Abstract This research aims at elucidating the greenhouse gas emissions and its related soil microbial properties in continuously flooded or intermittently drained paddy soils in Japan and Indonesia. The study in Japan comprises alluvial soil and peat, cultivated to rice variety *Nipponbare*, while in Indonesia comprised alluvial soil cultivated to rice variety *Siam Pandak*. Intermittent drainage was performed to half number of the plot in 6 days interval, starting at tillering or heading stage of rice, while the other half number of plot was kept flooded as control. The experiments were carried out to follow the randomized block design with three replications. Gas samples were taken in weekly basis, except during the treatments (i.e., every 2 days interval) and analyzed for methane (CH_4) and nitrous oxide (N_2O) concentrations. Soil samples were and analyzed for the population of methanogenic bacteria, denitrifiers, methane production and consumption potentials, and methanogenic substrate. Plant growth parameters were also observed. The results showed that intermittent drainage significantly reduced greenhouse gas emission from paddy soil of Indonesia and Japan without significant changes in soil microbial population. The reductions of greenhouse emission from Japanese peaty and alluvial paddy soil due to intermittent drained were about 32

and 37%, respectively. Meanwhile, the reductions in greenhouse gas emission from alluvial soil of Indonesia due to intermittent drainage were very similar to that of in Japan, i.e., average about 37%. This suggests that intermittent drainage can be an appropriate technology option to reduce the greenhouse gas emission from paddy soil in Japan and Indonesia.

Keywords Intermittent drainage · Methane (CH_4) · Nitrous Oxide (N_2O) · Methanogenic bacteria · Denitrifiers

Introduction

At the 15th Conference of Parties of United Nation Forum on Climate Change, 25 and 26% reductions of greenhouse gas emissions were aimed by Indonesia and Japan, respectively (<http://news.bbc.co.uk/2/hi/science/nature/82410>). To achieve the target, both countries have been attempting to invent, search, and implement technologies relevant to reductions of greenhouse gas emissions from contributing sectors.

Paddy field is considered as a significant source of methane (CH_4) and nitrous oxide (N_2O) emissions, two greenhouse gases, which have attracted considerable attention during the last decades because of their contribution to global warming (Harris et al. 1985; Bouwman 1990). Methane is produced by methanogens during organic matter decomposition, under an environment where the oxygen (O_2) and sulfate (SO_4^{2-}) are scarce (Bouwman 1990; Cicerone and Oremland 1988). Nitrous oxide is produced microbiologically during the anaerobic conditions of paddy soils (IPCC 2001; Mosier et al. 1996). The development of efficient irrigation water management would minimize the emission of these gases from paddy soil.

Intermittent drainage has been proposed as a recommended water management to reduce CH₄ emission from paddy soil (Boundia et al. 1996), intermittent drainage is also needed to remove hazardous organic compound in rice rhizosphere and to increase the availability of some nutrients (Miyake 1982). However, Nugroho et al. (1994) reported that intermittent drainage did not affect CH₄ emission or, inversely, some time emitted more CH₄ compared to continuously flooded soils in Indonesia. In case of N₂O, draining paddy soil prior to harvesting increased N₂O emission (Tsuruta et al. 1995).

There is a lack of information on the effect of intermittent drainage on the CH₄ and N₂O emissions from Indonesian paddy fields. The processes controlling the dynamics of CH₄ and N₂O under intermittent drainage are also poorly understood. Therefore, this research aims at elucidating the greenhouse gas emissions and its related soil microbial properties in continuously flooded or intermittent drained paddy soils in Japan and Indonesia.

Materials and methods

The study in Japan comprised peat and alluvial soils, while in Indonesia comprised alluvial soil. The soil characteristics are given in Table 1.

Site in Indonesia situated in catchments area of Barito River and its sub-catchments area comprised alluvial soil. Peat was taken from Togane city, situated in the backswamp of natural sand dune formed by the Pacific Ocean of Chiba Prefecture, Japan. The peat layers are buried at the depth of 50 cm because of the soil dressing practice in the area for long time (Dr. T. Anzai, Chiba Prefec. Res. Station, Pers. Commun.), the area is now used for rice and vegetable cultivation. Meanwhile, an alluvial soil in Kuzukuri city, located on the beach of the Pacific Ocean site in Chiba Prefecture, Japan was also taken. This area is dominated by sandy soil and cultivated to rice and vegetable crops (Fig. 1).

Experiment in Indonesia

To study the effect of water management on CH₄ and N₂O emissions in Indonesia, six plots each measuring 4 m × 5 m established at a farm in Sungai Rangas, South Kalimantan, by constructing a risen soil bed in between the

plots. The plots were plowed up to 25 cm depth at late rainy season 2004 and arranged to follow randomized block design with three replications. Chopped rice straw equivalent to 4 ton ha⁻¹ was incorporated into the soil. Basal fertilizers in the form of urea, SP-36, and KCl were applied at rate of 100 kg ha⁻¹ N, P₂O₅ and K₂O. Eh electrode then inserted in the soil up to 5 cm depth.

All pots were planted with rice seedling local variety *Siam Pandak*, which had been nursed for 21 days. In each plot, one hill containing three seedlings was transplanted spacing at 25 cm × 25 cm. At the same time, Eh electrodes were inserted into 5, 10, or 15 cm soil depths. The intermittent drainage in the three plots was conducted for 7 days interval, starting at the heading stage of rice until harvesting. The other three plots were kept flooded as control treatment. Soil samples were taken from three soil depths (i.e., 0–5, 5–10, 10–15, and 15–20 cm) at harvesting and used for determination of methanogenic and denitrifying bacterial population. The same plots were again used in dry season of year 2004 and rainy season of 2005. All materials and methods are the same with previous crop season, except that rice variety *Margasari* was grown at rainy crop season and microbial determinations were excluded.

Gas samples were collected in monthly bases until harvesting, except during the intermittent treatment when the gas samples were taken in every 2 days. Methane and N₂O fluxes were determined with chamber method. A chamber (50 cm wide, 50 cm length, and 50 or 100 cm height) was gently placed in order to enclose four rice plants. Gas samples were taken through capillary tube on the top of chamber with plastic syringe. Methane and N₂O concentrations were determined by a gas chromatograph (Shimadzu, GC-7A) equipped with FI or EC detectors, a gas sampler with 1 ml volume tube and an integrator (Shimadzu, C-R2A). The working conditions for the gas chromatography were as that described by Hadi et al. (2005).

The flux was calculated from temporal increase of the gas concentration inside the chamber with time. The emissions of greenhouse gases were calculated by integrating the fluxes with the duration of experiment (Yagi, 1997). Global warming potential (GWP) was calculated based on formula:

$$\text{GWP(gCO}_2\text{--C equivalent)} = \text{CO}_2 \text{ emission} + 23 \\ \times \text{CH}_4 \text{ emission} + 296 \\ \times \text{N}_2\text{O emission.}$$

The population of methanogenic bacteria was estimated by method described by Asakawa et al. (1997) with some modifications. Briefly, 5 ml of soil was taken into a 100 ml BOD bottle containing 45 ml ringer's solution under O₂-free N₂. Sample was then shaken for 15 min on mechanical shaker. Ten fold dilution series with five replicates were prepared, stopping at 10⁻⁷. Using sterile automatic pipette, 1 ml appropriate dilution was transferred into incubation tube (serum tube of 18 mm × 180 mm) containing 9 ml medium. The tubes were then placed in the dark at 25°C for 8 weeks. Each tube was examined for growth of methanogens at 4 and 8 weeks of incubation. The growth of each tube was recorded and the population of methanogens was then calculated by multiplying the dilution factor.

The population of denitrifying bacteria was counted by most probable number (MPN) method as described by Alexander (1982). In this method, 9 ml of medium was placed in incubation tube (No. 14). Twenty-five tubes were prepared for each sample. A Durham vial was withdrawn upside down. The tubes were then autoclaved at 121°C for 15 min. Using sterile automatic pipette, 1 ml of the appropriate dilution was inoculated after the medium was allowed to cool. The tubes were then placed in the dark at 30°C for 8 weeks. The positive tubes (i.e., tubes with gas bubble) were considered and the number of denitrifiers was computed on MPN tables.

Experiment in Japan

To compare the CH₄ and N₂O emission in alluvial soil with other soil, 2 kg of peat and 4 kg of alluvial soils were filled in plastic pots measuring 0.02 m⁻² (16 cm diameter, 20 cm height) in Japan. The pot arrangements and cultivation practices were the same as for previous experiment. After rice seedling variety *Nipponbare* were transplanted, the pots were placed in a glass house. The pots were flooded by daily watering to keep water level at 2–5 cm

depth until the time of treatment. Three pots of each treatment were prepared and used for gas and Eh measurement. Another three pots were prepared and kept in the same manner as for gas measurement and used for the determination of methane production and oxidation potentials and methanogenic bacterial population. The drainage was performed for 6 days by opening the stop cock in the bottom of the pot. Drained water was collected and analyzed for organic carbon content.

Methane and N₂O fluxes were determined with the same method as previously described. Methane production potential was estimated by incubation method described by Chithaisong et al. (1996). Methane oxidation activity was estimated by using propylene alternative substrate method (Watanabe et al. 1997). The plant root and plant above ground biomass and grain yield were also determined.

Statistical analyses

All statistical analyses were performed using the “SYSTAT 8.0” statistical package (SPSS 1996). The frequency distributions of all data were first tested for normality using Lilliefors Test. If normally distributed, differences between treatment were determined by analysis of variance (ANOVA) and least significant differences (LSD) test. All statistical considerations were based on *P* < 0.05 significant level.

Results and discussion

The averaged CH₄ emission from intermittently drained plot in Indonesia was 1,384 kg C ha⁻¹ season⁻¹, while from continuously flooded plot was 1,137 kg C ha⁻¹ season⁻¹. The averaged N₂O emissions from those plots were 1.97 and –19.7, respectively. The CO₂ emissions from both treatments were similar. In total (years 2004–2005),

Table 2 Total CH₄, N₂O, and CO₂ emissions, and their global warming potential from continuously flooded (CF) and intermittently drained (ID) plots in South Kalimantan

15–20	126.5 ^A (103.0)	20.7 ^a (24.3)	0.2 ^A (0.2)	0.4 ^a (0.7)

Numbers followed by the same capital letter are not different between depth in continuously flooded treatment, while the numbers followed by the same small letter are not different between depths in intermittent drainage treatment according to Fisher's LSD test

the reduction in global warming potential from paddy field of Indonesia due to water management was about 37% (Table 2). This indicates that water management can be an efficient technique to reduce greenhouse gas emission from Indonesian paddy field.

Water management did not significantly affect the population of either methanogenic bacteria or denitrifying bacteria. Only soil depth affected the population of denitrifying bacteria, with the lowest number in the lowest position of sample source (i.e., 15–20 cm soil depth) (Table 3). Luck in statistical differences was probably due to the high variability of bacterial data. Similar reason can be also applied to the gas data obtained from field experiment (Table 2). This problem has been also encountered by other researchers (Moore and Knowles 1990; Furukawa et al. 2005).

Data on Eh showed that the Eh in intermittently drained plot were higher than that of continuously flooded plot particularly at late stage of rice growth (Fig. 2). This can be the reason for the reduction in CH₄ emission from intermittently drained paddy field. High Eh values prevent CH₄ formation by methanogenic bacteria (Asakawa et al. 1997; Yoshida 1984). The fact that N₂O formation was not promoted in intermittently drained plot indicates that the N₂O was not formed during nitrification.

**Fig. 2** Redox potential (mV) at 5, 10, and 15 cm soil depth of continuously flooded (CF) and intermittently drained (ID) paddy field in Indonesia during dry crop season of Year 2005. Arrow indicates drainage period of ID treatment

The reduction of greenhouse emissions from Japanese peaty paddy soil due to intermittent drainage was about 32%, though the total N₂O emissions were similar in both treatments. The reduction in greenhouse gas emission from alluvial soil of Japan was similar to that of Indonesia, i.e., 37%. The N₂O emissions were 3.4 and 4.6 kg N ha⁻¹ season⁻¹ for corresponding treatments (Table 4). These results revealed that intermittent drainage can be applied in

Table 4 Methane and N₂O emissions from paddy soil in Japan

Soil Type	Treatment	CH ₄ (kg C ha ⁻¹ season ⁻¹)	N ₂ O (kg N ha ⁻¹ season ⁻¹)	GWP (kg C-CO ₂ eq ha ⁻¹ season ⁻¹)	% Reduction
Alluvial	CF	634.2 ^a	3.4 ^a	15,378	Base line

% Reduction = (GWP of CF – GWP of ID)/GWP of CF

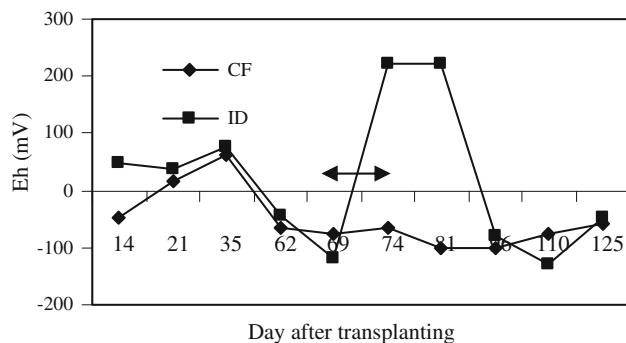

Fig. 3 Changes in redox potential of peaty paddy soil in Japan. *CF* continuously flooded and *ID* intermittent drainage. Arrow indicates drainage period for ID treatment

order to achieve targets of greenhouse gas emission reductions of Japan and Indonesia.

Similar to experiment in Indonesia, the redox potential increased rapidly soon after drainage of peaty paddy soils of Japan when both CH₄ production and oxidation potentials were suppressed remarkably (Fig. 3). Carbon leached out from peat soil (166 mg C m⁻²) was about one-tenth of that in sandy soil (1562 mg C m⁻²). These results suggested that the reduction of emitted methane due to substrate leaching was less important in the peat soil compared to sandy soil. This indicates that the reduction in CH₄ emissions was due to the decreases in CH₄ production since the emission is the balance between CH₄ production and oxidation (Conrad 1995). High redox potentials limit the CH₄ production activity by methanogens, hence reduced the CH₄ emissions during intermittent drainage.

Conclusions

It could be concluded that intermittent drainage significantly reduced the global warming potential of paddy soil of Japan and Indonesia without significant changes in soil microbial population or plant yield. The reductions were between 32% in peat and 37% in alluvial soils, which were

above the reduction targets of both countries. This suggests that intermittent drainage can be an appropriate technology option to reduce the greenhouse gas emission from paddy soil in Japan and Indonesia.
