Abstract Magnetic resonance signal intensity of focal liver lesions is affected by numerous pathologic factors. Lesion histologic features, such as cellularity, vascularity, stromal component, and intratumoral necrosis or hemorrhage, strongly affect T1 and T2 relaxation times. Additionally, intracellular content of certain substances, such as glycogen, fat, melanin, iron, and copper, may also have a substantial role in determining MR signal behavior. In this review we discuss the correla-

tions between MR imaging features and pathologic findings in benign and malignant focal liver lesions. Knowledge of imaging–pathology correlations greatly assist in characterizing focal lesions. Moreover, in certain tumor histotypes, such as hepatocellular carcinoma, careful analysis of lesion signal intensity may help predict the degree of tumor differentiation.

Keywords Liver · Liver neoplasms · MR imaging Diagnosis

Introduction

Magnetic resonance signal intensity of focal liver lesions depends on both histologic and cytologic features [1, 2, 3]. Among histologic characteristics, hypercellularity and hypervascular supply are usually associated with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. The stromal (fibrous) component, in contrast, reduces signal intensity on T2-weighted images. Necrotic areas may exhibit different features, depending on the type of the necrosis itself: Whereas liquefactive necrosis is highly hypointense on T1-weighted images and highly hyperintense on T2-weighted images by virtue of the increased water content, coagulative (dehydrated) necrosis shows the opposite behavior, being characterized by low signal intensity on T2-weighted images. Hemorrhagic areas may show different patterns, depending on the timing of the bleeding: The most common appearance is that of hyperintensity on T1-weighted images, caused by extracellular metahemoglobin (Fig. 1).

Intracytoplasmic accumulation of glycogen or fat may shorten T1 relaxation time of lesions increasing

signal intensity on T1-weighted images (Fig. 2) [4]. Melanin also has paramagnetic properties which increase the signal intensity on T1-weighted images. While intratumoral content of copper usually has limited influence on MR signal intensity of liver lesions, iron deposits may greatly reduce signal intensity, especially on T2-weighted images (Fig. 3) [5]. In hepatocellular lesions, the presence of Kupffer's cells and the degree of hepatocyte-like function influence MR signal intensity in images obtained after administration of tissue-specific MR contrast agents, such as reticuloendothelial-system-targeted agents and hepatobiliary agents [6, 7].

The signal intensity of a focal lesion on MR images is the outcome of its different histologic and cytologic features. Careful analysis of lesion signal intensity on MR images, therefore, is crucial for proper characterization of focal lesions [1, 2, 3]. In this article we review the MR imaging features of the most common benign and malignant liver lesions, highlighting imaging–pathology correlations.

Fig. 1 Subacute intratumoral bleeding, associated with extracellular metahemoglobin, gives a markedly high signal intensity both on **a** T1- and **b** T2-weighted MR images

Benign liver lesions

Hemangioma

Hemangioma is the most common benign liver tumor, with a prevalence of up to 7–20% in autopsy series. It is usually asymptomatic and incidentally detected. Hemangiomas are well-circumscribed, blood-filled masses of variable size. On cut sections, areas of fibrosis, hemorrhage, or thrombosis may be seen, especially in large hemangiomas. The blood-filled spaces or vascular channels that comprise hemangiomas are lined by a single layer of endothelial cells. The channels themselves are separated by thin, fibrous septa, which may form finger-like projections into the channels.

Owing to the high blood (water) content, hemangiomas appear as hypointense lesions on T1-weighted images and as markedly hyperintense lesions on T2-

Fig. 2 a Glycogen accumulation within macroregenerative nodules in cirrhosis give a markedly high signal intensity on T1-weighted MR images. **b** The lesions are isointense to liver on T2-weighted image

Fig. 3 a, b Iron deposits within macroregenerative nodules involving the whole liver parenchyma give a markedly low signal intensity on T2-weighted MR images

Fig. 4a, b Giant hemangioma. **a** On T1-weighted images the lesions appear definitely hypointense, whereas it is markedly bright on **b** T2-weighted images. Internal areas of fibrosis are detected as low-intensity bands both on T1- and T2-weighted images

weighted images. Imaging with heavily T2-weighted sequences, in fact, enhances the ability to differentiate hemangiomas from malignant tumors [8]. Low-intensity areas on T2-weighted images may sometimes be seen in the central portion of large hemangiomas, being usually associated with fibrosis (Fig. 4).

Dynamic MRI with extracellular contrast agent administration may display the slow perfusion pattern of hemangioma, showing peripheral nodular enhancement in the early phase, progressing centripetally to uniform (or almost uniform) enhancement in the delayed phase. Persistent hypointensity, in fact, is frequently seen in the central portion of large hemangiomas owing to fibrotic or thrombotic phenomena. Small (< 1.5-cm) hemangiomas, however, may show uniform enhancement in the arterial phase, which tend to persist in the delayed phase (Fig. 5) [9, 10, 11]. Hemangiomas may show increased signal intensity on T1-weighted images even after administration of superparamagnetic contrast agents, due to the T1 effect of the agent trapped within the vascular lacunae of the lesion [12].

Focal nodular hyperplasia

Focal nodular hyperplasia (FNH) accounts for approximately 8% of all primary hepatic tumors and represents

the second most common benign liver tumor after hemangioma. Most FNHs are seen in women in the third to fifth decades of life. Focal nodular hyperplasia arises as a localized hepatocyte hyperplastic response to an underlying congenital vascular malformation. Focal nodular hyperplasia may be associated with hemangiomas. The use of oral contraceptives is associated with FNH; however, it only promotes the growth of the lesion and does not induce its formation.

Focal nodular hyperplasia is a well-circumscribed mass, lacking a true capsule, and is characterized by a central scar of vascular connective tissue with prominent arterial vessels that extend outward, through fibrous septa, to the periphery of the tumor. These septa circumscribe nodules of hepatocytes and small bile ducts. Kupffer's cells are also present. The lesion does not show internal hemorrhage or necrosis: The growth of FNH, in fact, remains proportional to its blood supply. Of interest, FNH has an exclusive arterial blood supply, with no portal vein branches [13, 14].

Focal nodular hyperplasia is essentially a hyperplastic process, in which all the components of normal liver are present although abnormally organized. These pathologic features explain the typical MR appearance of this lesion. Focal nodular hyperplasia, in fact, is usually isointense or nearly isointense with respect to normal liver parenchyma both on T1- and T2-weighted images. The central scar, made by water-rich vascular connective tissue, appears hypointense on T1-weighted images and hyperintense on T2-weighted images [10, 15, 16, 17, 18].

After administration of an extracellular contrast agent, FNH demonstrates a peculiar behavior: In the

Fig. 5a–d Hepatic hemangiomas. **a** On the T2-weighted image, two hemangiomas are detected as markedly hyperintense lesions. During the dynamic, gadolinium-enhanced study (**b** arterial phase; **c** portal venous phase; **d** delayed phase), the largest lesion shows peripheral nodular enhancement in the early phase progressing centripetally to uniform enhancement in the delayed phase. The smaller lesion, in contrast, demonstrates uniform enhancement in the arterial phase, which persists in the portal and the delayed phases

arterial phase, the lesion shows clear-cut enhancement, with the central scar being unenhanced (Fig. 6). In the portal phase, the lesion undergoes rapid washout of contrast, becoming isointense to liver. The central scar may show delayed enhancement, particularly in medium-to-large-sized lesions [10, 19, 20].

After administration of reticuloendothelial-system-targeted agents, FNH, owing to the presence of Kupffer cells, shows signal intensity loss on T2-weighted images, similar to that of normal hepatic parenchyma, sparing the central scar [12]. Contrast uptake is also seen after injection of hepatobiliary agents, with variable signal intensity increase on T1-weighted images [6, 21, 22].

Hepatocellular adenoma

Hepatocellular adenoma (HCA) is an uncommon primary benign tumor. The incidence of HCA increased following the introduction of oral contraceptives, and oral contraceptives and androgen steroids therapy have been identified as definitive causative agents. Hepatocellular adenoma can also occur spontaneously or be associated with underlying metabolic disease. The diagnosis of this entity is clinically important because it can bleed, causing life-threatening hemorrhage, and because it has a potential, although very rare, for malignant transformation.

Hepatocellular adenoma presents as a solitary lesion in most cases and is typically a well-circumscribed tu-

Fig. 6a, b Focal nodular hyperplasia. **a** The lesion is nearly isointense to liver in the proton density-weighted MR image, with inhomogeneously hyperintense central scar. **b** On the contrast-enhanced T1-weighted image acquired in the arterial phase, the lesion demonstrates clear-cut enhancement, sparing the central scar

mor. The presence of large subcapsular arterial vessels accounts for its typical hypervascular nature. Hepatocellular adenoma has a propensity to outgrow its vascular supply, resulting in hemorrhage and occasionally rupture. Histologically, HCA is composed of cords of hepatocytes. Although the hepatocytes can produce bile, there are no bile ducts present to enable biliary excretion. The hepatocytes contain increased amounts of glycogen and sometimes fat [14].

The rich intracellular content of glycogen is the main element responsible for the increased signal intensity of HCA on T1-weighted images with respect to surrounding liver parenchyma. Areas of internal hemorrhage are typically depicted as markedly hyperintense areas on T1-weighted images, owing to the presence of extracellular metahemoglobin.

In dynamic contrast-enhanced MR studies, HCA shows early enhancement during the arterial phase, reflecting its hypervascularity, with rapid washout [23, 24]. Hepatocellular adenoma may also take up hepatobiliary agents and appear hyperintense with respect to the liver parenchyma on T1-weighted images [6, 21, 22].

Angiomyolipoma

Angiomyolipomas are rarely encountered in the liver, and can occur as solitary mass or as multiple lesions in association with tuberous sclerosis. They are composed of variable amounts of fat, smooth muscle cells, and vessels [25, 26]. The fatty nature of the tumor results in an hyperintense appearance on T1-weighted images [27]. The use of fat-suppressed or out-of-phase MR images can help in characterizing angiomyolipomas, showing signal intensity loss (Fig. 7) [28].

Macroregenerative and dysplastic nodules

Macroregenerative and dysplastic nodules typically arise in livers with chronic disease. They consist of hyperplastic or dysplastic hepatocytes, and may have malignant potential [29, 30, 31, 32, 33, 34]. They appear as small (< 2 cm) nodular lesions that are hyperintense or isointense on T1-weighted images and hypointense or isointense on T2-weighted images relative to the surrounding liver (Fig. 8). The increased signal intensity on T1-weighted images may be due to the increased intracellular content of glycogen, and resembles the appearance of well-differentiated hepatocellular tumors [9, 35]. Nodules with a malignant focus may show a nodule-within-a-nodule appearance.

Malignant liver lesions

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is a common malignancy throughout the world, with an estimated incidence of up to 1,000,000 new cases per year. The highest incidence rates are found in sub-Saharan Africa and the Far East. Areas of low incidence include North America and Northern Europe, whereas Mediterranean countries have an intermediate-to-high incidence. The geographic distribution of HCC is related to the etiology of the disease: In Western countries and in the Far East, most cases occur in patients with liver cirrhosis, following hepatitis B or C infection [1].

On gross pathology, most HCCs fall into one of two categories. The nodular form, which is characterized by the presence of one or more encapsulated or non-en-

Fig. 7a–d Angiomyolipoma. The lesion appears as a hyperintense nodule both on **a** T1- and **b** T2-weighted MR images, with a small central hypointense area. **c** Out-of-phase gradient-echo MR image shows definite signal intensity loss. **d** The fatty nature of the lesion is confirmed by its hypodensity, with negative attenuation values, on unenhanced CT

capsulated nodules, is seen predominantly in cirrhotic livers. The massive form, which consists in a large solitary and infiltrating tumor, is more frequent in developing countries, and, in most cases, there is no underlying cirrhosis. There is also a third so-called diffuse form, which is much less common than either of the former forms and is characterized by miliary infiltration of liver parenchyma. Four histologic patterns are distinguished: trabecular; pseudo-glandular; solid; and scirrhous (or sclerosing). Depending on the cellular characteristics, these tumors are also described as well-differentiated, moderately differentiated, poorly differentiated, or undifferentiated (anaplastic) [36].

The histologic pattern, the degree of tumor differentiation, the amount of fibrosis, the presence of internal

necrosis or hemorrhage, as well as the intracellular content of glycogen, fat, or metal ions greatly affect the MR appearance of the lesion [5, 37, 38, 39]. Nodular-type HCC is often well defined, possibly encapsulated. In contrast, the diffuse form of HCC is poorly marginated and shows an infiltrative pattern, with a high tendency to invade the portal vein branches. The signal intensity of HCC may be inhomogeneous and vary greatly, especially in the nodular form. The appearance may range from hypointense to iso- or hyperintense on T1-weighted images and from isointense to hyperintense on T2-weighted images. Usually, hyperintensity on T1-weighted images and isointensity on T2-weighted images are associated with well-differentiated tumors (Fig. 9) [40, 41, 42, 32]. High signal intensity on T1 may

Fig. 8a, b Macroregenerative nodules in Budd-Chiari syndrome. **a** T1-weighted image shows multiple, small, hyperintense nodular lesions within the diseased liver. **b** On the T2-weighted image, the lesions appear markedly hypointense

be due to the rich intracellular content of glycogen or fat, probably reflecting a defective release of these components by partially functioning hepatocytes [4, 43, 44].

Numerous additional findings may be visualized with MRI [42]. Tumor capsule is depicted as a thin rim with hypointense signal intensity on T1-weighted images due to its fibrotic composition. T2-weighted images delineate a single ring with hypointense signal intensity or a double ring with inner hypointensity and outer hyperintensity. Histopathology reveals two-layered capsules with a thin fibrous inner zone and an outer zone that consists of compressed small vessels and bile ducts. A mosaic pattern is a common MRI finding in HCC [45]. Intratumor-

Fig. 9a, b Multinodular hepatocellular carcinoma. **a** The T1-weighted MR image shows two lesions with different signal intensity: The larger tumor is hypointense to liver, whereas the smaller one is hyperintense. **b** On the T2-weighted image, the larger nodule is hyperintense, whereas the smaller one is isointense compared with surrounding liver parenchyma. Histology showed moderately differentiated hepatocellular carcinoma in the larger lesion and well-differentiated hepatocellular carcinoma in the smaller lesion

al, linear-like hypointense areas are detected on T1-weighted images and a nonuniform signal on T2-weighted images. Histopathologic correlation reveals intratumoral septa and a variety of histopathologic findings within the tumorous tissue. Central necrosis presents usually with hypointensity on T1-weighted images, with marked hyperintensity on T2-weighted images in the case of liquification. Hyperintense foci inside the nodules on T2-weighted images are likely to represent intratumoral sinusoidal dilation due to peliotic change.

Hepatocellular carcinoma is typically nourished by the hepatic artery and this elective vascularization can be demonstrated by dynamic contrast-enhanced MRI [46, 47, 48, 49]. Hepatocellular carcinoma typically shows peak of contrast uptake in the arterial phase of the dynamic MR study, corresponding to the arteriographic finding of neovascularity or staining (Fig. 10) [50, 51, 52, 53, 54, 55, 56]. Well-differentiated tumors, however, may not exhibit the typical hypervascularity of overt HCC and show slight progressive enhancement with no peak in the arterial phase [36, 37, 57]. Sclerosing HCC can show some delayed enhancement due to the abundant fibrous component [49, 58].

The contrast behavior of HCC after administration of hepatobiliary agents is dependent on the degree of

Fig. 10a–d Hepatocellular carcinoma with satellite lesions. **a** The T1-weighted MR image shows a nodular lesion which is slightly hyperintense with a hypointense peripheral rim. During the dynamic, gadolinium-enhanced study (**b** arterial phase; **c** portal venous phase; **d** delayed phase), the tumor shows clear-cut enhancement in the early phase with rapid washout. Small satellite nodules become visible around the tumor, and show the same enhancement pattern as the main lesion

differentiation of tumor cells: Whereas moderately or poorly differentiated lesions fail to take up hepatobiliary agents and appear hypointense to liver on enhanced images, well-differentiated tumor may show the opposite behavior, appearing hyperintense with respect to liver parenchyma as a result of the uptake and trapping of the agent within the tumor [6, 7, 59, 60].

Cholangiocellular carcinoma

Cholangiocellular carcinoma is a primary malignancy arising from the bile duct epithelium. The incidence of cholangiocellular carcinoma among primary liver cancer usually does not exceed 10% of cases. It is a disease of older individuals and occurs slightly more frequently in males than females. According to the site of origin, cholangiocellular carcinoma is classified into two types: intrahepatic and extrahepatic. The term cholangiocarcinoma should be used for intrahepatic lesions, whereas bile duct carcinoma should be preferred for extrahepatic neoplasms [61].

The intrahepatic or peripheral cholangiocarcinoma represents 10% of all cholangiocarcinomas. It arises from the internal wall of the small bile ducts, peripheral to the right or left hepatic ducts, and grows into the liver as a focal mass. The gross appearance of cholangiocarcinoma is that of grayish white, firm, solid, and fibrous mass. Characteristically, this malignancy has a large central core of fibrotic tissue, due to the desmoplastic reaction provoked by the neoplastic cells. Microscopically, cholangiocarcinoma represent an adenocarcinoma with glandular appearance. Mucus secretion and calcification are sometimes found, but there is no bile production [61].

The MR appearance of cholangiocarcinoma is that of a non-capsulated tumor, hypointense on T1-weighted images and hyperintense on T2-weighted images. Dilatation of the peripheral portion of the intrahepatic biliary ducts may be seen. The signal intensity of the tumor is variable according to the amount of fibrosis, necrosis, and mucinous material within the tumor. Central hypointensity may be seen on T2-weighted images, corresponding to central areas of fibrosis [62, 63, 64]. On dynamic contrast-enhanced MR studies, minimal to moderate peripheral enhancement is evident followed by progressive filling. Pooling of contrast within the tumor, reflecting the large amount of fibrous tissue, is typically seen on delayed MR images (Fig. 11) [65, 66, 67].

Fibrolamellar carcinoma

Fibrolamellar carcinoma is a rare neoplasm of hepatocellular origin that was considered in the past a variant of HCC, whereas it is now seen as an independent entity. In contrast to HCC, fibrolamellar carcinoma is seen in young patients without cirrhosis. Pathologically, this tumor usually presents as a large solitary mass with a lobulated contour and a central fibrous scar that may be calcified. Calcification is central, stellate, or nodular, and the amount of calcification is usually small relative to the large size. Satellite nodules may also be present. Abundance of fibrosis distributed in bands or laminae (hence fibrolamellar) is a hallmark of this neoplasm [68, 69, 70, 71, 72].

Fig. 11 a, b Intrahepatic cholangiocellular carcinoma. **a** The tumor is hypointense to liver on the T1-weighted image. **b** Pooling of contrast within the tumor, reflecting the large amount of fibrous tissue, is seen on the delayed, gadolinium-enhanced image

Magnetic resonance imaging reveals the tumor with a partial or complete capsule. In general, tumors are iso- or hypointense to the liver on T1-weighted images and iso- to hyperintense on T2-weighted images. The scar may have low signal intensity on both T1- and T2-weighted images, although cases of hyperintense scars on T2-weighted images have been reported [73, 74]. The tumor is not as vascularized as HCC.

Epithelioid hemangioendothelioma

Epithelioid hemangioendothelioma (EHE) is a rare malignant hepatic neoplasm of vascular origin that develops in adults. It should not be confused with infantile

Fig. 12a–c Epithelioid hemangioendothelioma. **a** On the T1-weighted image, two hypointense nodules are detected. **b** The lesions appear hyperintense on the T2-weighted image. **c** Delayed contrast-enhanced T1-weighted image shows peripheral, rim-like enhancement in the larger lesion, and homogeneous enhancement in the smaller lesion

hemangioendothelioma. Only recently has EHE been recognized as a distinct entity. It is a solid tumor composed primarily of epithelioid-appearing endothelial cells. The tumor has a variable clinical course between that of benign endothelial tumors (hemangiomas) and malignant angiosarcomas. Unlike most primary malignant hepatic tumors, two-thirds of patients affected are women, in the third or fourth decades of life. No risk factors of specific causes of hepatic EHE are known [75, 76].

Macroscopically, multifocal nodules varying in size from a few millimeters to several centimeters are seen. These nodules tend to coalesce, as they grow, to form large confluent masses, usually in the periphery of the liver, owing to the extension of the tumor through the tributaries of the portal and hepatic veins. These solid tumors characteristically have a dense fibrotic hypovascular central core and a peripheral hyperemic rim. The hepatic capsule overlying an EHE is frequently retracted inward, which is thought to be due to fibrosis induced by the tumor. This capsular retraction is an unusual feature in malignant lesions of the liver, and is suggestive of EHE [77].

Microscopically, the tumors are composed of dendritic spindle cells and epithelioid round cells within abundant matrix of myxoid and fibrous stroma. Neoplastic cells invade and eventually obliterate sinusoids, terminal hepatic veins, and portal veins. Approximately 30% of patients may demonstrate progressive sclerosis and eventual calcification [76, 77].

Concentric alteration in signal intensity, corresponding to the regions of different histology, are seen both on T1- and T2-weighted images. The MR images demonstrate subcapsular nodules of increased signal intensity on T2-weighted images similar to that of most malignancies, but not as intense as the characterizing high signal intensity of hepatic hemangiomas. Peripheral, rim-like enhancement is seen after administration of extracellular contrast agents (Fig. 12) [76, 78].

Angiosarcoma

Angiosarcomas are malignant neoplasms derived from endothelial cells that occurs primarily in adults with exposure to a variety of chemical agents and radiation. Although primary angiosarcoma accounts for less than 2% of all primary liver neoplasms, it is the most common sarcoma of the liver.

Primary hepatic angiosarcomas are highly aggressive and have an extremely poor prognosis. It occurs four times more frequently in males [79]. Macroscopically, there are two patterns of growth: multifocal nodules and large solitary mass. The tumor nodules varies in size from pinpoint foci to large nodules measuring several centimeters in diameter. The nodules may have a dark, red-brown appearance due to the presence of areas of internal hemorrhage. When angiosarcoma appears as a solitary, large mass, it does not have a capsule and frequently contains large cystic areas filled with blood debris.

Microscopically, hepatic angiosarcomas are composed of malignant vascular cells that may form poorly organized vessels, variable in size from cavernous to capillary, trying to form sinusoids. These vessels are lined with malignant endothelial cells. Tumor cells tend to grow along preformed vascular channels, particularly the sinusoid, and may form solid nodules or cavitory spaces [79].

Fig. 13a, b Angiosarcoma. **a** The tumor is hypointense to liver on the T1-weighted image. **b** Inhomogeneous peripheral enhancement, without nodular pattern, is seen on the gadolinium-enhanced image

With MR imaging, the signal intensity features of angiosarcoma are similar to those sometimes seen in hemangioma. Both tumors contain abundant blood-filled vascular spaces, which may exhibit high signal intensity on T2-weighted MR images. Peripheral enhancement after extracellular contrast agent administration may be seen, but it is not of the dense, discontinuous, and globular pattern that is typically seen in cases of hemangioma (Fig. 13) [80].

Lymphoma

Primary hepatic lymphoma is a rare disease. Lymphoma is considered to be a primary neoplasm of the liver when

the tumor is limited to hepatic parenchyma. Grossly, nodular and diffuse forms of hepatic lymphoma are seen. Hodgkin's disease occurs more often as miliary lesions than masses: Early in the disease liver parenchyma involvement is microscopic, but with time, small nodules from a few millimeters to several centimeters in size develop. In non-Hodgkin's lymphoma, the lymphocytic form tends to be miliary, whereas the large cells or histiocytic varieties are nodular masses [81, 82].

On MR images these tumors are hypointense on T1-weighted images and hyperintense on T2-weighted images due to the rich cellularity [16, 83, 84]. After administration of extracellular contrast agents, these tumors remain hypointense during all the dynamic study, due to their poor vascularity (Fig. 14) [1].

Liver metastases

Metastatic disease involving the liver represents one of the most common problems in oncology. The liver provides a fertile soil for metastases, not only due to its dual blood supply from both systemic and splanchnic system, but also because of the presence of humoral factors promoting cell growth and the discontinuous nature of endothelial lining of the hepatic sinusoid allowing open communication with the extracellular space of Disse. The liver is second only to regional lymph nodes as a site of metastatic disease. The true prevalence of metastatic disease is unknown, because most figures are based on autopsy series that reflect the end stage of a disease process, but between 30 and 70% (depending on the primary tumor) of patients who die of cancer have liver metastases at autopsy [85].

Liver metastases generally present the histotype of the primary neoplasm. The range of gross morphology of liver metastases, their localization, as well as their number is very wide. The shape of the lesion is usually roundish; nevertheless, the metastases from colorectal adenocarcinoma larger than 3 cm commonly have cauliflower aspect [86]. The majority of metastatic lesions have ill-defined margins; however, metastases from squamous cell carcinoma and those from endocrine tumor, often roundish, present sharp margins. The site of the metastases is usually intrahepatic, prevailing within the right lobe; exceptionally the metastases may be localized on the liver capsule, owing to the intraperitoneal spread (ovarian and colonic adenocarcinomas). The metastases from poorly differentiated adenocarcinomas and from endocrine tumors are usually numerous, smaller than 2 cm, and disseminated to the whole liver [87].

The signal intensity of the metastases differs from that of the liver since their T1 and T2 relaxation times are longer, owing to the higher content of free water molecules; therefore, on T1-weighted images the signal

Fig. 14a–c Lymphoma. **a** On the T1-weighted image, the tumor appears as a large, homogeneously hypointense mass. **b** The lesion is hyperintense on the T2-weighted image. **c** In the delayed, contrast-enhanced image, the tumor remains hypointense to liver

intensity of the metastases is lower than that of the hepatic tissue, whereas it is higher on T2-weighted images (Fig. 15). Some peculiar pathologic conditions, however, can modify the signal intensity of the metastases. Whenever liquefactive necrosis or infectious edema is present within the metastasis, the signal intensity further increases on T2-weighted images. On the other hand, if coagulative necrosis, fibrous matrix, or calcifications are present within the metastasis, the elevated signal intensity on T2-weighted images is decreased. Finally, whenever subacute intralesional hemorrhage or particular substances, such as melanin (seen in metastases from melanoma) or mucin (produced by metastases from mucinous carcinoma of the pancreas or

the ovary), are present within the metastatic tissue, the signal intensity of T1-weighted images is increased [88, 89].

After administration of extracellular contrast agents, enhancement of the liver is stronger than that of most metastatic lesions during both the arterial and the portal phases. Hypervascular metastases, however, show strong enhancement in the arterial phase, appearing definitely hyperintense with respect to liver parenchyma [88, 90]. Large hypervascular metastases receive arterial blood mainly in the periphery of the lesion than in the worse perfused center; thus, during the arterial phase, these metastases show an intense peripheral ring of enhancement, whereas during the following phases they show a progressive enhancement into the center which is gradually separated from that of the hepatic tissue [36, 88, 91, 92, 93]. Because metastases do not contain Kupffer's cells or normal hepatocytes, no uptake of reticuloendothelial-system-target agents or hepatobiliary agents is usually seen [22, 94, 95, 96].

Fig. 15a, b Carcinoid metastases. **a** T1-weighted image shows small, hypointense lesions in the right hepatic lobe. **b** The lesions appear definitely hyperintense on the T2-weighted image
