Abstract

Background: Previous studies established a role for the wearable cardioverter defibrillator (WCD) to effectively and safely bridge temporary risk for sudden cardiac death (SCD) in patients with advanced heart failure. The prognostic relevance of the WCD remains controversial.

Objectives: The authors investigated adherence to, as well as the safety and effectiveness of, WCD use in a real-world cohort of patients at high risk for SCD.

Material and methods: All consecutive patients ($n = 83$) receiving a WCD at a German tertiary care hospital between April 2012 and December 2019 were retrospectively included in this analysis. Patient characteristics were collected at the time of the index hospitalization. Using the Zoll® lifeVest® (ZOLL Medical Corporation, Chelmsford, MA, USA) network database, two separate investigators evaluated adherence to the WCD as well as arrhythmic events during WCD wear time.

Results: During 3680 wearing days (mean WCD wear time, 44 days) with a median daily wear time of 23.1 h, three arrhythmic events of relevance (sustained ventricular tachycardia, VT) occurred, one of which was sufficiently terminated by WCD shock. Another patient died from sudden cardiac death while pausing his WCD. Right bundle branch block correlated significantly with sustained VT occurrence ($r = 0.3315$; 95% CI −0.1265 to 0.3014; $p = 0.0022$). In 30 patients (36.1%) a cardioverter/defibrillator was implanted.

Conclusion: In a real-life clinical setting, the use of WCD in patients at high risk for sudden cardiac death is effective and safe and adherence to the device is high. The event rate for VA was lower than in comparable patient cohorts. Adherence remains a crucial issue as one patient in the present series died while not wearing the device.

Introduction

Patients with myocardial infarction or newly diagnosed advanced heart failure (i.e. left ventricular ejection fraction, LVEF < 35%) are at increased risk of sudden cardiac death (SCD) by arrhythmic events [1]. Immediate implantation of a cardioverter defibrillator (ICD) for primary prevention is not beneficial [2, 3] as treatment of the underlying cardiomyopathy (e.g. cardiac revascularization) and pharmacological

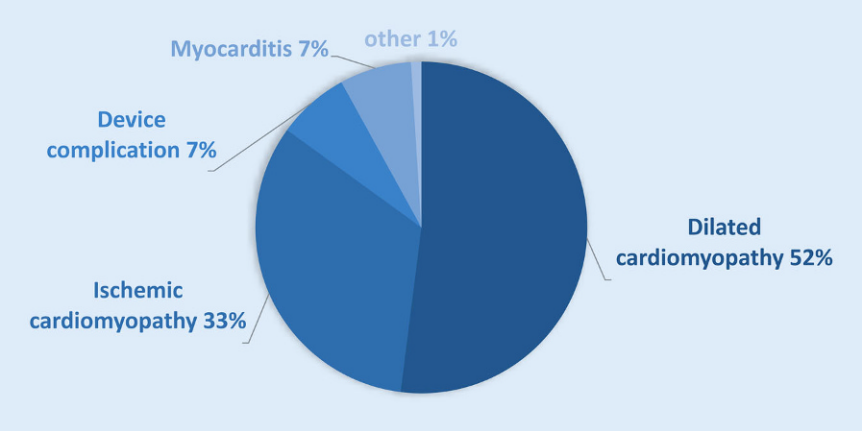

Fig. 1 ▲ Indication for wearable cardioverter defibrillator use

heart failure therapy significantly improves left ventricular function in about one third of patients [4–6]. Therefore, current guidelines recommend at least 3 months of maximum tolerated doses of guideline-directed medical therapy or a 6-week waiting period in the case of ischemic etiology before reevaluating LVEF as a surrogate of arrhythmic risk and possible definitive implantable cardioverter defibrillator (ICD) implantation [7, 8].

Previous studies established the wearable cardioverter defibrillator (WCD) as a bridging tool during the vulnerable interval to LVEF restitution or definitive ICD-implantation by sufficiently detecting and terminating ventricular arrhythmias (VA) [9–13]. According to current guidelines, WCD use has a IIa [14, 15] or IIb indication [8, 29] in patients at high risk for SCD by arrhythmic events. However, the prognostic role of the WCD remains controversial and a lack of profound evidence has led to uncertainty in decision-making regarding its use in clinical practice. Several studies documented inappropriate therapies and high rates of inappropriate alarming [16–18]. Occurrence of life-threatening ventricular tachycardia (VT)/ventricular fibrillation (VF) during WCD use was low (2.6%) in a meta-analysis [19], and the only prospective randomized trial on WCD therapy did not show a reduction in sudden arrhythmic deaths in patients with acute myocardial infarction and a LVEF of 35% or less [20]. In this trial, device adherence was unexpectedly low, representing a finding that was discussed as a major limiting factor of the study. Therefore, the authors investigated adherence, safety and effectiveness of WCD use in a real-world cohort of patients at high risk for sudden cardiac death.

Abbreviations

ARNI	Angiotensin receptor neprilysin inhibitor
BMI	Body mass index
CABG	Coronary artery bypass graft
CAD	Coronary artery disease
DCM	Dilated cardiomyopathy
ICD	Implantable cardioverter defibrillator
ICM	Ischemic cardiomyopathy
LBBB	Left bundle branch block
LVEF	Left ventricular ejection fraction
MRA	Mineralocorticoid receptor antagonist
RBBB	Right bundle branch block
SCD	Sudden cardiac death
VA	Ventricular arrhythmias
VF	Ventricular fibrillation
VT	Ventricular tachycardia
WCD	Wearable cardioverter defibrillator

Methods

Patient population

All consecutive patients ($n = 83$) receiving a WCD (LifeVest®, ZOLL Medical Corporation, Chelmsford, MA, USA) at a German tertiary care hospital between April 2012 and December 2019 were retrospectively included in this investigator-initiated registry. Patient characteristics were collected at the time of index hospitalization. The study protocol conforms to the 1975 Declaration of Helsinki (in its most recently amended version), and the local ethics committee approved the study. Patients with prior myocardial infarction, advanced heart failure with LVEF ≤ 35%, ventricular arrhythmic events, myocarditis or ICD explantation due to infection or complications were included. Allocation to WCD fitting remained at the discretion of the treating physician with regard to the patient's individual risk of VA (i.e. VF/sustained VT). The WCD wearing period was pre-set to 3 months, but could be adapted if substantial changes in arrhythmic risk (e.g. LVEF improvement) occurred earlier or if further medical therapy optimization was possible under prolonged WCD protection.

WCD programming

WCD programming was adapted to individual patient characteristics regarding prior arrhythmic events. In most patients the VT zone was programmed at 150 bpm with a response time of 60 s and the VF zone at 200 bpm with a response time of 25 s. In younger and more active patients the VT threshold was programmed higher. The first shock energy was set to 150 J. Follow-up visits with reevaluation of LVEF were scheduled 3 months after the initial hospitalization. Patients with previously explanted ICDs were followed-up according to clinical indications. ICD implantation was performed according to current guideline recommendations [8, 21] if LVEF remained ≤ 35% despite optimal medical therapy or if arrhythmic risk was unchanged despite increased LVEF (e.g. persistent scar after myocarditis).

Arrhythmic events and adherence

Using the Zoll® LifeVest® network database, two separate investigators (HA, CW) evaluated arrhythmic events during WCD wear time. Arrhythmic events were classified according to the 2015 ESC guidelines on VA and the prevention of SCD [22] as follows: adequate WCD shock for VF or sustained VT (VT ≥ 30 s in duration), sustained VT without shock (inhibited by patient), inadequate shock (without VF or sustained VT), non-sustained VT (three or more consecutive ventricular complexes in duration, terminating spontaneously in < 30 s), supraventricular tachycardia, bradycardia

Statistics

Descriptive statistics were performed using excel (Microsoft Corporation, Redmond, USA) and GraphPad Prism9 (GraphPad Software, San Diego, CA, USA). Data are presented as mean ± standard deviation unless otherwise specified. Categorical variables are presented by absolute and relative frequencies. Statistical comparisons between groups were performed using the Pearson chi-square test for categorical variables and paired and unpaired t-test or Wilcoxon rank sum test or one-way ANOVA for continuous variables where appropriate. Significance tests were two-tailed with $p < 0.05$ considered significant. Results are shown as effect size with 95% confidence interval.

Results

Patient population

Between 2012 and 2019, 83 patients received a WCD (78% male). Mean age at index hospitalization was 60 (SD 13) years. Median LVEF at baseline was 28% (12–69%). Guideline-directed heart failure medication containing beta-blocker, ACE-I/AT1-A/ARNI and mineralocorticoid receptor antagonist (MRA) was established in 86.7%. Baseline characteristics and comorbidities are shown in **Table 1**. The indication for WCD use was dilated cardiomyopathy (DCM) in over half of the patients (51.8%), ischemic cardiomyopathy (ICM) in one third (32.5%) and myocarditis or device complication (i.e. infection, lead problems) in 7% each (**Fig. 1**). One patient presenting with sustained VT received WCD as a bridge to decision following theophylline intoxication. Median LVEF at the end of WCD use improved by 12 to 40% (13–78%). A further two patients died during the follow-up period from non-cardiac causes. A total of 11 patients were lost to follow-up.

Arrhythmic events during wear time and definitive AICD implantation

A total of 25 patients (30%) had ventricular arrhythmic events (VF, sustained-/nonsustained VT) prior to WCD prescription. During WCD wear time three ventricular tachycardias lasting 30 s or more were detected in three patients. Of these, one patient after ICD explantation due to infection received one adequate WCD shock for sustained VT (**Fig. 2**). One patient inhibited WCD shock by repeatedly pressing the response button before VT was self-terminating after 289 s. The third was readmitted immediately after demission due to sustained VT (patient inhibited shock) and died in combined cardiogenic and hemorrhagic shock in the further course. Detailed information is shown in **Table 2**.

No inadequate therapies were applied but overall 989 inappropriate alarms appeared due to artefacts. An overview of all arrhythmic events is shown in **Table 3**. To further characterize potential factors that may determine risk for arrhythmogenic events we correlated a panel of risk markers to occurrence of sustained VT/VF. Of all tested variables as shown in **Table 4**, only right bundle branch block (RBBB) correlated significantly with sustained VT occurrence, with medium effect size ($r = 0.3315$; 95% CI −0.1265 to 0.3014; $p = 0.0022$). In 30 patients (36.1%) an ICD was implanted.

Device adherence

The mean WCD usage period was 44 (SD 32) days with a median daily wear time of 23.1 h (0–23.97 h). Daily WCD use was similar regarding sex, age, indication and total days of WCD wear (**Table 5**). Two patients returned their WCD directly after discharge due to discomfort. One patient with DCM died from sudden cardiac arrest while pausing his WCD. His prior daily wear time was 15.1 h/day.

Discussion

This study investigates the use of the WCD in a real-world setting of patients at high risk of SCD. WCD use was effective and safe. During wear time life threatening arrhythmic events were safely detected and efficiently terminated by the device. No inadequate WCD therapies were observed. The incidence of arrhythmic events was low as only few events of relevance occurred during WCD monitoring. Compared to similar cohorts, patient adherence to the device was high.

SCD due to VT/VF remains a preventable cause of death and the concept of WCD use provides a safe and effective approach for aborting death among patients at high risk of sudden arrhythmic death. Several prospective trials [11, 12] and real-world data [9, 10, 13] in different patient populations (e.g. early post myocardial infarction, non-ischemic cardiomyopathy) consistently proved effectiveness and safety. Accuracy and precision in the detection of ventricular tachyarrhythmia/ventricular fibrillation was high throughout all studies. Successful termination of VT/VF events was achieved in up to 98% with the first shock [23]. Rates of inappropriate shocks differ between patient cohorts and are reported as being up to 5.9% [14]. However, they fall below inappropriate shock rates in ICD patients, which have been shown to be up to 13% [24]. In the present study, three episodes of sustained VT were correctly detected and one (1.2%) of these was effectively treated by the device. This corresponds to a large German cohort of 6043 patients and US data which reported 1.6% of patients treated by WCD in response to VF/VT [7, 13]. However, the small number of relevant VA in our cohort (3.6%) differs from comparable reports describing up to 9.6% of VA [16–18, 25]. Whereas in comparable study collectives inappropriate shock treatments occurred in up to 2% [18], there was no inadequate therapy applied in the present cohort despite a relevant number of inappropriate alarms. Regarding indication for WCD, patient age and comorbidities, the authors' collective is comparable to others [16–18, 25] and shows even higher rates of arrhythmic events prior to WCD prescription (30%). Therefore, the low rate of arrhythmic events observed during WCD treatment cannot be entirely explained by divergent patient selection or a younger and healthier patient collective.

In the present study a high proportion of patients received guideline-directed drug therapy according to baseline data (beta-blocker 100%, ACE inhibitor/angiotensin receptor blocker 95%, mineralocorticoid receptor antagonist 87%). In comparable prior studies this ratio goes down to 90.3% for beta-blocker and 32.7% for MRA [16–18]. Stringent pharmacological heart failure therapy, in particular beta-Blocker therapy, may have prevented a higher incidence of arrhythmic events in the present cohort. Hypothetically, a high daily wear time as documented in this series may be suggestive of increased adherence to medication, which may have contributed to this finding. Another point is that a relevant proportion of patients experienced rapid recovery of LVEF and therefore WCD wearing was terminated (mean wear time: 44 days, median LVEF

improvement 12%). An ICD was implanted in 30 patients (36.1%) since LVEF remained ≤ 35% or due to evidence for unchanged arrhythmic risk despite increased LVEF (e.g. scar after myocarditis). Although rates of definitive ICD implantation appear relatively low compared to other studies (55% [18]), this data should be interpreted with caution as 11 patients (13%) were lost to complete follow-up.

Patient adherence is of crucial importance for effective WCD therapy as it emphasizes the patient's agreement to actively participate in the treatment concept [14]. In contrast to clinical studies investigating adherence to medication, which is often subject to self-report, adherence to WCD use can be monitored effectively by the treating physician. Registry data show that adherence to WCD use is high. Several case series report daily use of > 90% per day [9, 13, 26]. However, in the VEST trial, the only randomized controlled trial of WCD use, the wear time with the device was lower than anticipated even under trial conditions. Wear time of only 18 h per day and only 12 of 48 participants in the device group wearing the WCD at the time of death contributed to the primary result of the trial. Contrary to expectations, WCD use did not lead to a significantly lower rate of the primary outcome of arrhythmic death [20]. In the present cohort adherence to WCD was among the highest reported [19] at 23.1 h per day overall median wear time. However, although all patients signed informed consent to WCD therapy, individual adherence went as low as zero hours, resulting in one patient dying from SCD.

Nevertheless, one event per 1227 wearing days in contrast to nevertheless one SCD victim due to low adherence raises concerns about the effectiveness of WCD as well as appropriate patient selection to WCD. Patient allocation to WCD therapy is challenging as underlying cardiomyopathy, prior arrhythmic events, LVEF and other parameters mentioned above are only surrogates of further arrhythmic events and SCD. The observed correlation between RBBB and sustained VT occurrence might be biased by the relatively small cohort. The present findings support WCD use in patients with a clear and ongoing AICD indication that are temporarily unprotected, for example as a result of device explantation due to infection [27]. In the light of the low arrhythmic event rates it seems reasonable that other potentially high-risk patients for SCD receive guideline-directed medical therapy particularly including beta-blockers and recurrent echocardiographic LVEF reevaluation during index hospitalization before even considering WCD provision. Patient adherence is crucial for the effectiveness of WCD therapy. Despite relatively strong adherence in the present study, even more efforts (i.e. intensified use of local heart failure networks/planned close follow-ups) are necessary to maintain each individual patient's adherence as high as possible. Currently, about 5% of patients for whom the WCD is prescribed are ultimately considered unsuitable for appropriate and safe handling of the system or are unwilling to wear the WCD [23, 28]. Having said that, in the context of a particularly motivated high-risk patient, WCD may be considered as a safe and effective strategy for the prevention of SCD.

Study limitations

This study is limited by its monocentric, retrospective, nonrandomized character. Furthermore, patient allocation to WCD was not standardized. Both might have led to selection bias. Assignment to a single cardiac diagnosis resulted in overlap among disease types.

Conclusion

In a real-life clinical setting, the use of WCD in patients at high risk for SCD is effective and safe, and adherence to the device is generally high (◘ **Fig. 3**). Adherence remains a crucial issue as one patient in the present series died while not wearing the device. In the authors' cohort the event rate for VA was lower than expected.

Practical conclusion

- **The present findings support WCD use in patients with an ongoing ICD indication temporarily unprotected as a result of device explantation (e.g. due to infection).**
- **High-risk-patients for SCD should receive LVEF reevaluation during index hospitalization prior to WCD allocation as arrhythmic event rates appear lower with contemporary medical therapy.**
- **As adherence remains crucial for the effectiveness of WCD therapy, every effort should be made to promote each individual patient's adherence.**

Zusammenfassung

Alltagserfahrungen mit dem tragbaren Kardioverter/Defibrillator – klinische Effektivität und Einhaltung der Tragezeit bei Patienten mit hohem Risiko eines plötzlichen Herztods

Hintergrund: Frühere Studien belegen die Bedeutung des tragbaren Kardioverter/Defibrillators (WCD) für die wirksame und sichere Überbrückung eines temporären Risikos des plötzlichen Herztods (SCD) bei Patienten mit fortgeschrittener Herzinsuffizienz. Der prognostische Stellenwert einer solchen Therapie ist jedoch weiterhin umstritten.
Ziel der Arbeit: Wir untersuchten Adhärenz, Sicherheit und Effektivität der Kardioverter/Defibrillator-Weste im kardiologischen Versorgungsalltag einer Kohorte von Patienten mit hohem SCD-Risiko.
Material und Methoden: Alle 83 zwischen April 2012 und Dezember 2019 in einer deutschen Klinik der Tertiärversorgung mit einem WCD versorgten Patienten wurden retrospektiv in diese Analyse eingeschlossen. Die Basischarakteristika wurden im Rahmen der Indexhospitalisierung erhoben. Die Auswertung von WCD-Adhärenz und arrhythmogenen Ereignissen während der WCD-Tragezeit erfolgte durch zwei unabhängige Untersucher anhand der Daten des LifeVest® Network der Fa. Zoll® (ZOLL Medical Corporation, Chelmsford, MA, USA).
Ergebnisse: Während 3680 Tragetagen (mittlere WCD-Tragedauer 44 Tage) mit einer medianen täglichen Tragedauer von 23,1 h traten drei anhaltende ventrikuläre Tachykardien (VT) über 30 s Dauer auf. Davon konnte eine erfolgreich durch einen WCD-Schock terminiert werden. Ein anderer Patient erlag einem SCD, als er die Weste gerade nicht trug. Ein Rechtsschenkelblock korrelierte signifikant mit dem Auftreten einer anhaltenden VT ($r = 0{,}3315$; 95 %-Konfidenzintervall –0,1265 bis 0,3014; $p = 0{,}0022$). Bei 30 Patienten (36,1 %) wurde ein Kardioverter/Defibrillator implantiert.
Schlussfolgerung: Die Anwendung des WCD in einem Hochrisikokollektiv für SCD unter klinischen Alltagsbedingungen ist sicher und effektiv, die Adhärenz der Patienten ist hoch. Die Rate an Arrhythmieereignissen war geringer als in vergleichbaren Patientenkollektiven. Die Adhärenz bleibt ein entscheidendes Problem, da ein Patient bei fehlender individueller Compliance einem SCD erlag.
