**Abstract** Adult trematodes of the genus *Stegodexamene* Macfarlane, 1951 were recorded from the intestines of two species of freshwater eels, the Pacific short-finned eel *Anguilla obscura* Günther and the speckled longfin eel *Anguilla reinhardtii* Steindachner from the Pouembout and La Foa Rivers, New Caledonia, South Pacific. They were identified as *Stegodexamene anguillae* Macfarlane, 1951, a species previously reported only from eels in New Zealand. The morphology of adult *S. anguillae* seems to be practically identical with that of the later described *Stegodexamene callista* Watson 1984 from eels in Australia. The finding of *S. anguillae* in *A. obscura* and *A. reinhardtii* in New Caledonia represents new geographical and host records. In addition to this trematode, two larval specimens of a cestode of the order Proteocephalidea were found in the intestine of one *A. obscura* from the Pouembout River. No monogenean was found in eels of New Caledonia.

## Introduction

Although New Caledonia is an interesting area from the zoogeographical point of view, with a high degree of

endemism, almost no attention has been paid to the parasites of native fishes in freshwater habitats. As far as we know, the only two papers dealing with helminths of freshwater fishes in New Caledonia are those recently published dealing with the occurrence of camallanid nematodes, a new species of *Procamallanus* Baylis, 1923 from eels in New Caledonia and some other Pacific islands, and *Camallanus cotti* Fujita, 1927, a pathogenic parasite of fishes introduced into New Caledonia (Moravec et al. 2006; Moravec and Justine 2006). A few lepocreadiid trematodes have recently been reported from New Caledonian marine fishes (Bray and Justine 2006).

In July 2003 and September 2004, samples of eels from two localities in New Caledonia, the Pouembout and La Foa Rivers and swamps near Ponérihouen, were examined for the presence of helminth parasites. Results of the evaluation of nematodes recorded have already been published (Moravec et al. 2006), whereas those concerning the trematodes and cestodes are treated below.

## Materials and methods

Eels were caught by local fishermen in the Pouembout River near Pouembout (west coast, Province Nord) and by Dr. C. Pöllabauer by electrofishing in the La Foa River near La Foa (west coast, Province Sud), both localities in the mainland of New Caledonia, South Pacific. Some eels from Pouembout were kept in captivity for several months before their examination. Three native species of eels were obtained and examined in September 2004: Pacific short-finned eel, *Anguilla obscura* Günther (three specimens from Pouembout; body length 67–88 cm), speckled longfin eel, *Anguilla reinhardtii* Steindachner (two specimens from Pouembout

and 11 from La Foa; body length 71–72 and 18–45 cm, respectively), and the giant mottled eel, *Anguilla marmorata* Quoy et Gaimard (two specimens from La Foa; body length 28–45 cm). The eels were transported alive to the laboratory of the Institut de Recherche pour le Développement (IRD) in Nouméa, killed, and immediately examined for the presence of helminth parasites. One specimen of *A. reinhardtii* from Pouembout (body length 104 cm) and three specimens of *A. obscura* from swamps near Ponérighouen, east coast, Province Nord (body length 52–76 cm) were examined in July 2003 but had no digenleans. No parasites were found in the examined *A. marmorata*. The recovered trematodes and cestodes were washed in physiological saline and then fixed in hot 4% formaldehyde solution or, slightly pressed under the cover slip, in cold 4% formaldehyde solution. For light microscopic examination, the specimens were stained in carmine, dehydrated through an ethanol series, and mounted in Canada balsam as permanent slides. Drawings were made with the aid of a Zeiss drawing attachment. The scientific names of fishes follow Fishbase (Froese and Pauly 2006).

## Results

The following observations were made for *Stegodexamene anguillae* Macfarlane, 1951 (Trematoda: Lepocreadiidae).

### Description

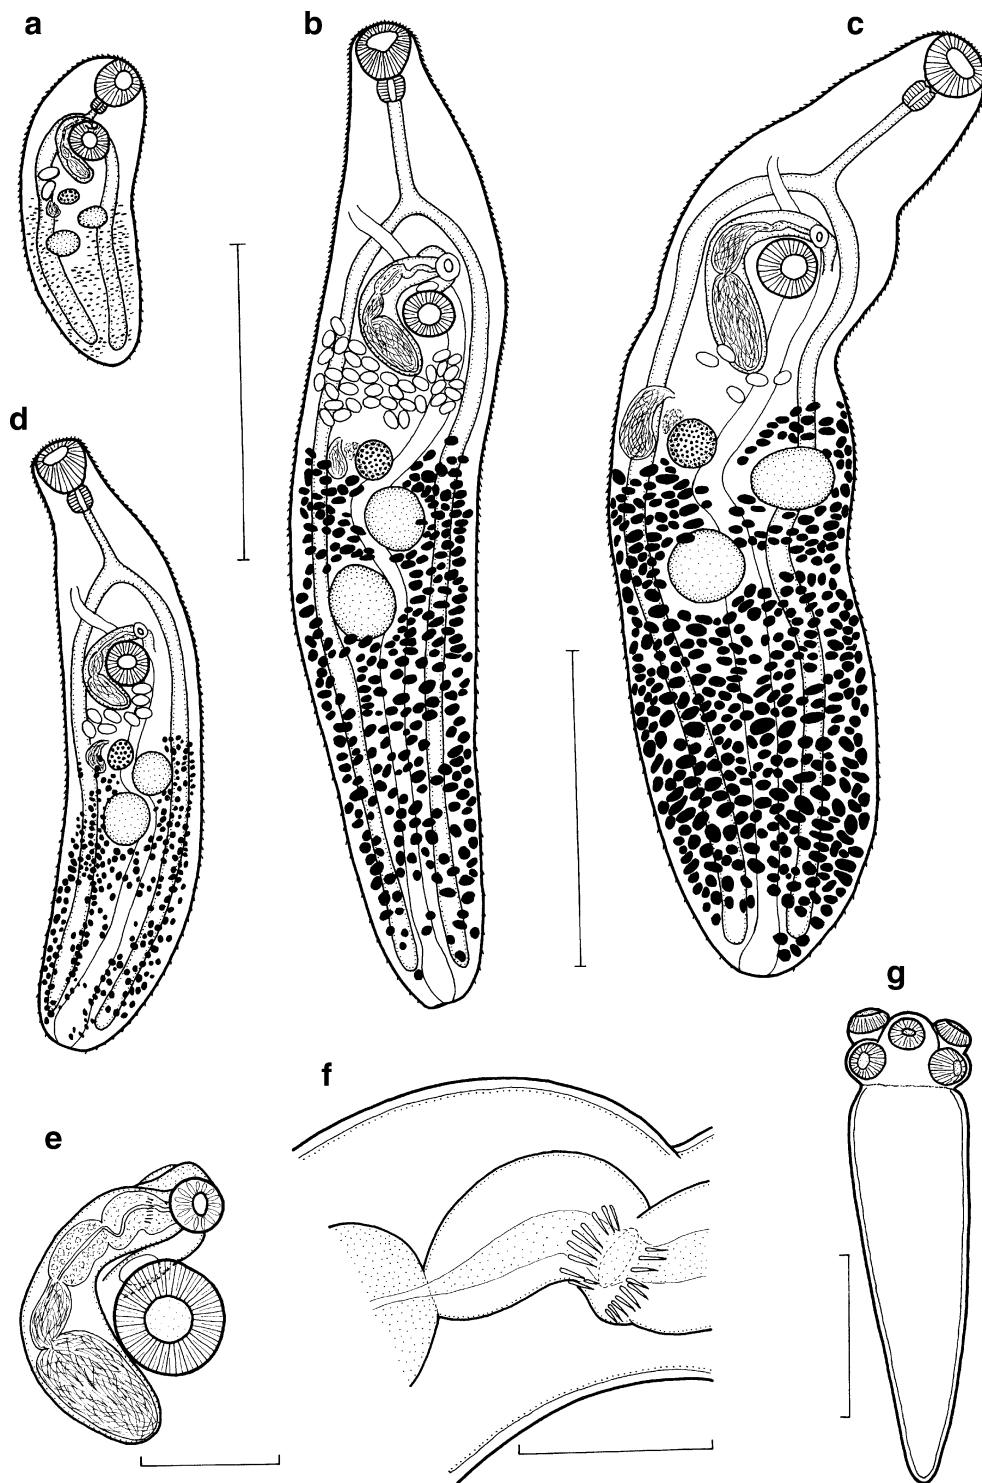

As shown in Fig. 1a–f, in our eight gravid specimens from *A. reinhardtii* (measurements of two largest specimens from *A. obscura* are in parentheses), the body is oval to elongate-oval, usually somewhat tapering towards anterior end, with the maximum width at about its middle. The body length is 1.09–3.58 (2.77–3.17) mm and the maximum width 394–721 (707–856) µm. The tegument is covered with minute spines. Remnants of the eyespots of cercariae (as scattered pigment granules) are present on the dorsal side. The oral sucker is oval, subterminal, 111–190 (150–204) µm long, and 138–218 (190–218) µm wide. The ventral sucker is circular to somewhat oval, situated approximately in the anterior third of the body, 126–204 (177–190) µm long, and 135–218 (177–231) µm wide; the size ratio of the oral to the ventral suckers is 0.95–1.14: 1. The prepharynx is very short and not visible in all specimens. The pharynx is oval, muscular, 51–105 (95–111) µm long, and 60–102 (95–120) µm wide, with a lobular anterior margin. The esophagus is narrow and 69–408 (299–313) µm long. The intestinal bifurcation is in the posterior part of the fore body, somewhat anterior to the ventral sucker (except for the smallest specimen where it is at the level of the anterior edge of ventral sucker). The caeca are narrow, ending

blindly close to the posterior extremity. The testes are two, oval to almost spherical, nearly equal in size, oblique, at about the middle of body. The anterior testis is situated on the opposite (left) side of the ovary, somewhat posterior to the ovary or nearly at its level, while the posterior testis is in about the same longitudinal line with the ovary. The anterior testis is 78–231 (231–326) µm long and 102–313 (272) µm wide; the posterior testis is 99–272 (299–313) µm long and 114–272 (245–354) µm wide. The external seminal vesicle is absent. The cirrus sac is claviform, 255–707 (435–503) µm long and 68–177 (136–204) µm wide, curved around the right side of the ventral sucker, extending into the hind body. It contains a bipartite seminal vesicle, a pars prostatica, and an invaginated cirrus; the posterior part of the seminal vesicle is oval and much larger than the anterior one; the cirrus is with small patches of tiny spines near its end (Fig. 1f), which are invisible in most specimens. The genital pore lies ventrally and slightly to the left of the midline between the ventral sucker and the intestinal bifurcation. The metraterm is distinct; glandular cells surrounding the exit of the metraterm and cirrus are present. The ovary is oval to spherical, 57–177 (136–204) µm long, and 84–204 (177–204) µm wide, pretesticular, situated somewhat asymmetrically to the right of the midline. The seminal receptacle is well-developed, 39–286 (258–394) µm long, and 30–136 (150–299) µm wide, located to the right from the ovary. Vitelline follicles are numerous, surround caeca dorsally, ventrally, and externally, and become confluent posterior to testes, extending from the ovary nearly to the end of the body. The vitelline follicles are poorly developed in the smallest specimens (Fig. 1a). Uterine loops are anterior to the ovary and contain 2–38 (5–12) eggs. The eggs are operculated, yellow-brown, 60–69 (63–69) µm long, and 36–45 (36–45) µm wide. The excretory bladder is tubular, long, somewhat curved between testes, extending anteriorly to at least the level of the intestinal bifurcation.

### Hosts

The hosts are the eels *A. obscura* and *A. reinhardtii* (Anguillidae, Anguilliformes), and the site of infection is the intestine. Localities are the Pouembout River near Pouembout, Province Nord (*A. obscura*, *A. reinhardtii*) and the La Foa River near La Foa, Province Sud (*A. reinhardtii*) in New Caledonia. The rate of infection in the localities was as follows. In the Pouembout River, the prevalence in *A. obscura* was one eel infected/three eels examined, and the intensity was 7 specimens; the prevalence in *A. reinhardtii* was 2/3, with an intensity of 14 and 25 specimens. In the La Foa River (*A. reinhardtii*), prevalence was 1/11 and intensity was 2 specimens. In the Ponérighouen swamps (*A. obscura*), prevalence was 0/3. The voucher specimens are

**Fig. 1** *Stegodexamene anguillae* Macfarlane, 1951 (a–f). *a* Smallest specimen with eggs, *b* large specimen with many eggs, *c* largest specimen, *d* small specimen with few eggs, *e* cirrus sac, *f* part of inverted cirrus with patches of spines inside cirrus sac. *g* *Proteocephalidea* gen. sp. larva (scale bars: *a–d*=1 mm; *e, g*=200  $\mu$ m; *f*=50  $\mu$ m)

deposited at the Muséum National d'Histoire Naturelle, Paris, France (Cat. Nos. JCN1273, JCN1274, JCN1275, JCN1311) and at the Institute of Parasitology, Biology Centre of the Academy of Sciences of the Czech Republic, České Budějovice (Cat. No. D-607).

In addition to *S. anguillae*, two cestode larvae of an unidentified genus and family, referable to the order

*Proteocephalidea*, were recorded from *A. obscura* caught in the Pouembout River near Pouembout, northern New Caledonia.

The two *Proteocephalidea* gen. sp. larvae were found free in the intestine of one of three eels examined. Their total body length including the scolex is 789 and 843  $\mu$ m. The length of the scolex is 136 and 150  $\mu$ m and its

maximum width is 231 and 286 µm, while the maximum width of the posterior part of the body (posterior to the scolex) is 204 and 340 µm. As shown in Fig. 1 (G), the scolex is with four small, almost circular suckers 84–99 µm in diameter. The top of the scolex is with a simple apical sucker measuring 36–60×63–75 µm.

The morphology of the scolex of these larvae and the freshwater environment suggest that they belong to the order Proteocephalidea. Adults of this order are parasites of freshwater fishes, amphibians, and reptiles (Khalil et al. 1994). The voucher specimens are deposited at the Muséum National d'Histoire Naturelle, Paris, France (Cat. No. JCN1277) and at the Institute of Parasitology, Biology Centre of the Academy of Sciences of the Czech Republic, České Budějovice (Cat. No. C-436).

## Discussion

The trematode genus *Stegodexamene* Macfarlane, 1951 was erected to accommodate the species *S. anguillae* Macfarlane, 1951, an intestinal parasite of freshwater eels originally described from *Anguilla dieffenbachii* Gray and *Anguilla australis schmidti* Philipps from New Zealand (Macfarlane 1951); from these two hosts in New Zealand, *S. anguillae* was also reported by Macfarlane (1952), Hewitt and Hine (1972), and Rid (1973). However, according to Froese and Pauly (2006), the latter fish occurs only in New Caledonia; therefore, it is probable that the second host was in fact *A. australis australis* Richardson, distributed on the coast of Australia and New Zealand, extending north to New Caledonia (Froese and Pauly 2006). Later *S. anguillae* was reported in New Zealand as a common parasite of the endemic New Zealand longfin eel, *A. dieffenbachii*, and the shortfin eel, *A. australis* (see, e.g., Manter 1954; Hine 1980; Hine and Francis 1980; Blair 1984; Graythorn and Taylor 2000).

Srivastava (1962) erected the genus *Rhynchocreadium* Srivastava, 1962 for the newly described species *Rhynchocreadium aculeatum* Srivastava, 1962 from the freshwater spiny eel *Macrognathus aculeatus* (Bloch) in India. Yamaguti (1971) took *Rhynchocreadium* for a subgenus of *Stegodexamene*, listing in it two species, *S. aculeatum* Srivastava, 1962 and *S. singhia* Pershad, 1965, both from the same host species (*M. aculeatus*) in India. At present, *Rhynchocreadium* Srivastava, 1962 is considered a junior synonym of the genus *Allocreadium* Looss, 1900 (family Allocraeidae; see Caira and Bogea 2005).

Consequently, in addition to the type species of *Stegodexamene*, the only other representative of this genus is *Stegodexamene callista* Watson, 1984 described from the speckled longfin eel *A. reinhardtii* Steindachner in Australia (Watson 1984). According to Watson (1984), adults of this

species are very similar to those of *S. anguillae*, differing from them in a somewhat smaller body size; a less extensive pars prostatica; their excretory bladder, which may extend even anterior to the intestinal bifurcation (not reported for *S. anguillae*); in more numerous flame cells (50 vs 42); and the presence of minute cirrus spines. However, all these differences are questionable.

The range of the body length of gravid specimens of the present New Caledonian material corresponds to both species. Regarding the number of flame cells, which can be studied with difficulties in living specimens only, Macfarlane (1951) believed that the flame cell pattern of *S. anguillae*, which he illustrated, was incomplete. As noted by Watson (1984), the minute cirrus spines were not reported by Macfarlane (1951), but these are difficult to observe and are easily overlooked; they were not visible in most mounted specimens of the present material. New Zealand adult specimens of *S. anguillae* obtained from *A. australis* were also studied by Watson (1984), who had not observed any morphological differences between *S. anguillae* and *S. callista*.

Therefore, the only interspecific differences between *S. anguillae* and *S. callista* should be in the structure of cercariae, namely in the number and arrangement of their caudal setae, provided that the observations on the life cycles published by Macfarlane (1951) and Watson (1984) are reliable. Nevertheless, a comparison of the New Zealand and Australian trematodes by molecular methods and new comparative studies of their life cycles conducted preferably by the same researcher are highly desirable to confirm the existence of *S. callista* as an independent species.

Because the body length in *Stegodexamene* specimens of the present material attains nearly the maximum length of *S. anguillae*, their morphology is in accordance with the description of this species, and there may be some doubts concerning the validity of another species, *S. callista*, which may parasitize the same host species (*A. australis*) as *S. anguillae*; they are identified as *S. anguillae*. This species, previously known only from New Zealand, is now reported for the first time from New Caledonia and *A. obscura* and *A. reinhardtii* represent its new host records.

Macfarlane (1951) mentions that in New Zealand, adults of *S. anguillae* occur in the intestines of eels longer than 35 cm (ca. 7 years old). Also in New Caledonia, this parasite was found only in larger eels (body length 45–72 cm in *A. reinhardtii* and 88 cm in *A. obscura*), whereas they were absent from ten smaller *A. reinhardtii* (body length 18–40 cm) and two *A. marmorata* (body length 28 and 45 cm) from the La Foa River. This is associated with the trematode's life cycle and the ecology of eels, where the source of infection for eels are some forage fishes (in New Zealand mainly of the families Eleotridae and Galaxiidae) serving as the second intermediate host of this parasite; metacercariae of *S. anguillae* encysted in fish tissues may be

progenetic, producing viable eggs capable of further development (Holton 1984; Poulin and Lefebvre 2005). The first intermediate hosts of *S. anguillae* in New Zealand are the gastropods *Potamopyrgus antipodarum* (Gray) and *Potamopyrgus badia* Gould (Hydrobiidae) (Macfarlane 1951). Field surveys show that in natural New Zealand eel populations, 26–78% of *A. australis* and 25–40% of *A. dieffenbachii* are parasitized by adult *S. anguillae* (Rid 1973; Hine 1980). The present data indicate that *S. anguillae* is a common parasite of eels also in New Caledonia. Although *S. anguillae* co-occurred with the nematode *Prociamallanus pacificus* Moravec, Justine, Würtz, Taraschewski et Sasal, 2006 in *A. obscura* and *A. reinhardtii* of the Pouembout River (Moravec et al. 2006), this nematode parasite was completely absent from eels of the La Foa River.

Although negative results are often not reported in parasitological papers, we believe it is worth mentioning that no swim bladder nematodes or monogeneans on gills were found in specimens of all three species of eels collected in New Caledonia. One of the *A. obscura* from Pouembout had small white dots on the gills, which contained myxozoan spores.

**Acknowledgements** Yann Pellequer (Direction du Développement Économique et de l'Environnement, Province Nord, Poindimié, New Caledonia) kindly provided the eels from Pouembout and Ponérihouen. Dr. Christine Pöllabauer (Erbio, Nouméa, New Caledonia) kindly organized two electrofishing expeditions to the La Foa and Dumbéa Rivers and is thanked for her collaboration, fish identification, and fruitful discussions. Julie Mounier, Anaïs Guérin, Audrey Guillou, Charles Beaufrère, and Eric Bureau, students, participated in the fishing expeditions and parasitological surveys. Angelo Di Matteo (IRD, Nouméa) is thanked for technical help. Thanks are also due to Irena Husáková from the Institute of Parasitology, Biology Centre, ASCR in České Budějovice for her technical assistance and help with the preparation of illustrations. This study was partly supported by grant no. 524/06/0170 from the Grant Agency of the Czech Republic and by the research projects of the Institute of Parasitology, ASCR (Z60220518 and LC522).
