Abstract

Extensive mitral annular calcification remains a technical challenge in mitral valve surgery. Decalcification and reconstruction of the mitral annulus is an established technique, but it is time consuming and technically demanding. This report presents the case of an 88-year-old diabetic female patient in whom edge-to-edge repair was completed quickly, with good early results thus being obtained.

Key words Mitral valve repair · Calcification

Introduction

Severe mitral annular calcification is a technical challenge in mitral valve surgery.^{1,2} Although decalcification has been described by several authors,^{2,3} it is a complex and time-consuming technique. This report presents a case in which edge-to-edge mitral valve repair provided good early results. The patient was a small 88-year-old woman. Postoperative echocardiography showed trace mitral regurgitation and no signs of mitral stenosis by means of a standard measurement technique.⁴

Case Report

An 88-year-old woman was referred to our department for mitral valve surgery. She had been hospitalized for congestive heart failure 4 months before surgery, and had New York Heart Association class 3 symptoms after that episode. Echocardiography revealed severe mitral regurgitation.

She had been relatively well for her age until she developed congestive heart failure. The patient was diabetic, and her blood glucose had been controlled by oral medication for 10 years. All other aspects of her medical history were unremarkable except for a history of a hysterectomy and cataract surgery. Her weight was 45.5 kg and her height 147 cm. A grade 3 systolic murmur was heard at the apex. There was no peripheral edema in the extremities. Her creatinine count was normal.

She underwent preoperative cardiac catheterization. Coronary angiograms showed only nonsignificant coronary disease. Left ventriculogram showed severe mitral regurgitation. The mean pulmonary artery pressure was 21 mmHg. Fluoroscopy showed severe calcification of the mitral annulus (Fig. 1). Typical horseshoe-shaped calcification was noted.

Preoperative transthoracic echocardiography showed severe mitral valve regurgitation and mild tricuspid regurgitation (Fig. 2). The measurements are summarized in Table 1. The direction of the regurgitant jet indicated that she had prolapse of the anterior leaflet. The echo also showed posterior mitral annular calcification (Fig. 3).

Timely surgery was desirable because the patient was elderly. Mitral valve repair using an edge-to-edge technique was planned, without the placement of an annuloplasty ring if it could be done. It was necessary to be strict about the results of water testing because the midterm results would be poor if water testing results were suboptimal in this strategy.⁵

At surgery, the patient was placed on cardiopulmonary bypass in the usual manner. The mitral valve was approached via the atrial septum. She had an anterior leaflet prolapse at the anterior edge of A1 segment. A ruptured chord was observed. Her posterior mitral annulus was severely calcified as expected. The annulus did not look dilated, so that an annuloplasty ring was not absolutely necessary to control her mitral valve regurgitation. An edge-to-edge repair was thus selected.

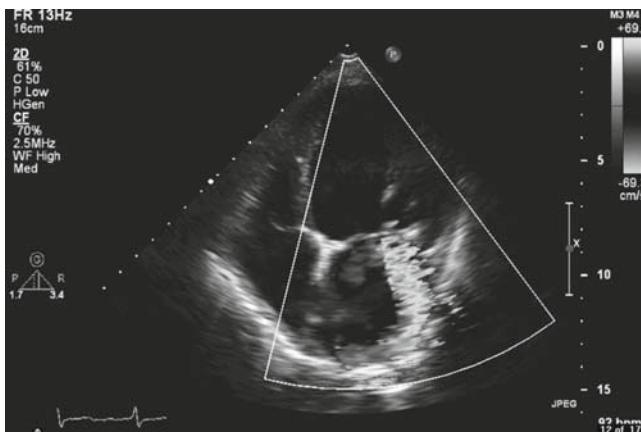

Fig. 2. Preoperative color Doppler echocardiography. The direction of the regurgitant jet suggested a prolapse of the anterior leaflet

Table 1. Preoperative echographic measurement

Left atrium	4.3 cm
Interventricular septum	1.0 cm
Left ventricular posterior wall	0.9 cm
Left ventricular diastolic diameter	5.7 cm
Left ventricular systolic diameter	4.4 cm
Fractional shortening	20.7%
Ejection fraction	41.7%
End-systolic volume	97.3 ml
Stroke volume	69.7 ml

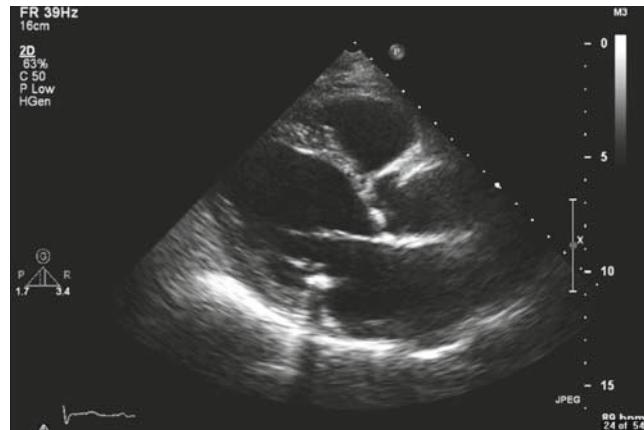

Fig. 3. Preoperative echocardiography. Posterior mitral annular calcification is noted

A paracommissural repair was done by sewing the A1 to P1 with three interrupted 5-0 polypropylene sutures (Fig. 4). The valve became competent, showing no leakage by water testing. The left atrium was closed. She was easily weaned off bypass. The mitral valve was competent according to an intraoperative transesophageal echo. Cardiac arrest was 33 min, pump time was 56 min, and operation time was 140 min.

The patient was extubated in 10 h. She stayed in the intensive care unit for 1 day. She developed atrial fibrillation on postoperative day 6, and did not suffer from any other complications.

A postoperative echo showed only trace mitral regurgitation. The mitral valve area was 4.10 cm^2 according to pressure half-time method, the mean pressure gradient was 2 mmHg across the mitral valve, and there was no sign of mitral stenosis. Although her postoperative course was uneventful apart from the atrial fibrillation, her hospital stay had to be relatively long for rehabilitation. She was able to be discharged from the hospital at 26 days after surgery.

Discussion

Mitral annular calcification is a technical challenge in mitral valve surgery.^{1,2} Decalcification is usually necessary to complete mitral valve repair or replacement in mitral valve regurgitation.^{1,2} David et al. described their technique of mitral annular decalcification and reconstruction of the annulus with a pericardial patch.³ Carpentier et al. applied “sliding atrioplasty” of the left atrium to cover the area of decalcification.² Both techniques apparently work well and can provide excellent long-term results.^{1,2} However, they may be too complex and time consuming for poor-risk patients. A surgical

mortality of up to 9% has been in patients undergoing extended decalcification procedures.¹

Edge-to-edge mitral valve repair is a relatively new technique introduced by Alfieri et al.⁶ This procedure is appealing for the treatment of patients with annular calcification, because the lesions can be treated by acting only on leaflets without the need for annuloplasty. However, Massiano et al. reported suboptimal results of $70\% \pm 15.0\%$ freedom from reoperation at 5 years in this patient population.⁵ From another point of view, their freedom from reoperation was excellent in patients whose water testing results were perfect: it was $98\% \pm 1.8\%$ at 5 years. Their data suggest that one should therefore have a lower threshold of accepting suboptimal water testing results in patients with annular calcification. No degree of leakage should be accepted. Since this patient's water testing results were perfect, good midterm results could therefore be expected.

The current patient was an 88-year-old woman. The average life expectancy of her age and sex was 6.4 years according to the life table published by the Japanese Ministry of Health, Labor and Welfare.⁷ Her chance to require a reoperation should be smaller because of her limited life expectancy.

Even with 33 minutes of cardiac arrest, the patient required hospitalization for more than 20 days. This particular patient may have required more time to recover and had more chance to develop postoperative complications if decalcification had been performed.

Other techniques, such as artificial chordae or triangular resection of the anterior leaflet, could have been used instead of the edge-to-edge technique to treat this patient. However, the lack of annuloplasty ring is generally associated with poorer long-term durability in mitral valve repair,⁸ the long-term results of isolated artificial chordae or triangular resection without ring annuloplasty is largely unknown. Edge-to-edge repair was chosen in this particular case because it was necessary to minimize the surgical time, and there was no

evidence showing other techniques were better in this patient population.

A careful follow-up is mandatory. Patients should be carefully selected for this strategy because of the previously reported suboptimal results in the literature.

Conclusions

Mitral valve regurgitation with severe mitral annular calcification was repaired in an 88-year-old woman using an edge-to-edge technique. This was achieved quickly and simply, with good early results being observed.
