ABSTRACT

Many disturbances are shifting in severity, frequency, and extent due to changing climate and human activities. Altered disturbance regimes can trigger shifts in ecosystem state where recovery to the pre-disturbance ecosystem is uncertain. In the western North American boreal forest, the intensification of wildfire can cause canopy dominance to switch from black spruce (*Picea mariana*) to deciduous trees such as Alaska paper birch (*Betula neoalaskana*) and trembling aspen (*Populus tremuloides*). Understanding the key mechanisms that determine the resilience and stability of these alternative community types is required for the prediction of future forest dynamics. Here, we as-

sess patterns of post-fire tree recovery across a pre-fire gradient of spruce- to deciduous-dominated forests in Interior Alaska and quantify compositional and environmental thresholds that support the resilience of alternative canopy types. We found post-fire organic soil depth of stands on a recovery trajectory to deciduous dominance (7.3 ± 5.5 cm) were similar regardless of pre-fire composition and significantly shallower than spruce (14.9 ± 9.0 cm) or mixed trajectories (10.4 ± 5.9 cm). Deciduous-dominated stands were highly resilient to fire, as 100% remained deciduous-dominated post-fire. Even when deciduous trees only accounted for a small proportion (12%) of the pre-fire stand, deciduous trees often became dominant after wildfire. We conclude that the establishment of deciduous bud banks and seed sources creates a strong hysteresis in stand recovery that reinforces the resilience of deciduous-dominated boreal forests to wildfire. Accounting for the resilience of this alternative stable state to wildfire suggests that shifts from spruce to deciduous dominance caused by shifting wildfire will have long-term effects on future structure and function of boreal forests and vegetation feedbacks to climate change.

Key words: Boreal forest; succession; ecological legacies; resilience; black spruce; deciduous.

HIGHLIGHTS

- Ecological legacies reinforce resilience of deciduous boreal forests to wildfire.
- Deciduous legacies create a strong hysteresis in post-fire stand recovery.
- Fire induced shifts from spruce to deciduous will persist across fire cycles.

INTRODUCTION

Patterns of disturbance and recovery shape the structure and function of many ecosystems and play a central role in driving ecosystem response to global change (Seidl and others 2014; McDowell and others 2020). The ability of ecosystems to recover their essential structure and function after a disturbance (that is, ecosystem resilience) is transmitted as legacies of past ecosystems via species traits and materials (Johnstone and others 2016). Many disturbances are exhibiting shifts in their severity, frequency, and extent due to changing climate and human activities (Mollicone and others 2006; Abatzoglou and Williams 2016). These altered disturbance regimes can modify key legacies (for example, seedbanks, seedbeds) and trigger shifts to alternative vegetation states that exhibit hysteresis (Ratajczak and others 2018), where recovery to the pre-disturbance ecosystem is unlikely (Johnstone and others 2010b; Kukavskaya and others 2016; Whitman and others 2019; Coop and others 2020). New ecosystem states may produce novel legacies that will similarly constrain future responses to disturbance, potentially inhibiting recovery to the original state even if external drivers return to prior conditions (Ratajczak and others 2018). Understanding how changes in ecological legacies interact with disturbances is essential for predicting dynamic ecosystem responses to global change (Foster and others 2022b).

Wildfire is the primary large-scale disturbance throughout the northwestern North American boreal forest. Much of this forest is dominated by conifer stands of black spruce (*Picea mariana*), where stand-replacing fires have historically occurred at approximately 100-year intervals (Johnstone and others 2010a). Forest succession under such short fire cycles is typically driven by early dominance of the post-fire cohort (Gutsell and Johnson 2002), although relay succession of stand composition is possible under longer fire-free intervals (for example, Taylor and Chen 2011). The

fire and climate regimes of this region have maintained persistent cycles of black spruce self-replacement for the past ~ 6000 years, indicating a high level of ecosystem resilience to wildfires (Lloyd and others 2006; Higuera and others 2009; Kelly and others 2013; Hoecker and others 2020).

Resilience of black spruce stands depends on legacies of the soil organic layer (SOL) and plant adaptations to disturbance, such as the semi-serotinous cones of black spruce triggered by fire to release stored seed (Johnstone and others 2016). Climate warming and drying in the boreal forest have led to increases in fire severity and frequency (Kelly and others 2013). This can reduce or eliminate the SOL and cause canopy dominance to switch from black spruce to deciduous trees such as Alaska paper birch (*Betula neoalaskana*) and trembling aspen (*Populus tremuloides*) (Whitman and others 2019; Johnstone and others 2020; Baltzer and others 2021; Hayes and Buma 2021). Post-fire regeneration patterns of deciduous trees depend on different legacies than black spruce. For successful post-fire regeneration via deciduous seed, mast seeding years must coincide with fires. However, both aspen and birch can regenerate prolifically and rapidly via vegetative reproduction (Greene and Johnson 1999; Frey and others 2003; Chen and others 2009). Once deciduous trees establish via seed following severe wildfire, their asexual regeneration strategies may reinforce the shift in boreal forest composition from the historic black spruce state to deciduous dominance.

As fire regimes continue to intensify in the North American boreal forest (Yue and others 2015; Young and others 2017), changes in forest composition from conifer dominance to alternative deciduous forest types could have important implications for biome C storage, wildlife habitat, forest products, future fire hazard, and feedbacks to earth system dynamics. However, under the rapidly changing environments of the twenty-first century, we often lack sufficient historical analogs to anticipate the resilience of long-lived organisms such as trees to intensifying disturbance regimes. For example, cold soils in high latitude or elevational areas have previously been understood to constrain deciduous-dominated states to a transient stage in successional recovery to conifer dominance (Cleve and others 1991). However, changing climate and fire conditions are altering both drivers and ecosystem feedbacks that may alter the stability of forest types (Johnstone and others 2016; Mekonen and others 2019). Prediction of future forest dynamics thus depends on understanding the key

mechanisms that will determine the resilience and stability of historic or alternative community types (Foster and others 2019; Mekonnen and others 2019). In the North American boreal forest, the potential for shifts from conifer to deciduous broadleaf forests, and their potential to mitigate C losses from fire and future fire risk, depends on whether demographic processes are sufficient to support stable persistence of deciduous stands under future disturbances.

Here, we assess post-fire regeneration across a gradient of spruce- to deciduous-dominated forests in Interior Alaska and quantify compositional and environmental thresholds that support resilience of alternative vegetation types to fire. Specifically, we determine the impact of pre-fire deciduous presence on post-fire recruitment patterns. We hypothesize that pre-fire deciduous presence will result in post-fire deciduous dominance due to reproductive legacies that reinforce the alternate successional trajectory of deciduous-dominated boreal forests. Given the known importance of SOL depth for black spruce self-replacement (for example, Johnstone and others 2010b), we also examine differences in post-fire SOL depth among successional trajectories. Our results not only demonstrate vulnerability of spruce to post-fire

replacement by deciduous trees, but also underscore high resilience of mixed and deciduous-dominated boreal forests to wildfire, thereby providing a basis for anticipating the consequences of altered successional trajectories for future forest dynamics.

METHODS

Study Area

Our study area was the boreal forest ecosystem that lies south of the Brooks Range and north of the Alaskan Range in Interior Alaska, USA (Figure 1). Temperatures across this region are highly continental and seasonally range from -50 to 38 °C with mean annual temperature of -3.3 °C and mean annual precipitation of ~ 285 mm, including $\sim 40\%$ from snow (Fairbanks International Airport, 1985–2015). This region is underlain by discontinuous permafrost, and soils are undeveloped, primarily ($\sim 90\%$) consisting of Inceptisols, Gelisols, Histosols, and Entisols (Osterkamp and Romanovsky 1999). Approximately 57% of the 370,000 km² Alaskan boreal forest area is dominated by coniferous trees, while 27% is a mix of conifers and deciduous tree species, such as aspen and Alaska paper birch, and 16% is unforested

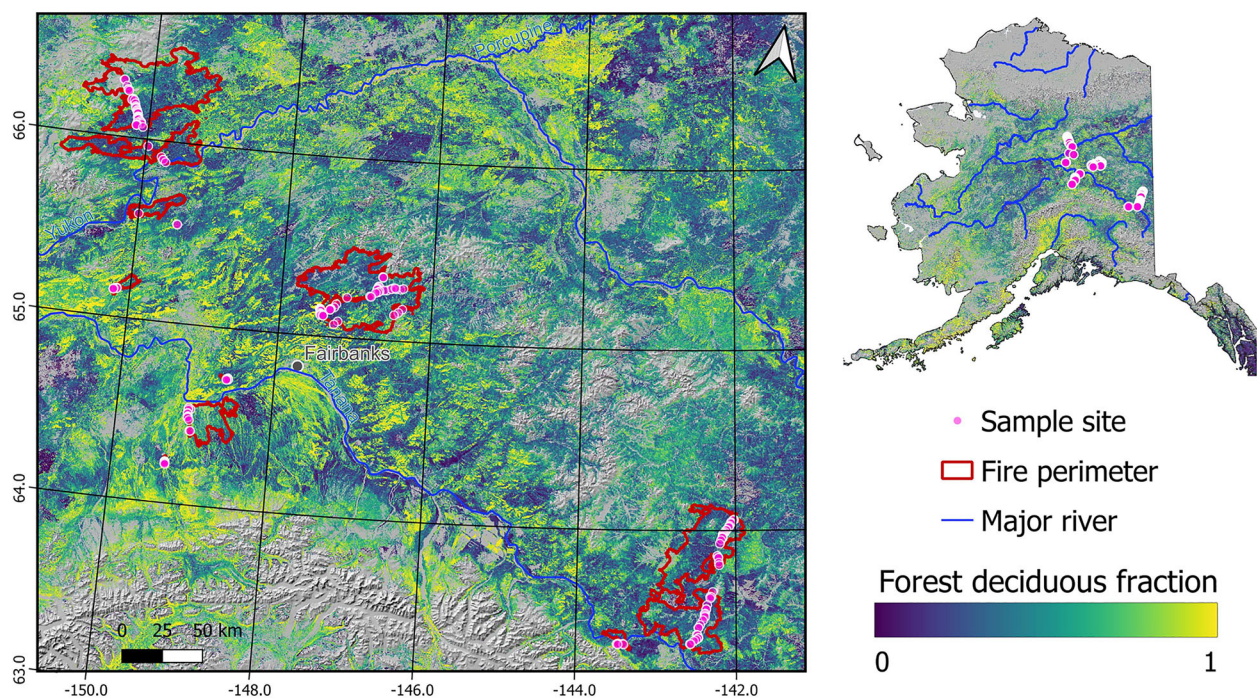

Figure 1. Sample sites and associated fire perimeters in the boreal forest of Interior Alaska. Forest deciduous fraction in 2000 is also shown for areas with $> 20\%$ tree cover based on maps by Massey and others (in review). Fire perimeters are from the Alaska Large Fire database.

wetland and tundra (Yarie and Billings 2002; Neigh and others 2013).

Field Methods

We collected and collated data on pre- and post-fire stand composition from 212 sites across Interior Alaska that burned between the years 2004 and 2014 (Figure 1). Sites were established by three independent research projects, but field measurements on pre- and post-fire trees were similar (Walker and others 2017; Johnstone and others 2020). Of the 212 sites examined, we established 88 pre-fire black spruce dominated sites in three separate fire complexes following the 2004 wildfires in Interior Alaska (details in Johnstone and others 2020; Mack and others 2021). In 2010 and 2011, we established an additional 82 sites in the same 2004 fire scars, but sites ranged in pre-fire composition from black spruce dominance to black spruce co-dominance with deciduous species (details in Walker and others 2017). In 2019, we established 42 new sites dispersed between six independent fire scars that were largely deciduous dominated pre-fire. We chose these sites using the Alaska large fire database and forest deciduous fraction maps (Massey and others In Revision). All sites were mature (> 70 years since previous fire) at the time of fire based on historical record of fires in the Alaskan Large Fire Database and confirmed with stand age reconstructions using tree ring analyses. Sampling took place 4–13 years after fire, once the regeneration patterns that set the trajectory of early succession have established (Johnstone and others 2020).

We estimated pre- and post-fire stem density and forest composition by measuring pre-fire (burned) trees and newly established seedlings. We counted all standing or fallen pre-fire trees and measured diameter at breast height (dbh) on all individuals taller than 1.4 m or basal diameter on all trees less than 1.4 m in height that were originally rooted in two parallel 2 m \times 30 m belt-transects. Similarly, we estimated post-fire density by counting post-fire seedlings within ten randomly positioned 1 m \times 1 m quadrats along the same two transects and measuring the basal diameter of at least one representative species per quadrat. We counted all post-fire stems of spruce, aspen, and birch that were rooted in quadrats, regardless of size. Given the range of time after fire that we sampled (4–13 years) we were unable to differentiate seedlings from vegetative regeneration.

Classification of Successional Trajectories

Using the survey data, we calculated total density (stems ha^{-1}) of each tree species pre- and post-fire. We used published allometric equations to calculate pre-fire (Alexander and Mack 2016) and post-fire (Johnstone and others 2020) species-specific aboveground tree biomass (g m^{-2}). We then calculated the proportion of deciduous stems relative to total stems in both the pre- and post-fire stand (relative deciduous density) and the proportion of deciduous biomass relative to total biomass in both the pre- and post-fire stand (relative deciduous biomass). We classified sites into pre- and post-fire tree species dominance classes based on a deciduous fraction index (DI) calculated from the survey data (DI = relative density plus relative biomass of deciduous tree seedlings divided by two and multiplied by 100). When DI was $\leq 33.33\%$, sites were classified as black spruce (hereafter Spruce). Sites were classified as mixed black spruce-deciduous (hereafter Mixed) if DI was $> 33.33\%$ and $< 66.66\%$, and as deciduous if DI was $\geq 66.66\%$. We used biomass rather than the more typical basal area because biomass accounts for the different allometric scaling relationships between black spruce and deciduous tree species. Based on pre- and post-fire DI and spruce density, we categorized sites in seven classes representing observed transitions in stand dominance after fire: (1) Spruce to Deciduous, (2) Spruce to Mixed, (3) Spruce to Spruce, (4) Spruce thinning (where stands remained spruce dominated after fire but did not regenerate with sufficient density for self-replacement to occur), (5) Mixed to Mixed, (6) Mixed to Deciduous, and 7) Deciduous to Deciduous.

Statistical Analyses

All analyses were performed using R statistical software version 3.5.2 (R Development Core Team 2018) and model results were plotted using the R package 'ggplot2' (Wickham 2016). To assess the impact of pre-fire DI on post-fire DI, we fit a generalized additive model (GAM) in the R package 'mgcv' (Wood 2017). GAMs are a nonparametric technique that fit smooth relationships between response and predictor variables (Wood 2017). The smooth for pre-fire DI was fit using thin plate splines and we set the basis dimension to 10 to allow for potentially complex nonlinear relationships. We used a Gaussian distribution and random intercept of fire scar to account for the spatial dependence of sites nested within fire scars. We

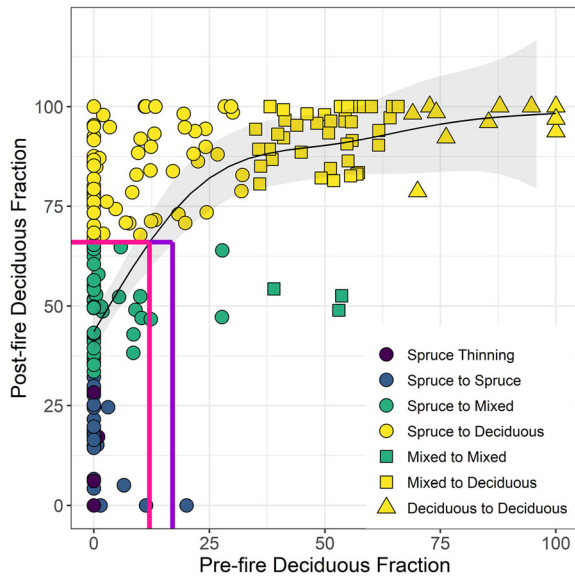

Figure 2. Post-fire deciduous fraction index as a function of pre-fire deciduous fraction index. Shapes represent different pre-fire species composition (circle = spruce, square = mixed, triangle = deciduous) and colors indicate post-fire succession trajectory (purple = thinning, blue = spruce, green = mixed, and yellow = deciduous). Black line represents generalized additive model fit with shading for the 95% confidence intervals. The pink line represents the threshold in pre-fire DI from which post-fire DI > 66% is likely to emerge based on model fit. The purple line represents the threshold in pre-fire DI from which post-fire DI > 66% will emerge with 95% confidence based on model fit.

also used restricted maximum likelihood for automated selection of smoothing parameters (Wood 2011). Model diagnostics were completed using the ‘gratia’ package (Simpson 2022).

To examine differences in post-fire SOL depth among the seven successional trajectories we fit linear mixed effects models (LMMs) using the R package ‘nlme’ (Pinheiro and others 2022). We included a random intercept of fire scar (nine levels) to account for the spatial non-independence of sites within fire scars and a variance structure (VarIdent) to account for changing variance with trajectory that was apparent in the model residuals (Zuur and others 2009). The significance of the fixed effect was assessed using a likelihood ratio test of the full model against the reduced model and verified using AIC (Zuur and others 2009). We confirmed that the statistical assumptions of homogeneity of variance and independence were not violated by visually inspecting residual versus fitted values, the explanatory variable, and each grouping level of the random intercept (Zuur and

others 2009). We used Tukey–Kramer post hoc analysis for multiple comparisons in the R package ‘emmeans’ (Lenth and others 2019) with a Bonferroni adjustment to test for differences in marginal means of SOL depths between post-fire trajectories within the same pre-fire class (for example, Spruce to Spruce vs. Spruce to Mixed) and among the same post-fire trajectory with different pre-fire classes (for example, Spruce to Deciduous vs. Deciduous to Deciduous).

RESULTS

Stands with > 12% pre-fire DI were likely to transition to deciduous dominance after fire (that is, post-fire DI was predicted to be > 66%) (Figure 2; pink line). Stands with > 17% pre-fire DI were expected to be exclusively deciduous dominated post-fire based on confidence intervals of fitted relationships (Figure 2; purple line). Out of 157 pre-fire spruce stands, we found 43% transitioned to deciduous dominance and 32% to mixed spruce-deciduous, whereas only 18% remained spruce dominant following fire. The final 7% of pre-fire spruce stands remained spruce dominated after fire but post-fire density was insufficient for self-replacement (that is, post-fire spruce density was lower than pre-fire spruce density; thinning). Notably, 100% of the 35 pre-fire deciduous stands self-replaced, while 93% of the 43 mixed stands transitioned to deciduous dominance, with the remaining 7% of sites continuing as mixed spruce-deciduous post-fire. Our results show that deciduous dominated forests are highly resilient to fire and that even a small component of deciduous stems (~ 12%) in the pre-fire stand can result in a transition of spruce forests to deciduous dominance in the first two decades post-fire.

Post-fire SOL depth differed between spruce stands that remained spruce versus transitioned to deciduous dominance following wildfire (Figure 3). Specifically, spruce stands that remained spruce had an average post-fire SOL of depth of 14.9 ± 9.0 cm, significantly (p value < 0.05) higher than spruce stands that transitioned to deciduous dominance (8.4 ± 6.4 cm). Spruce stands that transitioned to mixed or thinned had intermediate post-fire SOL depths of 10.7 ± 6.0 cm, and 14.6 ± 8.9 cm, respectively. Post-fire SOL depth of stands on a deciduous recovery trajectory (7.3 ± 5.5 cm) was similar regardless of pre-fire composition. Similarly, post-fire SOL depth of mixed stands (10.4 ± 5.9 cm) did not differ between stands that were pre-fire mixed or pre-fire deciduous (Figure 3).

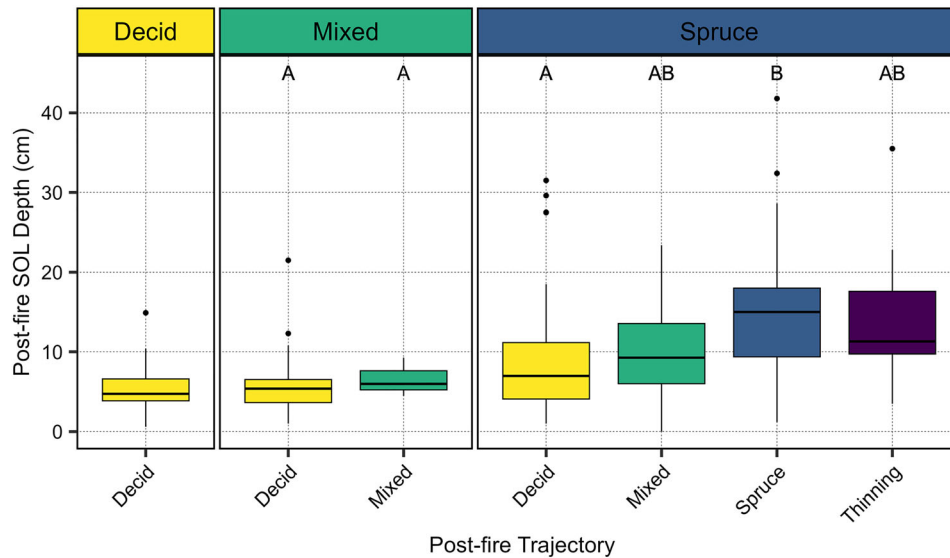

Figure 3. Post-fire soil organic layer (SOL) depth (cm) grouped according to post-fire trajectory (colors) and pre-fire class (panels). Colors indicate post-fire successional trajectory (purple = thinning, blue = spruce, green = mixed, and yellow = deciduous). Three panels represent pre-fire classes (deciduous, mixed, spruce) based on deciduous index (see classification of successional trajectories section in methods). Different letters above boxplots indicate significant differences (p value < 0.05) among SOL depths of post-fire trajectories within pre-fire dominance classes based on linear mixed effects models and Tukey's post hoc analyses. We also tested for differences in SOL depth of the same post-fire trajectory among pre-fire classes but did not observe any statistical differences.

DISCUSSION

Our analyses of an extensive dataset on pre-fire to post-fire composition shifts in boreal Alaska demonstrate the presence of deciduous trees in the pre-fire stand strongly impacts post-fire composition, generating strong hysteresis in the successional trajectories and dominant forest states across fire cycles (Figure 4). Stands with pre-fire deciduous fraction as low as 12% transitioned to deciduous dominance within the first 20 years post-fire. This is likely due to the presence of deciduous trees in the pre-fire stand providing a belowground bud bank for asexual regeneration that facilitates rapid and prolific post-fire colonization (Greene and Johnson 1999; Chen and others 2009). However, almost 30% of pure spruce stands (that is, no deciduous trees) still transitioned to deciduous dominance post-fire, highlighting the importance of deciduous seed availability and favorable seedbeds (that is, thin SOL) for the establishment of alternative deciduous trajectories (Johnstone and others 2010b; Brown and others 2015). With continued intensification of wildfire (Young and others 2017), spruce stands are likely to shift to alternative recovery trajectories leading to deciduous dominance, setting in motion the establishment of ecological legacies that will reinforce the resilience of

deciduous forest states across multiple fire cycles (Figure 4).

A key assumption of our findings is that patterns of post-fire regeneration reflect the composition of future boreal forest stands. Stand age reconstructions and longer-term observations of post-fire regeneration support this assumption. Specifically, early successional studies in northwestern boreal forests indicate the relative abundance of tree species recruiting during the initial 3–7 year period of post-disturbance regeneration is maintained through 2–3 decades of succession (Gutsell and Johnson 2002; Johnstone and others 2004; Shenoy and others 2011; Seidl and Turner 2022). This pattern holds even when changes in fire severity cause a shift from spruce to deciduous-dominated recovery (Johnstone and others 2020). Detailed reconstructions of tree ages further show that the trees that recruited immediately after fire dominate the canopy for at least a century of successional development (Johnson and others 1994; Gutsell and Johnson 2002). Relay succession is possible in mixed stands with a sufficiently long fire return interval, due to the shorter lifespan of aspen and birch compared to shade-tolerant conifers (Bergerson 2000; Taylor and Chen 2011) (Figure 4). However, succession in mixed canopy forests rarely leads to pure spruce even after 200 years in Interior

Figure 4. **A** Fire severity acts as a driver of the initiation of alternative stable states in black spruce forests, through impacts on the depth of the soil organic layer (SOL; underlying dark gray profile). Spruce-dominated stands show high stability and resilience to fire when fire severity is low and a thick SOL persists after fire. When the SOL decreases to an average depth of ~ 10 cm by more severe fire, there is an increased likelihood that seedbeds will support deciduous tree recruitment from seed, creating opportunities for post-fire communities to shift from black spruce (blue) to mixed (green) or even deciduous (yellow) dominance at very high severities (Figure 3). Once deciduous trees are present in the prefire stand, the positive effects of pre-deciduous tree density and biomass on post-fire deciduous recruitment (Figure 2) lead to system hysteresis, where the alternative deciduous-dominated state persists under similar climate and fire regimes. **B** Step changes in forest composition occur in association with fire events when severe fire, coupled with available seed, allows deciduous trees to colonize. Mixed deciduous-spruce stands may represent an intermediate state that can return to spruce dominance with a long fire-free interval or shift to deciduous dominance with the historical fire return interval. A return from deciduous to spruce dominance is unlikely even if fire severity returns to low levels unless fire frequency also greatly declines. Illustrated by Victor Leshyk, Center for Ecosystem Science and Society, Northern Arizona University.

Alaska (Fastie and others 2002; Kurkowski and others 2008), while the historic mean fire return interval is 70–120 years (Johnstone and others 2010a; Young and others 2017). Thus, forest composition initially established after fire in Interior Alaska likely persists until the stand burns again. Our results demonstrate that even if deciduous dominance declines to 12% of stand density and biomass (the metrics used in our analyses), this still provides enough of a budbank or seed source to ensure ample regeneration and subsequent dominance of deciduous trees after fire.

Post-fire observations (Johnstone and others 2010b, 2020; Baltzer and others 2021), experimental manipulations of burn depth (Johnstone and Chapin 2006), remote sensing of changes in deciduous fraction over time (Beck and others 2011; Massey and others In Revision), and modeling forecasts (Mekonnen and others 2019; Hansen and others 2020; Foster and others 2022a) provide support for the idea that deeper, more severe burning will lead to increasing abundance of deciduous stands on the landscape. Although all our pre-fire black spruce sites were established following the same year of fire our results align with these previous studies where fire severity

drives compositional shifts from black spruce to deciduous dominance. Here, we found that even relatively low pre-fire deciduous presence results in post-fire deciduous dominance, suggesting that once alternative deciduous trajectories are in place, they will likely be resistant to reverting to conifer dominance in subsequent fire cycles. Specifically, the vegetative regeneration strategies of deciduous trees make them highly resilient to disturbance as they can rapidly resprout following fire (Greene and Johnson 1999; Chen and others 2009). Although black spruce is still likely to establish in high abundance following fire in black spruce forests (Johnstone and others 2020; Baltzer and others 2021; Mack and others 2021), if deciduous trees are present their rapid colonization via vegetative regeneration gives them a competitive advantage over the slow growing black spruce, further reinforcing the deciduous trajectory. The combination of (a) increases in fire conditions conducive to deciduous tree recruitment and (b) strong ecological legacies that support subsequent deciduous resilience is likely to cause directional change and hysteresis in forest landscape responses to changing climate and fire. Model simulations that incorporate even a conservative version of this hysteresis

predict a substantial conversion of conifer to deciduous-dominated forests in Interior Alaska in the current century (Mann and others 2012; Foster and others 2022b).

Our finding that post-fire SOL was thinner in deciduous trajectories compared to spruce trajectories aligns with previous research on post-fire regeneration dynamics throughout the North American boreal forest (Johnstone and others 2010b, 2020; Baltzer and others 2021; Walker and others 2017). These studies highlight that high fire severity, measured as either total or proportional SOL combustion, can expose mineral soil and facilitate deciduous tree regeneration after wildfire. However, our measurement of post-fire SOL depth is not only driven by burn depth but is also a function of pre-fire SOL depth (Kane and others 2007; Johnstone and others 2020), which is affected by fire frequency and environmental conditions at the site. Deciduous forests are generally located in dry and warm landscape positions (Kurkowski and others 2008; Walker and others 2017) and therefore likely had thinner pre-fire SOL than spruce stands which are generally located at wet and cold landscape positions. In this study, we did not assess burn depth of the SOL and therefore could not reconstruct pre-fire SOL depth and total or proportional combustion. However, we found that post-fire SOL depth of deciduous trajectories did not differ among pre-fire tree compositional dominance classes, suggesting that post-fire SOL representative of seedbed conditions is a more important driver of deciduous recruitment and success than total or proportional combustion.

Historically, North American boreal forests have acted as a net C sink, accumulating C from the atmosphere over numerous fires cycles or centuries (Chapin and others 2006; Bond-Lamberty and others 2007; Kelly and others 2013). With the continued intensification of wildfires, these ecosystems could switch from net C sink to a net C source via deep burning of the SOL (Walker and others 2019). However, deep burning and the associated establishment of deciduous forests also impacts the boreal net ecosystem C balance and can result in fourfold net increase in C storage over the 100-year disturbance cycle (Mack and others 2021). Our results show that once deciduous trees become established, even at low densities in spruce stands, their reproductive strategies frequently enable them to dominate recovery after wildfire, thereby setting the stand on an alternative successional trajectory that is likely to persist across multiple fire cycles in boreal Alaska.

Moreover, although deciduous stands are generally considered resistant to burning (Parisien and others 2011; Girardin and others 2013; Rogers and others 2015), our findings suggest that when they do burn, their asexual regeneration strategies promote continued deciduous dominance. Lower resilience of spruce than deciduous stands to wildfire could leave spruce forests vulnerable to replacement by deciduous forests, especially as wildfires become more frequent and intense with warming over the coming decades (Foster and others 2022a). This switch to deciduous dominance not only alters the pattern of boreal forest C storage (Alexander and Mack 2016; Mack and others 2021), but could cool the atmosphere through higher albedo (Rogers and others 2013) and substantially decrease wildfire activity and risk (Parisien and others 2011; Girardin and Terrier 2015).

Critical next steps for understanding the persistence of deciduous boreal forests include assessing their resilience to other disturbances (for example, insect outbreaks and drought) and determining the drivers of fire occurrence and severity in these forests. As boreal forests store upwards of 30% terrestrial C, understanding these drivers is not only key to predicting the future structure and function of boreal forests but also for quantifying the role of fire in the global C cycle and its feedbacks to climate change.
