## **Abstract**

Slip usually occurs in the laminated structure of shale formations during hydraulic fracturing. In this paper, we used laminated shale to conduct macro and micro three-point bending experiments, as well as the visual hydraulic fracturing experiment to study the slip nucleation during fracture propagation, where the digital image correlation method (DIC) was used to monitor the interlaminar deformation. Based on the linear slip weakening model, a method to identify the slip nucleation zone (SNZ) using DIC was proposed, which could visually detect the formation of SNZ. In laminated shales from millimeter scale to decimeter scale, two asymmetric slip nucleation zones along the interface were observed on both sides of the opening-mode fracture tip before cohesionless slipping. The dominant path of slip could be predicted from the developed size of the conjugated SNZs. The linear slip weakening model considering the tensile fracture tip opening displacements (*w*) was discussed, according to which the SNZ length and interlaminar fracture energy would increase with *w* during quasi-static nucleation. After the cohesionless slipping, the residual slip zone was defned, which should be a part of the hydraulic fracture systems but was ignored in previous research. The fndings of this study could help to understand the generation mechanism of slips in shale reservoirs during hydraulic fracturing.

# **Highlights**

- A method for identifying the slip nucleation zone based on digital imaging was proposed.
- Two asymmetric interlaminar SNZs were found on both sides of the opening-mode fracture tip before cohesionless slipping.
- The dominant path of slip could be predicted from the developed size of the conjugated SNZs.
- The residual slip zone should be a part of the hydraulic fracture systems in shale formations.

# **1 Introduction**

Nowadays, conventional oil and gas resources are insufficient to meet energy demands. Since the success of the shale gas revolution in North America, unconventional geological resources such as shale oil and gas have drawn increasing attention around the world (Hu et al. [2020;](#page-14-0) Yan et al. [2017](#page-15-0); Zhang et al.  $2021$ ). Due to the low permeability of shale matrix, the production of oil and gas mainly depends on artifcial fracture systems (He et al. [2019;](#page-14-1) Wu et al. [2022;](#page-15-2) Zhou et al. [2022\)](#page-15-3). In feld application, hydraulic fracturing of horizontal wells has been widely used for its larger volume of stimulation (Nikolskiy and Lecampion [2020](#page-14-2); Saberhosseini et al. [2019](#page-14-3)). Infuenced by the in situ stress, the horizontal wells usually generate vertical opening-mode fractures. Meanwhile, as sedimentary rocks, the shale formations were characterized by lamination development (Pan et al. [2021](#page-14-4); Tan et al. [2017\)](#page-15-4). Thus, hydraulic fracture propagation in laminated shale formations has become a research focus (Jia et al. [2021](#page-14-5); Lin et al. [2017;](#page-14-6) Tan et al. [2017;](#page-15-4) Zou et al. [2016](#page-15-5)). In particular, the mechanical behaviors of interlaminar slip induced by the opening-mode fracture are the key issues to be discussed (Galybin and Mukhamediev [2014](#page-14-7)).

The analyses of microseismic monitoring toward in situ fracturing showed that hydraulic fracture (HF) could induce interlaminar slip (Tan & Engelder [2016](#page-15-6)), which would improve hydraulic conductivity (Zhao et al. [2013\)](#page-15-7). Thus, interlaminar slip is a potential factor promoting the production of shale formations (Zoback et al. [2012\)](#page-15-8). At present, the slip criteria of weak interface proposed by Renshaw and Warpinski et al. (Renshaw and Pollard [1995;](#page-14-8) Warpinski and Teufel [1987](#page-15-9)) are widely used to judge the occurrence of interlayer slip. To fnd the potential slip zone, Zhao and Gray [\(2021\)](#page-15-10) studied the distributions of the stress feld near the weak interface induced by HF based on linear elastic fracture mechanics. However, the related research mainly focused on the estimation of interlaminar slip, ignoring the slip process. Through an innovative hydraulic fracturing experiment, AlTammar and Sharma concluded that shear failure and slippage would be generated along the weak interface during fracture propagation (AlTammar et al. [2019\)](#page-14-9). Some researchers (Garcia et al. [2013;](#page-14-10) Yaghoubi [2019\)](#page-15-11) also used numerical simulations to study the propagation of hydraulic fractures in shale without discussing the generation mechanism of slip, especially induced by the opening-mode fracture. In fact, similar to the fracture process zone ahead of a cohesionless opening-mode fracture of rock materials (Chen et al. [2020](#page-14-11), [2021](#page-14-12); Zhang et al. [2018](#page-15-12)), a development process zone also exists at the weak interface during slip, showing stress softening or weakening in mechanical behaviors. It could be called slip weakening zone or slip nucleation zone (SNZ), referring to the studies about fault slip (Ampuero et al. [2002](#page-14-13); Chen & Knopoff [1986;](#page-14-14) Rice [1979](#page-14-15); Uenishi and Rice [2003](#page-15-13)).

The concept of slip nucleation was systematically introduced by Rice in the study of fault slip (Rice [1979\)](#page-14-15) when discussing the mechanics of earthquake rupture. Subsequently, Segall et al. (Segall and Pollard [1983\)](#page-15-14) described the nucleation process and propagation of granodiorite fault by feld observation. As for the constitutive model of SNZ, the slip weakening model was developed to describe the mechanical behaviors of SNZ (Palmer et al. [1973](#page-14-16); Rice [1979](#page-14-15)), which was an extension of the cohesive zone model from tensile fracture to shear slip (Barenblatt [1962](#page-14-17); Hillerborg et al. [1976](#page-14-18)). The slip weakening model could avoid the problem of stress singularity at the fracture tip, and the constitutive relationship of SNZ can be described by the kinetic and static friction forces and slip displacements. Based on the slip weakening model, Uenishi and Rice investigated the factors infuencing the critical length of SNZ and discussed the conditions of dynamic slip (Uenishi and Rice [2003](#page-15-13)). With regard to the research of SNZ induced by hydraulic fracturing, previous publications mainly focus on the fault slip (Azad et al. [2017](#page-14-19); Garagash and Germanovich [2012](#page-14-20); Zhang and Jeffrey [2016](#page-15-15)), ignoring the potential slip nucleation of the interlamination, such as the weak interface. In fact, the presence of SNZ would signifcantly afect the hydraulic fracture propagation of layered shale, which was neglected in previous studies. The study of SNZ can help to understand the generation of hydraulic fractures and the dissipation of fracture energy during fracturing in laminated shale reservoirs.

In this paper, the macro (specimen in centimeter scale) and micro (specimen in millimeter scale) three-point bending experiments and the visual hydraulic fracturing experiment were carried out using laminated shales with weak interfaces. From the digital imaging technique, a method for identifying the slip nucleation zone was proposed to study the formation mechanism of SNZ during opening-mode fracturing. This study can help to understand the development of hydraulic fractures in laminated shale.

## **2 Experimental Methods and Results**

## **2.1 Specimens and Experiments**

The laminated shale rock from Shaanxi, China was used to conduct the three-point bending experiments (Fig. [1a](#page-2-0)). As shown in the casting thin section (Fig. [1b](#page-2-0)), the Shaanxi shale rock was developed with weak interfaces. The argillaceous structures are mainly composed of reticular clay, followed by quartz, feldspar, mica debris, argillaceous iron, kaolinite, chlorite, etc. While the sand is rich of silty quartz and feldspar, with some debris. The pores are represented by interlaminar fractures, occupied by the residual organic matter. The MTS-816 testing system was used to carry out the macro three-point bending (Macro-TPB) experiments on centimeter-scale shale (Fig. [1](#page-2-0)c) to study the slip nucleation during opening-mode fracturing. As an efective means to study fracture mechanics, the three-point bending experiment could help to understand the mechanical behaviors of fracture initiation and propagation, similar to hydraulic fracturing. Due to the high brittleness of shale, the negative feedback method was used to control the fracture

opening displacement of the notch (COD) during Macro-TPB test, and the loading rate of COD was mainly set around 0.01 mm/min. The sizes of the specimens used in Macro-TPB experiments are listed in Table [1](#page-2-1) and Fig. [1](#page-2-0)e.

macro three-point bending tests; **f** sigma 500 FE-SEM system; **g** in situ loading system; **h** specimen of micro three-point bending test; **i** shale specimen of visual hydraulic fracturing experiment

For investigation of the micro-scale slip during fracture propagation, the feld emission scanning electron microscope (FE-SEM) with an in situ loading system (Zhang et al. [2021\)](#page-15-1) (Fig. [1f](#page-2-0)–g) was used to conduct micro three-point bending (Micro-TPB) experiment on the millimeter-scale shale. The FE-SEM is mainly composed of the electron optics system, signal detection system, vacuum system and computer, which uses the feld emission electron gun to generate electron beams and stimulate electronic signals on the surface of rock samples. After the processing of detectors and computers, these signals could be converted into electronic images. In our experiment, the millimeter-scale specimen (shown in Fig. [1h](#page-2-0)) was loaded by the in situ loading system, while the electronic photograph was obtained by FE-SEM every 5 N loading. Considering the weak mechanical properties of interfaces, all the shale specimens used in this paper were processed by wire cutting to decrease the damage.

To study the interlaminar slip nucleation during hydraulic fracture propagation, the visual hydraulic fracturing (VHF) experiment was conducted on the decimeter-scale shale specimen using the designed equipment (Chen et al. [2019](#page-14-21)). This equipment is mainly used to conduct hydraulic fracturing experiments on two-dimensional platelike specimens. In this paper, the specimen size of the marine laminated shale is  $200 \text{mm} \times 200 \text{mm} \times 50 \text{mm}$ , as in Fig. [1i](#page-2-0), and the far-feld stresses could be applied to the specimen by fat jacks. Compared with traditional hydraulic fracturing of three-dimensional specimens, the critical advantage of VHF is capable of observing the initiation and propagation of hydraulic fractures through the transparent acrylic window. The experimental system of VHF mainly consists of a loading device, a constant rate injection pump, pressure sensors, and a digital camera. The black and white speckles are sprayed on the specimen surface for monitoring the displacements using digital imaging during fracturing.

#### **2.2 Monitoring Methods**

When studying the deformation of interlaminations, it is critical to measure the displacement of specimens during loading. As a non-contact optical detection method for monitoring the deformation, the digital image correlation method (DIC) has been widely used in the research of rock fracture mechanics (Chen et al. [2019](#page-14-21); Pan et al. [2021;](#page-14-4) Xing et al. [2020](#page-15-16)). The signifcant advantage of DIC lies in its ability to depict the full-feld deformation and obtain continuous information with high accuracy (Xing et al. [2020\)](#page-15-16). The displacement changes are calculated according to the correlation of subsets before and after deformation, where the subset is a pixel value matrix (Xing et al. [2020\)](#page-15-16). As shown in Eq. ([1\)](#page-3-0) (Blaber et al. [2015](#page-14-22); Xing et al. [2020](#page-15-16)), the normalized crosscorrelation criterion is adopted to track the subsets, and the open-source package proposed by Blaber et al. was used for obtaining the displacements and strains in this paper (Blaber et al. [2015](#page-14-22)). Figure [1d](#page-2-0) shows the image of speckle quality and subset size of Macro-TPB specimens.

$$
\gamma = \frac{\sum_{(i,j)\in S} (f(\tilde{x}_{refi}, \tilde{y}_{refi}) - f_m)(g(\tilde{x}_{curi}, \tilde{y}_{curi}) - g_m)}{\sqrt{\sum_{(i,j)\in S} [f(\tilde{x}_{refi}, \tilde{y}_{refi}) - f_m]^2 \sum_{(i,j)\in S} [g(\tilde{x}_{curi}, \tilde{y}_{curi}) - g_m]^2}},
$$
(1)

where  $\gamma$  is the correlation coefficient of subset before and after deformation, *S* is the calculated area in correlation criterion,  $(\widetilde{x}_{\text{refi}}, \widetilde{y}_{\text{refi}})$  and  $(\widetilde{x}_{\text{curi}}, \widetilde{y}_{\text{curi}})$  are the local coordinates in the reference and current images, *f* and *g* are the grayscale intensity functions at position  $(x, y)$  in the reference and current images, and functions  $f_m$  and  $g_m$  refer to the average gray values of the reference and current subsets.

#### **2.3 Typical Results of the Macro‑TPB Experiment**

The typical Macro-TPB results of laminated shale specimens are shown in Fig. [2](#page-4-0), where Fig. [2](#page-4-0)a, b show the loading curves. Figure [2](#page-4-0)c, d show the horizontal (x-direction) displacement feld after fracture propagation, which present stepped characteristics because of the effect of weak interfaces. Unlike the fracture propagation in homogeneous rocks, fracture in laminated shale tends to reorient at the weak interface. With loading, the fracture frst extends along the direction of the prefabricated crack, and the propagation direction may change along the weak interface. Due to the high brittleness and interlamination development of shale, the loading curves in this paper are diferent from those in conventional experiments, with the characteristics of discontinuous decline.

The decrease of loading indicates the further propagation or slippage of fractures. Specifcally, the slow rise of loading stress means the quasi-static development of the fractures, while the sudden drop of stress indicates the fast propagation of the fracture. Taking Specimen A as an example, when the COD is close to 93 μm, the stress decreases and the slipping fracture forms. However, we fnd that the interlaminar deformation has already occurred before the stress drop, meaning that the slip nucleation zone is generated before the formation of a full slipping fracture.

# **3 Identifcation of the Slip Nucleation Zone from Digital Imaging**

### **3.1 Description Model of SNZ**

<span id="page-3-0"></span>SNZ is the development zone before the formation of a cohesionless slip (Azad et al. [2017;](#page-14-19) Uenishi and Rice [2003\)](#page-15-13), generally characterized by the slip weakening model in theory (Chen and Knopoff [1986](#page-14-14); Garagash and Germanovich [2012](#page-14-20); Kato [2012;](#page-14-23) Uenishi and Rice [2003](#page-15-13)). Figure [3a](#page-4-1) shows the schematic diagram of the slip nucleation zone ahead of an opening-mode fracture. When a weak interface exists ahead of the tensile fracture, if the shear stress is greater than the static friction of interlamination, SNZ will be generated along the bedding plane. In the slip weakening model, the slip displacement is zero at the end of the SNZ, and the slip displacement is the largest at the beginning. Friction force exists at the interlaminar surface, resulting in a negative stress intensity factor. Thus, the positive stress intensity factor generated by external stress would be counteracted, to avoid the singularity of the fracture tip (Chen and Knopof [1986](#page-14-14); Rice [1979\)](#page-14-15).

The linear slip weakening model (LSWM) is a common model for characterizing the constitutive relation of SNZ (Chen & Knopoff [1986](#page-14-14); Knopoff et al.  $2000$ ), which is

<span id="page-4-0"></span>**Fig. 2** Typical loading curves and horizontal displacement feld monitored by DIC. **a** Loading curve of Specimen A; **b** loading curve of Specimen B; **c** horizontal displacement contours of Specimen A; **d** horizontal displacement contours of Specimen B

<span id="page-4-1"></span>**Fig. 3** Schematic diagram of slip nucleation zone and linear slip weakening model. **a** Slip nucleation zone induced by a vertical tensile fracture; **b** distribution of slip displacements in *x*-direction; **c** relation of shear stress and slip displacement; **d** stress distribution in *x*-direction

<span id="page-6-2"></span>**Fig. 4** SNZ characterization at 78% of peak load of Specimen A. **a** ◂Contours of shear strain; **b**  $u(y)$  distribution at Line A; **c**  $u(y)$  distribution at Line B; **d**  $u(y)$  distribution at Line C; **e** distribution of  $|\Delta u(y)|$ at Line A; **f** distribution of  $|\Delta u(y)|$  at Line B; **g** distribution of  $|\Delta u(y)|$ at Line C; **h** distribution of  $|\Delta u(y)|$ max in *x*-direction; **i** identification of SNZ based on the contours of |Δ*u*(*y*)|

related to the static friction force  $(\tau_{\rm s})$ , kinetic friction force  $(\tau_d)$  and critical slip displacement  $(\Delta u_c)$  (Eq. ([2\)](#page-6-0)), as shown in Fig.  $3(c)$ . In the linear slip weakening model, the slip displacement is  $\Delta u_c$  and the interlaminar shear stress is equal to  $\tau_d$  at the beginning of SNZ ( $x = 0$ ). At the end of the SNZ  $(|x| = c)$ ,  $\Delta u$  is zero and the shear stress is $\tau_s$ , as shown in Fig. [3b](#page-4-1), d. The constitutive relation of SNZ along *x*-direction is shown in Eq.  $(3)$  $(3)$  (Chen and Knopoff [1986\)](#page-14-14).

In the cohesive zone model of Mode-Ι fracture, the fracture process zone was characterized as a cohesive fracture. In fact, the slip weakening model is the generalization of the cohesive zone model in Mode-II fracture (Rice [1979](#page-14-15)), so SNZ could also be understood as a cohesive slip for the similar effects of cohesions during fracture development. The signifcant feature of cohesive slip is that the interlaminar shear stress would vary with the slip displacements. The cohesionless slip could be divided into cohesionless slipping and cohesionless slipped fracture. If we consider the full process of interlaminar slip during fracture propagation, three parts can be summarized: 1) slip nucleation zone (cohesive slip):  $0 < \Delta u < \Delta u_c$ , and  $\tau$  will change with  $\Delta u$ ; 2) cohesionless slipping fracture:  $\Delta u > \Delta u_c$ , and  $\tau$  is equal to  $\tau_d$ , keeping constant; 3) cohesionless slipped fracture:  $\Delta u$ does not increase, and slip stops at this stage.

$$
\tau = \tau_s - \left(\tau_s - \tau_d\right) \frac{\Delta u}{\Delta u_c},\tag{2}
$$

$$
\tau(x) = \tau_s - \left(\tau_s - \tau_d\right) \frac{c - x}{c},\tag{3}
$$

where  $\tau$  is the shear stress,  $\tau_s$  static friction force,  $\tau_d$  kinetic friction force,  $\Delta u$  slip displacement,  $\Delta u_c$  critical slip displacement, and *c* the position where  $\tau = \tau_s$ .

#### **3.2 Identifcation of SNZ Using DIC**

Although the linear slip weakening model has been used in the study of SNZ (Chen and Knopoff [1986;](#page-14-14) Knopoff et al. [2000\)](#page-14-24), the relevant research lacked experimental verifcations using digital imaging. DIC has been widely used to monitor the Mode-Ι fracture development process (Gao et al. [2022](#page-14-25); Li and Einstein [2017;](#page-14-26) Lin et al. [2020;](#page-14-27) Pan et al. [2021\)](#page-14-4), but how to use DIC to identify the slip nucleation zone remains to be studied at present.

Based on LSWM, a linear variation of the slip displacement exists in the slip nucleation zone on both sides of the vertical tensile fracture tip. When the vertical measurement lines were selected to monitor the variation of horizontal displacements in the y-direction, significant discontinuities could be found from the displacement curves, where the discontinuity difference  $\Delta u$  is the slip displacement, decreasing from  $x = 0$  to  $x = c$ . In this paper,  $u(y)$ was used to investigate the interlaminar slip in the x-direction, while *u*(*x*) was mainly used to detect the opening of the Mode-Ι fracture in the y-direction.

Different from the strain concentration of  $\varepsilon_{xx}$  in the Mode-Ι fracture process zone, slip displacement Δ*u* would be generated in slip nucleation zone, leading to the concentration of  $\varepsilon_{xy}$ . As shown in Fig. [4a](#page-6-2),  $\varepsilon_{xy}$  concentrates at the weak interface because of the inducement of the tensile fracture. Three vertical monitoring lines (A/B/C) are selected in Fig. [4a](#page-6-2), and the corresponding displacement curves  $u(y)$  are shown in Fig. [4b](#page-6-2)–d, where an obvious discontinuity with large slip displacement is found at Line C. Nonlinear characteristics still exist at Line B, but the discontinuous feature of horizontal displacement disappears at Line A. The distribution characteristics of *u*(*y*) can provide a basis for judging the generation of SNZ. However, due to the objective error of DIC, it is impossible to defne the accurate position where the slip displacement is zero. Therefore, the size of SNZ is difficult to be identified by *u*(*y*) curves intuitively.

<span id="page-6-1"></span><span id="page-6-0"></span>To identify SNZ accurately, the absolute value |Δ*u*(*y*)| between the adjacent monitoring points of  $u(y)$  is introduced to characterize SNZ. As shown in Fig. [4](#page-6-2)f, g, |Δ*u*(*y*)| in the slip nucleation zone is higher than those in the elastic zone. At the end of SNZ, the distribution of  $|\Delta u(y)|$ at the weak interface approximates to the elastic zone (Fig. [4e](#page-6-2)). In the linear slip weakening model, the area where  $|\Delta u(y)| > 0$  is defined as SNZ. However, the objective error of DIC monitoring decides that  $|\Delta u(y)|$  won't be equal to zero, so a threshold  $\Delta u_k$  needs to be defined. That is, SNZ is considered formed when  $|\Delta u(y)| > \Delta u_k$ .  $\Delta u_k$  is associated with the monitoring error of DIC. As  $|\Delta u(y)|$  in SNZ is signifcantly higher than that in the elastic zone, it is reasonable to set  $\Delta u_k$  as the maximum of  $|\Delta u(y)|$  in the elastic zone. In this paper, we determine  $\Delta u_k$  by the average of  $\left|\Delta u(y)\right|_{\text{max}}$  in different positions of the elastic zone. Taking Specimen A as an example, the horizontal distributions of  $|\Delta u(y)|_{\text{max}}$  in the elastic zone are shown in Fig. [4](#page-6-2)h, where  $\Delta u_k = 1.35 \mu \text{m}$ .

The definition of thresholds  $\Delta u_k$  provides a standard to determine the length of SNZ. In this paper, we characterize SNZ by the contours of  $|\Delta u(y)|$ , of which the development scale and morphology could be identifed intuitively. As in Fig. [4](#page-6-2)i, when the calibration of the contours is limited in  $(0 - \Delta u_k)$ , the white zone where  $|\Delta u(y)| > \Delta u_k$  is the slip nucleation zone.

# **4 The Development Characteristics of the Slip Nucleation Zone**

# **4.1 Development of SNZ During the Opening of Tensile Fracture**

Based on LSWM, this paper proposed a method to identify the slip nucleation zone using DIC, showing the quasi-static development of SNZ before the formation of a cohesionless slip.

Figure [5](#page-7-0)a–d presents the development process of slip nucleation in Specimen A when the vertical tensile fracture length is 9.69 mm (referring to the y-axis of Fig. [5\)](#page-7-0). The development maturity of SNZ varies in the horizontal direction: SNZ is more developed when the position is closer to the tip of the tensile fracture (around  $x = 0$  mm), and the development of SNZ becomes less obvious far from the tip, consistent with the linear slip weakening model.

Before the cohesionless slipping of interlamination, the development lengths of SNZ  $(l<sub>s</sub>)$  on both sides of the tensile fracture tip increased with loading stress (Fig. [5](#page-7-0)a–d). Accord-ing to previous studies (Uenishi and Rice [2003](#page-15-13)),  $l_s$  of Mode-II slipping fracture depends on the shear modulus *G*, Poisson's ratio  $\nu$  and slip weakening rate *R*, as shown in Eq. ([4\)](#page-7-1) (Uenishi and Rice [2003\)](#page-15-13). In the linear slip weakening model,  $R = (\tau_s - \tau_d) / \Delta u_c$ , thus *l<sub>s</sub>* can be characterized by Eq. [\(5](#page-7-2)).

$$
l_s = \alpha \frac{\text{GR}}{1 - \nu},\tag{4}
$$

$$
l_s = \alpha \frac{G \Delta u_c}{(1 - v)(\tau_s - \tau_d)} , \qquad (5)
$$

where *G* is shear modulus,  $\nu$  Poisson's ratio, *R* slip weakening rate, and  $\alpha$  is a fixed constant.

According to Eq.  $(5)$ , a key parameter related to  $l<sub>s</sub>$  is the critical slip displacement  $\Delta u_c$ . To study the induced effect of Mode-I fracture on  $\Delta u_c$ , the fracture tip opening displacements (Lin et al. [2014](#page-14-28), [2020\)](#page-14-27) under diferent loading stress were characterized when the fracture propagates to the weak interface, as shown in Fig. [6a](#page-8-0). The critical slip displacement of SNZ presents a positive linear correlation with the Mode-Ι fracture tip opening displacement (Fig. [6](#page-8-0)b), as shown in Eq. ([6\)](#page-7-3). In the three-point bending experiments, the normal stress of interlamination increases with loading stress, so the change of interlaminar friction force should be considered. The experimental results show a linear correlation between the loading stress *P* and the fracture tip opening displacements *w* (Eq. ([7](#page-7-4))). In Specimen A, the values of the linear ftting parameters (a, b, c and d) are 0.60, 1.78, 0.10 and 0.24, respectively. Combining Eqs.  $(4)$  $(4)$ – $(7)$  $(7)$ , we can obtain the formula (Eq.  $(8)$  $(8)$ ) of SNZ length induced by a vertical tensile fracture in the three-point bending experiment, i.e.,  $l<sub>s</sub>$  is characterized by the fracture tip opening displacements. During the slip nucleation,  $l_s$  increases nonlinearly with  $w$  (Fig. [6c](#page-8-0)), consistent with the results obtained by DIC (Fig. [5a](#page-7-0)–d). The characterization of interlaminar fracture energy  $G_s$  and slip weakening rate  $R$ considering *w* are shown in Eq.  $(9, 10)$  $(9, 10)$  $(9, 10)$ , where  $G_s$  increases quadratically and *R* decreases nonlinearly with the increase of  $w$  (Fig. [6d](#page-8-0)).

<span id="page-7-3"></span><span id="page-7-2"></span><span id="page-7-1"></span>
$$
\Delta u_c = a \cdot w - b \,,\tag{6}
$$

<span id="page-7-4"></span>
$$
P = c \cdot w + d \tag{7}

# <span id="page-8-1"></span>**4.2 Formation of the Cohesionless Slipping Fracture from an SNZ**

<span id="page-8-3"></span><span id="page-8-2"></span>From the cohesive zone model of Mode-Ι fracture and the slip weakening model, when the vertical fracture arrives at the weak interface, the development process will be transformed from FPZ to SNZ if the interlaminar shear stress reaches the static friction  $(\tau_{\rm s})$ , and the increased energy mainly dissipates in the slip nucleation.

The appearance of SNZ indicates the formation of a slipping fracture. As shown in Fig. [5](#page-7-0)a–d and Fig. [7d](#page-9-0)–f, the generation of SNZ always presents in pairs, with asymmetric distributions, mainly due to the inhomogeneous distribution of interlaminar mechanical properties.

Figure [7a](#page-9-0)–c shows that the slipping fractures always propagate along the side with a longer SNZ after nucleation. The diference in length between the conjugated SNZs

<span id="page-9-0"></span>**Fig. 7** Fracture slip path and SNZ contour plot. **a** Fracture propagation path of Specimen B; **b** fracture propagation path of Specimen C; **c** fracture propagation path of Specimen D; **d** SNZ of Specimen B

when the tensile fracture length is 16.95 mm; **e** SNZ of Specimen C when the tensile fracture length is 5.28 mm; **f** SNZ of Specimen D when the tensile fracture length is 2.64 mm

determines the propagation direction of subsequent cohesionless slipping: the cohesionless slipping occurs in the direction with a larger SNZ length. Since the critical slip displacements  $\Delta u_c$  of the conjugated SNZs are the same at the beginning  $(x = 0)$ , the main factor affecting the development size of SNZ is the interlaminar mechanical properties referring to the calculation formula of SNZ length (Eq. ([5\)](#page-7-2)). In this paper, the slip nucleation factor  $\Omega$  is defined as shown in Eq.  $(11)$  $(11)$ , which is used to compare the mechanical properties of conjugated SNZs and judge the propagation direction of slip. In the conjugated SNZs, the cohesionless slips prefer to develop along the side with a larger  $Ω$ . Thus, the difference between kinetic and static frictions will be the decisive factor when the parameters  $G$  and  $\nu$  are the same.

<span id="page-9-1"></span>
$$
\Omega = \frac{G}{(1-\nu)(\tau_s - \tau_d)}\,,\tag{11}
$$

where  $\Omega$  is the slip nucleation factor.

# **4.3 Slip Nucleation of Millimeter‑Scale Specimen Scanned by an Electron Microscope**

Based on the Macro-TPB results, the slip nucleation and the formation of cohesionless slips during opening-mode fracturing have been studied on centimeter-scale specimens. To study the micro-scale slip nucleation, we adopted a real-time electron microscope to detect the fracture propagation of the millimeter-scale specimen in the Micro-TPB experiment.

Figure [8](#page-10-0)c shows the microscopic characteristics of Shaanxi laminated shale with 200 times magnification,

<span id="page-10-0"></span>**Fig. 8** Results of micro-scale fracture experiment. **a** Digital imaging of slip nucleation; **b** critical slip displacements; **c** electron microscope photos with  $200 \times$  magnification; **d** electron microscope photos with

100 × magnifcation: slip nucleation; **e** electron microscope photos with  $100 \times$  magnification: cohesionless slip

where the laminated distributions are more obvious. DIC analysis was carried out on the electron microscope photos with 100 times magnifcation (Fig. [8](#page-10-0)a). We found that when the micro-scale opening fracture propagated to the weak interface (Fig. [8](#page-10-0)d), a pair of conjugated SNZs appeared at the interlamination, as shown by the digital imaging in Fig. [8a](#page-10-0). Compared with the Macro-TPB results, the length of SNZ on the micro-scale is only hundreds of micrometers, and the critical slip displacements on the left/right sides of the tensile fracture tip are only 1.65 μm/1.35 μm (Fig. [8](#page-10-0)b), which is about an order of magnitude smaller than the Macro-TPB results.

Consistent with the Macro-TPB fracture experimental results, the SNZs observed in the Micro-TPB test present asymmetric developments (Fig.  $8a$  $8a$ ), and the side with a longer SNZ is accompanied by a larger critical slip displacement, following the prediction of Eq. ([5\)](#page-7-2). Finally, the cohesionless slipping fracture propagated along the side with a longer SNZ, as shown in Fig. [8e](#page-10-0). In summary, the development of SNZ and the formation of cohesionless slipping show similarities at the diferent scales of shale.

# **5 Discussion of the Fracture Nucleation During Hydraulic Fracturing in Laminated Shale**

# **5.1 An Experimental Validation from the Visual Hydraulic Fracturing**

In the laboratory, the three-point bending test is a common method (Lin et al. [2020](#page-14-27); Pan et al. [2021;](#page-14-4) Xing et al. [2019](#page-15-17); Zhang et al. [2018\)](#page-15-12) used to study the mechanical behaviors of hydraulic fractures. Based on the fracture results of laminated shale, we found the conjugated SNZs would be generated before fracture reorientation, and the cohesionless slip will appear on the side with a more developed SNZ. However, whether the development characteristics of the SNZ during hydraulic fracturing are consistent with the three-point bending experiments needs further validation. Therefore, using DIC to monitor the propagation of hydraulic fractures (AlTammar et al. [2019](#page-14-9); Li and Einstein [2019](#page-14-29)) will help to verify the conclusions, especially in laminated shale.

To study the slip nucleation during hydraulic fracture propagation, the visual hydraulic fracturing experiment was carried out on the shale specimen. Unlike in the three-point bending test, the shale specimen was applied with a constant stress perpendicular to the lamination, approximately 3 MPa, and the pressure fuid composed of water, guar gum, and red dye was injected. During the fracturing process, we found that a pair of asymmetrical slip nucleation zones also appeared when the hydraulic fracture propagated to the weak interface (Fig. [9](#page-11-0)c). With the increase of *w*, the development size of SNZ also increased (Fig. [9b](#page-11-0)), and the cohesionless slipping fracture was fnally generated on the side with a larger SNZ (Fig.  $9(d)$ ). According to Eqs. [\(5](#page-7-2)), ([6\)](#page-7-3), in hydraulic fracturing,  $l_s$  linearly increases with  $w$ , which is consistent with our monitoring results (Fig. [9](#page-11-0)b), indicating that the linear slip weakening model is reasonable for characterizing the quasi-static nucleation process.

Figure [9\(](#page-11-0)a) shows the experimental results of visual hydraulic fracturing in decimeter-scale shale, where the hydraulic fracture propagates from the vertical direction to the weak interface, as predicted by the longer SNZ. The analyses above indicate that the conclusions about the slip nucleation obtained by three-point bending experiments are suitable for discussing hydraulic fracturing in shale formations. In addition, the slip nucleation and cohesionless slip of laminated shale show similarities at diferent scales from millimeter, centimeter to decimeter.

# **5.2 The Residual Slip Zone After the Fracture Propagation**

The conjugated slip nucleation zones would appear before the fracture propagates along the interlaminations. However, how the shorter SNZ will change after fracture propagation is still unclear. In this paper, the residual slip zone (RSZ) is defned as the side with an initial SNZ, but without forming a cohesionless slip during hydraulic fracturing.

To determine whether slippage exists in RSZ, the horizontal displacement curves perpendicular to RSZ were studied. Figure [10a](#page-12-0)–d presents the displacement distribution near RSZ in diferent positions, when the fracture opening displacement is 44.34 μm and the corresponding vertical tensile fracture length is 11.89 mm. Signifcant discontinuities were observed in the horizontal displacement, indicating that slippage still exists in RSZ after fracture propagation. Figure [10](#page-12-0)a–d shows that the slippage becomes smaller at a farther distance from the fracture turning point, indicating that the slip nucleation is still retained in RSZ.

Since the initial SNZ size of the residual slip zone is smaller, it does not become the dominant path of cohesionless slip. However, when evaluating the hydraulic fracture system, not only macroscopic fractures but also the potential fractures represented by RSZ need to be studied. We found that slippage exists in RSZ. Therefore, RSZ also possesses hydraulic conductivity (Zhao et al. [2013](#page-15-7)) and should be regarded as a part of fracturing fractures of shale.

<span id="page-11-0"></span>**Fig. 9** Experimental results of the visual hydraulic fracturing in laminated shale. **a** Hydraulic fracture propagation path; **b** relationship between *w* and length of the longer SNZ; **c** SNZ when *w* is 13.63 μm; **d** horizontal displacement contours when *w* is 35.94 μm

## **5.3 Fracture Nucleation Modes During Hydraulic Fracturing**

Hydraulic fracturing is an efective technique in the stimulation of shale oil reservoirs. The fndings in this paper help to understand the slip nucleation behavior during hydraulic fracturing. However, the nucleation mode of hydraulic fractures in laminated shale still needs to be discussed based on the research in this paper and previous related works (AlTammar et al. [2019](#page-14-9); Chen et al. [2021](#page-14-12); Pan et al. [2021](#page-14-4); Yao [2012\)](#page-15-18).

The nonlinear development of hydraulic fractures in layered shale formations could be divided into two modes: one is the development of fracture process zone when the fracture propagates vertically, and the other is the development of slip

<span id="page-12-1"></span>**Fig. 11** Development characteristics of hydraulic fractures in laminated shale. **a** Diagram of FPZ development; **b** FPZ ahead of the prefabricated fracture in Specimen C; **c** constitutive relationship of FPZ;

**d** diagram of SNZ ahead of a hydraulic fracture; **e** LSWM considering the fracture tip opening displacements

nucleation zone when the fracture slips at the interlamination. As shown in Fig. [11a](#page-12-1), when the hydraulic fracture propagates vertically without reaching the weak interface, the fracture process zone (FPZ) will be developed in front of the fracture tip, presenting microfractures aggregation (Fig. [11](#page-12-1)a) as well as tensile stress softening (Fig. [11](#page-12-1)c) (Chen et al. [2021](#page-14-12); Elices et al. [2001;](#page-14-30) Lin et al. [2020\)](#page-14-27). It is common to describe the fracture process zone as a cohesive tensile fracture based on the cohesive zone model  $(Q.$  Lin et al.  $2020$ ), and the tensile stress ahead of hydraulic fracture will begin to soften when the rocks reach the tensile strength. The corresponding constitutive model is illustrated in Eq. [\(12\)](#page-13-0), which characterizes the relationship between tensile stress and fracture opening displacements. Combining with the existing FPZ identifcation method (Chen et al. [2021](#page-14-12)), the FPZ shape can be characterized based on DIC, as in Fig.  $11(b)$ .

$$
\sigma = f(w),\tag{12}
$$

where  $\sigma$  is the tensile stress.

The fully developed fracture process zone means the formation of a new fracture, and the vertical fracture will propagate forward. When the vertical fracture propagates near the weak interface, the interlaminar elastic deformation will occur frst (Fig. [11e](#page-12-1)). When the interlaminar shear stress reaches the static friction force, the interface becomes weakening, accompanied by the generation of SNZ. Due to the inhomogeneous distribution of interlaminar mechanical properties (different values of  $\Omega$ ), SNZs will present an asymmetric distribution (Fig. [11d](#page-12-1)). After the quasi-static slip nucleation, a cohesionless slip would be formed along the side with a longer SNZ. The linear slip weakening model considering the fracture tip opening displacements is shown in Fig. [11](#page-12-1)e (Chen and Knopoff [1986](#page-14-14); Rice [1979](#page-14-15)). With the increase of hydraulic fracture tip opening displacement, the development length of  $SNZ$   $l_s$  and interlaminar fracture energy  $G_f$  increase, but the slip weakening rate  $R$  decreases.

When the opening displacements of the hydraulic fracture tip increase to a certain value, the cohesionless slip will be generated along the side with a longer SNZ ( $\Omega$  is larger), while the other side will be transformed into a residual slip zone. RSZ was neglected in previous evaluations of hydraulic fracture systems. Although the formation of RSZ consumes fracture energy, slippage exists in RSZ. Therefore, RSZ should be the effective fracture with enhanced hydraulic conductivity, a part of the hydraulic fracture systems in shale formations.

# **6 Conclusions**

In this paper, the laminated shale was used in the macro and micro three-point bending experiments, as well as the visual hydraulic fracturing experiment, where DIC was used to monitor the interlaminar deformation. The slip nucleation during fracture propagation was observed in the shale specimens from millimeter scale to decimeter scale. The fndings could help to understand the generation process of interlaminar slip during hydraulic fracturing, summarized as follows:

- 1. Based on the linear slip weakening model, we proposed a method to identify the slip nucleation zone using DIC, visually detecting the SNZ size. Two asymmetric SNZs were observed on both sides of the tensile fracture tip before the formation of a cohesionless slip.
- <span id="page-13-0"></span>2. The cohesionless slipping direction could be predicted according to the development size of the conjugated SNZs, where the cohesionless slip will be generated along the side with a longer SNZ, as judged by the defned factor Ω. The side with a smaller diference value of kinetic and static friction force will be the preferred path of cohesionless slipping.
- 3. For SNZ development, the linear slip weakening model considering the fracture tip opening displacements was discussed. With the increase of *w*, SNZ length and interlaminar fracture energy will increase, whereas the slip weakening rate will decrease.
- 4. The results of visual hydraulic fracturing verifed the applicability of slip nucleation in shale formations, where two nucleation modes (FPZ and SNZ) will be generated during fracturing. With the characteristics of slippage, the residual slip zone was defned, which should be a potential part of the hydraulic fracture systems.
