Abstract

Objectives To construct a three-dimensional (3D) model of renal stones to facilitate comprehensive planning for percutaneous nephrolithotomy (PCNL) and to assist in surgery.

Methods Fifteen patients with complex renal stones, including one patient with a horseshoe kidney, eight patients with partial/complete staghorn, and six patients with multiple renal stones, participated in our study. Computed tomography images of the unenhanced, arterial, venous, and excretory phases were obtained before surgery. Image segmentation and 3D reconstruction of the renal stones were performed using Mimics 12.1 software. A virtual safe and reliable percutaneous renal access route were established for each patient by comprehensive planning based on the 3D model of renal stones. PCNL was subsequently performed with the assistance of the 3D model. Patient demographics, surgical details, and postoperative treatment parameters were recorded.

Results The 3D models of renal stones accurately represented the interrelationships between the intrarenal arteries and veins, collecting system, stones, and adjacent anatomical

structures. PCNL was completed successfully in all 15 patients. The mean operating time was 75.6 ± 13.4 min. The change in hemoglobin concentration was 1.2 ± 0.3 g/l. The one-stage stone-free rate was 93.3 %, and the final stone-free rate was 100 %. No major postoperative complications were noted, except for postoperative pain in one case. **Conclusion** Construction of a 3D model of renal stones with the aim of minimizing the risks of percutaneous procedures and achieving higher one-stage stone-free rates is feasible for comprehensive PCNL planning and assistance in patients with complex renal stones.

Keywords Complex renal stone · Three-dimensional model · Percutaneous nephrolithotomy · Comprehensive planning · Minimally invasive

Introduction

Percutaneous nephrolithotomy (PCNL) is the gold standard approach for managing large, multiple, or inferior calyx renal stones [1]. However, establishing an appropriate access route is challenging [2, 3], and it is a key to successful stone removal with minimal complications, especially for complex renal stones such as those in patients with a horseshoe kidney, staghorn calculi, or multiple renal stones. The risks of complications such as hemorrhage and injury to adjacent anatomical structures such as the pleura, colon, spleen, and liver are also high for PCNL for complex renal stones [4–7]. The best approach for managing these challenging cases is to remove the stones using the most minimally invasive procedure. We here suggest the novel approach of constructing a three-dimensional (3D) model of renal stones to facilitate comprehensive planning for PCNL and to assist in stone removal during surgery.

Patients and methods

From January to June 2012, 15 patients with complex renal stones (one patient with a horseshoe kidney, eight patients with partial/complete staghorn calculi, and six patients with multiple renal stones) who required PCNL were treated at our institution. Informed consent was obtained from all the patients, and the present study was approved by the Ethical Committee of Southern Medical University.

Construction of a three-dimensional (3D) model of renal stones

The patients were advised to lie in a prone position with the renal area of their abdomen on our PCNL cushion. Four-channel multi-detector row computed tomography (CT) images including the unenhanced, arterial, venous, and excretory phases were obtained using a 64 multi-detector row CT scanner (Philips, Brilliance 64, Netherlands) with 0.5-mm step intervals. The scan delay time for the arterial, venous, and excretory phases after intravenous injection of the contrast material was 25, 60, and 600–900 s, respectively. Image segmentation and 3D reconstruction were performed using Mimics 12.1 software (Materialise, Leuven, Belgium). The threshold value and manual division methods were combined and jointly interpreted by an experienced urologist and a radiology technician. The CT images from each patient were segmented by focusing on all aspects of the relevant structures including the renal parenchyma, intrarenal arteries, intrarenal veins, renal stones, the collecting system, spine, ribs, lungs, liver, spleen, and the skin on the back. All the 3D images were subsequently fused. The integrated 3D model of renal stones displayed all the related structures when the transparency was adjusted (Fig. 1).

Comprehensive planning for PCNL using a 3D model of renal stones

Preoperative PCNL planning was done by the surgeon using the simulation function in Mimics 12.1. The virtual

3D puncture needle was placed in the 3D model to mark the puncture channel. The simulation-reposition function, which includes the translation, rotation, and movement of the needle with a mouse, was used to control the planned puncture point and the direction of the needle in the 3D model in order to manage multiple stones simultaneously and to avoid damaging the intrarenal vasculature and adjacent anatomical structures. The 3D properties of the stones, such as the stone volume and surface area, were recorded using the Mimics 12.1 software [3]. The puncture depth (the depth of the puncture needle from the skin to the calyces), the horizontal distance between the planned puncture point and the median line of the spine, and the vertical distance to the 12th rib were also measured.

3D model used to assist with PCNL

The patients were placed in a prone position with the renal area of their abdomen on the PCNL cushion. This position was identical to that used during preoperative CT. The 3D model of the renal stones was displayed on one screen controlled by a surgical assistant on a separate computer. The needle insertion point was marked on the skin of the patients' back with reference to two lines marked in the 3D model: the horizontal distance between the planned puncture point and the median line of the spine and the vertical distance to the 12th rib (Fig. 2a). The image of the 3D model was zoomed in and rotated to display a 3D view of the planned puncture site (Fig. 2b). The real-time B ultrasound was adjusted; subsequently, the puncture line was manually marked on the ultrasound image by the surgeon on the basis of the 3D model view (Fig. 2c). The puncture needle was inserted from the needle insertion point marked on the patients' skin to the collecting system along the puncture line marked on the ultrasound image (Fig. 2d). During lithotripsy, the 3D model displayed the stones in the collecting system from various angles to provide more information on the anatomical structures. For each procedure, the operation time and the number of access ports were noted. The operation time was defined as the time

Fig. 1 Schematic of the process of creating an integrated three-dimensional model of renal stones

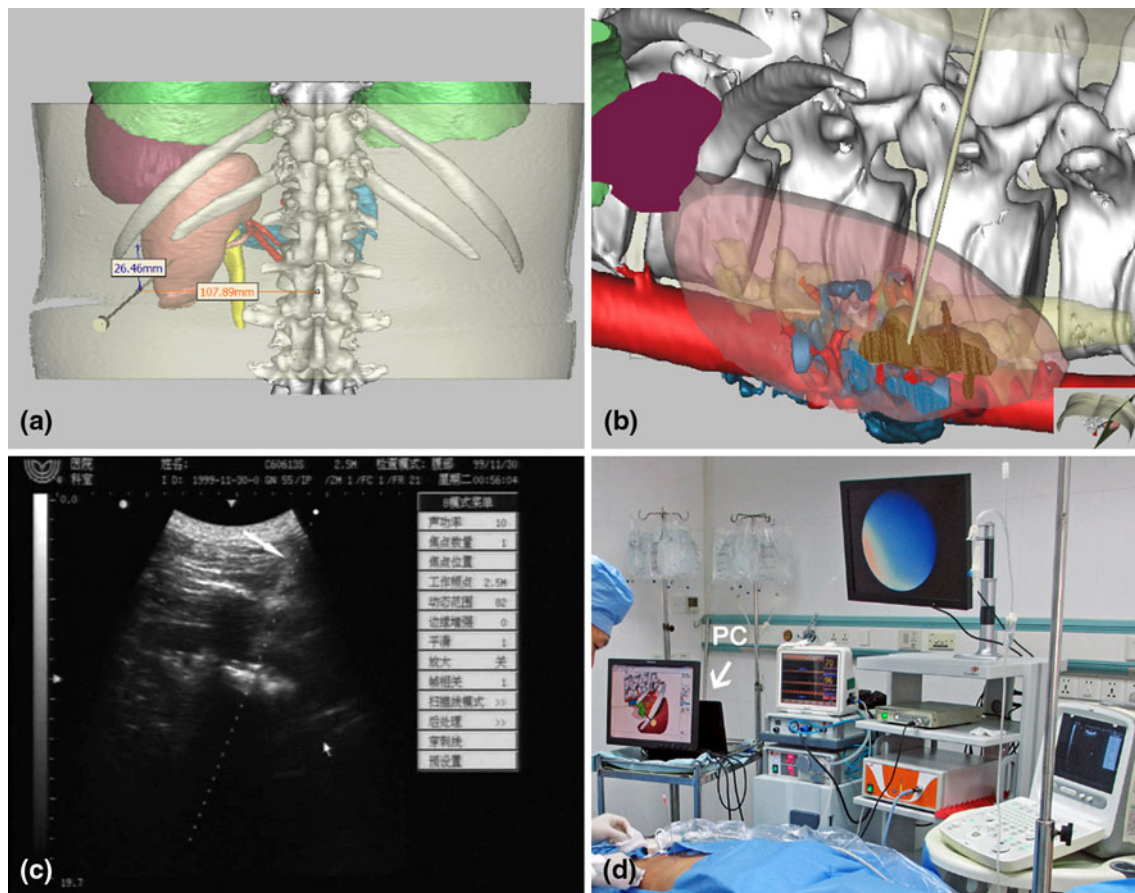

Fig. 2 Percutaneous nephrolithotomy performed under real-time B ultrasound guidance and with reference to the three-dimensional model

from the beginning of the needle puncture until the nephrostomy tube had been secured to the skin. Blood loss, blood transfusion rate, complication rate, and the number of stages required were also recorded. Blood loss was monitored by the postoperative decrease in hemoglobin levels and by the quantity of any blood transfusion. A kidney–ureter–bladder radiograph was used to monitor residual stone fragments on the first or second day after surgery and again after 2–4 weeks when the double J tube was removed. CT was used for radiopaque stones. The stone-free rate was defined as no any fragments >3 mm, which was accepted as clinically insignificant residual fragments [8, 9].

Results

Three-dimensional models of renal stones were constructed successfully for all 15 patients. The integrated 3D model of renal stones accurately represented the actual size of the kidney and its anatomical landmarks. By adjusting the transparency of the kidney, intrarenal arteries, veins, and collecting system with the stones were clearly visualized.

The number of stones, location of the collecting system, and dilation of the renal calyces were clearly visible. The interrelationships between the kidney and adjacent anatomical structures such as the spine, ribs, lungs, liver, and spleen were presented simultaneously. Preoperative comprehensive planning of PCNL was performed, and the puncture point and direction were planned before PCNL (Fig. 3).

With the aid of the 3D model, intraoperative PCNL was completed successfully in all 15 patients (Table 1). None of the patients required additional therapy. The mean stone volume was $11,591 \pm 6,889 \text{ mm}^3$, the mean operating time was $75.6 \pm 13.4 \text{ min}$, and blood loss was $1.2 \pm 0.3 \text{ g/l}$. No intraoperative complications occurred. The one-stage stone-free rate was 93.3 %. One of the patients required a second stage to clear a residual 6-mm stone. Two patients required two tracts (one for a 20F sheath and the other for a 16F) to clear stones on the basis of their preoperative plans. The final stone-free rate was 100 %. No postoperative complications were noted, except for postoperative pain in one patient (Clavien grade 1).

Image of complete staghorn (volume, 7,525 mm³) in a right kidney. **c**, **d**. Image of a 5,906-mm³ volume renal stone in a left horseshoe kidney. **e**. Two percutaneous renal access routes were

planned to remove multiple renal stones (volume, 4,466 mm³) in a left kidney. **f**. An 11th intercostal lower calyx access route was required to remove partial staghorn (volume, 15,876 mm³) in a right kidney

Discussion

Complex renal stones are a challenge during PCNL. A surgical puncture protocol is necessary for minimally invasive PCNL; therefore, PCNL in such cases is frequently performed using ultrasound or fluoroscopy-guided access. However, these only provide a two-dimensional, lower-resolution, and incomplete images of important anatomical structures. Detailed preoperative imaging can provide more information to aid selection of an optimal percutaneous approach. Three-dimensional CT reconstruction of the

pelvicalyceal system (PCS) and stones provides a global overview that can aid such planning and selection [10–12]. A 3D view of the renal arterial system and the PCS can help avoid segmental arterial injury [13]. Imaging-guided surgery includes preoperative imaging and planning, intraoperative imaging, and tracking. The rapid development of imaging-guided surgery and the confirmation of its feasibility for urological applications [14–16] have led to intraoperative imaging being combined with preoperative planned imaging or the needle guidance systems for PCNL procedures. Novel procedures involving laser-guided percutaneous kidney

access and iPad-assisted augmented reality have been found to be feasible for 3D puncture planning [17, 18], but there have been few clinical studies involving these applications. In our study, a 3D model that reconstructed the renal stones and associated anatomy of each patient was created using CT volume data; 3D reconstruction software (such as 3D Doctor and Mimics) is good for image segmentation [3, 19]. The reconstruction process is not so complex as is reported the similar 3D technique has demonstrated feasible in urinary

surgical procedures [15, 18, 20]. Spatial errors in our study were minimized by ensuring similar positioning and respiration during the preoperative CT imaging and intervention. The reconstructed 3D model accurately represented the interrelationships between the intrarenal arteries and veins, the collecting system, and the stones, all of which could be visualized by adjusting the transparency of the kidney. The smallest avascular area was included in the design to avoid severe bleeding as the most severe bleeding is caused by segmental artery injuries [21, 22]. Munver et al. reported bleeding rates of 16 % for supracostal and 4.5 % for subcostal tracts [23]. The incidence of colonic, splenic, and liver perforations generally ranges from 0 to 0.4 % [6, 7]. An appropriate channel can be identified during preoperative planning to avoid injuring the adjacent anatomical structures, especially when an access point above the 12th rib is used. Our 3D model provided essential information for choosing the optimal percutaneous access for PCS.

The crucial procedure during PCNL is the puncture and dilatation of the tract to obtain proper renal access. Because of our 3D model, the puncture route was already planned, which promoted the cumbersome locating process easier. With rigid nephroscopy, it is difficult to remove some stones because of the acute angle of the kidney calyces. Although flexible nephroscopy has advantages in treating special cases [24, 25], it is too expensive for common use. An appropriate puncture channel is very helpful for rigid nephroscopy because it facilitates the management of multiple stones. An intraoperative panoramic view of the stone and collecting system provides more information than endoscopy, which promotes one-stage clearance of staghorn stones.

In our initial clinical experience, our 3D model of renal stones aided comprehensive planning for PCNL and assisted in surgery. Clearance was achieved for all 15 patients with complex stones. The one-stage stone-free rate was 93.3 %. The surgeon was also more confident and comfortable with the calyceal puncture because of the comprehensive preoperative planning.

The present study has some limitations. The patients were exposed to increased radiation because four-channel multi-detector CT rather than a conventional unenhanced CT scan was used. Extra time was required between image acquisition and the intervention. There was no real-time automatic fusion of images. Prospective comparative studies are required to confirm the value of this method. However, we present a new and effective method for managing complex stones. The 3D model of renal stones provided detailed information for comprehensive planning of PCNL and assisted in surgery. Furthermore, as the number of 3D models of complex stones reconstructed using this novel approach increase, a database of 3D stones can be developed to help train urology residents in PCNL.

Conclusions

We demonstrated that constructing a 3D model of renal stones is technically feasible for comprehensive PCNL planning and assistance in patients with complex renal stones. It can be recommended in patients with complex stones to minimize the risks associated with percutaneous procedures and to achieve higher one-stage stone-free rates.
