### **Abstract**

Since the VEI 4 eruption of November 2002, El Reventador volcano (Ecuador) has been the site of persistent open-vent activity characterized by frequent (hourly) Vulcanian—Strombolian explosions and occasional (every few years) efusion of lava fows. The conduit processes that sustain this continuous eruptive activity are still poorly understood. Here, we combine high temporal resolution thermal infrared imaging with seismic recordings and DOAS-derived SO<sub>2</sub> fluxes focusing on a period of Vulcanian-style activity on 22–23 February 2017. Thermal imagery captured the emission and ascent dynamics of 26 plumes during the observation period, including those fed by explosions and degassing episodes. While most explosions have associated seismic signals, a few are marked by the absence of measurable seismic activity. Degassing episodes also show very few associated seismic signals. Explosions and degassing events seem to follow a sequence that can be explained by changes in the conduit permeability associated with rapid (over time scales of minutes) rheological stifening of magma in the uppermost portion of the conduit to reduce degassing efficiency. Periods of open-vent outgassing alternate with periods of conduit capping resulting in system pressurization and leading to Vulcanian explosions that re-open the conduit allowing outgassing to resume.

#### **Resumen**

Desde la erupción VEI 4 de noviembre de 2002, el volcán El Reventador (Ecuador) ha sido protagonista de una actividad persistente en sistema abierto (open-vent) caracterizada por explosiones Vulcanianas — Estrombolianas frecuentes (en el orden de horas), y efusión de fujos de lava y piroclásticos ocasionales (en el orden de meses a años). Los procesos en el conducto que sustentan esta continua actividad eruptiva son aún poco conocidos. En este trabajo combinamos el análisis de imagen térmica infrarroja en alta resolución temporal con análisis de señales sísmicas y flujo de SO<sub>2</sub> obtenido mediante DOAS, enfocándonos en el periodo de actividad tipo Vulcaniana ocurrida durante el 22 y 23 de febrero de 2017. Las imágenes térmicas registraron la dinámica de emisión y ascenso de 26 plumas durante el periodo de observación, incluyendo aquellas alimentadas por explosiones y episodios de desgasifcación. Aunque la mayoría de las explosiones tienen señales sísmicas asociadas, unas pocas se caracterizan por la ausencia de actividad sísmica registrada en los sensores. Los periodos de desgasifcación también presentan señales sísmicas asociadas muy pequeñas. Las explosiones y eventos de desgasifcación parecen seguir una secuencia o ciclo que puede ser explicado por cambios en la permeabilidad del conducto asociados a una variación rápida (en la escala de minutos) de la rigidez del magma en la parte más somera del conducto, con lo que se limitaría la efciencia de la desgasifcación. La alternancia de periodos de desgasifcación en conducto abierto con periodos de taponamiento del conducto da lugar a una presurización del sistema derivando en explosiones Vulcanianas que vuelven a abrir el conducto, lo que reanuda la secuencia con un nuevo proceso de desgasifcación.

## **Introduction**

Vulcanian eruptions involve short-lived intermittent explosive events that can continue for periods of years (Mercalli [1907\)](#page-13-0). They are small to moderate in size, feeding eruptive columns typically reaching less than 10-km height, but which can collapse to generate pyroclastic flows (e.g., Marchetti et al. [2009;](#page-13-1) Yokoo [2009](#page-13-2); Hall et al. [2015](#page-12-0)). Numerous recent volcanic eruptions have been catalogued as Vulcanian including at Sakurajima volcano in Japan since 1955 (Miwa and Toramaru [2013\)](#page-13-3), Fuego volcano in Guatemala in 1978 (Wilson and Self [1980](#page-13-4)), Soufrière Hills volcano in Montserrat in 1997 (Formenti et al. [2003\)](#page-12-1), Tungurahua volcano in Ecuador in 2013–2014 (Hidalgo et al. [2015](#page-12-2); Hall et al. [2015](#page-12-0); Battaglia et al. [2019](#page-12-3); Gaunt et al. [2020](#page-12-4)), and El Reventador volcano in Ecuador since 2002 (Lees et al. [2008](#page-13-5)). Such Vulcanian eruptions can either be caused by phreatomagmatic or purely magmatic processes (cf. Clarke et al. [2015](#page-12-5)), but the classic model for magmatic Vulcanian eruptions is that they originate from the rupture of a gas-impermeable plug formed in the upper part of a magma-flled conduit (e.g., Fagents and Wilson [1993;](#page-12-6) Self et al. [1979](#page-13-6); Sparks [1997](#page-13-7); Woods [1995\)](#page-13-8). Vulcanian eruptions are most commonly found at volcanoes erupting magmas of basaltic andesite to dacitic composition and usually emit only small amounts of ejecta  $(< 1 \text{ km}^3$ ; Morrissey and Mastin [1999](#page-13-9)). The velocity at which the material is expelled from the vent during Vulcanian explosions has been linked to the amount of gas involved in the event (Self et al. [1979](#page-13-6); Wilson and Self [1980](#page-13-4); Formenti et al. [2003;](#page-12-1) Clarke et al. [2015\)](#page-12-5).

El Reventador volcano is a stratovolcano located on the rear-arc zone at the boundary of the Eastern cordillera and Amazon basin in Ecuador (Fig. [1a](#page-1-0)). Its currently active cone is located inside a horseshoe-shaped amphitheater that is a 4-km wide (north–south) and 6-km long (northwest–south-east) and open to the southeast (Fig. [1b\)](#page-1-0). Since 1541, this volcano has experienced more than 20 eruptive episodes (Siebert et al. [2011](#page-13-10); Naranjo et al. [2016](#page-13-11)) of which seven

<span id="page-1-0"></span>**Fig. 1 a** Location of El Reventador in Ecuador where yellow symbols are volcanoes active during the Holocene. Note that El Reventador is located to the east of the eastern side of the cordillera in Ecuador. **b** Enlargement on the current active cone at El Reventador, where "Azuela CAMP" is the site from which measurements were made and

"REVN" is the proximal seismic station. **c** Map of the region to the West of El Reventador showing the location of the distal seismic station ("CAYA"), located in the northern fank of Cayambe volcano, and the city of Quito

occurred in the twentieth century (Hall et al. [2004\)](#page-12-7). The frst and the longest episode of the twentieth century took place from 1898 to 1912, and subsequent eruptive episodes had variable durations of up to 3 years, each separated by periods of around 12 years of quiescence. The last eruptive episode of the twentieth century ended in 1976. All of these eruptive episodes were "moderate" to "moderate-large" in scale (i.e., VEI 2–3), with Strombolian to Vulcanian eruptive styles (cf. Newhall and Self [1982](#page-13-12)), and produced blocky lava flows, small-volume pyroclastic and debris fows, and ash fallout (Hall et al. [2004](#page-12-7); Samaniego et al. [2008](#page-13-13)). El Reventador's most recent and still ongoing (at the time of writing) eruptive episode began in November 2002 with a VEI 4 explosion that destroyed the summit and crater of the cone, leaving deep notches on the northern and southern margins of the summit, and produced an eruptive column that rose up to 16–17 km above the crater (Hall et al. [2004](#page-12-7)). Pyroclastic flows were produced and reached the Coca river,  $\sim$  9 km to the east of the active vent, destroying the main oil pipelines and the road leading to the oilfelds of Ecuador. Ecuador's capital city, Quito, located  $\sim$  100 km to the west (Fig. [1c](#page-1-0)), had to close down its international airport for eight days to allow ash clean-up operations that required removal of 1–2-mm ash produced by the intense ash fall of November 3 (Hall et al. [2004\)](#page-12-7). During the frst year after the paroxysmal event, two lava flows were emplaced from the summit and from a lateral vent in the southeastern cone fank (Samaniego et al. [2008;](#page-13-13) Naranjo et al. [2016\)](#page-13-11). After around 1 year of quiescence, in 2004, new lava flows formed, followed by the alternation of effusive and mildly explosive periods (Lees et al. [2008](#page-13-5); Ortiz et al. [2020\)](#page-13-14). By 2015, the volcanic cone had a similar shape to that which existed before 2002 (Ortiz et al. [2020](#page-13-14)). Between 2016 and 2018, Almeida et al. ([2019\)](#page-12-8) documented a series of morphologic changes in the upper edifce, including the existence of two active vents in January 2016, a lateral eruption in June 2017, and a partial summit collapse in April 2018. By the time of our observations in February 2017, five effusive episodes had been identified by Naranjo et al. [\(2016](#page-13-11)) and Arnold et al. [\(2017\)](#page-12-9). The discharge rate within each of the efusive periods was variable, with a general decreasing trend from one period to the next (Lees et al. [2008](#page-13-5); Naranjo et al. [2016](#page-13-11); Arnold et al. [2017\)](#page-12-9). From 2012 through 2020, and continuing during effusive episodes, a variable number of explosions (up to 50 per day) were recorded by the local monitoring network operated by the Instituto Geofísico of Escuela Politécnica Nacional (IGEPN) (cf. Ramon et al. [2021](#page-13-15)). These transient explosions typically produced ash columns of variable ash content and height, ascending up to 2 km above the summit crater (e.g., Instituto Geofísico [2010,](#page-13-16) [2018,](#page-13-17) [2019](#page-13-18)). Similar activity has been observed at other open-vent andesitic through dacitic systems as, for example, Sangay in Ecuador (Johnson and Lees [2000](#page-13-19)), Karymsky in Kamchatka (Johnson and Lees [2000](#page-13-19)),

and Santiaguito in Guatemala (Johnson et al. [2008;](#page-13-20) Sahetapy-Engel et al. [2008;](#page-13-21) Sahetapy-Engel and Harris [2009](#page-13-22)). Models proposed to explain the generation of such explosions include accumulation of gas under a near-surface structure, i.e., a plug or a viscoelastic lava dome acting as pressure valve, that is released by the mechanical failure of the blocking structure (Johnson and Lees [2000;](#page-13-19) Johnson et al. [2008](#page-13-20)). A second model explains ash eruptions at such open-vent system as being generated by slip events to cause shear-induced magma fragmentation at the conduit boundaries around the ascending dacite plug (Gonnermann and Manga [2003](#page-12-10); Bluth and Rose [2004](#page-12-11); Sahetapy-Engel et al. [2008](#page-13-21)).

Here, our aim is to analyze the ongoing volcanic activity at El Reventador to propose an explanation for the generation of the Vulcanian explosions and the associated plume dynamics. We present 2 h of quasi-continuous thermal video to describe the evolution of the activity and the duration of each explosion and propose a classifcation based on explosion characteristics. The flux of  $SO<sub>2</sub>$  emitted during the same period was measured by scanning DOAS (Diferential Optical Absorption Spectroscopy; Platt and Stutz [2008\)](#page-13-23) while the seismic activity was recorded by broadband seismometers at both proximal  $({\sim}4 \text{ km})$  and distal  $({\sim}45 \text{ km})$  locations (REVN and CAYA, Fig. [1c\)](#page-1-0). Together, these observations suggest a sequence of four phases of activity refecting evolving conditions in the shallow conduit. The sequence starts with no degassing and pressure build-up and is followed by destruction of a cap during a Vulcanian explosion. Thereafter, there is a phase of open-vent degassing punctuated by small Strombolian explosions as gas slugs episodically reach the surface. Afterwards, a new plug develops by cooling of the uppermost magma in the conduit, causing gas emissions to decrease until the system becomes fully plugged again; thereafter, the cycle recommences.

## **Methodology**

The dataset analyzed here was acquired during a feld campaign in February 2017 and consists of three types of recordings: (1) thermal infrared video, (2) scanning DOAS for  $SO_2$ fux, and (3) seismic. These we used together with visual observations and major element composition analysis of the emitted ash, which was simultaneously collected with the geophysical data sets (cf. Thivet et al. [2021](#page-13-24)).

#### **Thermal analysis**

Thermal videos were recorded from the Azuela CAMP site, located 4.5 km to the ENE of the active crater (latitude 0.07577S, longitude 77.62473 W, altitude 2160 m a.s.l., Fig. [1b\)](#page-1-0). We used an Optris PI 640 thermal infrared  $(8-14 \mu m)$  camera with a lens that produces a field of view

of  $15^{\circ} \times 11^{\circ}$  and a  $640 \times 480$  pixel image. The pixel size corresponding to a 4.5-km distance to the summit is 1.85 m. Videos of explosive events were captured at a rate of 32 frames per second (fps), with the thermal recording covering a quasi-continuous period of 2 h, from 23h14 UTC on February 22 to 01h33 UTC on February 23.

To track and define thermal waveforms associated with the explosive events, a region of interest was defined directly above the crater rim (R1, Fig. [2](#page-3-0)) to capture any emission of hot fragments, ash, and/or hot gases (Harris and Ripepe  $2007a$ ). A second region of interest  $(R2)$ was placed 1.85 or 3.7 m vertically above R1 (Fig. [2\)](#page-3-0) to determine the ascent velocity from the delay in waveform onset between R1 and R2 (Sahetapy-Engel et al. [2008](#page-13-21)). Retrieving the kinetic temperature of fragments and hot gasses requires a correction for atmospheric absorption and emission, as well as emissivity effects (Harris [2013](#page-12-13)). Here, since we are interested in the relative changes of thermal signal instead of the absolute kinetic temperatures, and given minimal atmospheric effects at these altitudes (cf. Harris [2013](#page-12-13)), we present our data in terms of uncorrected brightness temperatures (cf. Matsushima [2005](#page-13-25); Bani et al. [2013a,](#page-12-14) [2013b\)](#page-12-15). The thermal amplitude is defined as the difference between the peak temperature and background temperature in any waveform (Harris and Thornber [1999;](#page-12-16) Ripepe et al. [2005\)](#page-13-26). The timestamps for the time series were recorded using the operating computer, cross-calibrated to GPS time.

Durations of ash and/or gas venting were also obtained from these thermal time series. In most cases, the starting and ending points of an explosion are clearly defned (Fig. [3\)](#page-4-0). In some cases, however, when there is a phase of slow ash dispersal at the end of the event, the defnition of the end of the explosion becomes ambiguous. In such a situation, we defne the end of the event as the instant when the temperature inside the region R1 drops below the limit set as twice the background temperature (Fig. [3\)](#page-4-0).

# *SO<sub>2</sub>* flux

To estimate  $SO_2$  flux, we used a scanning DOAS from a fxed position at the Azuela CAMP site (Fig. [2](#page-3-0)). During measurements, the plume rose several hundred meters vertically above the summit before drifting to the east, enabling both horizontal and vertical scanning of the plume. Thirty-three spectra per scan were collected with a step angle of 0.9°, covering a horizontal scanned length of  $\sim$  2.5 km in the horizontal configuration (Fig. [2a](#page-3-0)). The angular resolution was maintained when switching to the vertical confguration. The spectrometer used was

<span id="page-3-0"></span>**Fig. 2 a** Layout of the measurement setup. The thermal camera and the DOAS were located 4.5 km to the east of the active cone. Two regions of interest (R1 and R2) are placed directly above the crater to track any fuctuation in the temperature due to hot material exiting the vent. The temperature of the background was also measured in the clear sky region as indicated. Also marked is the horizontal scanning plane covered by the DOAS. **b** Timeseries obtained from R1 to R2. Defnition of the time delay between the peak temperature recorded at R1  $(t_1)$  and R2  $(t_2)$  as used to calculate ascent speed, onset time (the time to move from background temperature,  $T_0$ , to peak temperature,  $T_{max}$ ), and thermal amplitude  $(T_{max}-T_0)$ (after Harris and Ripepe [2007a,](#page-12-12) [2007b](#page-12-17)). Example is from the

![](_page_3_Figure_9.jpeg)

onset of explosion 4

![](_page_4_Figure_2.jpeg)

<span id="page-4-0"></span>**Fig. 3** Time series from regions of interest R1 (red line) and R2 (blue line) for explosions (**a**) *11* and (**b**) *13*. When hot pulses of ash and/ or gas transit through R1 and R2, they trigger an impulsive increase in temperature, followed by a slower decrease. Objects frst cross R1 and then R2, causing a delay between the two waveforms. Peaks that appear frst in R2 before R1 correspond to hot bombs and blocks falling back to the ground. The time delay between a peak at R1 and its corresponding pike in R[2](#page-3-0) is signaled as  $\Delta t$  (Fig. 2)

an Ocean Optics USB2000 + with a spectral range of 290–440 nm and a spectral resolution of 0.5 nm FWHM. The  $SO<sub>2</sub>$  column amounts (ppm.m) were retrieved using standard DOAS calibration and analysis procedures (Platt and Stutz [2008](#page-13-23)). Reference spectra included in the nonlinear ft were obtained by convolving high resolution  $SO_2$  (Bogumil et al. [2003\)](#page-12-18) and  $O_3$  (Voigt et al. [2001\)](#page-13-27) cross-sections with the instrument line shape. A Fraunhofer reference spectrum and Ring spectrum, calculated in DOASIS (DOAS Intelligent System; Kraus [2006\)](#page-13-28), were also included in the ft. Measurements were made between 13h21 and 14h15, UTC, on February 23, 2017. The plume speed was calculated following the method described above in the paragraph of thermal analysis but also applied to periods of passive degassing. The plume transport speed relative error is conservatively assumed to be around 30–35%, which is towards the higher end of the range of past estimates (e.g., Arellano et al. [2008;](#page-12-19) Bani [2012;](#page-12-20) Bani et al. [2013b\)](#page-12-15).

#### **Seismicity**

We used two broadband seismic stations from the permanent monitoring network of the IGEPN: REVN located 4 km from the summit of El Reventador and CAYA located 45 km to the west on the northern flank of Cayambe volcano (Fig. [1\)](#page-1-0). Both stations are equipped with Trillium Compact 120 s sensors with Q330 Kinemetrics digitizers. Data are recorded with a 100-Hz sampling frequency. Station REVN records both explosion quakes and tremors from El Reventador. Instead, station CAYA, while normally used to monitor the activity at Cayambe volcano, also records the most energetic explosionquakes from El Reventador.

#### **Ash composition**

Ash fall deposited during the observation period was collected and analyzed for major element bulk composition. To do this, 100 mg of sample was mixed with 300 mg of LiBO<sub>2</sub>, melted in an induction oven at 1050 °C for 4.5 min using graphite crucibles. The resulting glass beads were then dissolved in a solution of deionized water and nitric acid (200 ml) and fnally diluted by a factor of 2000. The solutions were analyzed by ICP-AES (An ULTIMA-C Horiba scientifc, Jobin–Yvon spectrometer was used) at the Laboratoire Magmas et Volcans in Clermont-Ferrand (France).

## **Results**

The activity we observed at El Reventador on 22 and 23 February 2017 was dominated by intermittent explosions that fed ash plumes up to about 1 km above the summit, before detaching and being pushed to the east by the prevailing wind. The activity reports of IGEPN show a mean of 40 explosions per day and a similar number of long-period (LP) seismic events were recorded by station REVN. A small area of incandescent lava could be seen on the upper part of the northern flank of the cone. Most of the ejected blocks and bombs remained within the summit crater; although, during larger explosions, incandescent blocks were seen rolling down the flanks of the cone (Fig. [4\)](#page-5-0).

## **Thermal data**

Thirteen explosions of variable thermal amplitude were recorded over the 2-h measurement period. Another 13 less energetic <span id="page-5-0"></span>**Fig. 4** Thermal infrared images of the summit area. **a** A small area of the deposit of a recent lava flow was recognizable on the northern fank. **b** During energetic explosions, most of the ejected blocks and bombs rolled down the fanks of the cone

![](_page_5_Figure_3.jpeg)

degassing events were also recorded during this observation period. All thermal infrared videos are available in the Electronic Supplementary Material (ESM Video 01-Video 19).

Thermal amplitudes of the explosions varied between 40 °C for the less energetic (minor) events (explosion 7) and up to 263 °C for the most energetic (major) events (explosion 3). Minor explosions only lasted for around 10 s, while major explosions persisted for up to 140 s. The 32 Hz acquisition rate of the thermal recording allowed a detailed thermal waveform to be generated for each event, highlighting successive thermal peaks within each explosive discharge. Figure [5](#page-5-1) shows an example of a sequence of thermal images acquired during an explosion with the corresponding thermal waveform. In this example, at least 11 thermal peaks are recorded over the 30 s of duration of the event highlighting a series of explosive pulses (cf. Harris et al. [2008\)](#page-12-21). Generally, as in the Fig. [5](#page-5-1) waveform, the highest thermal amplitude recorded during any single explosion corresponded to the frst or second peak, and amplitudes thereafter declined (cf. Figure [3\)](#page-4-0), consistent with a waning emission.

![](_page_5_Figure_7.jpeg)

<span id="page-5-1"></span>**Fig. 5** Sequence of thermal images acquired during explosion *2* and the corresponding thermal waveform for the Region of Interest labelled in (**a**). Labelled letters on the waveform related to the location of thermal video frames (**a**) through (**l**). The eruption lasted 30 s with 11 peaks each associated with a burst of material passing through the ROI (cf. Harris et al. [2008](#page-12-21))

The time delay between consecutive peaks varies from 0.03 to up to 0.6 s, implying a decrease in velocity with increased delay (Fig. [2b](#page-3-0)). For our travel distance between R1 and R2 of 3.7 m, this gives velocity end members of 3 to 120 m  $s^{-1}$ , with an average of  $27 \text{ m s}^{-1}$ . We see from Fig. [3](#page-4-0) that the delay between any two peaks increases with time during any individual event, increasing from 0.06 to 0.19 s in Fig. [3a](#page-4-0) and from 0.13 to 0.25 s in Fig. [3b](#page-4-0). This is consistent with a decrease in emission velocity with time, from 30 to 10 and 20 to 7 m s<sup> $-1$ </sup> in the two cases, respectively. The decay in thermal amplitude is also consistent with an event that decays in energy with time.

On the basis of thermal waveform (i.e., their thermal amplitude and duration), we classifed the recorded emissions into three types (Fig. [6\)](#page-6-0).

- Type A (Fig.  $6a$ ), is characterized by the highest thermal amplitudes (263 °C), longest durations (140 s), and highest plumes  $(>800 \text{ m})$ .
- Type B (Fig. [6b](#page-6-0)), is characterized by moderate thermal amplitudes (175 °C), durations of around 25 s and plume heights reaching up to 400 m
- Type C (Fig.  $6c$ ) is characterized by the lowest thermal amplitudes (100 $\degree$ C), durations of about 15 s and plume heights of up to 300 m

This all implies a decrease in energy between each event type. We fnd that each event type tends to occur in a specific sequence (Fig.  $7a$ ). Type B and C events tend to occur together, with type B punctuating clusters of repeated, at the

![](_page_6_Figure_8.jpeg)

<span id="page-6-0"></span>**Fig. 6** Thermal and seismic waveforms for **a** type A eruptions of phase 4, **b** type B eruptions of phase 2, and **c** type C eruptions of phase 1. Thermal images in the right-hand panels correspond to the times shown as numbers (1–13). The thermal waveforms and duration of the type A explosions in phase 2 are similar to those of Sakurajima volcano (as plotted in red in **a**; data from A. Harris: Sakurajima eruption on July 27, 2013). The corresponding thermal images at Sakurajima, taken at similar time intervals as the Reventador ("Rv") are marked "Sk". In the case of type A eruptions during phase 4 (a), the thermal waveform and duration are comparable with those recorded at Stromboli volcano ("St") (as plotted in red in **a**; data from A. Harris: eruption at Stromboli recorded on June 03, 2008). The full videos with corresponding seismic and thermal waveforms from El Reventador can be found in the ESM

rate of 0.2–0.7 Hz, type C events (Fig. [7b\)](#page-7-0). Such sequences are typically followed by explosion free periods (Fig. [7c](#page-7-0)), which are terminated by single, discrete type A events (Fig. [7d](#page-7-0)). Explosion-free periods show the existence of very low amplitude (10 °C) single-peaked waveforms of 12–20 s in duration and which are associated with exhalations of gas (Fig. [7c](#page-7-0)). Within the sequence of Fig. [7e,](#page-7-0) three individual events of around 30 s in duration occurred with one minute delays, with decreasing thermal amplitudes.

## *SO<sub>2</sub>* flux

Figure  $8a$  shows the fluctuation of  $SO_2$  column amount retrieved from the DOAS data. Sunrise was at about 06h30 (local time), even though light conditions at 08h00 were not optimal for DOAS measurements, there was sufficient light intensity to perform scanning considering that our system has the capacity to modify automatically the integration time to allow acquisition of spectra with light intensity within an acceptable range. During our measurements, clouds started to develop progressively, frst around and over the summit, then directly above the scanner, as well as inside the caldera and between our observation site and the vent, forcing us at frst to change the scanning orientation from horizontal to vertical, and fnally to end the measurements. This also caused some periods of unreliable data (Fig. [8a](#page-8-0)). A mean plume velocity of 5.6 m  $s^{-1}$  was obtained using the thermal infrared camera video, allowing us to convert to  $SO<sub>2</sub>$  flux for approximately 1 h of data as reported in Table [1](#page-8-1). Fluxes fuctuated between 0.8 and 1.5 kg s<sup>-1</sup> with a mean SO<sub>2</sub> emission rate of  $1.1 \pm 0.7$  kg s<sup>-1</sup> (Fig.  $8b$ ). The daily SO<sub>2</sub> emission rate from El Reventador was about  $95 \pm 60$  tons per day during our observation.

## **Seismicity**

Using recordings from station REVN (Fig. [1](#page-1-0)), we identified nine signals that can be considered as explosion quakes, these are colored in blue in Fig. [9.](#page-9-0) These explosion quakes are also clearly identified in the recordings of the station CAYA. Ten transient signals observed at CAYA are unrelated to the activity at El Reventador and are colored in red in Fig. [9.](#page-9-0) These seismic signals correspond to volcano-tectonic events or ice quakes originating from Cayambe itself. In addition, three episodes

<span id="page-7-0"></span>**Fig. 7 a** Temperature time series from region of interest R1 (Fig. [2\)](#page-3-0) and the corresponding seismic signals from REVN and CAYA (Fig. [1\)](#page-1-0). The main explosions are numbered from 1 to 13. Four distinct behavior, outlined with diferent background colors, can be distinguished from the thermal recording, including (**b**) a nearly continuous occurrence of type B and C events, **c** type A and B events (explosions 3, 9, 10, 11), **d** the low amplitude passive degassing phase, and **e** successive type A and B event (explosions 5, 6, 7, 12, 13). Phases I, II, III, and IV occurred successively and repeated themselves once over the 2-h recording, each sequence of phases lasting around 1 h and 15 min

of harmonic tremor were identified at REVN, colored green in Fig. [9](#page-9-0). Finally, both stations recorded a regional earthquake whose hypocenter was located in northern Peru by IGEPN (Figs. [7](#page-7-0) and [9](#page-9-0)).

The harmonic tremor episodes lasted a few minutes and always appeared after an explosion quake. All type A events (explosions 5, 6, 7, 12, and 13) were recorded as low frequency waveforms by the proximal

<span id="page-9-0"></span>**Fig. 9 a** Timeseries of brightness temperature from thermal infrared imagery on which the thirteen type A and B explosions are identifed. **b** Seismic signals from station REVN, located 4 km to the east of the active crater. **c** Seismic signals from station CAYA, located 45 km to the northwest of El Reventador. Most of the explosions that can be identifed at the proximal seismic station appear at the distal station as well (marked in blue). The seismic events colored in red are not

seismic station (REVN) but not all of them appear in the distal (CAYA) seismic recordings (Fig. [9\)](#page-9-0). Thermally, these explosions are associated with the highest energy events and have variable thermal amplitudes. However, theses amplitudes are not directly correlated to the amplitude of corresponding seismic signals.

#### **Bulk ash composition**

The ash is of andesitic composition with  $SiO<sub>2</sub>$  contents around 58 wt. % (Table [2\)](#page-9-1). The bulk ash composition falls in the trend displayed by whole rocks of El Reventador as reported by Samaniego et al. [\(2008\)](#page-13-13) (Fig. [10](#page-11-0)).

related to El Reventador activity; they are volcano-tectonic events or ice quakes from Cayambe and a regional earthquake. Harmonic tremor episodes are highlighted in green and are all preceded by an explosion. The sequence of explosions 5, 6, and 7 produced high thermal amplitudes but low seismicity. Instead, explosions 12 and 13 produced low thermal amplitudes but moderate seismic amplitudes

<span id="page-9-1"></span>**Table 2** Bulk composition of ash samples collected following a Vulcanian explosion at El Reventador on 22 February 2017

Oxide	Weight content $(wt\%)$
SiO <sub>2</sub>	57.98
$Al_2O_3$	17.67
Fe <sub>2</sub> O <sub>3</sub>	6.93
MgO	3.76
CaO	6.73
Na <sub>2</sub> O	3.57
$K_2O$	1.84

$P_2O_5$	0.37
Ba	0.14
Sr	0.10
Total	100.08
$H_2O$	0.24

#### **Discussion**

Based on coupled patterns in the thermal and seismic waveforms, as well as trends in the  $SO<sub>2</sub>$  flux time series, we can group our data into four successive phases (Fig. [7a](#page-7-0)). We emphasize that the dynamics presented in this work is representative of our period of observation and must then be extrapolated with caution, but we believe it gives a useful guide to the dynamics driving El Reventador's open-vent persistent explosive activity.

Phase 1 consists of about 30 min of quasi-continuous, minor bursts of gas and ash as seen in the thermal time series as a series of type C and B events (Fig.  $7a$ ; ESM Video 03). These events appear with variable amplitudes in the proximal seismic station but are barely recorded by the distal seismic station (Fig. [7b](#page-7-0)).

Phase 2 consists of a single or series of type A and B explosion(s) that last around 2 min (Fig.  $7d$ ; ESM Video 07). These events are clearly distinct from explosions seen in phase 1 as they expel an appreciable quantity of ballistics covering the upper part of the edifce and occasionally generate minor rock falls and pyroclastic density currents (cf. ESM Video 07 and ESM Video 03). Seismicity with high amplitude mirrors the high thermal amplitude signal (Fig. [7d](#page-7-0)). The duration, the waveform, and thermal amplitude of the explosions occurring in this phase (Fig. [6a\)](#page-6-0) are similar to those of ash venting occurring at Santiaguito volcano (Johnson et al. [2004;](#page-13-29) Sahetapy-Engel et al. [2008](#page-13-21); Marchetti et al. [2009](#page-13-1)) and Vulcanian explosions at Sakura-jima volcano (Yokoo [2009\)](#page-13-2). Figure [6b](#page-6-0) shows the comparison between a type A explosion of phase 2 at El Reventador and one of Sakurajima's Vulcanian explosion recorded in July 2013 (A. Harris, unpublished data), where the duration and shape of the waveform are similar. We thus interpret these event types to be similar in terms of source, emission, and ascent dynamics. We thereby label them "Vulcanian" and assume they are related to stick–slip of a highly viscous plug as at Santiaguito (cf. Bluth and Rose [2004](#page-12-11); Sahetapy-Engel et al. [2008\)](#page-13-21) or, more likely, failure of a high viscosity cap in the true Vulcanian sense (Johnson and Lees [2000;](#page-13-19) Hall et al. [2015](#page-12-0)).

Phase 3 consists of 10 to 15 min of passive degassing (Fig. [7c](#page-7-0); ESM Videos 08 and 09). During this phase no explosions are recorded, either in the thermal or seismic records (n.b., signals registered at the CAYA station are not associated with El Reventador).

Finally, phase 4 consists of a period of about 10 min in which we record a series of type B explosions (Fig. [7d;](#page-7-0) ESM Videos 10, 18, and 19). The seismic amplitude of these events is very small when compared to the seismic amplitude associated with the explosions recorded in phases 1 and 2 (Fig. [6\)](#page-6-0) and is the only case where seismic and thermal

signals are decoupled. The waveform of the thermal signal and the duration of the individual explosions in this phase (Fig. [6\)](#page-6-0) are comparable to those observed in explosions at Stromboli (e.g., Harris and Ripepe [2007a](#page-12-12); Harris et al. [2012](#page-12-22); Patrick et al. [2005\)](#page-13-30) and Villarrica (Marchetti et al. [2009](#page-13-1)), as shown in Fig. [6c](#page-6-0). We thus interpret these event types to be similar in terms of source, emission, and ascent dynamics. We thereby label them "Strombolian" and assume they are related to bubble bursting at a relatively low viscosity surface (Shinohara [2005](#page-13-31); Patrick et al. [2007\)](#page-13-32) or at-least one that is thinly capped (Gurioli et al. [2014](#page-12-23)).

Activity developed through these four phases twice during the 2-h observation period. Although the  $SO_2$  flux measurements could not be obtained concurrently (DOAS measurements rely on good sunlight while thermal measurements are best performed at night), they also oscillate over a timescale of about 1 h, thus following the same timescale of trend observed in the thermal and seismic recordings by visual observations.

Phase 1 characteristics can be interpreted as a conduit which is mostly plugged or in the process of plug development. Degassing occurs as short bursts of "ash venting" associated with thermal and seismic signals and decreases over time, potentially indicating progressive sealing of the system. Ash venting may be the result of stick–slip events impacting the developing plug (cf. Neuberg [2000](#page-13-33); Lensky et al. [2008\)](#page-13-34). Such process can lead to a decrease in the permeability of the upper part of the conduit and, subsequently, to an increase in the pressurization of the system. The progressive decrease of the  $SO_2$  flux, as evidenced in this work, further supports this observation. Phase 1 would hence correspond to the formation of a gas-impermeable cap in the upper part of the conduit (Del Bello et al. [2015](#page-12-24); Capponi et al. [2016](#page-12-25)), probably caused by cooling and degassing of the shallowest portion of the magma column, which induces a rheological stifening and increases magma viscosity (Gurioli et al. [2014\)](#page-12-23). The energetic type A explosion(s) characterizing phase 2 (Fig.  $6a$ ) can be interpreted as the culmination of pressure accumulation in the conduit, an accumulation which is fnally released by one or a series of energetic explosions (Fig. [7a](#page-7-0)) destroying the cap. This model is consistent with the ejection of ballistics, the high amplitudes in both the thermal and seismic signals and the similarity with waveforms recorded during "Vulcanian" events at other systems (cf. Figure [6\)](#page-6-0). During phase 3, which is explosion-free, unhindered degassing occurs, and is interpreted as a period of purely open vent (uncapped) activity. Finally, in phase 4, with the system still in an open-vent confguration, gas slugs can travel through the upper part of the conduit and burst at the free surface producing intermittent "Strombolian" explosions. The thermal amplitude of some of these explosions is not mirrored by the seismic amplitude, possibly because of a source at a shallower level

<span id="page-11-0"></span>**Fig. 10**  $K_2O$  versus  $SiO_2$  classifcation diagram (Peccerillo and Taylor [1976\)](#page-13-35) showing the composition of lavas extruded from El Reventador volcano between 2002 and 2005 (Samaniego et al. [2008](#page-13-13)) and the ash sample collected during our observation period

![](_page_11_Figure_2.jpeg)

than those with appreciable seismic amplitude at both proximal and distal stations (Fig. [7e\)](#page-7-0). Our thermal, seismic and, to a lesser extent,  $SO_2$  flux observations therefore highlight cyclic transitions at El Reventador between plugged and open vent confgurations (Fig. [11\)](#page-11-1).

# **Conclusion**

Our analysis of thermal, seismic, and  $SO<sub>2</sub>$  flux measurements at El Reventador clearly highlights the temporal succession of diferent types of explosive and degassing activity that can be classifed into four phases. Phase 1 is characterized by frequent, nearly continuous, explosions of small thermal and seismic amplitude diminishing with time, indicating the progressive self-sealing of the conduit. This restricts the gas fow and builds up pressure in the conduit. Phase 2 is characterized by one or several large explosions, associated with high thermal and seismic amplitudes and durations, indicating the destruction of the impermeable cap created during phase 1. Phase 3 is characterized by passive, unhindered degassing indicating entirely open vent conditions while phase 4 sees the episodic bursting of presumably isolated gas slugs at the surface. The entire sequence is repeated twice in a 2-h observation period suggesting a cyclic oscillation between plugged and open vent confgurations at El Reventador. The similarity with thermal and seismic waveforms from other classic Strombolian and

<span id="page-11-1"></span>![](_page_11_Figure_7.jpeg)

Vulcanian (VEI 2 through 4) systems suggests the operation of common and globally applicable degassing and explosive processes that cause caps to develop and decay, thereby driving changes in eruption style.
