**Abstract** With the introduction of fat-suppressed gradient-echo and fast spin-echo (FSE) sequences in clinical routine MR visualization of the hyaline articular cartilage is routinely possible in the larger joints. While 3D gradient-echo with fat suppression allows exact depiction of the thickness and surface of cartilage, FSE outlines the normal and abnormal internal structures of the hyaline cartilage; therefore, both sequences seem to be necessary in a standard MRI protocol for cartilage visualization. In diagnostically ambiguous cases, in which important therapeutic decisions are required, direct MR arthrography is the established imag-

ing standard as an add-on procedure. Despite the social impact and prevalence, until recent years there was a paucity of knowledge about the pathogenesis of cartilage damage. With the introduction of high-resolution MRI with powerful surface coils and fat-suppression techniques, visualization of the articular cartilage is now routinely possible in many joints. After a short summary of the anatomy and physiology of the hyaline cartilage, the different MR imaging methods are discussed and recommended standards are suggested.

**Keywords** Cartilage · Anatomy · MRI

### Introduction

With the introduction of high-resolution MRI with powerful surface coils and fat-suppression techniques, visualization of the articular cartilage is now routinely possible in many joints. Cartilage damage is very well visualized. This prominent position of MRI in diagnosis and staging of cartilage lesions is due to the newest developments in cartilage repair. Advances in molecular biology have put MRI in an even more prominent clinical position.

### Anatomy and physiology of the hyaline cartilage

The term “hyaline” cartilage refers, somewhat misleadingly, to the amorphous, homogeneous appearance of cartilage matrix by light microscopy; however, cartilage is actually quite fibrous and demonstrates marked 3D anisotropy. Cartilage can be divided into four (or five)

zones, depending on the differentiation of the most superficial zone into one or two compartments, and is based on the morphology and arrangement of chondrocytes and the staining properties of the matrix. The deepest layer, representing 5% of the entire volume, is calcified and serves to anchor an extensive network of collagen fibrils that radiate toward the surface in dense bundles linked together by bridging fibrils. More superficially, the collagen fibrils become thinner and more randomly organized, with numerous, obliquely oriented fibrils to resist the shearing forces that arise there. Ultimately, the fibrils band together at the articular surface to form a compact, tangentially arranged layer that is relatively impermeable to water. This fine network of collagen fibrils is further organized into parallel leaves or laminae that radiate vertically from the calcified zone. Superficially, these laminae become thinner and arch over to form highly packed horizontal leaves at the articular surface (Fig. 1) [1, 2, 3, 4, 5, 6].

**Fig. 1** Different layers of hyaline cartilage and subchondral bone with vessels. Figures 1, 2, and 3 are from [63]

Between the deep calcified zone and the uncalcified cartilage lies the so-called tide mark representing the mineralized front of the calcified cartilage (Fig. 2). In case of severe stress with overloading, the mineralization zone can be duplicated or even multifolded. This is due to a quick repair process that builds new mineralization fronts leaving behind deep zones of uncalcified cartilage (Fig. 3). The chondrocytes produce the collagen fibrils and as ground substance proteoglycans. The distribution of proteoglycans within the cartilage matrix is related to mechanical requirements. This distribution varies markedly from joint to joint, geographically within a single articular cartilage, and as a function of age. There are structural changes in proteoglycans that occur during aging that differ from those of degenerative osteoarthritis.

The negatively charged proteoglycans of the cartilage exert osmotic pressure to draw water into the cartilage, which counteracts mechanical pressures, forces water out, and produces an expansion pressure that is resisted by the tension in the collagen fibers. Under physiological conditions, the stiff collagen fibers prevent proteoglycans from taking up water maximally [2, 3, 4].

The extreme smooth surface of the hyaline cartilage serves as gliding surface with a very low resistance. The elasticity of the hyaline cartilage is, only to a very small degree, a load cushion. The majority of the load forces are usually taken up by the subchondral bone (30%), whereas normal hyaline cartilage takes only 1–3% of the load forces. In addition to its “lubricant” task, hyaline cartilage dissipates loading forces to a larger surface, which lowers the maximal load. It must also be empha-

**Fig. 2** Histological section with hematoxylin and eosin staining. The tidemark (*solid arrow*) borders calcified and uncalcified cartilage and represents the mineralization front. The calcified cartilage is connected to the cortical endplate. A subchondral vessel reaches the tidemark (*open arrow*)

**Fig. 3** Histological section of hyaline cartilage with duplication of the tide mark (*arrows*)

sized that the subchondral bone and hyaline cartilage are a functional unit in load dissipation and uptake, vascularization, nutrition, and repair mechanisms. During physiologic articular loading and unloading, the cartilage and subchondral region are deformed. This maintains nutrition. Complete immobilization with steady unloading results in decreased synthesis of proteoglycans and fibrils by the chondrocytes and loss of cartilage. Conversely,

exercise increases synthesis, leading to thickening and swelling of cartilage.

Normal replacement of cartilage begins from the calcified cartilage, which, throughout life, has the same thickness. Calcified cartilage is absorbed from the subchondral side by invading tiny vessels, as it advances into the uncalcified cartilages. This leads to constant remodelling of the joint and reduces the incongruity of the joints. Increasing joint congruency with aging diminishes physiologic loading, unloading, and nutrition, and may be one cause of aging. Uncalcified cartilage may become thinner with age.

## Imaging

The purpose of cartilage imaging is to visualize the surface of the cartilage, as well as its matrix thickness, volume, and subchondral borders. Currently, MRI is the standard imaging method for this purpose.

T1-weighted spin-echo (SE) imaging can depict boundaries between cartilage and subchondral bone but is relatively poor at demonstrating cartilage–fluid interfaces (Fig. 4) [7]. In a non-blinded study of naturally occurring lesions in 20 cadaveric knees, only 70% of lesions were detectable [8]. With conventional T2-weighted spin-echo-sequences the signal of cartilage decreases much faster than that of joint fluid. This mismatch increases the contrast between cartilage and effusion; however, the signal-to-noise ratio is generally insufficient to support high spatial resolution. Furthermore, the preferential loss of signal from the deep layers of cartilage with long echo times obscures the interface between cartilage and subchondral bone, which makes it difficult to obtain an accurate measurement of cartilage thickness or volume [9, 10]. One study demonstrated only a 52% accuracy rate with conventional T2-weighted SE sequences to detect naturally occurring lesions in the patello-femoral joints of cadaver [10].

In high-field MRI (7.05 T), short-TE projection reconstruction MR microscopy proved to be reliable for measurements of cartilage thickness in an *ex vivo* study [11]. The signal in cartilage is highly dependent on the relative orientation of its collagen fibers, and moreover the deep layer of the cartilage shows rapid signal decay due to short T2 relaxation times. The good result has been attributed to the ability to use short TE to obtain MR signal also from structures with short T2. As the deep layer of cartilage was homogeneously hyperintense, the delineation from the hypointense tidemark/cortical bone was improved.

Fast spin-echo (FSE) imaging combines the heavy T2-weighting, magnetization transfer effects and relative preservation of high signal intensity in the marrow fat to produce images in which articular cartilage has extremely low signal intensity, whereas joint fluid and subchon-

**Fig. 4** Magnetic resonance imaging of the knee joint (T1-weighted spin echo): Boundaries between uncalcified cartilage and subchondral bone (including calcified cartilage) are well demonstrated. Boundaries between cartilage and synovial fluid are not recognizable

dral bone exhibit high signal intensity. Thus, contrast between cartilage and adjacent joint fluid and bone marrow is high [12]; however, the boundary between the calcified deepest layer of cartilage, which can thicken in cases of degeneration, and the subchondral bone may be obscured. Since FSE sequences allow multiple acquisitions to be obtained within a reasonable imaging time, T2-weighted FSE imaging can provide sufficient signal-to-noise ratio to allow a high in-plane resolution matrix (Fig. 5). The unusual T2 behavior of cartilage is exclusively due to the presence and organization of collagen [13, 14]. Collagen, with a highly regular structure, tends to immobilize water molecules and promote dipolar interactions between their protons, thus accelerating T2 relaxation.

An *ex vivo* study using magnetic resonance microscopy (MRM) showed a good correlation between a trilaminar appearance of the cartilage and histology [15]. In this study, a hypointense superficial layer, an intermediate hyperintense layer, and a deep hypointense layer were found. The authors claimed that the different signal intensities might represent the different concentration of collagen concentration, which are maximum in the superficial and in the deep layer. A 90° rotation around the longitudinal axis of the bone led to loss of trilaminar appearance, which was attributed to the different (anisotropic) collagen fiber orientation, thus leading to a reduced dipole-to-dipole interaction with a corresponding in-

**Fig. 5** Magnetic resonance imaging of the knee joint (axial T2-weighted fast spin echo, FSE): hyaline cartilage with a hyperintense focal defect on the medial patellar cartilage of the femoral joint shows an extremely low signal, which contrasts strongly to the high signal intensity of joint fluid as well as to the relatively bright fatty marrow signal

crease in T2 relaxation. T2-weighted FSE sequences are therefore useful not only due to the high contrast between cartilage and adjacent synovial fluid for the detection of surface defects, but also for the detection of early matrix damage, potentially at a stage at which cartilage is still salvageable [16].

Because of the multiple refocusing  $180^\circ$  radiofrequency pulses, the T2-weighted FSE sequence is relatively insensitive to magnetic susceptibility artifacts, which may be important in patients who have undergone previous arthroscopy and ligamentous reconstruction, and can be used to accurately detect associated meniscal and ligamentous pathology.

However, FSE imaging as a two-dimensional sequence is limited to a minimum section thickness of 3 mm. Thinner slices (2 mm) can now be obtained with two-dimensional FSE sequences on higher performance gradient subsystems, which are currently becoming commercially available; however, multiplanar reconstructions, which are often important in evaluating the curved structures in joints, cannot be performed.

Gradient-echo (GRE) sequences with a longer TE decrease the relative signal intensity of cartilage and improve cartilage fluid contrast but only at the cost of signal-to-noise ratio and, therefore, spatial resolution. Moreover, due to magnetic susceptibility artifacts from the deep calcified layer of cartilage and cancellous sub-

**Fig. 6** Magnetic resonance imaging of the knee joint (reversed pulse sequence of fast imaging steady precession DESS, lateral): The hyaline cartilage exhibits an intermediate signal, whereas joint fluid has a high signal intensity. Solid tissues, such as menisci, are not well delineated

chondral bone, long TE GRE sequences obscure the cartilage bone interface and make quantification of cartilage difficult [17, 18]. Clinical studies using such sequences have reported poor results with sensitivities ranging from a low of 31% to a high of 87% [19].

Gradient-echo sequences with short TE suffer from poor contrast between cartilage and joint fluid; thus, additional contrast must be available. A possibility offered by one manufacturer is the combination of a standard fast imaging steady precession (FISP) sequence with PSIF, the reversed pulse sequence of FISP, which results in the double-echo steady-state (DESS) sequence. With this sequence, in addition to the GRE sequence, T2\*-weighting is achieved by transverse magnetization from steady-state components and from the high-frequency (PSIF) pulse. The PSIF part of the sequence leads to high T2 contrast, whereas the FISP part provides representative morphological images. As a result, joint fluid exhibits high signal intensity and provides a better delineation of cartilage surface, as the cartilage has a medium signal intensity (Fig. 6). Since a 3D technique is possible with this sequence, thin contiguous slices can be obtained; however, there are some disadvantages with this

**Fig. 7** Magnetic resonance imaging of the knee joint (double-echo steady-state, DESS): There is a poor contrast between articular cartilage and solid surrounding tissue

technique. Firstly, a significant amount of joint fluid is necessary for optimal delineation of cartilage surfaces, which is not always present. Secondly, the contrast-to-noise ratio between cartilage and solid surrounding tissue, in particular menisci, is low, which poses a problem in delineation and segmentation for volume measurements. By combining DESS with selective water excitation in principle an indirect fat suppression is performed; however, since synovial fluid is also strongly enhanced

by this technique, the contrast-to-noise ratio between the hyperintense articular cartilage and bright synovial fluid is poor (Fig. 7) [20]. In this study the 3D DESS sequence thus was found to be only moderately accurate in detecting patellar cartilage abnormalities. It proved to be superior to sagittal TSE for the detection of cartilage softening, but not for the detection of surface lesions. For cartilage softening, the sensitivity of 3D DESS was better than that of TSE (73 vs 53%). The same was true for the specificity (75 vs 65%), and the accuracy (70 vs 62%). For surface lesions, the values for TSE were 43 vs 60%, 92 vs 92%, and 83 vs 86%, respectively. In another study [21],  $A_z$  values [area under the receiver operating characteristics (ROC) curves] for water-excited 3D DESS and 3D fast low-angle shot (FLASH) were 0.96, which was significantly higher than for all 2D pulse sequences.

The addition of frequency-selective fat suppression to 3D spoiled GRE sequences results in a significant increase in contrast-to-noise ratio between cartilage and joint fluid and cartilage and subchondral bone, demonstrating articular cartilage as a band of high signal intensity. After suppression of fat, signal intensities are re-scaled by the MR unit to render articular cartilage the brightest structure in the joint, with joint fluid and subchondral bone demonstrating a relatively lower signal intensity (Fig. 8).

In a recent study, a trilaminar appearance was attributed to a truncation artifact on a fat-suppressed 3D spoiled GRE sequence [22]. This phenomenon is most apparent in the phase-encoding direction at interfaces at which there is an abrupt and marked change in signal intensity. When there are two such interfaces a summation effect occurs which is observed as a thin hypointense line within the central tissue.

The advantage of fat-suppressed 3D spoiled GRE sequences is the relatively high signal intensity of articular cartilage in contrast to low signal intensity from the surrounding tissue (Fig. 9). Three-dimensional acquisition

**Fig. 8** Same patient as in Fig. 7 **a** (T2-weighted FSE): The central patellar cartilage lesion is slightly hyperintense. **b** (3D GRE with fat suppression): Hyaline cartilage is a band of high signal intensity with a focal hypointense lesion within the patellar cartilage. Synovial fluid and subchondral bone (with calcified cartilage) show a lower signal intensity

yields images with higher resolution and contrast-to-noise ratio than two-dimensional acquisitions. Thin imaging sections allow high-quality multiplanar reconstructions which are useful to evaluate the patellar and trochlear surfaces with images perpendicular to facets where the articular surface is curved. Finally, thin-section volume acquisitions allow segmentation and accurate 3D reconstructions of articular cartilage (Fig. 10) [10, 23, 24, 25, 26].

Fat-suppressed, 3D spoiled GRE imaging is easy to perform, widely available, and, contrary to other cartilage imaging techniques, such as magnetization transfer imaging, it requires no postprocessing of data and avoids misregistration artifacts.

The use of a fat-suppressed, 3D spoiled GRE sequence has been shown to result in an accuracy of 91%,

a sensitivity of 87%, and a specificity of 97% [24]. As with other techniques, the highest accuracy was achieved with the patello-femoral joint and higher-grade defects were detected with greater accuracy. A major drawback is the relatively long examination time of 10–15 min, which makes it less attractive for routine clinical use. To decrease the scan time, faster and stronger gradients are now available. Moreover, examination time can be reduced by using selective water excitation instead of spectral presaturation. To speed up examination time, a recently developed 3D multishot echo planar imaging (EPI) sequence with fat suppression can be used for evaluation of the hyaline articular cartilage. The performance of the fat-suppressed 3D EPI sequence and the 3D GRE sequence with fat suppression in the evaluation of articular cartilage was compared using histology as a reference. Both sequences showed comparable performance, but the scan time for the EPI sequence was reduced by a factor of four which makes it more suitable for clinical routine [27].

In a clinical study [28], fat-suppressed 3D FLASH sequence, however, was less precise for grading of cartilage lesions than CT arthrography, which was used as a reference. Moreover, it did not show as many fissures.

The 3D spoiled GRE sequence with fat suppression provides 3D information that is useful for determining the volume and 3D configuration of cartilage [29, 30, 31]. Thin-section acquisition allows accurate volumetric measurements not only of the cartilage layers of the knee joint, but also of smaller joints with an accuracy of 5% and an interobserver variability of 3.3–9.6%. Newer results show a variation of only 1.9% [32]. These measurements may be helpful in the serial evaluation of disorders that affect cartilage integrity diffusely and in conditions that cause progressive cartilage loss such as osteoarthritis and inflammatory arthropathies [33].

Subtraction magnetization transfer (MT) contrast imaging can also show the hyaline cartilage with positive contrast [34]. Magnetization transfer contrast is a relatively new technique that alters MR image contrast by means of a relaxation mechanism different from that of conventional T1-, T2-, or T2\*-weighted imaging (Fig. 11). In this technique, continuous or pulsed radiofre-

quency irradiation is applied during a standard MR imaging sequence to selectively saturate protons with restricted mobility associated with an increase in macromolecules. The T2 decay in the macromolecular pool is too rapid to contribute signal to conventional MR images. This MR-invisible pool is, however, in thermodynamic equilibrium with the MR visible pool of mobile protons in bulk water within the same tissue. Cross-relaxation magnetization transfer can occur between the two pools. Selective saturation of the macromolecular protons perturbs this equilibrium and evokes a net transfer of magnetization from the water protons to the macromolecular pool. Since the macromolecular protons do not contribute to the signal in the MR image, this magnetization transfer manifests as a loss of signal intensity in tissues in which these two proton pools are tightly coupled. Woolf et al. [35] demonstrated that a significant amount of MT occurs in articular cartilage, whereas no significant MT occurs in synovial fluid. With T2\*-weighted GRE sequences, these changes can be used to produce increased contrast between high signal intensity cartilage compared with standard sequences [33]. Subtraction of MR imaging data obtained with a pulsed MT technique from that obtained without an MT technique generates images in which con-

**Table 1** Direct MR arthrography. The amount of contrast agent required depends on the joint to be examined

trast reflects tissue differences in MT. This technique depicts the hyaline articular cartilage as a band of high signal intensity tissue contrasted to adjacent low signal intensity joint fluid and subchondral bone, similar to the fat-suppressed 3D GRE sequences [34]; however, this technique is not widely available, requires post-processing of the data, and can result in misregistration artifacts due to changes in patient positioning. The latter artifact could be significantly reduced by the development of a so-called dynamic MTC, which means that within one sequence non-MTC and MTC scans can be acquired, and misregistration artifacts are eliminated.

Magnetization transfer is a collagen-dependent mechanism to achieve signal loss in cartilage. Disruption or loss of the collagen matrix in cartilage results not only in a small increase in proton density, but also eliminates the attenuating effects of collagen-dependent T2 relaxation and MT. As a result, the signal intensity increases in areas of matrix damage or early chondromalacia, which theoretically, offers a technique for visualization of early cartilage disease. Unfortunately, MT with current instrumentation results only in a moderate contrast-to-noise ratio; thus, this technique has not proven to be superior to other available MR imaging techniques [36].

The transfer of magnetization from protons in tissue water to protons in collagen also can unintentionally be caused by off-resonance irradiation of neighboring slices during conventional multislice imaging. This effect increases with the number of slices used and is most pronounced in FSE imaging because of the multiple 180° refocusing pulses used in this technique [37].

The detection rate for cartilage lesions without surface defects by MTC MR imaging was 80%, corresponding to an increased collagen concentration [38].

The use of gadolinium compounds for the imaging of articular cartilage has been applied in several different forms. Direct MR arthrography, where a 2-mmol dilute solution containing gadolinium compounds is injected directly into the joint (with or without the help of X-ray fluoroscopy), dramatically improves contrast between cartilage and arthrographic fluid [39]. The amount of contrast medium used depends on the investigated joint and can vary from 1 to 3 ml, to 15 to 25 ml (Table 1).

**Fig. 12** Knee joint (direct MR arthrography, T1-weighted SE): The synovial fluid is hyperintense. There is a cartilage defect within the patella representative of first-stage chondromalacia

After injection of the contrast medium, the joint should be moved to ensure an even distribution of the contrast medium (Fig. 12). The examination should be finished 30–45 min after the intra-articular injection to avoid increased dilution of contrast medium. Moreover, the contrast medium might be taken up by cartilage, thus lowering the delineation of the surface of the cartilage [39]. Magnetic resonance arthrography (MRA) has proved to be 100% specific for FISP and T1-weighted sequences, and very sensitive, with detection rates of 87 and 85% [40]. The accuracy of the method was 88 and 87% for both sequences, respectively.

Direct MRA is routinely used as an adjunct in diagnostically ambiguous MRI examinations, where a definitive diagnosis is mandatory (e.g., before surgery).

The only other imaging modality that offers potential as an equally diagnostic alternative to standard MRA is the newly “re-developed multi-slice” CT arthrography.

Indirect MRA, with a less invasive intravenous injection of 5–15 ml 0.1 mmol gadolinium compounds, has also been used; however, with this method, there are many inherent disadvantages, including less contrast, enhancement of overlying structures, and no capsular expansion. These disadvantages prevent the widespread use of this method; thus, indirect MR arthrography may

be limited to those cases in which an invasive procedure is contraindicated or where the absence of a fluoroscopy unit renders direct arthrography impractical.

### Quantitative 3D analysis of cartilage

Quantitative image processing and analysis techniques play an increasingly important role in evaluating cartilage loss and monitoring response to medical and surgical therapy [41, 42, 43]. Several investigators have reported the use of 3D reconstructions of the articular cartilage with subsequent volumetric quantification of the entire cartilage surface. With this technique, cartilage is segmented from the surrounding tissues using a signal-intensity-based thresholding technique applied to a cartilage-sensitive MRI sequence [44]. In the knee joint, the intraobserver reproducibility error for measurements of 3D cartilage volumes have been reported to range between 3.6 and 6.4%, and the interobserver error was 7.8% in the same study. For the tibial cartilage morphometry, spoiled 3D GRE sequence with selective water excitation, the precision of volume and mean thickness measurements was between 2.3 and 2.6% in healthy volunteers and patients with severe osteoarthritis, whereas the precision was lower for maximal tibial cartilage thickness [45]. Recent developments proved that specific MR sequences (3D FT spoiled gradient-recalled acquisition in the steady state) allow very sensitive reproduction of quantitative cartilage measurements [43].

### Postoperative imaging of cartilage repair

With recent advances in the treatment of articular cartilage disorders, including osteochondral autografts and autologous chondrocyte implantation, noninvasive MRI has gained additional importance with the determination of the structural success of surgical intervention.

In the assessment of different cartilage repair techniques, proton-density and T2-weighted FSE sequences have proved to be most useful in the postoperative follow-up. Cartilage transplants should be evaluated with respect to their morphology and signal intensity. For morphology the degree of defect repair (filling of the defect), the integration to the border zone (possible demarcation border to the surrounding cartilage), the surface of the transplant, the subchondral lamina, and the subchondral bone should be evaluated.

The signal intensity of the osteochondral autograft (“mosaicplasty”) shows marked hyperintensity on T2-weighted FSE images in the early postoperative period (3–6 months), representing edema. Conversion to similar signal intensity in comparison with the native hyaline cartilage over a period of approximately 6–12 months is caused by development of fibrovascular tissue. Within

the follow-up period of 18 months, however, many transplanted osteochondral autografts still showed a fissure-like gap to the neighboring original cartilage, indicating that the transplant had still not been integrated. Other problems were the lack of development of new cartilage at the donor site (demonstrated by MRI), and the difficulty to find sufficient donor sites in patients potentially in need of cartilage transplants. Consequently, young patients with acute (traumatic) cartilage lesions should have been exclusively selected for transplantation of osteochondral autografts.

For chondrocyte transplantation, 3D cell transplants are cultivated *ex vivo*, subsequently implanted after local application of growth factors. The signal intensity of the chondrocyte autograft shows conversion of marked hyperintensity on T2-weighted FSE images in the early postoperative period to similar signal intensity in comparison with the native hyaline cartilage, probably representing transformation into hyaline cartilage, over a period of approximately 6–12 months (S. Marlovits and S. Trattnig, pers. commun.). Magnetic resonance imaging shows smoothening of the border between transplanted and original cartilage, indicating integration. One possible future problem could be a constant cartilage overgrowth. The problem to differentiate between a normal from an abnormal signal behavior of the transplant in the postoperative course is not yet solved, but recent studies show that the use of more sophisticated techniques, such as delayed contrast-enhanced techniques or diffusion-weighted imaging, may be more helpful in the definition of an intact transplant.

### Future developments

The glycosaminoglycans (GAG) of the hyaline cartilage comprise approximately 5% of tissue weight. The GAGs are a constitutive part of proteoglycans. The basis of dGEMRIC is the following: GAGs have abundant charge side groups that confer a negative fixed charge density (FCD) to the cartilage matrix. Mobile ions distribute in the tissue to reflect the local GAG concentration. In particular, dGEMRIC is concerned with the distribution of the negatively charged MRI contrast agent Gd(DTPA)<sub>2</sub>. If injected intravenously, the contrast agent will penetrate cartilage from both the synovial surface as well as from bone [46, 47], and will then distribute into areas of cartilage that are depleted of GAG at a higher concentration than in areas of high GAG [48]. Gd(DTPA)<sub>2</sub> has a concentration-dependent effect on the MR parameter T<sub>1</sub>; therefore, T<sub>1</sub> images in the presence of Gd(DTPA)<sub>2</sub> reflect the Gd(DTPA)<sub>2</sub> concentration, and hence tissue GAG concentration. (It is important to emphasize that this use of Gd(DTPA)<sub>2</sub> – to measure GAG in the tissue requires penetration of Gd(DTPA)<sub>2</sub> – into the tissue, and thus this method, differs from those which use the con-

**Fig. 13** Graphic presentation of the normal ion distribution. Negatively charged GAG moieties (*white*), and otherwise evenly distributed ions within the cartilage and synovial fluid

trast agent to better delineate anatomic defects early after injection.).

dGEMRIC has been validated both *in vitro* and *in vivo* as a non-destructive surrogate of histologic analysis of GAG distribution in cartilage [46, 48, 49, 50, 51]. A clinical protocol for dGEMRIC has been recommended [47], and pilot clinical studies have been applied to the evaluation of osteoarthritis in knees [47, 52, 53] as well as dysplasia in hips [54]. The GAGs represent one of the major macromolecular constituents of cartilage and are critical to this mechanical support function, and thus are presumed to be necessary for a fully functional ACT implant.

These GAGs have moieties that are ionized under physiological conditions. In degenerative osteoarthritis the amount of GAGs decreases with the intensity of the disease.

Ionic contrast medium applied intravenously as double-dose Gd-DTPA<sup>-2</sup> is distributed in relation to the GAG concentration. The even or uneven distribution within the cartilage takes between 45 and 270 min depending on the investigated joint and location. In normal (healthy) cartilage, the uptake will be very low, and in cartilaginous disorders, uptake due to the lack of charged GAGs is high.

In the future, this method could allow visualization of abnormal cartilage tissue at a very early stage in rheumatoid and degenerative diseases (Figs. 13, 14).

The GAGs could also directly or indirectly affect contrast in other imaging methods. The GAGs contribute to the MT effect in cartilage [55, 56]; however, this effect is

**Fig. 14** Magnetic resonance imaging of the patellar cartilage (3 T; T1-weighted SE), 120 min after i.v. ionic contrast application: diffusion of contrast medium into the cartilage (*arrow*)

very small relative to the effect of collagen on MT, and therefore it may be difficult to use MT to follow changes in cartilage disease.

Cartilage is essentially a fluid-filled “sponge” comprising approximately 75% of cartilage weight. In early disease, the percentage of water in cartilage goes up by a few percent. The cause of hydration changes remain unclear but includes the loss of or damage to solid matrix elements. Changes in hydration can be seen directly by obtaining a proton-density-weighted image. Unfortunately, the sensitivity is very low, given the relatively small changes in hydration with diseases.

T1 and T2 relaxation times depend on hydration [57, 58]. T2 may be very sensitive to hydration changes and is used to identify focal cartilage lesions.

Interpretation of T2 differences, however, requires caution. Differences in T2 across the cartilage may, in part, reflect collagen orientation issues due to the “magic angle” effect [59]; therefore, suggested cartilage T2-mapping still requires further clinical evaluation. In addition, the interpretation of T2 differences is complicated because of the non-mono-exponential behavior of T2 in cartilage. Altogether the false-positive rate could be quite high.

The diffusion coefficient of water in cartilage also increases with increased hydration. Since hydration generally increases with cartilage degeneration, the diffusion coefficient of water would be expected to track degeneration [60, 61]. Unfortunately, high-precision diffusion measurements are technically difficult due to motion artifacts and cannot be used routinely as yet.

Use of high-resolution surface coils may improve the detail resolution of the cartilage matrix. Initial results have demonstrated that the radial structure of hyaline cartilage can be depicted (Figs. 14, 15).

**Fig. 15** Magnetic resonance imaging of the patellar cartilage (high-resolution 3D GRE with fat suppression): radial matrix of the patellar cartilage

Optical coherence tomography (OCT) might be another promising method to achieve high-resolution images in cartilage disease [62]. Similar to ultrasound, it measures the intensity of backreflected infrared light. The axial resolution is very high (5–15  $\mu\text{m}$ ). As the method had originally been developed for imaging the transparent tissues of the eye, the imaging penetration in non-transparent tissues is limited to approximately 4 mm. Cartilage has, to date, only been imaged in osteoarthritis in vitro. As OCT is optical fiber based, it could be integrated with arthroscopes. A possible future application might therefore be the use as an additional tool in arthroscopy.

### Recommended MR imaging standards

Although there are still innumerable new cartilage sequences (e.g., fluctuating equilibrium magnetic resonance, FEMR) reported each year, the generally accepted MR imaging standard is dual FSE and 3D GRE with fat suppression. While FSE allows visualization of intracartilaginous structural abnormalities, 3D GRE outlines the thickness and surface of uncalcified cartilage, synovial fluid, and subchondral bone, together with calcified cartilage. The 3D reconstruction is easily performed in all dimensions with 3D GRE. In unclear cases where an exact (pre-therapeutic) diagnosis is warranted, direct MR arthrography is the unsurpassed method of choice (Tables 2, 3).

**Table 2** Technical principles. *FSE* fast spin echo; *GRE* gradient echo; *PD* proton density; *FOV* field of view

Direct MR arthrography. Sequences that have been established for visualization of cartilage lesions

Imaging protocol	Indication
T2 FSE (PD T2-weighted)	Intrachondral lesion
3D GRE+FSE	Surface defects

Technical details

Small FOV, large matrix size  
Slice thickness  $\leq 2$  mm (with 3D: 1.5–1/mm)  
Two or more planes  
Surface coil

## Pathologies that require cartilage imaging

The following pathologies require cartilage imaging:

1. Degenerative osteoarthritis before invasive therapies
2. Follow-up of cartilage/subchondral region
3. Osteochondritis dissecans/osteonecrosis
4. Rheumatoid disease before invasive therapies
5. Cartilage/subchondral fractures (including metaphyseal fractures)
6. Cartilaginous blastomas
7. Rare metabolic diseases (e.g., calcium pyrophosphate dihydrate, gout)

**Table 3** Advantages and disadvantages of the sequences recommended in Table 2

	Advantages	Disadvantages
3D GRE+FSE	High contrast/noise ratio Cartilage/joint effusion  Cartilage/bone marrow High resolution (out of plane) Multiplanar reconstructions Volumetric measurements	Long examination time Insensitive to bone marrow edema and subchondral cysts Sensitive to susceptibility artifacts
Dual FSE	High contrast/noise ratio Cartilage/joint effusion Cartilage/bone marrow High resolution (in-plane) Less sensitive to susceptibility artifacts Excellent subchondral imaging	Hyperintense bone marrow Limited out-of-plane resolution No multiplanar reconstructions
