**Abstract** We report in this paper the characterization of *Dxbp-1*, the *Drosophila* homologue of the *xpb-1* gene that encodes a “bZIP”-containing transcription factor that plays a key role in the unfolded protein response (UPR), an evolutionarily conserved signalling pathway activated by an overload of misfolded proteins in the endoplasmic reticulum (ER). *Dxbp-1* is ubiquitously transcribed, and high levels are found in embryonic salivary glands and in the ovarian follicle cells committed to the synthesis of the respiratory appendages. Loss of function of *Dxbp-1* induced a recessive larval lethality, thus, revealing an essential requirement for this gene. The *Dxbp-1* transcript was submitted to an “unconventional” splicing that generated a processed *Dxbp-1s* transcript encoding a DXbp-1 protein isoform, as is the case for yeast, *Caenorhabditis elegans* and vertebrate *hac1/xbp-1* transcripts after UPR activation. However, in the absence of exogenously induced ER stress, the *Dxbp-1s* transcript was also detectable not only throughout embryonic and larval development but also in

adults with a high level of accumulation in the male sexual apparatus and, to a lesser extent, in the salivary glands of the third-instar larvae. Using a *Dxbp-1:GFP* transgene as an in vivo reporter for *Dxbp-1* mRNA unconventional splicing, we confirmed that *Dxbp-1* processing took place in the salivary glands of the third-instar larvae. The *Dxbp-1* gene appears, thus, to play an essential role during the development of *Drosophila*, hypothetically by stimulating the folding capacities of the ER in cells committed to intense secretory activities.

**Keywords** *Drosophila*, *xbp-1* · Unconventional splicing · UPR signalling · Secretion

## Introduction

The X-box binding protein-1 (Xbp-1) was first characterized as a bZIP-containing transcription factor that binds to the *cis*-acting X-box sequence present in the promoter region of the genes of the human major histocompatibility complex class II (Liou et al. 1990) and in the *tax*-dependent enhancer of HTLV1 (Yoshimura et al. 1990). Mammalian and *Caenorhabditis elegans xbp-1* genes were further shown to be the orthologues of the yeast *hac1* gene, a key player in the unfolded protein response (UPR; Cox and Walter 1996; Mori et al. 2000; Yoshida et al. 2001; Shen et al. 2001; for a review see Schroder and Kaufman 2005). UPR is an evolutionarily conserved signalling pathway that is activated by an over-accumulation of either misfolded or unfolded proteins in the endoplasmic reticulum (ER) lumen as the result of mutations, drug treatments or environmental stresses. UPR activation elicits several adaptative responses to maintain ER function, in particular, by restricting the import of novel proteins and by stimulating the degradation

of abnormal proteins accumulated in the ER lumen. To restore ER function, UPR activation induces (1) an up regulation of genes encoding ER chaperones, folding enzymes and proteins involved in the ER-associated degradation (ERAD) system and (2) an inactivation of eIF4 $\alpha$  mediated by PEK/PERK kinase, resulting in a global inhibition of the translational machinery to limit the import of novel proteins (for a review see Schroder and Kaufman 2005). However, when these two processes are not sufficient to restore ER homeostasis, UPR activation eventually commits cells to apoptosis through the activation of the Jun–N-term kinase pathway (Urano et al. 2000b; Nakagawa et al. 2000; Rao et al. 2001). Xbp-1 and ATF-6 are two transcription factors containing a “bZIP” domain and are key players in the UPR (Yamamoto et al. 2004). ATF6 is a transmembrane ER protein that is comprised of a luminal-sensing domain and a cytosolic “bZIP”-containing region (Haze et al. 1999; Lee et al. 2002; Shen et al. 2005). In an early stage of UPR signalling, ATF-6 is activated by S2P-mediated cleavage of its cytosolic domain that is then transported to the nucleus (Yoshida et al. 1998; Ye et al. 2000; Lee et al. 2002; Shen et al. 2005). The activation of Xbp-1 relies upon a completely different and, as far as we know, specific post-transcriptional mechanism. The native unprocessed *xbp-1* messenger RNA (mRNA), *xbp-1u*, encodes a transcription factor, Xbp-1u, that displays poor transcriptional activities and low stability (Yoshida et al. 2006; Tirosh et al. 2006). It has been shown that, after ER stress and UPR activation, the *xbp-1u* mRNA is cleaved by the site-specific endoribonuclease Ire-1 at two sites separated by 26 nucleotides (nt; in vertebrates) or 23 nt (in *C. elegans*), and then re-ligated by a tRNA ligase (Sidrauski and Walter 1997; Urano et al., 2000a; Yoshida et al. 2001; Lee et al. 2002). This unconventional “splicing” of 23 nt (or 26) takes place approximately in the middle of the Xbp-1u open reading frames (ORF). This induces a frame-shift in the resulting processed transcript, *xbp-1s*, that encodes a novel protein that displays the same N-terminal region as Xbp-1u, including the “bZIP” domain, but a distinct C-terminal region that contains a potent trans-activation domain (Yoshida et al. 2001). In the nucleus, activated ATF6 and Xbp-1s bind to the UPR and ER stress response elements (UPRE and ERSE, respectively) found in the promoter region of genes encoding ER resident proteins, such as chaperone proteins, folding enzymes and ERAD proteins, and activate their transcription (Yoshida et al. 1998; Lee et al. 2003; Yamamoto et al. 2004).

In *C. elegans*, *xbp-1* RNAi-depleted worms are highly sensitive to ER stress, but these mutants are viable under physiological conditions, thus, showing that this gene does not play an essential role during development (Shen et al. 2001). Nevertheless, *pek-1(ok275); xbp-1(RNAi)* double mutant worms arrest their development at or before the

L2 larval stage, suggesting that the two genes mediate redundant pathways that are essential for survival. In contrast, Reimold et al. (2000) and Zhao et al. (2003) have shown that the functions of vertebrate *xbp-1* are crucial during development, and that it is essential for the viability of embryos both in mice and frogs. In mouse, *xbp-1* is required for cardiac myocyte survival (Masaki et al. 1999), liver development (Reimold et al. 2000), skeletal formation and terminal differentiation of immature plasma cells into immunoglobulin secreting B-lymphocytes (Iwakoshi et al. 2003a,b; for a review see Wu and Kaufman 2006). In addition, these data suggest that *xbp-1* does not play a crucial role during early embryonic development in mammals. On the other hand, in *Xenopus*, *xbp-1* is essential during the early stages of embryo development. It forms a regulatory loop with bone morphogenetic protein-4 (BMP-4), which is required for mesoderm and neuroderm differentiation (Zhao et al. 2003; Cao et al. 2006). All together, these data suggest that *xbp-1* has been recruited during vertebrate evolution to play several essential roles during development, particularly in cells committed to intense secretory activities in mammals and in the BMP-4 pathway in frogs.

In this present research, we report the first study of the function of *Dxbp-1*, the *Drosophila xbp-1* orthologue. Our results show that, like in vertebrates, this gene plays an essential role during development. We observed that, in the absence of exogenously induced ER stress, the unconventional splicing of *Dxbp-1* takes place throughout development and in adult tissues, particularly in secretory organs such as the larval salivary glands and the male accessory glands. Moreover, using an *UAS-Dxbp-1:GFP* transgene as a reporter for *Dxbp-1* processing, we confirmed that putative Ire-1 dependent unconventional splicing took place in the salivary glands of the third-instar larvae. All together, our data support the hypothesis that, as in mammals, *Dxbp-1* plays an essential role during the development of *Drosophila*, particularly in tissues that show high levels of secretory activity.

## Materials and methods

### *Drosophila* stocks

*Drosophila melanogaster* stocks were raised on a standard cornmeal, yeast, agar medium at 25°C. The *Dxbp-1<sup>k13803</sup>*, *Df(2)Exel<sup>6042</sup>*, *Df(2)<sup>CC2</sup>*, *da-Gal4*, *en-Gal4* and *puc<sup>e69</sup>-lacZ* lines are described in FlyBase, and relevant fly stocks are available from the Bloomington Stock Centre at Indiana University. The *pDI:GFP* protein trap line and the *lio-Gal4* driver line were kindly provided by Alain Debec (Bobinnec et al. 2003) and Jean-Maurice Dura (Taillebourg et al.

2005), respectively. *Dxbp-1<sup>k13803</sup>* has been shown to contain an insertion of the *P[w<sup>+</sup>; lacZ]* enhancer trap transposon (Bier et al. 1989) in the 5'-UTR region of the *Drosophila xbp-1* gene. In all experiments, the *w<sup>1118</sup>* stock was used as a wild-type control.

#### UAS-Dxbp-1:GFP construct

In the *UAS-Dxbp-1:GFP* construct, a genomic DNA fragment, corresponding to the 5' region of the *Dxbp-1* gene and extending 488 bp downstream from the unconventional intron and, thus, containing the entire *Dxbp-1u* ORF, was amplified by PCR with additional 5' BamHI and 3' KpnI restriction sites and cloned as an XbaI-KpnI fragment into the *pUAS<sub>P</sub>-GFP* vector (Januschke et al. 2002) in-frame with the ORF of the *Dxbp-1u* RNA. Transcription of the *UAS-Dxbp-1:GFP* construct, which was verified by sequencing, was predicted to encode a fluorescent Dxbp-1s:GFP protein after the removal of the 23-bp intron. We generated *UAS-Dxbp-1:GFP* transgenic lines as previously described, using a *w<sup>1118</sup>* strain as a recipient stock (Rubin and Spradling 1982).

#### RNA in situ hybridisation

For in situ hybridisation, RNA probes were synthesized with T7 or T3 RNA polymerase and a *Dxbp-1* fragment as template, extending from position +511 to +1,380. We amplified this DNA fragment by PCR, using two pairs of primers designed to include either a T7 promoter sequence within the 3' backward oligonucleotide or a T3 promoter within the 5' forward primer.

#### Total and polyA<sup>+</sup> RNA isolation and RT-PCR

Total RNA was isolated using the RNeasy kit (Qiagen), and polyA<sup>+</sup> RNA was further purified using the Oligotex mRNA kit (Qiagen). For RT-PCR experiments, 10 µg of total RNA or 1 mg of polyA<sup>+</sup> RNA were reverse transcribed with random hexamers and the first-strand cDNA synthesis kit for RT-PCR (Roche). To visualize the processing of the 23-bp intron, we carried out PCR amplifications of the newly synthesized complementary DNA (cDNA) templates using the forward primer 5'-CAGATGCATCAGCCAATC CAAC-3' and the backward primer 5-GAGTGA GACCTTTCAACAC-3' that were predicted to amplify fragments of 191 bp (*Dxbp-1u* RNA) or 168 bp (the *Dxbp-1s* RNA). PCR products were separated by electrophoresis in 4% metaphor (FMC) gels. All RNA samples were tested for a possible contamination by genomic DNA through RT-PCR, using a couple of primers flanking the 64-bp conventional intron common to both *Dxbp-1* RNA transcripts.

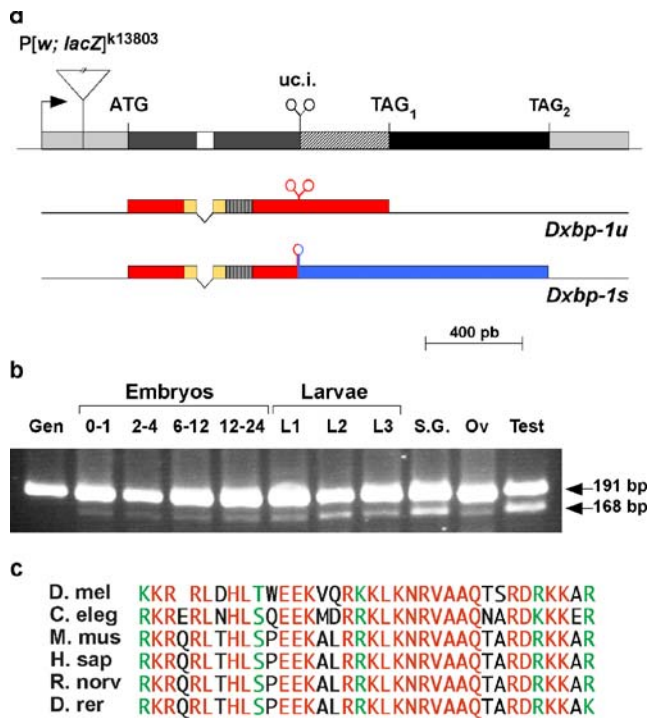

## Results

### Structure of the *Dxbp-1* gene and transcripts

The structure of the *Drosophila xbp-1* gene was first deduced from the annotated *Drosophila* genome sequence determined by the Berkley *Drosophila* genome project (release 3.2 of the annotated *D. melanogaster* genome) and from the partial or complete sequencing of numerous expressed sequence tag (EST) clones carried out by the Berkley *Drosophila* genome project. However, the predicted structure of *Dxbp-1* transcripts did not fit with the sequence of several EST clones. The annotated *Drosophila* genome sequence predicted two *Dxbp-1* RNA species, *Dxbp1-RA* and *Dxbp1-RB*, as a result of the alternative splicing of a 53-nt intron in *Dxbp1-RB*. Although sequencing data from 16 EST clones confirmed the structure of the *Dxbp1-RA* transcript, none of the sequenced EST corresponded to the predicted *Dxbp1-RB* transcript isoform. Three ESTs corresponded to an alternatively spliced transcript distinct from the predicted *Dxbp1-RB* by the splicing of 23 nt instead of 53 (Fig. 1a). Because of this inconsistency, we sequenced a set of PCR fragments encompassing the complete *Dxbp-1* genomic region, and we performed RT-PCR experiments using several couples of primers flanking the predicted or observed introns and RNA extracted from various tissues or at various developmental stages. The amplified RT-PCR products were also sequenced to determine intron lengths and sequences with precision.

Our data confirmed that the *Dxbp-1* gene gave rise to the transcription of two RNA isoforms. The major transcript that corresponded to the predicted *Dxbp1-RA* RNA was composed of two exons, 591 and 1552 nt in length, separated by a 64-nt intron flanked by canonical 5', GUAAGU, and 3', CAG, consensus sequences. The predicted translation product of this transcript was a 307-aa protein, whose amino-terminal region contained a "bZIP" domain; a 35-aa region rich in basic amino acids followed by seven evenly spaced leucine residues forming a "leucine zipper" dimerization domain (see Figs. S1 and 1a).

The second *Dxbp-1* RNA differed from the major transcript only by the absence of a 23-nt sequence located 304 nt downstream from the common 64-nt intron. The predicted 498-aa protein encoded by this transcript displayed the same 188-aa-long amino-terminal region as the protein encoded by the unprocessed *Dxbp1-RA* transcript, but showed a distinct carboxy-terminal domain because of the frame shift induced by the splicing of this 23-nt intron (see Figs. S1 and 1a). This 23-nt intron was not flanked by canonical splice site consensus sequences, and visual and *in silico* analyses revealed the presence of complex secondary structures in the flanking sequences. These included a long

**Fig. 1** Structure and expression of *Dxbp-1* transcripts. **a** The  $P[w; lacZ]^{k13803}$  transposon is shown inserted into the 5'-UTR-region of the *Dxbp-1* gene. Intergenic sequences are depicted as *single lines*. Untranslated exonic sequences are represented by *light grey boxes* and open reading frames are shown as *dark grey* (common *Dxbp-1u/Dxbp-1s* ORF), *black* (*Dxbp-1s*-specific ORF) and *striped* (*Dxbp-1u/Dxbp-1s* overlapping ORFs) boxes. The intron is represented as an *empty box*, and the unconventional intron (uc. i.) is indicated by *two convergent stem-loop structures*. Arrow shows the direction of transcription. The translation initiation codon (ATG) and the two termination codons (TAG<sub>1</sub> and TAG<sub>2</sub>) are indicated above the *Dxbp-1* transcribed region. The structure of the *Dxbp-1u* and *Dxbp-1s* transcripts is shown below. Untranslated sequences are represented by *single lines*. The *Dxbp-1u* ORF and that shared by the *Dxbp-1u* and *Dxbp-1s* transcripts are indicated as *red boxes*, with the basic domain coloured in *yellow*, and the “leucine zipper” as a *hatched box*. The *Dxbp-1s*-specific ORF is shown as a *blue box*. Unprocessed and spliced unconventional introns are depicted by *two convergent stem-loops* and by a *single stem-loop*, respectively. **b** RT-PCR analysis of the expression of the *Dxbp-1u* and *Dxbp-1s* transcripts. PCR amplifications were performed using genomic DNA (Gen) as control or reverse-transcribed polyA<sup>+</sup> RNA extracted from 0 to 1 h, 2 to 4 h, 6 to 12 h and 12 to 24 h embryos or total RNA extracted from the first (L1), second (L2) and third (L3) instar larvae or dissected third-instar larval salivary glands (SG), ovaries (Ov) or male sexual apparatus (Test), as templates. The length of the two RT-PCR products was determined by the direct sequencing of the amplified fragments. **c** The sequence alignment of the basic domain of *D. melanogaster* (*D. mel*), *Caenorhabditis elegans* (*C. eleg*), *Mus Musculus* (*M. mus*), *Homo Sapiens* (*H. sap*), *Rattus norvegicus* (*R. norv*) and *Brachydanio rerio* (*D. rer*) Xbp-1 proteins

stem and two evolutionarily conserved stem-loop structures showing strong structure and sequence similarities with the Ire-1 endoribonuclease cleavage sites identified in worms and vertebrates (see Fig. S2). Thus, although the *Dxbp-1* gene did not display any significant sequence similarities

with the fish, mammal or worm *xbp-1* genes outside the region coding for the basic domain (64% identity and 80% similarity; Fig. 1c), the presence of these conserved features indicates that this gene is the *Drosophila xbp-1* orthologue. These data also suggested that the *Dxbp-1* transcript was submitted to an Ire-1-mediated unconventional “splicing” similar to that of the yeast *hac1*, and worm and vertebrate *xbp-1* transcripts after UPR signalling. In agreement with the nomenclature used for worms and vertebrates, we will refer to *Dxbp-1u* as the unprocessed transcript and to *Dxbp-1s* as the spliced *Dxbp-1* transcript.

We showed that the level of *Dxbp-1s* was increased in flies fed for 24 h with tunicamycine, a drug that inhibits protein glycosylation and folding, and consequently induces UPR signalling (see Fig. S3). Because we also detected *Dxbp-1s* in the absence of exogenously induced ER stress (see Fig. S3), we determined the stage and tissue specificities of the two *Dxbp-1* transcripts by RT-PCR, using either total or polyA<sup>+</sup> RNA extracted from embryos at various developmental stages (first, second and third instar larvae), the dissected third instar larval salivary glands, and adult ovaries and testes. Both transcripts were detected in all samples analysed, but the levels of accumulation of the *xbp-1s* transcript compared to those of the *xbp-1u* form differed in the various stages and tissues analysed. Although levels of *Dxbp-1s* were low or barely detectable when compared to those of *Dxbp-1u* in embryos and in ovaries, its relative accumulation was significantly increased in the salivary glands of the third-instar larvae and, even more so, in the sexual apparatus of adult males (Fig. 1b).

*Dxbp-1* has an essential function during development

The  $l(2)^{k13803}$  line (Torok et al. 1993) has been shown to contain an insertion of the  $P[w; lacZ]$  enhancer trap transposon (Bier et al. 1989) in the 5'-UTR region of the *Dxbp-1* gene (Fig. 1a). We used PCR experiments to confirm that this line contains an insertion of the  $P[w; lacZ]$  transposon at position +156 relative to the predicted start site of the transcription of the *Dxbp-1* gene. The lack of complementation between  $l(2)^{k13803}$  and  $Df(2)CC_2$  or  $Df(2)Exel_{6042}$ , two deficiencies that delete *Dxbp-1*, was a first indication that the recessive lethal phenotype in line  $l(2)^{k13803}$  was due to the  $P[w; lacZ]$  insertion in the gene. Then, we generated 100  $l(2)^{k13803}; w^-$  revertant lines following  $\Delta[2-3]$  transposase-induced mobilization of the transposon, and we isolated 43 homozygous viable and fertile lines. In all these lines, we mapped the excision event by PCR analysis and subsequent sequencing of the amplified fragments. Precise excision of the transposon was detected in 28 of the 43 lines, therefore, demonstrating (1) that the recessive lethality of line  $l(2)^{k13803}$  was due to

the insertion of the *P[w; lacZ]* transposon leading to a mutation of the *Dxbp-1* gene and (2) that line *l(2)<sup>k13803</sup>* did not contain a second recessive lethal or sterile mutation. We, therefore, refer to this mutation as *Dxbp-1<sup>k13803</sup>*.

We observed that 95% of *Dxbp-1<sup>k13803</sup>* homozygous animals hatched and, at that time, were indistinguishable from control. However, as individuals aged, they remained at the first instar stage, became sluggish and sick before dying after two to four days. A very similar phenotype was observed in hemizygous *Dxbp-1<sup>k13803</sup>* individuals obtained with either *Df(2)CC<sub>2</sub>* or *Df(2)Exel<sub>6042</sub>*, showing that *Dxbp-1<sup>k13803</sup>* is either an amorphic or a strong hypomorphic mutation. All together, these data suggest that the *Dxbp-1* gene has an essential function during development.

#### Detection in situ of *xbp-1* transcripts during oogenesis and embryogenesis

The pattern of accumulation of *Dxbp-1* mRNA during oogenesis and embryogenesis was established by whole-mount in situ hybridisation. Data showed that *Dxbp-1* transcripts accumulated almost ubiquitously throughout embryogenesis and oogenesis (data not shown). However, we detected significantly higher levels of *Dxbp-1* RNAs superimposed on this ubiquitous pattern of expression: (1) during oogenesis in follicle cells that are committed to the synthesis of the respiratory appendages (Fig. 2a), (2) during embryogenesis, in the labial segment of stage 11 embryos (Fig. 2b) and (3) in the salivary glands of stages 14 to 17 embryos (Fig. 2c). In addition, a segmented pattern of *Dxbp-1* transcript accumulation was detectable in stage 10–11 embryos (Fig. 2b).

#### Unconventional splicing of *Dxbp-1s* occurs in the salivary glands of the third-instar larvae

Because the structure of the two *Dxbp-1* transcripts made it impossible to design a *Dxbp-1s*-specific probe to establish the pattern of accumulation of this RNA isoform by in situ hybridisation, we constructed an *UAS-Dxbp-1:GFP* transgene as a tool to visualize *Dxbp-1* unconventional splicing. In this construct, a genomic fragment encompassing the 5'-UTR of the *Dxbp-1* gene, the entire *Dxbp-1u* ORF, including the unconventional intron and 488 bp of 3' downstream sequences, was cloned upstream from the reporter green fluorescent protein (GFP) gene in the *pUASp:GFP* vector (Januschke et al. 2002). The construct was designed to reveal unconventional splicing through the production of a fluorescent DXbp-1s:GFP fusion protein after the splicing of the 23-nt intron (see Fig. 3a and Materials and methods). A similar transgenic model has been designed in the mouse for monitoring ER stress (Iwawaki et al. 2004). We first tested various ubiquitous

**Fig. 2** Accumulation pattern of the *Dxbp-1* transcript during oogenesis and embryogenesis. (a–c) Whole-mount in situ hybridisations with a *Dxbp-1* anti-sense RNA probe on **a** early stage 14 ovarian follicle, **b** stage 11 and **c** stage 17 embryos. **d** Whole-mount in situ hybridisation with a *Dxbp-1* sense RNA probe on a stage 11 embryo. Note that the intensely labelled cells observed in the labial segment of stage 11 embryo likely correspond to the salivary gland anlagen. Gal4 drivers, such as *act5C-Gal4*, *arm-Gal4* or *da-Gal4*, as well as more specific drivers, such as *en-Gal4*. However, none of these drivers allowed us to detect fluorescent cells at any stage, even in larvae fed with drugs known to induce the UPR pathway such as tunicamycin, dithiothreitol or thapsigargin. Because the *Dxbp-1s* transcript appeared to accumulate at a relatively high level in salivary glands of the third-instar larvae (Fig. 1b), we analysed the expression of the *UAS-Dxbp-1:GFP* construct using the *lio-Gal4* driver line (Taillebourg et al. 2005) that leads to high levels of

**Fig. 3** In vivo detection of *Dxbp-1* RNA processing. **a** Structure of the *UAS-Dxbp-1:GFP* transgene. *Dxbp-1* sequences shown as light grey (5'-UTR), dark grey (*Dxbp-1u* and *Dxbp-1s* shared ORF), empty (common intron), hatched (*Dxbp-1u/Dxbp-1s* overlapping ORFs) and black (3'-truncated *Dxbp-1s* specific ORF) boxes were inserted between *UAS* sequences (dotted box), and the GFP-encoding gene (green box) in the *pUAS<sub>P</sub>-GFP* vector (Januschke et al. 2002) in phase with the *Dxbp-1u* ORF. An arrow points in the direction of transcription. Translation initiation (ATG) and termination (TAG<sub>*Dxbp-1u*</sub> and TAG<sub>*GFP*</sub>) codons are indicated above the transcribed sequence. Underneath is depicted the predicted structure of the encoded transcripts. Whereas, the native RNA should encode the *bona fide* DXbp-1u protein (colours as in Fig. 1a), the processed *Dxbp-1s:GFP* transcript resulting from the splicing of the unconventional intron (uc. i.) is predicted to encode a fluorescent DXbp-1s:GFP fusion protein (colours as in Fig. 1a with the GFP encoding sequences indicated as a green box). **b** Salivary glands of *lio-Gal4; UAS-Dxbp-1:GFP* third-instar larvae showing strong specific nuclear fluorescent staining

expression of the Gal4 transcription factor in the salivary glands of the third-instar larvae. In *lio-Gal4; UAS-Dxbp-1:GFP* third-instar larvae, we observed a strong GFP fluorescent staining in the salivary glands (Fig. 3b). Consistent with the fact that the DXbp-1u and DXbp-1s proteins are transcription factors, this GFP staining was restricted to salivary gland nuclei. Moreover, an increase in the GFP staining was observed in larvae fed for 24 h with tunicamycine. This demonstrates that putative Ire-1-dependent splicing does indeed occur in salivary

glands (Fig. 4). These results, which are also consistent with our RT-PCR data, confirmed that unconventional splicing of *Dxbp-1* occurred at relatively high levels in salivary glands of third-instar larvae.

## Discussion

In this study, we have analysed the structure, expression pattern and requirement during the development of a novel *Drosophila* gene encoding a “bZIP” protein. This gene was identified as being the *Drosophila* orthologue of the *xbp-1* gene, as deduced from (1) the strong sequence similarities of the basic domain of the encoded protein with that of vertebrate and nematode Xbp-1 protein, (2) the conservation of both structure and sequences of putative Ire-1 cleavage sites in the *Dxbp-1* transcript, (3) and the unconventional splicing of a 23-nt intron, which so far has been detected in *xbp-1* transcripts only.

The UPR pathway and its major components such as the *per/perk*, *ire-1* and *hac1/xbp-1* genes have been conserved during the evolution from yeast to mammals (for a review see Ma and Hendershot 2001), but in higher eukaryotes, the *xbp-1* gene has also been shown to possess functions that are essential during development, independently from pathological or drug-induced ER stresses (for a review see Wu and Kaufman 2006).

### Conserved requirement for *xbp-1* in secretory cells

In mammals, the first indication of a possible link between the *xbp-1* gene and secretory activities was provided by an in situ hybridisation analysis that revealed an abundant transcription of the gene in exocrine glands and in osteoblasts during skeleton formation (Clauss et al. 1993). It was further shown that, at later stages, *xbp-1* is required for terminal differentiation of plasma cells into antibody-secreting B cells (Reimold et al. 2001; Gass et al. 2002; Iwakoshi et al. 2003a,b). Indeed, whilst *xbp-1*<sup>-/-</sup> hematopoietic cells underwent normal B-cell activation, germinal centre differentiation and class-switch recombination, they failed to secrete immunoglobulins, which is the final step in B-cell differentiation (Reimold et al. 2001). In addition, an increased accumulation of *xbp-1s* mRNA has been observed upon the induction of the differentiation of the mouse B-cell lymphoma CH12 cells into antibody-secreting B-cells by lipopolysaccharide. The level of *xbp-1s* transcript started to increase after 8–12 h of stimulation and then peaked at 32 h, whereas a sharp increase in the accumulation of Xbp-1s protein was detected after 24 h of stimulation, just before an increased translation of Ig chains (Gass et al. 2002). These data seem to corroborate the hypothesis that *xbp-1* plays a key role during the very last

**Fig. 4** ER stress increases processing of *Dxbp-1:GFP* transcripts. Feeding *lio-Gal4; UAS-Dxbp-1:GFP* larvae tunicamycin increases fluorescent labelling of salivary gland nuclei. All salivary glands were photographed in a single shot to fully visualize the increased fluorescent staining of the salivary glands of *lio-Gal4; UAS-Dxbp-1:GFP* third instar larvae fed with 50  $\mu\text{g}/\text{ml}$  of tunicamycin for 24 h (left) compared to that of *lio-Gal4; UAS-Dxbp-1:GFP* control larvae (right)

stage of lymphocyte B-cell differentiation, that is, Ig secretion (Gass et al. 2002). More recently, Lee et al. (2005) designed *xbp-1<sup>-/-</sup>* mouse embryos whose early lethality, which is due to severe impairment of hepatocyte development (Reimold et al. 2000), was rescued by targeting the expression of an *xbp-1* transgene in liver cells. These mice showed defects that were restricted to secretory organs, such as exocrine pancreas and salivary glands, and they died at an early post-natal stage due to a lack of pancreatic digestive enzymes (Lee et al. 2005). These data all argue in favour of the postulate that *xbp-1* plays a key role in secretory organs in mammals.

Our results also suggest that *Dxbp-1* plays an important role in cells showing an intense secretory activity in *Drosophila*. Firstly, in situ hybridisation data revealed that this gene is expressed in two groups of 50 follicle cells that will secrete in less than 2 h the large quantity of proteins required for the synthesis of the two respiratory appendages at late stages of oogenesis. However, because it is not possible to design a *Dxbp-1s*-specific probe to detect *Dxbp-1s* by in situ hybridisation, we were not able to establish which of the *Dxbp-1* mRNA isoforms, *Dxbp-1u* or *Dxbp-1s*, had accumulated in these follicle cells. Secondly, our RT-PCR experiments revealed that the *Dxbp-1s* transcript is comparatively more abundant in two types of tissue: (1) the paragonia, which are two accessory glands of the male sexual apparatus that secrete a large quantity of proteins that are transferred with the sperm during copulation and, (2) to a lesser extent, in the salivary glands of third-instar larvae. Thirdly, in agreement with this latter observation, we have confirmed with the *Dxbp-1:GFP* transgene used to

detect *Dxbp-1* unconventional splicing that significant levels of presumptive Ire-1-dependent processing of the *Dxbp-1* transcript take place in the salivary glands of third-instar larvae, a tissue that is committed to the synthesis of large quantities of glue proteins right at the end of the third larval instar. These data suggest that, like the mouse gene, the *Dxbp-1* gene is active in secretory cells.

Because secretory cells display intense translational and post-translational activities such as covalent modifications and protein folding, their requirement for an active Xbp-1 protein likely reflects their important needs in ER resident proteins, such as chaperones proteins and modifying enzymes, that are encoded by genes directly activated by the Xbp-1s protein. In this context, it would be interesting to determine whether ATF-6, the second “bZIP” transcription factor of the UPR pathway, also plays a role in secretory cells. It could be proposed that this “physiological” aspect of the UPR pathway, i.e. the maintenance of ER homeostasis in secretory cells, is the ancestral function of the *xbp-1/hac1* and *ire-1* genes.

#### *xbp-1* plays an essential role during development

During the early stages of the *Xenopus* development, both the xXBP-1 protein and the BMP-4 protein are components of a regulatory loop that is essential for mesoderm and neuroderm differentiation (Zhao et al. 2003; Cao et al. 2006). During this process, xXBP-1 acts both as an activator of *BMP-4* and a repressor of *Xvent-2* genes through direct binding to their promoter sequences. This dual activity of xXBP-1 depends upon its association with various co-factors

such as c-Jun, p300 and Smad1 to form transcriptional activator complexes, or with Smad6 and Smad7 in the case of inhibitory complexes (Cao et al. 2006).

Mouse XBP-1<sup>-/-</sup> embryos died between E12.5 and E13.5 after organogenesis was completed and showed growth retardation, liver hypoplasia and reduced blood cell production (Reimold et al. 2000). The lethality in these mutant embryos could be rescued by targeting the expression of *xbp-1* in hepatocytes only (Lee et al. 2005). Thus, the absolute requirement of xXBP-1 during the early stages of embryonic development in frogs appears to be absent in mammals. This suggests that *xbp-1* was recently recruited in amphibians to play a role in the early patterning of the embryo. Alternatively, this function of *xbp-1* in early frog development might have disappeared or became masked during mammal evolution by the function of a yet unidentified gene. In this context, it would be interesting to use morpholino-mediated gene knockdown to determine whether *xbp-1* also plays an essential role during early embryonic development in fishes such as the zebrafish.

In *Drosophila*, the segmented pattern of the expression of *Dxbp-1* in fully elongated germ-band embryos suggested a role for this gene during embryonic development, particularly in embryo patterning. However, the lack of detectable phenotype of *Dxbp-1* homozygous or hemizygous mutant embryos did not support this hypothesis. Alternatively, this lack of embryonic phenotype might be due to either residual, albeit sufficient, *Dxbp-1* function in available mutants or from maternal *Dxbp-1* contribution that provided sufficient *Dxbp-1* function for the completion of embryonic development. All attempts to isolate a molecularly null allele of *Dxbp-1* that would allow us to perform a germ line clone analysis and generate embryos devoid of maternal *Dxbp-1* contribution have failed so far. Whether *Dxbp-1* is essential for embryonic development, thus, remains to be established.

Whereas *Dxbp-1* mutants hatched normally, homozygous or hemizygous larvae hardly grew at all and did not moult. They lived for 2 to 4 days as sluggish L1s and then died. Thus, in contrast to *C. elegans* in which *xbp-1* null mutants were fully viable and fertile (Shen et al. 2001; Calfon et al. 2002), our data demonstrate an essential requirement for *Drosophila xbp-1* during larval development. Because [<sup>35</sup>S] methionine incorporation experiments suggested that protein synthesis was not significantly decreased in mutant larvae (data not shown); this larval lethality might be due to impaired secretory processes. The growth defects might reflect a lack, or at least a severe reduction, in the secretion of digestive enzymes, and the moult inhibition is possibly the consequence of defects in ecdysone secretion.

Whatever the function of *Dxbp-1* during embryogenesis is, this gene appears to play an essential and evolutionarily

conserved role in *Drosophila*, hypothetically, by stimulating the folding capacities of the ER in cells committed to intense secretory activities.

**Acknowledgements** We thank Jean Maurice Dura for kindly providing the *lio-Gal4* driver line and all the members of the laboratory for helpful discussions throughout the course of this work. We also thank the two anonymous reviewers for their insightful comments and suggestions. S.S. was supported by a predoctoral fellowship from the Fondation pour la Recherche Médicale.
