ORIGINAL PAPER

Nonlinear dynamic behaviors of electrochemical corrosion of Ti-48Al-2Cr-2Nb alloy at high applied potentials

Xianmiao Zhang[1] · Zhijian Luo[1] · Cuijiao Liao[1]

Abstract

Chronoamperometry (CA), phase space reconstruction, correlation dimension, multifractal detrended fluctuation analysis (MFDFA) combining linear sweep voltammetry (LSV), electrochemical impedance spectroscopy (EIS), and surface morphology observation were used to systematically analyze the nonlinear dynamics behavior of electrochemical dissolution of Ti-48Al-2Cr-2Nb alloy at high applied potentials. The relationships of applied potential E with nonlinear dynamic characteristic (saturation correlation dimension D_2', Hurst exponent H, the area of the spectrum S) and electrochemical corrosion parameters (capacitance ratio (C_a/C_b)) were analyzed, respectively. The results show that non-uniform corrosion at low potentials (7–13 V) results in rough surfaces; a higher potential (16 V) contributes to obtaining smoother surface. The growth of saturated correlation dimension reveals that the corrosion behavior of Ti-48Al-2Cr-2Nb alloy changes from non-uniform corrosion to uniform corrosion. The number of major variables in the electrochemical system is 6 for 7–13 V and is 7 for 16 V. The inversely proportional relationships of the area of the spectrum S and Hurst exponent H between the applied potential, respectively, testify that high potential is favorable for uniform corrosion of Ti-48Al-2Cr-2Nb alloy.

Introduction

TiAl alloys have excellent corrosion resistance, high specific strength, and stiffness, which make them good applications in many fields, such as the turbine blade of automobiles and aero-engine [1–3]. However, their high-quality and efficient machining is a concern of researchers [4–6]. Electrochemical machining (ECM) has a great potential in machining processes of complex integral structures and high hardness materials and is a preferred machining method for TiAl alloys [3, 7–11].

In order to obtain excellent electrochemical machining condition, many researchers pay many attentions on the effects of the electro-dissolution behavior of these alloys on their machining properties using conventional electrochemical methods, such as cyclic voltammetry, linear sweep voltammetry, chronoamperometry, and electrochemical

impedance spectroscopy [12–19]. The results of previous investigations have shown that the electrochemical dissolution behaviors of TiAl alloys are obviously affected by the microstructure of these alloys, the electrolyte composition, and the electrolyte temperature as well as the applied potential. There is an obvious oscillation behavior when these alloys are corroded at higher potential, high concentration electrolyte, and high electrolyte temperature. At present, the nonlinear oscillation behavior of TiAl alloys has not been studied. However, ECM is a typical electrochemical system that applies high potential [20–22], has very complex nonlinear characteristics because of the strong coupling of multiple physical fields, and presents obvious chaotic characteristics [23–25]. Moreover, two-phase TiAl alloy (γ-TiAl and α_2-Ti$_3$Al phase) has complex microstructures and dissolution characteristics. The above two reasons increase the difficulty of the stable and high-quality electrochemical machining of TiAl alloy [9, 26]. Electrochemical dissolution behavior is an aspect that affects the machining performance; the nonlinear behavior of current density during electrochemical dissolution is also very important aspect; it is a reflection of the evolution of electrode interface structure [21, 27, 28].

Therefore, it is indispensable to employ a nonlinear dynamic method to study complex dynamic dissolution behavior to get stable surface quality and find the optimal machining conditions. The dynamic characteristics of current density or potential in the electrochemical dissolution process can obtain a lot of detailed information about the dissolving mechanism of materials [21, 29–31]. However, previous studies focus on the simple evolutionary behavior of current or potential during electrochemical corrosion at low potentials [20, 24, 25, 32], and there are few studies about their fluctuation characteristics of dynamic corrosion behavior at high potentials, let alone systematic analysis.

In this paper, the nonlinear dynamic characteristics of chronoamperometry corrosion at high potentials of Ti-48Al-2Cr-2Nb alloy were analyzed by using nonlinear dynamics methods such as phase space construction, correlation dimension, and multifractal detrended fluctuation analysis to find the inherent law of dissolution behavior and disclose the nonlinear dynamical structure of the electrochemical systems. Electrochemical impedance spectroscopy was adopted to reveal the electrode/solution interface structure for before and after chronoamperometry corrosion. Linear sweep voltammetry (LSV) and surface morphology observation as a supplementary analysis were carried out.

Experimental

In this experiment, an ingot of as-cast Ti-48Al-2Cr-2Nb (at.%) alloy was cut into samples with the size of 5.2 mm × 5.2 mm × 10 mm, and the samples were ground by SiC sandpaper with different granularity (200, 600, 2500, and 4000 mesh) and have exposed area about 0.25 cm^2 as working electrodes of electrochemical measurement. The polished samples with 1-μm alumina polishing powder and the corroded samples were observed by scanning electron microscope (SEM, ZEISS Sigma 300) equipped with EDS in BSE and SE mode, respectively. Before observation, all samples were cleaned by ultrasonic cleaners to remove contaminants attaching to the surface and dried at 50 ℃ in the drying oven. In addition, phase identification of Ti-48Al-2Cr-2Nb alloy was performed by XRD (Ultima IV) using Cu Kα radiation (40 kV, 40 mA) for an angle range of 5–90°.

Electrochemical measurements were performed on the Bio-Logic SP150B-20A electrochemical workstation based on a three-electrode system consisting of a reference electrode (Ag/AgCl in saturated KCl), an auxiliary electrode (a large piece of Pt foil with an area of 4 cm^2), and a working electrode. To understand the dissolution behavior of Ti-48Al-2Cr-2Nb alloy, linear sweep voltammetry (LSV) (open circuit potential E_{ocp} to 16 V) with a scan rate of 100 mV/s and chronoamperometry (CA) at the potentials of 7 V, 10 V, 13 V, and 16 V for 30 s with the sampling

frequency of 167 Hz were carried out in electrolyte solution (500 ml, 20 wt.% $NaNO_3$). Current density was corrected with the exposed area of each working electrode, the current density time series of CA with a length of 2^{12} (4096) for nonlinear dynamics analysis were extracted from the later stage of curves, and the length of the data is not less than 2^{10} following the effective analysis requirement of multifractal detrended fluctuation analysis (MFDFA) [33, 34]. Electrochemical impedance spectroscopy (EIS) in the frequency range of 10^{-2} to 10^5 Hz with a perturbation amplitude of 10 mV was also performed to analyze the dissolution mechanism assisting CA and LSV and to characterize interface structure. A transmission line equivalent circuit model [35] was used for the analysis of EIS in Zview software. Before measurement of EIS, open circuit potential was recorded for 2 h.

Variational mode decomposition (VMD) [36, 37] was used to reduce noise in the time series of current density before phase space reconstruction, calculation of correlation dimension, and MFDFA analysis. Electrochemical nonlinear dissolution behavior was analyzed combining nonlinear characteristic parameters of the current density with LSV, EIS, and SEM.

Results and discussions

### Phases and microstructures of Ti-48Al-2Cr-2Nb alloy

Figure 1 provides the phases and microstructures of Ti-48Al-2Cr-2Nb alloy obtained by XRD and SEM in SE mode, respectively. The phase composition is more γ-TiAl phase and less $α_2$-Ti_3Al phase (see Fig. 1a), which verify that Ti-48Al-2Cr-2Nb alloy is two-phase alloy. The microstructure of Ti-48Al-2Cr-2Nb alloy was observed with SEM in SE mode after erosion by Kroll solution (V_{water}:V_{HF}:V_{HNO3} = 50:2:1), which illustrates Ti-48Al-2Cr-2Nb has lamellar structure (see Fig. 1b).

Electrochemical dissolution behavior

Linear sweep voltammetry

Figure 2a exhibits a linear sweep voltammetry curve. The current density experiences a stabilized region zone tending to zero (E_{ocp} to 4 V), a transition zone (4 V to 5 V), a sharp increase zone (5 V to 5.6 V), and an approximately linear growth region (5.6 V to 16 V) showing more and more evident characteristics of oscillation with the increasing potentials. It's worth noting that the stabilized region zone is composed of a passivation zone (E_{ocp} to 0 V), two transition zone (0 V to 0.4 V and 1.9 V to 2.4 V), a transpassivation zone (0.4 V to 1.9 V), and a rapid growth zone

Fig. 1 Microstructures and phases of Ti-48Al-2Cr-2Nb alloy: **a** XRD and **b** SEM in BSE mode
with small oscillation (see Fig. 2b). The oscillation behavior, which is one representation of electrochemical system at large applied potential far away from the equilibrium state, is closed related with the kinetic process of electrochemical corrosion dissolution, such as adsorption, desorption, and diffusion of corrosion products, the evolution of oxidation products, and types of corrosion [20, 21, 28, 30, 31].
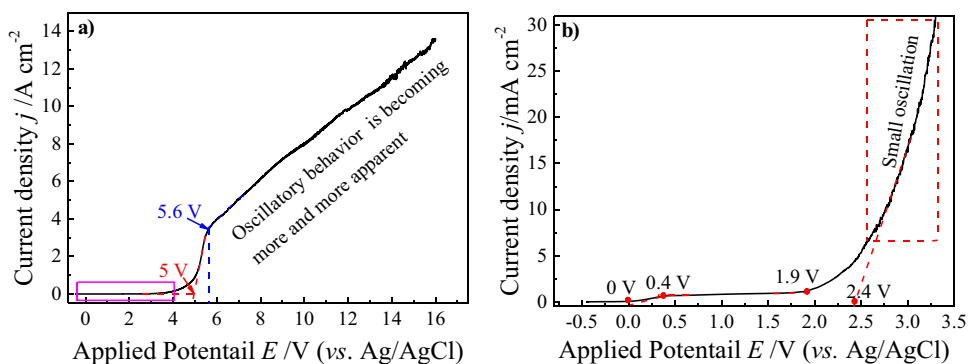

Chronoamperometry and denoising

Figure 3a shows the current density of chronoamperometry at different potentials. There are large fluctuations in the early and small fluctuations in the middle and later on the current density curve of each potential; the oscillation at the same time becomes more and more apparent with the increase of the applied potentials, which goes well with the above LSV. Four thousand ninety-six data points were intercepted from current density curve (see Fig. 3a, marked with a green dotted line box) to quantify the evolution behavior. Before nonlinear dynamic analysis, VMD was applied to denoise for the current density of each potential [36, 37]. The denoised time series of the current density at different potentials are exhibited in Fig. 3b and remain the inherent characteristics of the evolution of the current density.

### Electrochemical impedance spectroscopy analysis

In the view of the electrochemical system, the nonlinear dynamic characteristics of current density are mainly influenced by the applied potential E and the electrode/electrolyte interface structure. Electrochemical impedance spectroscopy (EIS) before and after chronoamperometry and the fitting analysis were carried out to get information on the interface structure of the electrode/electrolyte.

The Bode plots of EIS for Ti-48Al-2Cr-2Nb alloy before and after chronoamperometry at different potentials are shown in Fig. 4a, b, respectively. In Fig. 4a, the electrochemical impedance modulus at each potential is the same shapes: a solution resistance region in the high-frequency region and a linear growth region with a similar slope in the middle- and low-frequency region. The phase angle is also similar in the evolution law: there is a sharp increase in the high-frequency region, a very slow growth in the medium-frequency region, and a rapid decline in the low-frequency region. The electrochemical impedance spectra after chronoamperometry at different potentials also have a similar structure (as exhibited in Fig. 4b). Compared to before corrosion, the impedance modulus and phase angle have a delayed increase with the decrease of the frequency, but their growth rate increases, namely, the samples after corrosion

Fig. 2 **a** Linear sweep voltammetry curve of Ti-48Al-2Cr-2Nb alloy and **b** the partial enlarged drawing of **a**
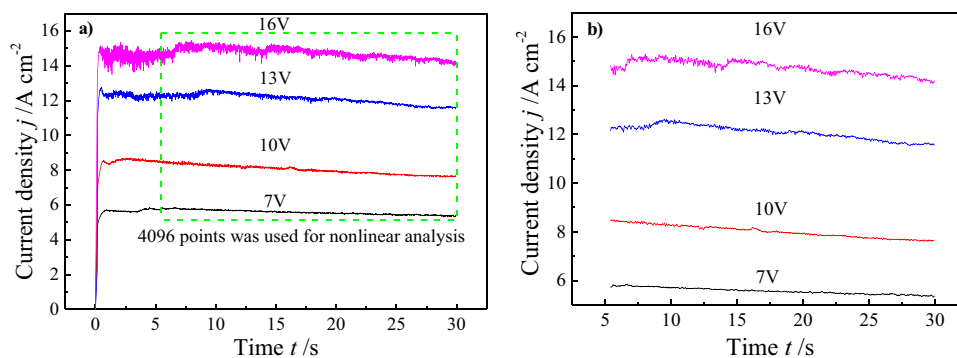

show more obvious resistance characteristics and narrower
frequency capacitive characteristics. The maximum imped-
ance moduli decrease obviously, and the maximum-phase
angle has a slight rise. Among the corroded samples, EIS of
the sample after CA corrosion at 7 V differs from the other
three samples.

The fitting analysis is necessary by an equiva-
lent circuit to obtain quantitative information of elec-
trode interface structure. A Maxwell transmission line
$(R_0(RC)_6)$ (as shown in Fig. 4c) [35, 38] consisting
of six RC parallel branches was used to fit all imped-
ance spectra, where R_0 is the polarization resistance
and R_i ($i = 0, 1, …, 6$) and $C_i = (1, 2, …, 6)$ are adsorp-
tion resistance and adsorption capacitance of the ith electro-
chemical reaction, respectively. The C_b and C_a represent the
sum total of C_i before and after corrosion, respectively. The
fitting curves suggest that the fitting accuracy is satisfactory
and the corresponding parameters are listed in Table 1.

For the same electrode system, the difference in the
adsorption characteristics has closely related to the rough-
ness of the electrode surface after corrosion associating
with the dissolution behavior of the material in the corro-
sion process. In the case of two-phase Ti-48Al-2Cr-2Nb
alloy, γ-TiAl and α$_2$-Ti$_3$Al have different dissolution char-
acteristics. If the difference is not significant, the surface
of the corroded electrode is smooth. On the contrary, it is

rough. So, the capacitance ratio C_a/C_b can be used to char-
acterize electrode coarsening after electrochemical corro-
sion. Figure 5 provides the change curve of C_a/C_b with the
applied potential, the value of C_a/C_b increases and reaches
the maximum value when the applied potential is 10 V, and
then it linearly declines with the rising potential. The result
suggests that the potential makes the electrode rapidly cor-
rode and coarsen the surface, the coarsening of the electrode
surface is the most serious when the potential reaches 10 V,
the electrodes become smoother with the rise of the applied
potential, and the error bar size of C_a/C_b has a similar vari-
ation trend with C_a/C_b value. The reasons for this shift can
be attributed to the crystal structure of the Ti oxide during
electrochemical corrosion of Ti-48Al-2Cr-2Nb alloy [39].

Nonlinear dynamic analysis

Phase space reconstruction and quantitative characterization

Figure 6 illustrates two-dimensional projections of phase
space reconstruction and saturation correlation dimen-
sion D_2' at different potentials; the delay time τ is 0.042 s,
0.030 s, 0.024 s, and 0.024 s for 7 V, 10 V, 13 V, and 16 V,
respectively; and the corresponding optimal m is 6, 6, 6, and 7
according to the optimization conditions ($m \geq 2 D_2' + 1$) [40].
Two maximal eigenvalues of the vectors in phase space were

selected as two vectors of the *X*-axis and *Y*-axis, respectively [41]. Figure 7a–e shows the diagrams of phase space reconstruction at different potentials. There is a strange attractor with a rodlike structure for current density at each potential [28, 30, 31], and they symmetrically distribute along the 45° diagonal line in a certain region of phase space. The length of the attractor along the 45° direction extends with the increase of the applied potentials, which represents an overall fluctuation of the current density. The width of the rodlike structure diminishes with the extension of corrosion time and arises with the increase of the potentials. Finally, the width difference of rodlike structure in the later period becomes small, which expresses the local fluctuation of current density in the corrosion process. The current density gradually becomes stable with the prolonging of corrosion time.
Fig. 5 C_a/C_b change curve vs. applied potential

The correlation dimension D_2 at different embedding dimensions m was calculated to quantify the structure of strange attractors. D_2 changes with m and reaches the maximum value when m is 4 or 5, namely, saturated correlation dimension D_2'. It rises gently from 7 to 10 V and then increases rapidly from 10 to 16 V (see Fig. 6f), which suggests the corrosion behavior changes from non-uniform corrosion to uniform corrosion with the increase of the applied potentials [30, 42]. The fractal dimension of an attractor has an important physical meaning and expresses the minimum number of variables in the evolution of a corresponding dynamical system (degrees of freedom) [20–22, 30, 42, 43]. The result indicates that the electrochemical reaction becomes more and more intense, and the evolution of electrochemical system structure is more and more complex [44] with the increase of the applied potential. According to $m \geq 2\,D_2' + 1$ [40] and the expansibility of strange attractor trajectories, 6 is selected as the minimum embedding dimension m' for 7 V, 10 V, and 13 V, and 7 is selected for 16 V, which indicates the electrochemical system at 16 V has more factors than at 7 V, 10 V, and 13 V.
Multifractal detrended fluctuation analysis

Current signals in electrochemical system show obvious multifractal characteristics [45]; it has trends of some kind and is nonlinear and nonstationary [46]. Multifractal detrended fluctuation analysis shows a clear advantage in the multifractal characterization of nonlinear and nonstationary time series [34, 47–49]. It was applied to characterize multifractal features of current density at different potentials in the present work.
Fig. 6 **a–e** Phase space reconstruction and **f** saturation correlation dimension $D_2^{'}$ at different potentials

Hurst exponent H was computed based on detrended fluctuation analysis [34] when segment size s ranges from $s_{min} = 16$ to $s_{min} = 512$. The values of H are larger than 1.0, are less than 1.5, decline with the increase of the applied potential (7 V to 13 V), and then increase (13 V to 16 V) (see Fig. 7), which indicates that current density is nonstationary signals [34, 48, 50]. At the lower potentials (7 V and 10 V), the values of H (1.29 and 1.22) are closer to 1.5, which reveals the current fluctuation behavior at low potentials is characterized by Brown noise because of the non-uniform corrosion [34]. However, the values of H

(1.12 and 1.17) at higher potentials (13 V and 16 V) are closer to 1.0, and the current density fluctuation behavior has the characteristics of 1/f noise [34].

Multifractal spectrum can express some information associated with the dynamics of the current density time series. Figure 8a displays multifractal spectra $f(\alpha) \sim \alpha$ of current density at different potentials. The curves show a single hump and right-skew structures with a high level of similarity and exhibit typical features of the multifractal spectrum [51]. For the quantitative analysis, the area of the spectrum S is computed. The inverse proportional relationship between the area of the spectrum S and the applied potentials is shown in Fig. 8b. The current density time series records the amplitude of the current density fluctuation varying with time; the amplitude represents energy of the current density fluctuation [47, 52]. So we think that the area of the spectrum S of the current density time series hides total information on the energy of current density fluctuation. The inverse proportional relationship suggests that the energy of current density fluctuation decreases with the increase of the high potential, and the multifractal property of the multifractal spectrum is weakened, which prove that the two-phase Ti-48Al-2Cr-2Nb alloy is more conducive to uniform corrosion at high potentials [26].

Surface morphology observation

Surface morphology after CA corrosion at different potentials is provided as shown in Fig. 9. The corrosion

Fig. 7 Change curve of Hurst exponent H with applied potentials E

Fig. 8 **a** Multifractal spectra $f(\alpha) \sim \alpha$ and **b** the relationships between the applied potentials E and S

morphology is related to the applied potential and the microstructure of Ti-48Al-2Cr-2Nb alloy. There are three typical corrosion patterns appearing on the corroded surface at each potential: pit corrosion (marked by white arrows), selective corrosion of the lamella that is not parallel to the surface, and grain boundary corrosion (marked by red arrows) (see Fig. 9). The pit corrosion is closely related with the direction of the lamella and is manifested on the parallel surface lamella. The selective corrosion of γ-TiAl lamella attributes to the fast dissolution rate of γ-TiAl compared with α_2-Ti$_3$Al and is most non-evident on the corroded surface at 16 V. The grain boundary corrosion can be found on the corroded samples at 7 V and mainly appears on the corroded samples at 10 V, 13 V, and 16 V. In addition, the depth of the grain boundary corrosion is larger at 10 V and 13 V than that at 16 V (marked by red arrows) (see Fig. 9). By naked eye,

it is difficult to evaluate the degree of roughness of corroded samples accurately; combined with the above result of the change curves of C_a/C_b and the applied potentials (see Fig. 5), we conclude that the high potential makes a uniform corrosion when the applied potential is higher than 10 V.

Figure 10a exhibits a cross-section of the corroded sample at 16 V with clean water and without ultrasonic cleaning. The corroded layer has large pores formed by oxygen formation and loose lamellar structures (see Fig. 10a), which are independent of the direction of the lamella. The X-ray elemental mapping images (Fig. 10b, c) verify that the corrosion layer is rich titanium, the lamellar structure is mainly α_2-Ti$_3$Al phase, and the γ-TiAl phase in Ti-48Al-2Cr-2Nb alloy is preferentially corroded. Figure 10d-f proves that the corroded layer consists some oxides, the Cr element almost dissolves, and the Nb element is partially soluble.

Discussion

Two-phase Ti-48Al-2Cr-2Nb alloy consists of alternating γ-TiAl and α_2-Ti$_3$Al, which have different dissolution behaviors. Compared to the α_2-Ti$_3$Al phase, the γ-TiAl phase is preferentially corroded because of the higher content of Al (see Fig. 10a). The difference in dissolution rate between γ-TiAl and α_2-Ti$_3$Al is the most important factor affecting surface roughness. In addition, the dissolution behavior of special structures (such as grain boundary) is another major factor influencing the surface roughness. Capacitance ratio C_a/C_b cooperating surface morphology observation can verify the above result (see Fig. 5 and Fig. 9).

The local and global fluctuations of the current density of CA corrosion ascribe to the dissolution behavior of Ti-48Al-2Cr-2Nb alloy and electrochemical system structure. Non-uniform corrosion (for example, pit corrosion, the preferential corrosion of γ-TiAl, and grain boundary corrosion) of the alloy results in major fluctuations of current density in the earlier stage, and uniform dissolution causes small fluctuations in the later period (see Fig. 5). There are six control variables in the electrochemical system when the applied potential is not more than 13 V, and there are seven control variables when the potential is 16 V.

In general, non-uniform corrosion is more likely to occur at low potential, which results in frequent and irregular changes of current density. On the contrary, the higher the potential, the easier the uniform corrosion, and the energy of local fluctuation of the current density becomes weaken. So, the area of the spectrum S collaborating with Hurst exponent H can well reflect the evolution characteristics of the different corrosion behavior (see Figs. 8 and 7).

Conclusion

The nonlinear dynamic behavior of the current density time series of CA of Ti-48Al-2Cr-2Nb alloy was carried out from various perspectives combined with LSV, EIS, and SEM, and conclusions could be drawn as follows:

1. The surface of the corroded samples firstly coarsens with the increase of the potential (7 V to 10 V) and then becomes smoother with the increasing potential (10 V to 16 V), which testifies that a higher potential contributes to obtaining smoother surface.
2. The saturation correlation dimension with increasing applied potentials in electrochemical dissolution of Ti-48Al-2Cr-2Nb alloy reveals that the corrosion behavior of the alloy changes from non-uniform corrosion to uniform corrosion.
3. The multifractal characteristics of electrochemical dissolution of Ti-48Al-2Cr-2Nb alloy also reflect a shift in corrosion behavior.
