**Abstract** Data from long-term monitoring sites are vital for biogeochemical process understanding, and for model development. Implicitly or explicitly, information provided by both monitoring and modelling must be extrapolated in order to have wider scientific and policy utility. In many cases, large-scale modelling utilises little of the data available from long-term monitoring, instead relying on simplified models and limited, often highly uncertain, data for parameterisation. Here, we propose a new approach whereby outputs from model applications to long-term monitoring sites are upscaled to the wider landscape using a

simple statistical method. For the 22 lakes and streams of the UK Acid Waters Monitoring Network (AWMN), standardised concentrations (Z scores) for Acid Neutralising Capacity (ANC), dissolved organic carbon, nitrate and sulphate show high temporal coherence among sites. This coherence permits annual mean solute concentrations at a new site to be predicted by back-transforming Z scores derived from observations or model applications at other sites. The approach requires limited observational data for the new site, such as annual mean estimates from two synoptic surveys. Several illustrative applications of the method suggest that it is effective at predicting long-term ANC change in upland surface waters, and may have wider application. Because it is possible to parameterise and constrain more sophisticated models with data from intensively monitored sites, the extrapolation of model outputs to policy relevant scales using this approach could provide a more robust, and less computationally demanding, alternative to the application of simple generalised models using extrapolated input data.

## Introduction

Headwater catchments incorporate a major proportion of the total stream length of many river systems

(Bishop et al. 2008), and are intimately linked to the landscapes they drain. Monitoring in headwater systems thus provides a uniquely long-term insight into the biogeochemical and ecological processes that govern natural ecosystems, their condition, and their response to anthropogenically imposed change. Long-term monitoring is, however, challenging to maintain in the face of uncertain funding, changing policy priorities, and reliance on the sustained commitment of small numbers of individuals (Nisbet 2007). While the importance of monitoring is increasingly recognised by scientists and policymakers, there is often little connection between information obtained from detailed catchment studies, and the whole-landscape (national or international) scale at which policy decisions must be taken. This problem is accentuated where catchment studies have developed on an individual, ad hoc basis, often at scientifically interesting but atypical locations, and without consistency of measurements or methods between sites. Recognition of this issue has led, in some countries, to the establishment of centrally coordinated national monitoring networks. In the UK, 22 existing and new monitoring catchments were combined into the UK Acid Waters Monitoring Network (Monteith and Evans 2005), with standardised measurements and protocols, consistent sampling dates, and centralised analyses providing a greater degree of representivity and comparability (Patrick et al. 1991). Similar networks have been established in other countries. such as the 14 sites of the GEOMON network in the Czech Republic (Fottová 1995). At the international level, data from sites within national monitoring programmes have been combined into international programmes, with the aim of providing scientific support to decision-making at this scale. For example, the UNECE Convention on Long-range Transboundary Air Pollution (CLRTAP, Sliggers and Kakebeeke 2004), which is responsible for international agreements to abate atmospheric sulphur, nitrogen, ozone and particulates, established a number of International Cooperative Programmes (ICPs) to collate national monitoring data, including (for catchments) the ICP on Integrated Monitoring and ICP Waters (e.g. Skjelkvåle et al. 2005).

Despite these drives towards integration and aggregation of monitoring, the gap between monitoring and decision-making remains. Taking both the UK and CLRTAP examples, decisions on pollution abatement are ultimately made on the basis of mapped estimates of ecosystem sensitivity and exposure to damaging pollutant levels. These are derived from calculated (static) critical loads models, or more recently from dynamic biogeochemical models (Hettelingh et al. 2008). In either case, the approach used is to combine limited measurement data with extrapolated parameter values, and then to apply the model to very large numbers of locations. In the UK, for example, freshwater critical loads are calculated for 1752 surface waters where a chemical measurement exists, and terrestrial critical loads are calculated for 1-8 habitats within approximately 240,000 1 km grid squares, based on default parameter sets (Hall et al. 2004). Dynamic model applications have followed the same general structure, using the MAGIC model (Cosby et al. 2001) for surface waters, and the VSD model (Posch and Reinds 2009) for soils.

Thus, policy decisions are made based on very limited and often highly extrapolated input parameters for critical loads or dynamic models. Opportunities for evaluating predictions against reality are limited, and even where (as for surface water MAGIC simulations) models have been calibrated against observations, these are often single time points (e.g. from synoptic surveys), so that it is not possible to gauge whether the simulated trajectory of historic change adequately reproduces observations.

In this context, long-term monitoring performs several roles. Firstly, intensive catchment studies have in many cases provided the process insight and detailed measurements to support model development (e.g. Cosby et al. 1985; Tipping 1996; Gbondo-Tugbawa et al. 2001). Secondly, they have been used to test the outputs from models applied at large spatial scales against the small subset of sites with long-term observations (e.g. Forsius et al. 1998; Jenkins et al. 2001; Oulehle et al. 2007; Reinds et al. 2009). Thirdly, monitoring sites have been used to undertake more complex simulations, for example incorporating additional environmental drivers and scenarios for land management and climate (e.g. Evans 2005; Beier et al. 2003; Aherne et al. 2008; Sjøeng et al. 2009; Futter et al. 2009); detailed carbon and nitrogen cycles (e.g. Belyazid et al. 2006; Futter et al. 2009); and more sophisticated methods for parameter and uncertainty estimation such as Bayesian calibration (Larssen et al. 2007; Reinds et al. 2008). While much of this work has appeared in the scientific literature, and may indirectly have supported the development and application of models at larger scales, the higher data demands of more complex model applications preclude their parameterisation to a wider set of datapoor locations. In other words, there is currently little direct linkage between the detailed time series datasets obtained from catchment monitoring studies, and the simplified catchment models that ultimately underpin national and international-level policy development.

We propose that this disconnection between smallscale monitoring and large-scale modelling could potentially be removed, via an alternative approach to the use of monitoring data in models. Rather than attempt to use monitoring data to estimate the parameters of detailed process models, recent approaches have empirically related monitoring data to simple readily available regional scale data, such as catchment characteristics (Cooper et al. 2004). Simple relationships between water quality and landscape class have then been used for spatial extrapolation. This approach relies on the spatial coherence of hydrochemical response for locations with the same landscape. A similar approach may be taken to temporal interpolation; just as hydrochemical conditions are dependent on spatially varying catchment characteristics, they are also dependent on temporally varying external drivers such as climate and deposition. Long term monitoring datasets provide local measurements of temporal variability over time, but extrapolation to regional scales represents a significant challenge.

Since critical loads based methods to support pollution abatement policies first evolved in the 1980s, long-term monitoring datasets have increased greatly in number and duration. Furthermore, comparisons of these datasets have often shown remarkable temporal coherence among sites across wide gradients of geographical location, catchment characteristics, exposure to air pollutants, climate and land management (Evans and Monteith 2001; Watmough et al. 2004; Davies et al. 2005; Fölster et al. 2005; Monteith et al. 2007; Erlandsson et al. 2008). The implication is that headwater catchments are responding in a consistent fashion to a set of external environmental drivers, whose effect can be inferred from responses even if not explicitly identified. Here, we utilise this observed temporal coherence as the basis of a method for analysing and predicting chemical change at one site, based on observed change at other sites. We then extend this approach, in order to extrapolate modelled changes from a small number of monitoring sites to predict changes at unmonitored sites, as an alternative to modelling these sites explicitly. We present examples of the application of this approach, discuss its advantages and disadvantages compared to direct modelling, and consider its potential utility for upscaling from a limited set of monitoring catchments to larger and more policy-relevant spatial scales.

## Methods

## Site description

We based our study on the 22 catchments of the UK Acid Waters Monitoring Network (AWMN, Fig. 1). The network, which was initiated in 1988, comprises 11 lakes and 11 streams distributed across upland areas of the UK. The sites span a wide range of anthropogenic and marine ion deposition, land cover (5 catchments contain plantation conifer forest, the remainder comprise acid grassland and/ or heathland and blanket bog), soil type (including peats, podzols, gleys and rankers), climate (range of mean temperatures 3 to 10°C, mean annual rainfall 0.87 to 3.5 m), and topographic position (mean altitude 166 to 914 m) (Table 1; Patrick et al. 1991; Monteith and Evans 2000). Lakes are sampled at a consistent quarterly frequency, and streams monthly to allow for their greater short-term variability. Analyses follow strict protocols to ensure intra- and inter-site comparability (Patrick et al. 1991) and have been subjected to rigorous analytical quality control comparisons (Gardner 2008). All samples are now analysed at either the Centre for Ecology and Hydrology, Lancaster, or at the Freshwater Fisheries Laboratory, Pitlochry. The analysis presented here is based on 19 full years of chemical data, from 1989 to 2007.

## Time series standardisation

Previous time series analyses of the AWMN dataset (e.g. Evans and Monteith 2001; Davies et al. 2005) have shown that, despite substantial differences in the

**Fig. 1** Location of the UK Acid Waters Monitoring Network sites (site names corresponding to the numbers shown are given in Fig. 6)

mean and variance of most chemical variables between sites, underlying patterns of temporal variation in rescaled (or standardised) data often show strong similarities. To demonstrate these underlying patterns, measured concentrations at each sampling site *s* and date *t* ( $C_{st}$ ) were standardised over time, by subtracting the site mean for the whole time series ( $\bar{C}_s$ ) and dividing by the site standard deviation ( $\sigma_s$ ) so that

$$Z_{st} = \frac{(C_{st} - \overline{C}_s)}{\sigma_s} \tag{1}$$

The time series of standardised concentrations  $(Z_{st}$  referred to as 'Z scores') thus have a mean of zero and a standard deviation of 1. Exploratory analysis suggests that this standardisation leads to new series which show temporal consistency following an approximate model

$$Z_{st} = x_t + \varepsilon_{st} \tag{2}$$

where  $x_t$  is a temporal effect which is independent of location and  $\varepsilon_{st}$  is a zero mean uncorrelated error term with variance independent of both location and time. Such a model implies that temporal effects are essentially multiplicative, so that sites with generally high concentrations will tend to have high variability over time in absolute but not in relative terms. This effect is to some extent moderated by the presence of a sample mean in the definition of the standardised variable.

The behaviour of  $x_t$  might be further modelled as, for example

$$x_t = a + bt + \eta_t. \tag{3}$$

Equation 3 is appropriate if the time effect follows a linear trend. The combination of Eqs. 2 and 3 constitutes a hierarchical linear model which could be formally analysed as such. The model description presented here is intended to provide a general view of methodology, rather than focusing on a detailed statistical analysis. For this study, we simplified the chemical time series further, by first taking an annual mean of all samples collected within each year (so that t in Eq. 2 represents years), and then undertaking the standardisation procedure as above based on annual rather than individual sample values. The resulting time series of annual mean Z scores permits direct comparison between quarterly sampled lakes and monthly-sampled streams, and is directly comparable to the annual time step at which many biogeochemical models, such as MAGIC and VSD, typically operate.

Finally, we calculated median annual Z scores for each year across a set of sites (either all sites, or a defined subset). Again, this approach was used previously by Evans and Monteith (2001) and Davies et al. (2005), but based on individual sampling dates and for lake and stream subsets. 10th and 90th percentile Z scores were also calculated, providing evidence of the stability of the variance of  $\varepsilon_{st}$  between years.

For this study, we focused on a key water quality variable, Acid Neutralising Capacity (ANC), which is widely used for modelling and monitoring assessments. While alternative formulations exist, the preferred method for calculating ANC in the AWMN is based on measured (Gran) alkalinity (Alk),

inorganic Al concentration  $(Al_{inorg})$  and an estimate organic acid concentration (OA) based on a conversion from dissolved organic carbon (DOC) concentration (Eq. 4; see Evans et al. 2001 for further details):

$$ANC = Gran Alkalinity + OA - Al_{inorg}.$$
 (4)

The same methodology was also applied to calculate Z scores for DOC, sulphate  $(SO_4)$ , and nitrate  $(NO_3)$ . Median annual Z scores were calculated for all 22 AWMN sites, and for subsets of lakes/streams, and moorland/forest catchments.

Extrapolating from monitored to unmonitored sites

The fundamental assumption in extrapolating to a new site is that it follows a coherent temporal pattern to another site, or set of sites as indicated in Eq. 2. The time series of Z scores for this site, or group median Z score for a set of sites, can thus be directly back-transformed to give estimates of  $C_{st}$  for the new site according to Eq. 5, and following the notation of Eq. 1:

$$C_{st} = (Z_{st} \times \sigma_s) + \bar{C}_s. \tag{5}$$

In the case that  $\bar{C}_s$  and  $\sigma_s$  are known, this calculation is straightforward (where Z scores are calculated for annual mean data,  $\bar{C}_s$  and  $\sigma_s$  are the mean and standard deviation of the annual means, rather than the raw data). At most unmonitored sites, however, it is unlikely that these statistics will be known, and they must therefore be estimated. At many sites in the UK Freshwater Critical Loads dataset, water quality data exist from two or more separate time points: for example, the Welsh Acid Water Survey of over 100 surface waters was repeated in 1985 and 1995 (Stevens et al. 1997), while a set of 48 lochs in Galloway, Southwest Scotland, has been sampled on seven occasions between 1979 and 1998 (Ferrier et al. 2001). For sites such as these for which  $C_{st}$  and  $Z_{st}$  are available at two or more time points  $t = t_1, t_2, \ldots$  a sequence of equations of type (5) can be used to solve for  $\bar{C}_s$  and  $\sigma_s$ , either using two simultaneous equations, or statistically. We examined heuristically whether we could accurately predict long-term ANC mean and standard deviation from samples collected at two time points based on the AWMN sites. In general, we found that a good estimate of long-term mean could be obtained from the mean of any two sampling years. Figure 2 shows the example fit based on the years 2007 and 1992. A reasonable estimate of the standard deviation could also be obtained from a regression of the standard deviation against the absolute difference between the two samples (e.g. Fig. 2b, for the same years). We assumed that the regression equations obtained by this method were applicable to other sites where samples had been collected in the same years. Clearly, it is essential that such a predictive relationship be obtained in order to support any subsequent extrapolation.

# Extrapolating from modelled to unmodelled sites

The method described permits the extrapolation of measured water quality data from a monitored site to

a site at which two sets of synoptic survey data are available. In principle, the same approach may be applied to modelled data, by substituting measured annual means with output values from a biogeochemical model applied to the monitored site. The potential advantages of this approach over direct application of the same model to the unmonitored site are (i) that data-rich monitoring sites can support a more accurate and/or sophisticated model parameterisation, and (ii) that model outputs can be tested or constrained (e.g. Larssen et al. 2007) against observed time series, rather than simply calibrated to a single point in time.

For this study, we undertook two illustrative model output extrapolations based on previous, well-parameterised and tested applications of the MAGIC model to monitoring sites. For the first example, we used a calibration of MAGIC to the Afon Gwy, a Mid-Wales stream that has been monitored by the Centre for Ecology and Hydrology since 1980. MAGIC was applied with a two soil layer structure, detailed parameterisation using local measurements, and calibration against both soil solution and stream chemical data (Evans et al. 2008). Outputs from the model were used to predict ANC change at Llyn Llagi, an AWMN lake catchment located 65 km to the north, in the Snowdonia region of North Wales. Predicted ANC changes at Llyn Llagi were compared both to

Fig. 2 Relationship between a mean annual ANC (1989–2007) and the mean of two years (2007 and 1992); and b standard deviation of mean annual ANC and the absolute difference in ANC between 2007 and 1992, for all AWMN sites

observations from the site, and to predictions from a simpler direct calibration of MAGIC to Llyn Llagi as part of a regional suite of MAGIC applications. This application was based on a single soil layer, parameterisation data extrapolated from national or regional datasets and calibration to a single year of water chemistry data (Evans et al. 2007).

Secondly, we took a recent calibration of MAGIC to the River Etherow catchment in the South Pennines, England (Helliwell et al., in prep.), which employs a Bayesian parameter estimation method to fit the full time series of monitoring data (Larssen et al. 2007). This simulation was used to predict ANC change for a suite of 27 sites within the region which were sampled in 1998 (Evans et al. 2000) and again in 2001–2002 (Helliwell et al. 2007). Predictions were again compared against direct MAGIC simulations to all sites, which formed part of the regional model application described above.

# Results

#### Standardised annual time series

Untransformed annual mean ANC, SO<sub>4</sub>, NO<sub>3</sub> and DOC time series for the individual AWMN sites (Fig. 3) highlight the extent of between-site heterogeneity in terms of mean concentrations, rates of change, and short-term variability. Standardisation, on the other hand (Fig. 4), highlights the degree of underlying temporal coherence across the network. For SO<sub>4</sub>, there was a very pronounced decline in concentrations during the late 1990s, and high coherence between sites (mean annual 10th-90th percentile range 1.03 standardised units). ANC showed a consistent increase, with the fastest rate of change coinciding with the period of SO<sub>4</sub> decrease, and a reasonable level of coherence (mean 10th-90th percentile range 1.54). In contrast, there has been no clear trend in NO<sub>3</sub> concentrations, and relatively high variability among sites (mean 10th-90th percentile range 2.04). However, all sites showed a clear  $NO_3$ peak in 1996. DOC has increased at all sites, with low variability between sites (mean 10th-90th percentile range 1.25). There was some indication of a reversal in the rising trend between 2001 and 2004, but concentrations subsequently rose to unprecedented levels during 2006–2007.

To a large extent, these observations reinforce previous inferences from analyses of monthly stream and quarterly lake data, namely that reduced S inputs to UK upland surface waters have led to a large reduction in runoff SO<sub>4</sub> concentrations, partial recovery from acidification as evidenced by rising ANC (e.g. Davies et al. 2005), and an apparently associated increase in the leaching of DOC (e.g. Evans et al. 2006). Temporal variations in NO<sub>3</sub> leaching appear to be mainly linked to climate fluctuations, such as occurrence of soil freezing, rather than directly to deposition (Monteith et al. 2000; Cooper 2005). The relatively low temporal coherence in NO<sub>3</sub> between sites suggests that local factors such as land-management (notably tree maturation, felling and replanting in forested catchments), as well as N saturation status, may also have influenced NO<sub>3</sub> leaching.

Reducing time series to annual mean values tends to highlight underlying trends rather than short-term variations, particularly for streams (cf. Fig. 1 of Davies et al. 2005). It also permits direct comparisons among sites sampled at different frequencies, and between different site types. Here, we compared lakes and streams, and forested and moorland catchments. Studies in North American and Scandinavian lakes have shown a substantial role of lakes in the processing of carbon and nutrients (e.g. Dillon and Molot 2005; Algesten et al. 2003). UK lakes in high rainfall upland areas typically have shorter residence times than those in continental areas, and here their impact on long-term trends is less clear. On the other hand, there is strong evidence that catchment afforestation of parts of the UK (primarily exotic conifer plantation on moorland during the post-war period) significantly amplified the effects of acid deposition, due to increased base cation uptake and pollutant scavenging from the atmosphere by the forest canopy (NEGTAP 2001). Evidence of greater present-day acidification relative to adjacent moorlands has led to predictions that afforested catchments may not respond to reduced acid deposition in the same way as moorland catchments, resulting in suppressed recovery or even ongoing acidification (e.g. Jenkins et al. 1990; Helliwell et al. 2001).

Our analysis shows, for all variables analysed, a tight correlation between median annual Z scores for the two pairs of catchment subsets (Fig. 5). No clear deviation is apparent between ANC Z scores for forested and moorland catchments that might support

Fig. 3 Untransformed annual mean time series for ANC, sulphate, nitrate and DOC concentrations for all sites in the UK Acid Waters Monitoring Network

the conclusion that forests are stopping recovery from acidification. However, because Z scores do not permit comparison of the magnitude of change at individual sites, this observation does not exclude the possibility that moorland and forest catchments are recovering at different rates. Similarly, neither the presence of lakes or forests appears to have influenced the trajectory of DOC or NO<sub>3</sub> leaching, although differences in rate of change again cannot be discounted on this basis alone. Overall, the data do not support the subdivision of the AWMN sites according to catchment or surface water type. We were also unable to detect sufficient evidence of geographical clustering in the pattern of Z score variations to justify subdividing data into regional subgroups (see below).

Extrapolating from monitored to unmonitored sites

Based on the analysis above, suggesting no strong geographic or typological clustering of Z score

variations among the sites, we henceforth treated all AWMN sites as a single group. For ANC, we then attempted to predict annual ANC concentrations at each site, based on back-transformation of median annual Z scores for the remaining 21 sites. Equation 5 was applied, firstly based on known mean and standard deviation values, and then on values estimated from only two years of data, 1992 and 2007 (Fig. 2).

Predictions of ANC based on known mean and standard deviation had root mean square error (RMSE) values ranging from 3.3 to 22.6  $\mu$ eq l<sup>-1</sup> (median 8.1  $\mu$ eq l<sup>-1</sup>). With the exception of the few sites showing little overall ANC trend (e.g. Loch Coire nan Arr, Narrator Brook), annual ANC predictions captured the underlying trend at most sites. The method was most successful at capturing inter-annual trends at sites in Southwest Scotland (Round Loch of Glenhead, Loch Grannoch, Dargall Lane), Northwest England (Scoat Tarn, Burnmoor Tarn), North Wales (Llyn Llagi) and the Eastern part of Northern Ireland (Beaghs Burn, Bencrom River). These sites, all of

Fig. 4 Standardised annual mean (Z score) time series for ANC, sulphate, nitrate and DOC concentrations for all sites in the UK Acid Waters Monitoring Network. Bold central line

which are clustered around the Irish Sea (Fig. 1), show particularly coherent behaviour and thus dominate the median Z score calculation for the dataset as a whole. Prediction of inter-annual variations becomes poorer with distance from this central cluster, as might be expected given the increasing heterogeneity of short-term climatic and depositional patterns across larger spatial scales. We were unable to identify other clear regional clusters, although it is likely that these would emerge given additional monitoring datasets in (for example) Northern Scotland or Southern England.

The second method, in which mean and standard deviation were estimated from two observation years, provides a more meaningful test of the utility of this method for extrapolating from monitored to unmonitored sites. ANC predictions based on 1992 and 2007 'survey' years (Fig. 6) resulted in only small increases in RMSE at most sites (range 3.1 to 26.8  $\mu$ eq l<sup>-1</sup>, median 9.5  $\mu$ eq l<sup>-1</sup>). With few exceptions, this method

shows median annual Z score for all sites, outer lines show 10th and 90th percentile values

thus remained effective in reproducing the trend in annual mean ANC.

Extrapolating from modelled to unmodelled sites

## Upscaling to a single site

For the Llyn Llagi AWMN site, ANC was modelled directly in MAGIC based on regional-scale parameter data (Fig. 7a), and indirectly based on annual Z scores derived from a site-specific MAGIC application to the Afon Gwy (Fig. 7b), which were backtransformed using known (Fig. 7c) and estimated (Fig. 7d) mean and standard deviation values. The direct regional MAGIC application to Llyn Llagi captures the approximate trend in ANC, but (since the model application did not incorporate short-term variations in driving variables) does not reproduce the short-term variation. RMSE over the period of observations is 7.0  $\mu$ eq l<sup>-1</sup>. Modelling the site

Fig. 5 Comparison of median annual Z scores between lakes and streams, and forested and moorland catchments, for ANC, nitrate and DOC

indirectly using the Z score approach gave no discernable reduction in model performance (RMSE 7.3 and 6.4  $\mu$ eq l<sup>-1</sup> based on known and estimated mean and standard deviation respectively), and appeared to capture both the trend and some of the between-year variation in ANC. Comparing long-term simulations, the indirect simulations suggest a slightly greater responsiveness of the site to changing atmospheric deposition, with pre-industrial 1850 ANC values of around 70  $\mu$ eq  $l^{-1}$  compared to 56  $\mu$ eq  $l^{-1}$  in the direct application, and forecast 2050 ANC of around

Fig. 7 Simulated long-term ANC (*line*) and observed annual means (*circles*) for **a** Afon Gwy based on a previous site-specific model application (Evans et al., 2008); **b** Llyn Llagi based on a previous regional-scale model application; and for

45  $\mu$ eq  $l^{-1}$  compared to 37  $\mu$ eq  $l^{-1}$  in the direct application.

# Upscaling to multiple sites

Simulated ANC for the South Pennine reservoirs is shown in Fig. 8, modelled directly by multiple MAGIC applications to all sites, and indirectly by Z score transformation from a single MAGIC calibration to the River Etherow AWMN site. Agreement between the two modelling methods is generally good; the indirect simulation suggests a higher preindustrial ANC, and slightly greater acidification at the deposition peak in 1970. Without historic data against which to compare, the relative accuracy of the two hindcast simulations cannot be evaluated. However, differences between the two sets of forecast simulations are rather small: for 2050, mean predicted ANC for the regional dataset is 73  $\mu$ eq l<sup>-1</sup> based on the Z score approach (11 sites having ANC below the critical limit of 20  $\mu$ eq 1<sup>-1</sup>), compared to a

Llyn Llagi based on a Z score transformation of the MAGIC simulation for the Afon Gwy for c known and d estimated ANC mean and standard deviation

mean of 55  $\mu$ eq l<sup>-1</sup> based on the direct MAGIC application (9 sites with ANC < 20  $\mu$ eq l<sup>-1</sup>). Thus, in this example, the two methods would lead to similar interpretations regarding future regional water quality status.

#### Discussion

Despite considerable typological and geographical variation, the 22 AWMN sites show high temporal coherence in a range of key water quality variables, including  $SO_4$ , DOC, ANC and—to a lesser extent— $NO_3$ . Standardisation of data to annual mean Z scores appears to be an effective method for comparing the behaviour of sites with contrasting absolute concentrations, short-term variability and sampling frequency. Applications of this approach include comparison and differentiation of sites according to typology or location, potentially providing insight into the processes controlling water quality variation

**Fig. 8** Simulated ANC at four time points for a set of 27 South Pennine reservoirs modelled directly using MAGIC, and indirectly by Z score transformation from a site-specific application of MAGIC to the River Etherow AWMN site. *Boxes* show median, lower and upper quartiles, whiskers 10th and 90th percentile simulated values for all sites

across the landscape. Our analysis suggested little differentiation in water quality variations between sites according to catchment type; we found no impact of lake presence on long-term DOC variations, or of plantation forests on ANC variations. The Z score approach also has potential utility for identifying individual sites showing atypical behaviour (e.g. due to local management or pollution factors), and for identifying individual analytical outliers. The method has been tested here on data from semi-natural upland ecosystems, and it is doubtful whether the same approach would be as effective in more heterogeneous agricultural or urban-influenced areas, where diffuse and pointsource pollution are likely to be more catchmentspecific. Nevertheless, several studies have shown coherent chemical variations in lakes influenced by agricultural inputs (e.g. George et al. 2000; Blenckner et al. 2007; Knowlton and Jones 2007), suggesting that external factors such as climate remain important biogeochemical drivers in these systems. Analysis of temporal coherence in these systems may support the identification of underlying signals from climate or large-scale land-management change, which may not be discernable from the analysis of individual sites.

There are several prerequisites to using the Z score approach for model upscaling. Firstly, it is vital that long-term monitoring data are available for a sufficient number of sites to identify temporal coherence, derive average Z scores, and to allow subdivision according to typological or geographical factors where these lead to differing biogeochemical behaviour. This is greatly facilitated by consistently operated networks such as the AWMN, although by reducing data to annual means it may be possible to combine data from independently operated sites and/ or multiple networks. Secondly, the method will only be applicable for areas or ecosystems within which coherent behaviour can be demonstrated; it will become progressively poorer with increasing geographical distance, or typological difference, from the sites used to calculate median Z scores. Thirdly, to predict change at an unmonitored site it is necessary to have sufficient measurements from which to estimate long-term solute concentration means and standard deviations for that site. In this study, we were able to derive reasonable estimates of both parameters from two years of (sufficiently separated) 'survey' data, a minimum data requirement likely to be available for large numbers of surface waters. Finally, long-term biogeochemical model simulations are required for representative sites in order to derive representative Z scores.

In this respect, this modelling approach has significant potential advantages over previous largescale biogeochemical model applications, which have in general involved repeated model application to large numbers of individual sites within one or more regions (e.g. Evans et al. 1998; Moldan et al. 2004; Wright et al. 2005; Chen and Driscoll 2005; Hettelingh et al. 2008). At the regional and national scale, modelling inevitably has to be undertaken using relatively simple models, parameterised with limited and/or extrapolated input data, and making little or no use of available long-term datasets. On the other hand, if biogeochemical variations are coherent across a range of sites, it may be possible to obtain a more accurate simulation of long-term change by extrapolating outputs from more detailed model applications at the smaller number of sites for which direct measurements are available. More sophisticated site-based models are likely to be better able to incorporate other drivers of change, such as climate, rather than deposition alone. Modelling techniques such as Bayesian parameter estimation (e.g. Larssen 2005; Reinds et al. 2008) can be used to constrain parameter estimates to fit a time series of observations (rather than a single observation point), thereby improving the accuracy of simulations, and permitting the generation of uncertainty ranges on future predictions.

A number of caveats apply to these conclusions. Firstly, in the method presented, individual water quality variables can only be extrapolated individually. If applied to the full suite of dissolved solutes, this would not ensure maintenance of charge balance constraints. Extrapolation to new (survey) sites also assumes that these sites are comparable to those for which long-term data exist, and caution is therefore required to ensure that upscaling is restricted to sites with similar catchment characteristics, and within a reasonable geographical range. Outputs from highly complex site-specific models, for example those that integrate biogeochemical processes with vegetation competition and succession (e.g. Wamelink et al. 2009) are unlikely to be appropriate for upscaling using this method. Finally, application of the method in the current study has been limited to a small number of illustrative examples, and more rigorous testing is required prior to larger-scale application. Nevertheless, given clear evidence of coherence in biogeochemical trends, we believe that there are significant potential advantages in terms of both model performance and computational time requirement, in extrapolating outputs from a smaller number of more detailed model applications to monitoring sites, compared with extrapolating inputs in order to run simple models at a larger number of poorly characterised sites.

Acknowledgements This study was supported by the UK Department of Environment, Food and Rural Affairs, under Contract AQ0801. We are grateful to the many people and organisations who have helped to maintain the UK Acid Waters Monitoring Network through the many challenges of its 20 years of operation. We also thank two anonymous reviewers for their constructive assessments of the manuscript.
