two or more LLHs may agree on the choice to be made, as long as there is no unanimous decision all of them must be run since any LLH could in principle return the best function value (i.e., number of patients treated).

Notice that the two methods presented above are related since the hyperheuristic actually uses in part the philosophy of the pilot method. Indeed, CHOICE-PILOT( $\Xi$ ) and CHOICE-HYPER( $\Xi$ ) can be regarded as two complementary approaches: the first one can take any decision at a given time using a single heuristic  $\Xi$  as pilot; the second one can only take a limited set of decisions at any time (only those returned by the LLH set  $\Xi$ ), but uses multiple LLHs as independent pilots for each decision. Furthermore, it is possible to define a blended approach PILOT(HYPER( $\Xi$ )), that uses the hyperheuristic with LLH set  $\Xi$  as pilot for the construction process. This approach and all preceding ones will be experimentally compared next.

### 4 Experimental results

We have conducted an extensive empirical evaluation of the heuristics presented. The experimental setup is similar to that used in Argon et al. (2008). To be precise, we have initially considered a problem formulation involving two patient classes. These can be regarded as the two most critical classes (excluding expectant casualties) of typical field triage methods, since patients in the 'green' class are usually delayed until these most critical casualties are treated. Notice at any rate that later on we will test the scalability of heuristics in a 3-class scenario. We have generated N = 5,000problem instances for each of three different severity conditions. In all cases, this first set of experiments assumes operating times  $\tau_i$  are uniformly distributed in (0.5, 2.0); we enforce  $\tau_1 > \tau_2$ , i.e., class  $c_1$  patients require more time to be operated than those of class  $c_2$ . As to the lifetime distribution, we assume it to be Weibull-distributed with shape parameter  $\alpha_i = 1.5$  (i.e., increasing hazard rate). The scale parameter  $\beta_i$  is set such that the corresponding initial abandonment rate  $r_i$  is within a given interval. These intervals represent different severity conditions as mentioned before. Thus, we have  $r_i \in (0.1, 0.5)$  (denoted as S1),  $r_i \in (0.5, 2.0)$  (S2) and  $r_i \in (2.0, 5.0)$  (S3), respectively, representing increasingly critical conditions (in the first case operating rates are higher than abandonment rates, in the second case they are in the same interval, and in the third case, abandonment rates are higher than operating rates). Again, we enforce  $r_1 > r_2$  so that  $c_1$  patients are more critical than  $c_2$  patients. The initial number of patients  $x_i \in [1, 20]$  in each class is uniformly selected at random in each instance, and the number of operating rooms  $\rho$  is set to 5.

The results for the three scenarios are shown in Figs. 1, 2 and 3. Notice first the outcome of the basic heuristics T, R,  $r\mu$  and TCF (respectively labeled as T, R, r, and C in the figure). Consistently with Argon et al. (2008), T and R perform better in a scenario in which abandonment rates are very high, whereas  $r\mu$  performs better in scenarios of more moderate severity. Likewise, TCF provides the worst results, in particular in the most critical scenarios in which the very myopic policy of focusing on class  $c_1$  results in multiple impatient deaths in class  $c_2$ . Conversely, when the situation

**Fig. 1** Percentage of patients treated in scenario S1, using Weibull-distributed lifetimes and deterministic operating times. The *top figure* corresponds to the mean percentage of patients treated in both classes, and the *bottom one* to patients in the most critical class. The *error bars* indicate the standard deviation of the mean. In this figure and in all subsequent ones, algorithms are labeled as *C* time critical first; *T* triangular; *R* rectangular;  $rr\mu$ ; *H* HYPER( $\Xi$ ); *PX* = PILOT(*X*). Note the different ordering of algorithms in each subfigure

Fig. 2 Percentage of patients treated in scenario S2, using Weibull-distributed lifetimes and deterministic operating times. The *top figure* corresponds to the mean percentage of patients treated in both classes, and the *bottom one* to patients in the most critical class. The *error bars* indicate the standard deviation of the mean. Note the different ordering of algorithms in each subfigure

Fig. 3 Percentage of patients treated in scenario S3, using Weibull-distributed lifetimes and deterministic operating times. The *top figure* corresponds to the mean percentage of patients treated in both classes, and the *bottom one* to patients in the most critical class. The *error bars* indicate the standard deviation of the mean. Note the different ordering of algorithms in each subfigure

**Fig. 4** Rank distribution of the different algorithms in the three scenarios considered (Weibull-distributed lifetimes, deterministic operating times) in increasing criticality from *top* (S1) to *bottom* (S3). As usual *each box* comprises the second and third quartiles, the *vertical line* marks the median, the *circle* marks the mean, the *whiskers* span 1.5 times the interquartile-distance, and the *dots* are outliers

is less critical, TCF is comparatively closer to the remaining basic heuristics since less patients leave class  $c_2$  before treatment.

Consider now the results of the PILOT( $\Xi$ ) and HYPER( $\Xi$ ). Regarding the former, pilot methods based on each of the four basic heuristics have been considered. As to the latter, we have considered  $\Xi = \{T, R, r\mu\}$ , leaving out TCF due to its poorer performance. As it can be seen, there is a marked difference between basic heuristics and the corresponding pilot method. Notice also that the hyperheuristic also provides better results than those of the basic heuristics. Although differences seem smaller in the most critical scenario, they are still significant. Actually, a Wilcoxon signed-rank test (Wilcoxon 1945) (used to perform a statistical comparison on paired samples) indicates that in all cases both PILOT( $\Xi$ ) and HYPER( $\Xi$ ) are significantly (at the standard 0.05 level) better than the corresponding LLH  $\Xi$ . Furthermore, check Fig. 4 in which we plot the distribution of ranks of each algorithm in each of the three scenarios. These ranks are computed by sorting the algorithms on each of the 5,000 instances, assigning rank 1 to the best algorithm in a certain instance and rank *k* (*k* being the total number of algorithms) to the worst one. In case of a tie, the average of the positions involved is used as rank.

Table 1 Results of Holm's test using PILOT(HYPER( $\Xi$ )) as control algorithm

PILOT(HYPER( $\Xi$ )) consistently provides the best rank, followed by PILOT(T), and PILOT(R) that rank close to each other (like T and R do). To ascertain the significance of these ranks, we have first performed both Friedman's test (Friedman 1937) and Iman-Davenport's test (Iman and Davenport 1980) on the data. Both tests indicate that there are significant differences, so we have subsequently performed Holm's test (Holm 1979) using PILOT(HYPER( $\Xi$ ))—the algorithm with the best mean rank as control algorithm. The results of the test—shown in Table 1—indicate that this control algorithm ranks significantly better than the remaining algorithms in S1 and S2. In S3 no significant difference in rank can be found for PILOT(R), PILOT(T) and PILOT(HYPER( $\Xi$ )). This result can be explained by the improved performance of T and R in this scenario boosting the corresponding pilot methods as well. As an aside note, computational times per problem instance were around 1–2 ms for the LLHs, about 6– 40 ms for pilot methods and the hyperheuristic, and about 0.3 s for PILOT(HYPER( $\Xi$ )) (times measured on an Intel Core 2 Quad Q6600 2.4 GHz).

Next, we have done experiments in order to determine the influence of some problem parameters on the performance of the different methods. In the first place, we have analyzed the impact of having a different number of operating rooms available. To this end, we have again generated 5,000 instances as defined above, each of them with

Fig. 5 Rank distribution of the different algorithms in scenario S2 as a function of the number of operating rooms available

a number of operating rooms  $\rho$  drawn from a uniform distribution  $\rho \in \{2, \ldots, 10\}$ . Subsequently, we have grouped problem instances according to the number of operating rooms, and performed a separate rank analysis on each group. The results are consistent with those shown before for  $\rho = 5$ . In the most critical scenario S3, Holm's test rejects differences between PILOT(R), PILOT(T) and PILOT(HYPER( $\Xi$ )) regardless of the number of operating rooms. In S1 and S2, the test is passed using the latter as control algorithm. Figure 5 shows the rank distribution for S2. Note that T and R perform better than  $r\mu$  for lower number of operating rooms, whereas for a larger number the opposite is true. This can be interpreted in light of the myopic measure of expected number of abandonments during operation not coping well with the fact that there may be many operations in parallel. More foresight is required in this case to achieve better decision-making. Note in this sense that for very low values of  $\rho$  rank differences are lower as well (yet still statistically significant). Pilot methods keep performing the best, closely followed by the hyperheuristic, which ranks the third for  $\rho < 7$ , ties with PILOT( $r\mu$ ) for  $7 \le \rho \le 9$  (no statistical difference using a Wilcoxon signed-rank test), and is only overcome by the latter for  $\rho = 10$ . Computational times per instance are 1–4 ms for LLHs, about 15–70 ms for pilot methods and the hyperheuristic, and about 0.8 s for PILOT(HYPER( $\Xi$ )).

Fig. 6 Rank distribution of the different algorithms in scenario S2 as a function of the total number of patients

The next issue to be tackled is the scalability of heuristics, either in terms of the number of patients or in the number of patient classes. Regarding the former we have repeated the experiments following the previous methodology but using this time an initial number of patients  $x_i \in [1, 100]$ , i.e., a fivefold increase in the upper limit. In this case, T and R are found to be better than  $r\mu$  for larger number of patients. See for example Fig. 6, in which ranks are shown for S2. Wilcoxon signed-rank test indicates that T and R perform significantly better than  $r\mu$  for more than 40 patients. Notice also the improved performance of the HYPER( $\Xi$ ) for larger number of patients, only second after PILOT(HYPER( $\Xi$ )). This suggests using several pilots (either directly or indirectly) in these larger instances as a more scalable strategy. Computational times per instance range in this case from 5 to 10 ms for the LLHs to 0.1–0.3 s for pilot methods and the hyperheuristic, and are about 4.7 s for PILOT(HYPER( $\Xi$ )).

Subsequently, we have considered patients classified into three classes rather than two. We have generated 5,000 instances enforcing as before that more critical patients have also longer operation times. The ranks of the algorithms are shown in Fig. 7. Note that since heuristic R is not directly generalizable to more than two classes, we

Fig. 7 Rank distribution of the different algorithms in S1 (top), S2 (middle) and S3 (bottom) when patients are sorted into three classes

have used neither it nor PILOT(R) in this case (also, HYPER( $\Xi$ )) does not include R in the LLH set). The results in this case are qualitatively the same as for two classes, T outperforming  $r\mu$  in S3 and PILOT(HYPER( $\Xi$ )) being the best algorithm in S1 and S2 (Holm's test is passed). In S3, Holm's test rejects there is a significant difference between PILOT(HYPER( $\Xi$ )) and PILOT(T), as it was the case for two classes. As to the hyperheuristic, it ranks consistently above the basic heuristics. We have also conducted experiments on a mixed scenario in which the abandonment rates of  $c_1$  patients correspond to S3 (the most critical scenario), those of  $c_2$  patients correspond to S2, and those of  $c_3$  to S1 (the less critical scenario). In this case, the performance of T is degraded due to its myopic choice function being too conservative and resulting in many impatient deaths in  $c_1$ . This performance drop also affects the hyperheuristic, which performs comparably to PILOT(TCF) (no statistical difference according to Wilcoxon signed-rank test), and below the remaining pilot methods. Computational times per instance are in this case 1–5 ms for the LLHs, 0.02–0.16 s for pilot methods and the hyperheuristic, and about 1.8 s for PILOT(HYPER( $\Xi$ )).

Finally, experiments have been done to determine the influence that stochastic operation times have on the performance of the heuristics. As mentioned in Sect. 3.1, we model this by assuming operating a patient in class  $c_i$  takes a minimum time  $\tau_i$  plus an

Fig. 8 Rank distribution of the different algorithms in S2 for stochastic operation times

excess time which is exponentially distributed with parameter  $1/(\eta_i \tau_i)$ . We consider  $\eta_i \in (0, 0.25)$ , and enforce  $\eta_1 > \eta_2$ . In this new scenario, pilot methods use the minimum time  $\tau_i$  as an optimistic approximation to operation time. We have generated 5,000 instances for each scenario S1, S2, and S3. We perform M = 15 runs of each algorithm on each problem instance and take the median value for ranking purposes. Computational times per instance are 1–4 ms for LLHs, about 10–70 ms for pilot methods and the hyperheuristic, and about 0.9 s for PILOT(HYPER( $\Xi$ )).

As expected, the results indicate that pilot methods are sensitive to the presence of noise, although their performance does not degrade excessively. Quite interestingly, T and R heuristics improve their relative performance in S2 and S3 with increasing values of  $\eta_i$ , e.g., see Fig. 8. A ranksum test on T and R versus their respective pilot methods indicates that the rank differences are significant (except for R vs. PILOT(R) in 0.15 < max( $\eta_1, \eta_2$ )  $\leq 0.2$ ). In particular, this means that when all instances are considered there is a moderate but significant advantage of the pilot methods. The hyperheuristic ranks the first (or statistically indistinguishable from the first) in S3 for max( $\eta_1, \eta_2$ )  $\geq 0.1$ , and in S2 for max( $\eta_1, \eta_2$ )  $\geq 0.05$  (in S1 the best algorithm is PILOT(HYPER( $\Xi$ )) as supported by Holm's test). The reason why the hyperheuristic

performs better than other pilot methods in these instances can be found in the fact that the former is less 'risky': it accepts the choice taken by the LLHs if there is agreement among them; on the contrary, other pilot methods may take decisions departing from those of a certain LLH on the basis of future gains as indicated by looking ahead. However, if there is uncertainty in this information a risky decision might not be ultimately as beneficial as initially thought.

Table 2 provides a global perspective of how the different techniques compare in this last setting. Entries in the table indicate the percentage of instances in which a certain algorithm outperforms another one (with statistical significance using a Wilcoxon ranksum test to compare all runs of two algorithms on each problem instance). Across the whole set of instances there is a trend of superiority for the metaheuristic approaches. This superiority is less marked in S3 where pilot methods are better than the LLHs they are based on in a net 4–5% of instances (save for TCF where the net superiority is much larger). This can be explained by the extremely severe condition of patients in this scenario, whose abandonment rates are larger than operating rates, leading to many impatient deaths in all cases (thus leaving a narrow margin for improvement). The uncertainties in operation times are also large with regard to survival expectancies in that scenario and hence the higher impact they have on pilot methods. On the other hand, the metaheuristics are remarkably better than the LLHs in S1, where the uncertainty in operation times is comparatively smaller with respect to the larger life expectancy of patients.

## **5** Conclusions

The allocation of limited medical resources to the victims of a mass casualty incident is a complex task due to the number of factors involved (not to mention its ethical ramifications). The main contribution of this paper has been the design and extensive analysis of metaheuristics (hyperheuristics and the pilot method) for dealing with this decision-making problem. The results have been positive and provide evidence on the potential usefulness of this kind of methods in this context. Quoting (citealthick07allocating), the science of triage (in particular, tertiary triage, namely the effective assignment of limited resources under competing patient demands) is nascent and very much in need of more robust and researched strategies. In this sense, the techniques described in this work should be considered as a step in this direction. Indeed, metaheuristic approaches have been shown as effective high-level methods to coordinate the application of low-level heuristics designed for this prioritization problem. The results indicate they are competitive in multiple scenarios with different features regarding the number of operating rooms, patients, and triage classes. They are, however, sensitive to the presence of large uncertainties in operation times, in particular in the most severe scenarios where these uncertainties are comparatively larger with respect to lifetime expectancies. It is possible to conceive the use of specialized mechanisms to deal with uncertainty in this context. This constitutes a line of future work.

There are many other avenues for further research. Regarding the problem model, more complex scenarios could be considered, e.g., involving survival probabilities

Table 2 Statistical analysis of the results using Wilcoxon ranksum test

Each entry in the table indicates the percentage of instances in which the algorithm labeled in the row outperforms the algorithm labeled in the column. Note that the sum of diagonal-symmetric entries do not necessarily add up to 100% since it is possible that no statistically significant difference can be established for certain instances

after treatment. Other metaheuristic frameworks, e.g., evolutionary algorithms, could be used here as well. The use of population-based techniques would involve among other issues investigating whether they can provide an adequate tradeoff between performance and computation-time. The application of machine learning strategies is also worth considering as a means to adaptively control the application of low-level heuristics in this domain.

Acknowledgments The author wishes to thank the referees for their useful comments which have contributed to improve the paper.
