Abstract

Background/objective Recent studies observed an association between increased serum uric acid (SUA) levels and renal damage in lupus. However, the predictive value of UA for the development of long-term renal dysfunction in lupus nephritis (LN) is still unknown. The aim of this study was to evaluate if SUA may be a predictor of long-term renal outcome in LN.

Methods Eighty biopsy-proven LN patients > 7 years of follow-up were selected. SUA levels were measured in sera stored at -70°C . All patients had serum stored from LN baseline, and 32 also had stored serum from 6 and 12 months after LN. Renal outcome was addressed after 7 years of follow-up to determine if SUA could be a predictor of long-term renal outcome. A good long-term renal outcome in 7 years was defined as a creatinine clearance (CrCl) ≥ 90.0 mL/min/1.73 m², and poor if $\text{CrCl} < 90$ mL/min/1.73 m². Patients were divided in two groups according to the renal outcome to assess whether SUA levels at different time points of follow-up could differentiate such groups. An ROC curve was plotted to assess accuracy.

Results SUA levels at baseline and 6 months were not able to differentiate good from poor long-term renal outcomes in LN (respectively $p = 0.37$, $p = 0.28$), but at 12 months ($p = 0.02$), they could clearly differentiate the two groups. ROC curve (12 months) accuracy was 0.76. SUA cutoff was 6.05 mg/dL (sensitivity = 0.67, specificity = 0.89, positive predictive value = 0.85, negative predictive value = 0.73).

Conclusion SUA levels < 6.05 mg/dL at 12 months of follow-up is a predictor of good long-term renal outcome in lupus nephritis.

Key Points • Previous studies reported an association between increased serum uric acid level and short-term renal damage in lupus patients.

- The predictive value of serum uric acid for the development of long-term renal dysfunction in lupus nephritis was never assessed.
- At 12 months of follow-up serum uric acid clearly differentiated good from poor long-term renal outcome in lupus nephritis.
- SUA level < 6.05 mg/dL at 12 months of follow-up was a predictor of good long-term renal outcome in lupus nephritis.

Introduction

Hyperuricemia has been reported to be associated with chronic kidney disease (CKD) in several clinical conditions, and recent studies also observed an association between increased serum uric acid (SUA) levels and renal damage in lupus [1, 2]. Previous cross-sectional studies detected that higher levels of SUA in systemic lupus erythematosus (SLE) patients were closely related to renal involvement [3–5]. In fact, Liu et al. showed a higher prevalence of increased uric acid (UA) in lupus nephritis (LN) patients with CKD (stages 1–3) mostly due to renal under-excretion [3].

Lupus nephritis is a critical condition that affects up to 60% of SLE patients, and despite recent treatment improvements, 30% of patients still experience some degree of renal impairment in the long-term follow-up [2, 6]. Good predictors of long-term outcome are therefore needed to better assess the severity and provide an accurate treatment guidance [6]. In fact, the effectiveness of treat-to-target strategies in rheumatoid arthritis [7] and SLE [8] have driven the search for these prognostic parameters for other rheumatic diseases.

Until now, 24 h proteinuria (24 h PTU) has been considered the best single predictor of long-term (7 years) renal outcome in lupus patients [9, 10]. Recently, our group extended this observation demonstrating that 24 h PTU is also valid for an ethnically diverse group of SLE patients and for those with more severe LN [11]. Importantly, these studies also showed that the addition of other variables commonly used in LN response criteria, such as creatinine and hematuria, did not improve the predictive value of 24 h PTU [9–11].

Regarding SUA, one previous study in SLE patients reported an association between increased SUA levels and short-term renal damage [1], but there are no data concerning the predictive value of SUA for the development of long-term renal dysfunction in LN. Therefore, the aim of the present study was to evaluate if SUA levels could be considered a predictor of long-term renal outcome in patients with lupus nephritis.

Methods

Patient selection and study design

A total of 108 biopsy-proven LN patients with at least 7 years of available longitudinal follow-up data at the Rheumatology Division of our tertiary University Hospital were consecutively selected for this study. All enrolled patients had biopsy-proven LN and met ACR criteria for the diagnosis of SLE [12]. Data were obtained in a 3-month interval using a standardized electronic database protocol established in 2000 that included data on demographics, clinical and laboratory findings, and treatments. Serum UA at biopsy and follow-up was

measured using a $-70\text{ }^{\circ}\text{C}$ stored biorepository sera that was previously validated.

Twenty-seven patients were excluded: seven due to missing relevant data, six due to the development of early end-stage renal disease (ESRD) that required dialysis in the first year after the nephritis onset, and 14 due to lack of stored sera during nephritis flare. Patients who were diagnosed with ESRD at any time after the first year of follow-up were included. Eighty patients with biopsy-proven LN were enrolled for this study.

All persons gave their informed consent prior to their inclusion in the study. No patient data was included in this manuscript. The study was performed in accordance with the ethical standards laid down in the 1964 Declaration of Helsinki and its later amendments and was approved by the Local Ethics committee.

Validation of stored serum UA

The serum UA analysis was performed using a biorepository serum stored at $-70\text{ }^{\circ}\text{C}$. Since samples were stored for several years, we performed a laboratorial validation analysis with five frozen samples that had SUA assessed at the same time of biorepository blood collection. A high correlation was observed between SUA results obtained at the time of blood collection and in $-70\text{ }^{\circ}\text{C}$ stored sera ($r = 0.99$ $p < 0.05$), with a variation coefficient of 12% which allowed us to use these frozen samples in the present evaluation.

Definition of long-term renal outcome

A good long-term renal outcome was defined as a creatinine clearance (CrCl) $\geq 90\text{ mL}/\text{min}/1.73\text{ m}^2$, and conversely, a poor long-term renal outcome was defined as a $\text{CrCl} < 90\text{ mL}/\text{min}/1.73\text{ m}^2$ in 7 years. Creatinine clearance was estimated using the Modification of Diet in Renal Disease (MDRD) index that defines normal renal function as a MDRD $\text{CrCl} \geq 90.0\text{ mL}/\text{min}/1.73\text{ m}^2$ and defines mild decrease of renal function as a MDRD CrCl between 60 and $89\text{ mL}/\text{min}/1.73\text{ m}^2$ [2, 13].

Statistical analysis

SUA and creatinine clearance were evaluated at baseline, after 6 months, 12 months, and at 7 years of follow-up. Anti-dsDNA antibodies, serum albumin and Systemic Lupus Erythematosus Disease Activity Index (SLEDAI) score were assessed only at baseline. Renal flares were defined as significant increase in PTU levels ($\text{PTU} > 500\text{ mg}/24\text{ h}$ if previously negative or $\text{PTU} > 3\text{ g}$ if previously $> 500\text{ mg}/24\text{ h}$). Absolute values were used for PTU, CrCl , and albumin. Anti-dsDNA was considered only as present or absent. The ability of SUA at these different time points to predict a good long-term renal outcome (defined as $\text{CrCl} \geq 90\text{ mL}/\text{min}/1.73\text{ m}^2$) at 7 years

was assessed. The same analysis was also performed with CrCl ≥ 60 mL/min/1.73 m² cutoff. A multivariate analysis (multiple logistic regression) was also performed to understand the independence of variables (only variables with $p < 0.05$ were imported into the model).

The patients were divided in two groups according to the renal outcome: good outcome (CrCl ≥ 90.0 mL/min/1.73 m² in 7 years) and poor outcome (CrCl < 90 mL/min/1.73 m² in 7 years) to assess whether SUA levels at different time points of follow-up were able to differentiate such groups. Mann–Whitney, Student's *t* test, and Fisher test were used for the comparisons. Correlations between SUA and CrCl at different set time points were calculated with Spearman test.

A receiver operating characteristic (ROC) curve of SUA was plotted to assess its accuracy (AUC), sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and confidence interval 95% (CI) in predicting long-term outcome. The SUA cutoff was defined using the Youden index.

All analyses were performed using SigmaStat software. Statistical significance was set as $p < 0.05$.

Results

Demographic, clinical, and histological features

Of the total LN patients ($n = 80$), 71 patients (88.75%) were women and 35 patients (43.75%) were non-Caucasian. The mean age was 29.85 ± 9.37 years old. At baseline, LN patients had a mean SCr of 1.75 ± 1.3 mg/dL, MDRD CrCl of 68.16 ± 43.4 mL/min/1.73 m², PTU of 5.7 ± 4.7 g/24 h, albumin concentration of 2.4 ± 0.8 g/dL, and a mean SLEDAI of 9.5 ± 4.2 . Almost two thirds had positive anti-dsDNA ($n = 53$, 66.25%), 58 SLE patients (72.50%) had CrCl < 90 mL/min/1.73 m², and 38 SLE patients (47.50%) had CrCl < 60 mL/min/1.73 m², inferring a severe subset of patients. The distribution of histological classes among studied patients was as follows: class II (6.25%), class III–IV (56.25%), and pure class V (36.25%) (Table 1).

At the end of the 7 years follow-up, a total of 33 patients (41.25%) had a good long-term outcome of a CrCl ≥ 90 mL/min/1.73 m², 31 patients (38.75%) had a CrCl < 60 mL/min/1.73 m², 18 patients (22.5%) were on dialysis, and 7 patients (8.75%) died (primarily due to infections).

Baseline data and long-term renal outcome

To investigate if long-term renal outcome could be predicted by baseline data, LN patients were divided into two groups (CrCl at 7 years ≥ 90.0 mL/min/1.73 m² and < 90 mL/min/1.73 m²). Most of the baseline data were comparable between groups: serum UA (7.25 ± 4.75 vs. 6.43 ± 2.92 mg/dL; $p = 0.35$), 24-h PTU (6.70 ± 5.7 vs. 5.06 ± 3.85 ; $p = 0.13$), serum

Table 1 Baseline features of patients with lupus nephritis

| Baseline features | Total $n = 80$ |
|--|------------------|
| Female, n (%) | 71 (88.75) |
| Caucasian, n (%) | 45 (56.25) |
| Age (mean \pm SD) | 29.85 ± 9.37 |
| Creatinine serum (mg/dL) (mean \pm SD) | 1.75 ± 1.3 |
| Creatinine clearance (mL/min/1.73 m ²) (mean \pm SD) | 68.16 ± 43.4 |
| Proteinuria (g/24 h) (mean \pm SD) | 5.7 ± 4.7 |
| Serum albumin (g/dL) (mean \pm SD) | 2.4 ± 0.8 |
| Complement C3 (mg/dL) (mean \pm SD) | 83.5 ± 9.1 |
| SLEDAI score (mean \pm SD) | 9.5 ± 4.2 |
| Anti-dsDNA positive, n (%) | 53 (66.25) |
| WHO class II, n (%) | 5 (6.25) |
| WHO class III/IV, n (%) | 45 (56.25) |
| WHO pure class V, n (%) | 29 (36.25) |

albumin (2.23 ± 0.80 vs. 2.52 ± 0.92 g/dL; $p = 0.13$), complement C3 (78.44 ± 35.3 vs. 65.5 ± 26.2 mg/dL; $p = 0.08$), positive anti-dsDNA (66% vs. 66%; $p = 0.94$), and SLEDAI scores (9.06 ± 3.91 vs. 9.85 ± 5.39 ; $p = 0.43$). Only serum creatinine (1.29 ± 0.81 vs. 2.06 ± 1.60 mg/dL; $p = 0.013$) and CrCl (83.44 ± 47.26 vs. 57.42 ± 37.36 mL/min; $p = 0.007$) were statistically different at baseline among groups (Table 2).

Assessing renal flares

The analysis of renal flares revealed that both groups (CrCl at 7 years ≥ 90.0 and < 90 mL/min/1.73 m²) exhibited a similar number of flares during follow-up (1.60 ± 0.92 vs. 1.47 ± 0.61 , $p = 0.45$).

Performance of SUA levels at baseline, 6 months, and 12 months

SUA levels within the first year of follow-up were assessed in both groups (CrCl at 7 years ≥ 90.0 and < 90 mL/min/1.73 m²). Figure 1 shows that SUA levels were not able to differentiate long-term renal outcomes at baseline (7.25 ± 4.75 vs. 6.43 ± 2.92 mg/dL; $p = 0.37$), nor at 6 months (4.97 ± 2.12 vs. 5.86 ± 2.35 mg/dL; $p = 0.28$). However, at 12 months, SUA was able to differentiate good from poor long-term renal outcomes (4.66 ± 2.12 vs. 6.51 ± 2.45 mg/dL; $p = 0.02$).

The same analysis was performed using a less stringent CrCl cutoff at 7 years of ≥ 60.0 and < 60 mL/min/1.73 m². Using this less stringent cutoff, SUA levels were not able to differentiate good from poor long-term renal outcomes at baseline (6.68 ± 4.22 vs. 6.88 ± 3.04 mg/dL; $p = 0.82$), nor at 6 months (5.21 ± 1.98 vs. 5.91 ± 2.72 mg/dL; $p = 0.42$). However, at 12 months, SUA was able to differentiate good

Table 2 Comparison of clinical and laboratorial features between good (MDRD \geq 90 mL/min/1.73 m²) and poor (MDRD < 90 mL/min/1.73 m²) long-term renal outcome groups

LN lupus nephritis, SD standard deviation, *n* number, SUA serum uric acid, SLEDAI Systemic Lupus Erythematosus Disease Activity Index, IS immunosuppressive drugs

**P* < 0.05

from poor long-term renal outcomes (5.01 \pm 2.19 vs. 6.83 \pm 2.61 mg/dL; *p* = 0.03).

The multivariate analysis could not demonstrate independency of any variable pointed in the univariate analysis. Due to the sample size, the power of this analysis is low.

ROC curve at 12 months

The ROC curve with the higher AUC (the 12 months curve) demonstrated a good accuracy (AUC = 0.76, *p* < 0.05) in predicting long-term renal outcome, Fig. 2. The cutoff for SUA was 6.05 mg/dL, with a sensitivity of 0.67 (CI 95% =

0.44–0.84, *p* < 0.05), specificity of 0.89 (CI 95% = 0.68–0.97, *p* < 0.05), positive predictive value of 0.85, and negative predictive value of 0.73. The cutoff that maximized the sensitivity and specificity was 6.05 mg/dL.

Correlations between SUA and current CrCl

The SUA is inversely correlated with the current CrCl at 12 months of follow-up (*r* = -0.46, *p* = 0.004). However, the same analysis did not show correlation between SUA and CrCl at baseline (*r* = -0.19, *p* = 0.23) and 6 months of follow-up (*r* = -0.19, *p* = 0.90).

Fig. 1 Comparisons between serum uric acid (mg/dL) at baseline, 6 months, and 12 months follow-up of lupus nephritis in patients with good and poor long-term renal outcome

Using the SUA cutoff of 6.05 mg/dL

Dividing the patients into two groups using the SUA cutoff of 6.05 mg/dL at 12 months, it was possible to differentiate in a long term (7 years of follow-up): the creatinine levels (1.24 ± 2.20 vs. 4.48 ± 3.88 mg/dL, $p = 0.007$), the CrCl (117.10 ± 55.95 vs. 41.63 ± 41.65 mL/min/1.73 m², $p = 0.00004$), the creatinine increase (delta -0.08 ± 2.41 vs. 2.94 ± 4.20 , $p = 0.02$), and SLICC damage index (1.28 ± 1.27 vs. 2.46 ± 1.45 , $p = 0.02$) at the end of follow-up.

As SUA was moderately correlated with the CrCl at 12 months of follow-up, we performed a separated analysis excluding patients with moderate/severe CrCl reduction (MDRD CrCl < 60 mL/min/1.73 m²) to understand if this elevated SUA was not only predicting patients who were already in CKD at 12 months. In this separated analysis, SUA at 12 months remained a good predictor of long-term CrCl (120.16 ± 55.2 vs. 75.65 ± 34.60 mL/min/1.73 m², $p = 0.02$) in the subgroup of patients with normal/mild decrease in MDRD.

Fig. 2 Receiver operating characteristic curve of uric acid at 12 months of follow-up. ROC receiver operating characteristic curve. Area under the curve (AUC) = 0.76, sensitivity = 0.67 (confidence interval 95% = 0.44–0.84, $p < 0.05$), specificity = 0.89 (confidence interval 95% = 0.68–0.97, $p < 0.05$), positive predictive value (PPV) = 0.85, and negative predictive value (NPV) = 0.73

Discussion

This is the first study to demonstrate that serum uric acid at 12 months of follow-up can predict long-term renal outcome in lupus nephritis.

In the present study, biopsy-proven LN was an inclusion criterion allowing a more accurate definition of renal involvement related to disease and not to other conditions [14], which were not considered in previous reports [1–3]. In addition, a long-term follow-up is required to define predictors of CKD [9, 15] since short-term assessment is not reliable to define renal survival, as demonstrated in the original National Institute of Health trial [16].

The balanced representation of severe and non-severe nephritis histological classes was important to assure a more precise calculation of predictive values. In fact, previous reports have demonstrated that proliferative classes had worse outcome [9, 15, 17]. Of note, the possible influence of nephritis flares during follow-up on renal outcome [18] was minimized herein by the fact that patients with poor and good outcomes exhibited comparable number of nephritic flares.

The results of our study indicate that uric acid is stable after years of storage at -70 °C, with a high correlation between

SUA results obtained at the time of blood collection and in stored sera ($r = 0.99$; $p < 0.05$). Validation was essential since some previous studies [19, 20] demonstrated that serum uric acid concentrations were unstable after 48 h of storage at $-4\text{ }^{\circ}\text{C}$, whereas others observed a minor decrease in uric acid concentration over time which was neither statistically nor clinically significant [21].

We confirmed previous report that baseline estimate of glomerular filtration rate is an important parameter associated with long-term renal survival in lupus [22, 23]. However, in the present study, baseline SUA and 6 months SUA was not associated with long-term renal outcome nor current MDRD CrCl, despite the known association of SUA levels and renal function [24, 25]. This discrepancy may be explained by the fact that several SUA interferences may be present during the induction treatment such as hypertension, weight gain, and some drugs such as diuretics, antiproteinuric, and immunosuppressive drugs.

The novel demonstration that SUA levels at 12 months is a long-term predictor of renal outcome in SLE is in line with the reported association between increased SUA levels and progression of chronic kidney disease in non-CKD individuals [26–28]. In fact, a recent study in SLE has also detected an association between increased baseline SUA levels and higher scores of renal damage in a short-term follow-up (3 years) [1].

Experimental data have demonstrated that increased uric acid levels can both be a marker and cause/accelerate renal disease [29]. Whether elevated SUA is only a marker of subclinical chronic kidney disease or also a risk factor for renal dysfunction requires further studies. Notwithstanding that, persistence of hyperuricemia seems to be more relevant in the long run than in the initial presentation, suggesting that irreversible subclinical renal damage may underlie hyperuricemia at 1-year follow-up.

Reinforcing this possibility, a retrospective study analyzing 177 renal biopsy-proven LN showed that the hyperuricemic group had higher pathological kidney scores (including activity, chronicity, and tubulointerstitial impairment) than those without hyperuricemia [30]. Accordingly, in vitro and experimental studies have demonstrated that SUA can lead to tubular injury, endothelial dysfunction, oxidative stress, and intrarenal inflammation [31].

The retrospective study design is a limitation and may have hampered the accurate evaluation of some confounding factors such as diet, alcoholism, weight, drugs, and clinical conditions (hypertension, diabetes, and dyslipidemia) that may interfere in SUA levels [32]. The small sample size also precluded us from having a definitive conclusion whether SUA is independently related to the long-term renal outcome in LN patients or it is a reflex of underlying renal damages. Hyperuricemia is a known a risk factor for CKD, and these findings may be not only specific for LN patients but also useful for the management of their condition. Independent of the cause, persistent elevation of SUA seems to be relevant for long-term renal survival.

In conclusion, SUA level $< 6.05\text{ mg/dL}$ at 12 months is a predictor of good long-term renal outcome in lupus nephritis. Whether elevated SUA is only a marker of subclinical chronic kidney disease or also an additional risk factor for renal dysfunction in lupus patients that will require intervention to decrease its levels remains to be determined.
