ARTICLE

Scalar Transport over Forested Hills

Andrew N. Ross

Received: 13 April 2010 / Accepted: 13 June 2011 / Published online: 30 June 2011

Abstract Numerical simulations of scalar transport in neutral flow over forested ridges are performed using both a 1.5-order mixing-length closure scheme and a large-eddy simulation. Such scalar transport (particularly of CO_2) has been a significant motivation for dynamical studies of forest canopy–atmosphere interactions. Results from the 1.5-order mixing-length simulations show that hills for which there is significant mean flow into and out of the canopy are more efficient at transporting scalars from the canopy to the boundary layer above. For the case with a source in the canopy this leads to lower mean concentrations of tracer within the canopy, although they can be very large horizontal variations over the hill. These variations are closed linked to flow separation and recirculation in the canopy and can lead to maximum concentrations near the separation point that exceed those over flat ground. Simple scaling arguments building on the analytical model of Finnigan and Belcher (Q J Roy Meteorol Soc 130:1–29, 2004) successfully predict the variations in scalar concentration near the canopy top over a range of hills. Interestingly this analysis suggests that variations in the components of the turbulent transport term, rather than advection, give rise to the leading order variations in scalar concentration. The scaling arguments provide a quantitative measure of the role of advection, and suggest that for smaller/steeper hills and deeper/sparser canopies advection will be more important. This agrees well with results from the numerical simulations. A large-eddy simulation is used to support the results from the mixing-length closure model and to allow more detailed investigation of the turbulent transport of scalars within and above the canopy. Scalar concentration profiles are very similar in both models, despite the fact that there are significant differences in the turbulent transport, highlighted by the strong variations in the turbulent Schmidt number both in the vertical and across the hill in the large-eddy simulation that are not represented in the mixing-length model.

1 Introduction

In recent years there has been significant interest in the dynamics of forest-canopy–boundary-layer interactions over complex terrain. A significant motivation for this work has been the understanding of advective effects in flux measurements (notably CO_2) over forest canopies and to improve the flux estimates as a result (see Finnigan 2008 and other papers in the same invited feature). The analytical work of Finnigan and Belcher (2004) has been an important step in understanding these dynamics. Finnigan and Belcher (2004) extended the linear theory of Hunt et al. (1988) for neutral flow over a hill to include the effects of a forest canopy, and demonstrated the ubiquity of flow separation in deep canopies. The analytical solutions break down for small hills when advection at the canopy top becomes comparable to the perturbation shear-stress divergence at leading order. Subsequent numerical simulations by Ross and Vosper (2005) using a 1.5-order turbulence closure scheme demonstrated that in these cases vertical advection at the canopy top is important at leading order. Streamlines show flow into the canopy over the upwind slope and out of the canopy just downwind of the hill crest. This leads to a feedback between the canopy flow and the larger scale pressure field over the hill, with a subsequent downwind shift in the surface pressure field, an increase in pressure drag and a downwind shift in the maximum near-surface speed-up over the hill. Similar conclusions were drawn from large-eddy simulations (LES) of flow over a small hill (Ross 2008) using the same model and from the LES of Patton and Katul (2009). Other LES (Dupont et al. 2008) have reproduced the wind-tunnel experiments of Finnigan and Brunet (1995). These LES do not rely on the use of a first-order canopy turbulence closure scheme, which has been a topic of some debate in the literature (Finnigan 2000; Pinard and Wilson 2001; Katul et al. 2004).

Experimental observations are still relatively rare, with the only significant wind-tunnel study both within and above a canopy over a hill being that of Finnigan and Brunet (1995). Recent water flume experiments (Poggi and Katul 2007a,b,c) have provided more detailed measurements and support many of the conclusions drawn from the modelling work. They have also provided important measurements of the unsteady nature of the canopy flow, particularly in the recirculation region (Poggi and Katul 2007a).

The impact of this dynamical work for those measuring fluxes is summarized in Belcher et al. (2008). From an analytical point of view, applying this theoretical work to study scalar transport has been difficult since scalar profile observations above forest do not agree with simple boundary-layer theory even over flat terrain, although some recent progress has been made (Harman and Finnigan 2008). Katul et al. (2006) have attempted to consider the impact of the dynamics on CO_2 fluxes using an ecophysical canopy model driven by a simplified analytical wind field based on Finnigan and Belcher (2004). This demonstrates the impact that the dynamics have on scalar concentrations and fluxes, however unfortunately the small hill and canopy they used to demonstrate the results (the same as that used in Finnigan and Belcher 2004; Ross and Vosper 2005) violates the assumptions of the full analytical model, let alone the simplified version adopted by them. Observational studies, notably the ADVEX (ADVection EXperiment) project (Feigenwinter et al. 2008), have begun to investigate the impact of advection for flux sites. Some of these studies, for example Zeri et al. (2010), provide qualitative support for the theoretical predictions of Finnigan and Belcher (2004) and Katul et al. (2006). With all this in mind, there is still a need for a systematic assessment of the impact of canopy dynamics on scalar transport over hills, which we seek to address.

While there is debate in the literature about whether first-order turbulence closure schemes should be used for canopy flows, from a practical point of view they are useful. They are simple enough that they are amenable to analytical analysis (e.g. Finnigan and Belcher 2004)

and computationally cheap enough to allow realistic simulations to be conducted. Studies such as Pinard and Wilson (2001), Katul et al. (2004) and Ross (2008) have shown that in terms of the mean flow they produce similar results to higher order closure schemes, to LES and to experiments. This is principally because they correctly reproduce the canopy-top turbulence that dominates the canopy flow. They do less well in terms of representing the turbulence deep in the canopy (e.g. Ross 2008), but this is not significant for the mean flow since the mean velocity gradients are low in that region. In terms of scalar transport the picture is less clear. There may be significant gradients in the scalar concentration deep in the canopy depending on the sources and sinks, and hence there may be more significant errors in the turbulent scalar fluxes. There are also questions about the behaviour of the turbulent Schmidt number (the ratio of the turbulent diffusivities for momentum and scalars) within and just above the canopy (see e.g. Harman and Finnigan 2008). Nonetheless the fact that first-order closure schemes are amenable to analytical study allows a more complete analysis of the role of advection in scalar transport. While the results of such models may not exactly represent reality they offer a useful guide to likely different flow regimes and scalings that can be tested against observations or limited numerical results from models with more complex turbulence schemes. Finally, since such simple models are being used practically through computational necessity, it is valuable to understand their behaviour and possible limitations and to seek ways of improving them. For these reasons our study primarily concentrates on first-order closure schemes of scalar transport, although comparison will be made with a LES in Sect. 5.

Section 2 describes the numerical model used here and the simulations of passive scalar transport. Section 3 presents some simple scaling arguments based on the analytical model of Finnigan and Belcher (2004) for flow over a canopy-covered hill. This provides insight into the dominant processes controlling variations in scalar concentration and flux in the upper canopy and in the boundary layer above. Results of the first-order simulations are presented and discussed in Section 4 and compared with the scaling arguments developed. Limitations of first-order closure schemes are discussed, and to partly address this results from a LES are presented in Section 5 for comparison. Section 6 discusses the implications of this work for flux measurements and finally Section 7 offers conclusions and topics for further study.

2 Simulations of Passive Scalar Transport

2.1 Model Description

Simulations were carried out using the BLASIUS model from the UK Met Office (Wood and Mason 1993), which can be operated with a first-order or a 1.5-order mixing-length turbulence closure scheme. It can also be used for LES. It has previously been used in both modes for studying the dynamics of flow over canopy-covered hills (Brown et al. 2001; Ross and Vosper 2005; Ross 2008).

For all the simulations presented here an idealized two-dimensional, sinusoidal, periodic hill is used with the hill surface, z_s, given by

$$z_s = \frac{H}{2}\cos(kx) \tag{1}$$

where H is the height of the hill, $k = \pi/(2L)$ is the hill wavenumber and L is the half width of the hill at half height. The length of the domain is always $4L$, i.e. the domain contains exactly one hill. Neutral flow is assumed in all cases and periodic boundary conditions are

used meaning that the simulations actually represent neutral flow over an infinite series of sinusoidal ridges. In all the simulations presented here the domain has 128 grid points in the horizontal. For the majority of simulations the domain depth is fixed at 1,500 m. A stretched grid with 80 grid points is used in the vertical with a resolution of 0.5 m near the surface increasing gradually to 33.5 m at domain top.

A uniform canopy density, $a = 0.2{-}0.6\,\mathrm{m}^{-1}$ and a fixed canopy drag coefficient ($C_\mathrm{d} = 0.25$ or $C_\mathrm{d} = 0.15$) were used for all simulations, giving values for the canopy adjustment length, $L_\mathrm{c} = 1/(C_\mathrm{d}a)$ of 6.67−26.7 m. Unless otherwise stated the canopy height $h = 10\,\mathrm{m}$, although some simulations are conducted with $h = 5$ m or $h = 20$ m. These canopy parameters are all representative of observations in real forests and correspond to values used in previous theoretical work, allowing direct comparison. The flow is driven by a horizontal pressure gradient corresponding to a geostrophic wind speed of $10\,\mathrm{m\,s}^{-1}$. Full details of the parameter values used in the simulations are given in Sect. 4. The simulations are consistent with those presented in Ross and Vosper (2005) and Ross (2008) allowing direct comparison of the results.

The mixing-length closure simulations presented in the first part of the study were all conducted with the 1.5-order closure scheme with a prognostic equation for turbulent kinetic energy. Full details of the scheme are given in Ross and Vosper (2005). The 1.5-order closure scheme requires an additional empirical parameter, β, which measures the ratio of friction velocity to mean wind at canopy top, to be specified. For most simulations this is taken as 0.3, as in Ross and Vosper (2005) and consistent with observations over real forests. This parameter controls the relationship between L_c, the canopy mixing length, l, and displacement height, d, as described in Finnigan and Belcher (2004) and Ross and Vosper (2005). The effect of modifying β is studied in Sect. 5 and compared to results using large-eddy simulation.

In Sect. 5 the model is used to conduct LES. The model set-up is identical to that described in Ross (2008), to which the reader is referred for a full discussion of the requirements for a successful LES and the model set-up. The requirements to adequately resolve the larger eddies in the canopy places a strong limitation on the number of cases, the canopy and the size of hills that can be modelled. For these reasons the hill is taken as $H = 10\,\mathrm{m}$ and $L = 100\,\mathrm{m}$. The canopy has $C_\mathrm{d} = 0.15$, $a = 0.25\,\mathrm{m}^{-1}$ and $h = 20\,\mathrm{m}$, the domain height is limited to 132 m, and the domain has $288 \times 192 \times 96$ grid points, giving a horizontal and vertical grid spacing of 1.39 m. This differs from the majority of the mixing-length simulations described herein, and is a result of the computational limitations imposed by the LES. Where direct comparison is made between the LES and mixing-length closure results, the mixing-length closure simulations have been performed with an identical model set-up in terms of domain size, hill size and canopy parameters, although the horizontal resolution is slightly lower.

2.2 Scalar Releases

The majority of the simulations presented involve a constant uniform release rate for a passive scalar tracer within the canopy. In order to allow a steady-state solution a sink of equal magnitude is distributed over the top 500 m of the domain to balance the source. For the simulations using the shallow LES domain, the sink is over the top 20 m of the domain. Zero-flux boundary conditions are used at the ground and at the top of the domain so the total tracer in the domain is conserved. In this case the units of the tracer are arbitrary, however a canopy release rate of $10^{-2}\,\mathrm{m}^{-3}\,\mathrm{s}^{-1}$ is used. A one-dimensional simulation is run with the tracer concentration initially set to unity throughout the domain. Once this simulation has

reached a near-equilibrium state then the profiles are used to initialize the two-dimensional simulations. The same tracer set-up is used for the LES described in Sect. 5.

3 Scaling Arguments for the Importance of Advection

There are four independent length scales in the problem (H, L, h and L_c); the canopy mixing length, l, is proportional to the canopy adjustment length, L_c, so is not independent. These length scales give three non-dimensional parameters controlling the dynamics of flow over a forested hill, namely the hill slope, H/L, the ratio of the hill width to the canopy adjustment length scale, L/L_c, and β times the canopy depth non-dimensionalized on the canopy mixing length, $\beta h/l$. Note that the inclusion of the non-dimensional empirical parameter, β, is for convenience since it is this group that appears in the analytical solution for the background flow and for the perturbations over the hill in Finnigan and Belcher (2004).

The turbulent transport equation for a scalar tracer, c, in a turbulent canopy flow can be written as

$$\frac{Dc}{Dt} = \frac{\partial}{\partial x_i}\left(K_c \frac{\partial c}{\partial x_i}\right) + S \tag{2}$$

using a first-order turbulence closure with K_c the eddy viscosity or turbulent diffusivity for scalars; S is the source/sink term for the scalar tracer. Here molecular diffusion is neglected. In a homogeneous, steady flow then the source/sink term is exactly balanced by the divergence of the vertical scalar flux term and so

$$S = -\frac{\partial}{\partial z}\left(K_c \frac{\partial c}{\partial z}\right). \tag{3}$$

Following other recent theoretical and modelling studies (e.g. Finnigan and Belcher 2004; Ross and Vosper 2005), consider two-dimensional flow over a series of sinusoidal ridges covered by a uniform canopy. The flow can be considered as a mean horizontal flow $U(z)$ plus a perturbation $(u(x,z), w(x,z))$. Finnigan and Belcher (2004) give an analytical solution for this perturbed flow within and above the canopy. Similarly the scalar concentration may be considered as a mean value, $C(z)$ plus a perturbation, $c(x,z)$. All perturbations are assumed small, allowing the transport equation to be linearized.

For the homogeneous, flat ground case then, from Finnigan and Belcher (2004), we have

$$U(z) = \begin{cases} U_h e^{\beta z/l} & z < 0 \\ \dfrac{u_*}{\kappa} \log\left(\dfrac{z+d}{z_0}\right) & z \geq 0 \end{cases} \tag{4}$$

and

$$K_c = l_m^2 \frac{dU}{dz} = \begin{cases} \beta l U_h e^{\beta z/l} & z < 0 \\ u_* \kappa (z+d) & z \geq 0 \end{cases} \tag{5}$$

where l_m is the mixing length, which is constant within the canopy and scales with height above, u_* is the friction velocity and U_h is the velocity at canopy top. The displacement height d and the roughness length z_0 are determined from β and l. Substituting this into Eq. 3 and integrating gives

$$\frac{dC}{dz} = \begin{cases} -\dfrac{Sh}{\beta l U_h}\left(1 + \dfrac{z}{h}\right) e^{-\beta z/l} & z < 0 \\ -\dfrac{c_*}{\kappa(z+d)} & z \geq 0 \end{cases} \tag{6}$$

and

$$C = \begin{cases} \dfrac{Sh}{\beta^2 U_\mathrm{h}}\left(1+\dfrac{z}{h}+\dfrac{l}{\beta h}\right)\mathrm{e}^{-\beta z/l} - \dfrac{Sh}{\beta^2 U_\mathrm{h}}\left(2+\dfrac{l}{\beta h}\right)+c_1 & z<0 \\ -\dfrac{c_*}{\kappa}\log\left(\dfrac{z+d}{z_0}\right)+c_1 & z\geq 0 \end{cases} \tag{7}$$

for some constant c_1, where $Sh \equiv u_* c_*$, assuming that $\partial C/\partial z = 0$ at $z = -h$.

From Finnigan and Belcher (2004) we may take the analytical solution for the perturbed velocity and eddy viscosity, a solution that is valid when $H/L \ll 1$, $\beta h/l \gg 1$ and $kL_\mathrm{c}\exp(\beta h/l) \ll 1$. Assuming perturbations in the scalar are also small, we may linearize about the perturbations in both the scalar and velocity fields to give

$$U\frac{\partial c}{\partial x} + w\frac{\partial C}{\partial z} = \frac{\partial}{\partial x}\left(K_\mathrm{c}\frac{\partial c}{\partial x}\right) + \frac{\partial}{\partial z}\left(K_\mathrm{c}\frac{\partial c}{\partial z} + K_\mathrm{c}'\frac{\partial C}{\partial z}\right). \tag{8}$$

The linearized eddy viscosity terms can be written in terms of the velocity field (see Finnigan and Belcher 2004) as

$$K_\mathrm{c} = l_\mathrm{m}^2\frac{\mathrm{d}U}{\mathrm{d}z}, \tag{9a}$$

$$K_\mathrm{c}' = l_\mathrm{m}^2\frac{\partial u}{\partial z}. \tag{9b}$$

In the upper canopy and just above the canopy horizontal derivatives scale on the horizontal length scale L while vertical derivatives scale on the mixing length, l. Using this we see that the first term on the right-hand side of (8) is small ($O(l^2/L^2)$) compared to the second term. Similarly, the first and second terms on the left-hand side are small ($O(l/L)$) compared to the second and third terms respectively on the right-hand side, and so may be neglected. This also makes use of the continuity equation to scale $w \sim ul/L$, and leaves a balance between the two components of the vertical turbulent transport perturbation term on the right-hand side. Equating these two terms and integrating gives

$$\frac{\partial c}{\partial z} = \left(\frac{c_*}{u_*}\right)\frac{\partial u}{\partial z} \tag{10}$$

and so

$$c = \frac{c_*}{u_*}u + c_0(x) \tag{11}$$

for some function $c_0(x)$. Taking the expression for u from Finnigan and Belcher (2004) and assuming that the contribution, $c_0(x)$ from the deep canopy is small, or at least scales in the same way, gives

$$c \sim \frac{Sh}{U_\mathrm{h}}\frac{H}{L}\frac{L_\mathrm{c}}{L}\frac{U_0^2}{U_\mathrm{h}^2} \tag{12}$$

near canopy top. Here U_0 is the velocity at the middle layer height and gives a velocity scale for the outer flow, see Finnigan and Belcher (2004) for details. Note that this scaling means that the leading order ($O(l/L)$) correction to the tracer field resulting from the hill results from a balance between the changes in the turbulent transport term due to changes in the tracer profile and changes in the eddy viscosity. At leading order there is no net change in the turbulent flux. Changes in the turbulent flux must come from a second-order balance ($O(l^2/L^2)$) with the advection term.

Table 1 Hill and canopy parameters for the various two-dimensional mixing-length closure simulations performed

Parameter	Values
L (m)	100–1600
a (m^{-1})	0.2–0.6
h (m)	5–20
H/L	0.00625–0.2
L/L_c	3.75–240
$\beta h/l$	1.39–8.33

Using this scaling the magnitude of the tracer advection term can be derived as

$$U\frac{\partial c}{\partial x} \sim S2\beta^2\frac{\beta h}{l}\frac{H}{L}\frac{L_c^2}{L^2}\frac{U_0^2}{U_h^2} \tag{13}$$

near canopy top, allowing direct estimation of the importance of advection compared to the canopy source term, S.

4 Tracer Concentrations and Fluxes over Complex Terrain

A large number of simulations with a constant tracer release were carried out over a range of different parameter values, and are summarized in Table 1. In particular simulations corresponding to the narrow and wide hill examples discussed in Ross and Vosper (2005) were performed. The tracer profiles for these simulations are shown below.

Figure 1 shows horizontally-averaged vertical profiles of relative tracer concentration compared to the flat ground case for various experiments given in Table 1. In all simulations the horizontally-averaged scalar flux is the same and constant with height since the sources and sinks of the scalar are fixed and the simulations are run to a quasi-steady state, however there are clear differences in the horizontally-averaged scalar concentrations. Figure 1a shows results for four simulations with different slopes H/L and fixed hill width and canopy parameters ($L/L_c = 10$ and $\beta h/l = 5.55$). This corresponds to the small hill width case described in Ross and Vosper (2005) where vertical advection at canopy top is important. Increasing the slope leads to greater vertical velocities into and out of the canopy and so increases the tracer transport by the mean flow. This gives significantly lower average concentrations of tracer within the canopy compared to the flat ground case, and slightly higher concentrations above. Figure 1b shows profiles for five simulations with fixed $H/L = 0.1$ and $\beta h/l = 5.55$ and varying L/L_c, i.e. fixed slope and canopy parameters and varying hill width. Here decreasing L/L_c (i.e. smaller hill widths compared to the canopy adjustment scale L_c) again leads to an increase in vertical advection at canopy top, increased tracer transport and lower averaged concentrations within the canopy. Finally Fig. 1c shows profiles for three simulations with fixed $H/L = 0.1$, $L/L_c = 5$ and varying $\beta h/l$, i.e. fixed slope, hill width and canopy density and varying canopy height. Increasing the canopy height leads to a deeper region of flow convergence/divergence in the canopy and hence, by continuity, a greater vertical velocity at canopy top. This is turn increases tracer transport and leads to a significant reduction in tracer concentration within the canopy and a slight increase above. Note that only the simulation with the deepest canopy demonstrates a strong increase in tracer concentration above the canopy. In all other cases the additional tracer from within the canopy is redistributed over a sufficient depth in the boundary layer that the increases in concentration are not large.

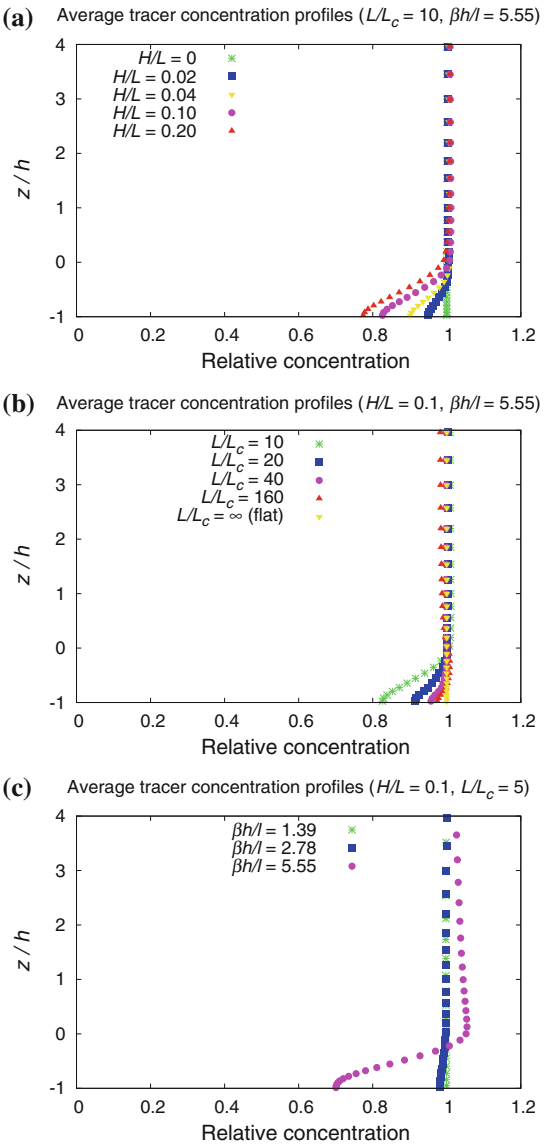

Fig. 1 Horizontally-averaged vertical profiles of tracer concentration relative to the equivalent profile over flat ground. Height is non-dimensionalized on the canopy height, h. Canopy top is at $z/h = 0$. **a** Shows profiles for a fixed canopy and hill width, but for different hill heights, i.e. increasing slope, H/l. **b** Shows profiles for a fixed slope and canopy, but for different scale hills. **c** Shows profiles for a fixed hill and different canopy depths

For the $\beta h/l = 1.39$ case the canopy is sufficiently shallow that no flow separation occurs. These cases with $L/L_c = 5$ are an extreme example. For wider hills with larger values of L/L_c (not shown) the relative changes in average concentration are smaller, but a broadly similar effect is seen. Deep in the canopy the average tracer concentrations are reduced as a result of the induced flow, and is more pronounced for deeper canopies where the induced flow is larger. In the upper canopy the change in tracer concentration is less for most simulations. For the deepest canopies, however, an increase in average concentration is observed as in the small L/L_c case.

Overall these simulations demonstrate reductions in mean scalar concentration deep within the canopy (for a canopy source of tracer) resulting from more efficient transport between the

canopy and the boundary layer above for steep and/or narrower hills and for deeper/denser canopies. For the cases with the deepest canopy there can actually be an increase in mean scalar concentration near canopy top. These features can be attributed to an increase in the average vertical transport by the mean flow between the canopy and the boundary layer above and is entirely in accord with expectations based on the analytical work of Finnigan and Belcher (2004) and numerical simulations of Ross and Vosper (2005). For the case of a tracer sink within the canopy (as is the case for CO_2) then the signs of the changes would be expected to be reversed so higher concentrations would be observed deep within the canopy.

Figure 2a, b shows colour contour plots of the scalar concentration for two simulations—a small ($L/L_c = 10$) and large ($L/L_c = 160$) hill, both with slope $H/L = 0.1$ and $\beta h/l = 5.55$. Also plotted in Fig. 2c for comparison are the results over flat ground. The figures are plotted in a terrain-following coordinate system so that the vertical axis is height above the surface. This allows direct comparison of the two figures, despite the differences in scale of the two hills. The figures also show the streamlines of the flow, and in both cases the streamlines entering and leaving the canopy indicate significant vertical advection at canopy top ($z/h = 0$). Note that the spacing of the streamfunction contours is different within (solid lines) and above (dotted lines) the canopy. This reflects the fact that velocity magnitudes within the canopy are much smaller than those above. The canopy-averaged results in Fig. 1 show that the mean concentration in the canopy is reduced in both cases compared to the simulation over flat ground, particularly for the small hill case. Figure 2 shows that this mean value disguises the significant horizontal variations in scalar concentration that occur throughout the canopy. In both cases concentrations deep in the canopy over the upwind slope are decreased as a result of advection of lower concentration air from above the canopy being transported down into the canopy and the high concentration air within the canopy being transported up out of the canopy both through advection and enhanced turbulent mixing. In general the concentrations in the recirculation region over the lee slope are higher, particularly near the separation and reattachment points. The precise location and magnitude of the maximum concentration varies between the two simulations. For the small hill (a) there is a tall thin band near the separation point at the front of the recirculation region with very high concentrations. The high concentration is associated with the stagnation of the flow near the separation point. Although the mean concentration in the canopy is lower than the case over flat terrain, the maximum concentration near the stagnation point is higher than values in the canopy over flat terrain. In contrast, over the large hill (b) the maximum concentration is a much wider and shallow region located at the rear of the recirculation region near the reattachment point. For intermediate hill widths (not shown) there are maxima in concentration at both locations, with both maxima slightly weaker.

Deep in the canopy velocities and turbulent transport are small in the background state, and the low mean velocity fields imply that there is little advection. Any induced background flow will therefore have a significant impact on tracer concentrations through a combination of advection and changes in turbulent transport. The separation and reattachment points are both stagnation points of the flow and these regions are therefore associated with low flow velocities and with reduced eddy viscosities (and hence lower turbulent transport). This would tend to suggest that concentrations would be highest in these regions, as observed. Whether or not the maximum is at the separation or reattachment point seems to be rather sensitive to the details of the flow and the turbulence scheme. Analysis of a number of simulations shows that the minima in eddy viscosity at these two stagnation points are always quite similar in magnitude, but that the maximum concentration corresponds to the smallest values of this eddy viscosity. In many cases the concentrations actually increase at the other stagnation point.

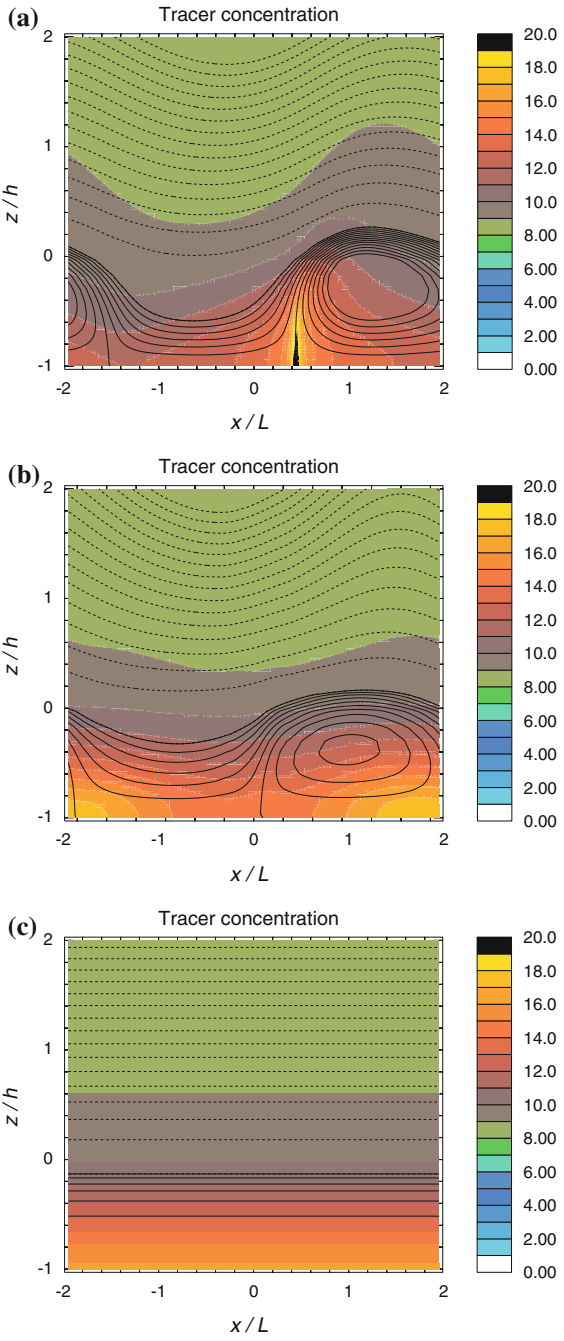

Fig. 2 Scalar concentration (*colours*) and streamlines (*lines*) over **a** a small hill ($L = 100\,\mathrm{m}$), **b** a large hill ($L = 1600\,\mathrm{m}$) and **c** flat ground. In both **a** and **b** the hill slope is the same ($H/L = 0.1$) and the canopy is the same ($L_c = 10\,\mathrm{m}^{-1}$ and $\beta h/l = 5.55$). The scalars are plotted in a terrain-following coordinate system. Streamlines are plotted as lines of constant streamfunction with the *solid contours* at intervals of $0.2\,\mathrm{m}^2\,\mathrm{s}^{-1}$ (mostly within the canopy) and the *dotted contours* at intervals of $5\,\mathrm{m}^2\,\mathrm{s}^{-1}$ (mostly above the canopy). This reflects the small velocities within the canopy compared to above

A more quantitative analysis of this across all the simulations supports this broad picture. Scaling analysis using the solution of Finnigan and Belcher (2004) gives the ratio of vertical advection to the pressure gradient term in the upper canopy as

$$\lambda = \frac{\pi}{4}\frac{L_c}{L}\exp\left(\frac{\beta h}{l}\right), \tag{14}$$

(Eq. 36 in Finnigan and Belcher 2004). The relationship between the location of the maximum scalar concentration in the canopy and the role of vertical advection can be quantified through the non-dimensional parameter that is required to be small in order that the vertical velocity at canopy top is negligible in the analytical model (Finnigan and Belcher 2004; Ross and Vosper 2005). Figure 2 suggests that the maximum tracer concentrations are closely linked with the separation region in the lee of the hill crest. To explore this Fig. 3a shows the location of the maximum tracer concentration relative to the separation point, $\xi = (x - x_s)(x_r - x_s)$, plotted against λ. Here x_s is the separation point and x_r the reattachment point so a value of zero for ξ means the maximum occurs at the separation point, while a value of 1 denotes the reattachment point. The figure clearly delineates two regimes. For cases where $\lambda > 5$ the maximum surface concentration occurs very close to the separation point, while for simulations where $\lambda \ll 5$ then the maximum concentration occurs near (but usually just upwind of) the reattachment point. In these cases the separation region is sufficiently weak that the maximum in scalar concentration occurs near the bottom of the hill or at the trailing attachment point of the separation region ($x_{\mathrm{trmax}} \approx 2$). Looking at individual cases it is clear that λ is not the sole quantity determining the location of flow separation. For a given canopy and hill width λ is fixed (e.g. simulations with $\lambda \approx 20$). Varying the hill height (and hence slope) still has an impact on the location of the flow separation, and hence the maximum in scalar concentration (as shown, for example, in Ross and Vosper 2005). Increasing the hill slope tends to shift the separation point closer to the hill summit as the greater adverse pressure gradient promotes earlier flow separation. In each case the scalar maximum is very close to the separation point as shown in Fig. 3a. For very sparse canopies increasing the hill height controls whether or not separation occurs. This is seen in the simulations with $\beta h/l = 1.39$ here, and only the one with the steepest slope exhibits separation.

The effect of the advection on the maximum concentration of the tracer is shown in Fig. 3b, which plots the maximum surface concentration normalized on the value in the equivalent flat canopy simulation ($c_{\mathrm{max}}/c_{\mathrm{flat}}$) plotted against λ. Although the data do not collapse as well as Fig. 3a it is clear that for small values of λ where advection is small then (as expected) $c_{\mathrm{max}}/c_{\mathrm{flat}} \sim 1$ and concentrations vary little from those over a flat canopy. In contrast, for $\lambda > 5$ there is a larger spread in the values of $c_{\mathrm{max}}/c_{\mathrm{flat}}$. Maximum concentrations are increased, in this case by up to 50% in some simulations, although again the actual maximum value is not solely determined by λ. For a fixed canopy and hill width, then increasing the hill height (and hence the slope, H/L) leads to an increase in the maximum tracer concentration as a result of more pronounced differences in the eddy viscosity between the separation and reattachment points.

A number of simulations were conducted with twice the horizontal and vertical resolutions to check the sensitivity of the results to model resolution. Doubling the resolution made no qualitative difference to the results. From a quantitative point of view there was almost no difference in the location of the separation region, or the maximum tracer concentrations deep in the canopy, although there was a slight increase in the calculated depth of the separation region with increased vertical resolution. Most sensitivity was observed at canopy top, where the strong vertical shear in the wind speed makes a high vertical resolution most necessary. Even here differences in canopy-top velocities and tracer concentrations were at most a few percent.

The conclusion of this analysis is that maximum concentrations almost always occur close to stagnation points. In the 1.5-order closure model the details of which separation

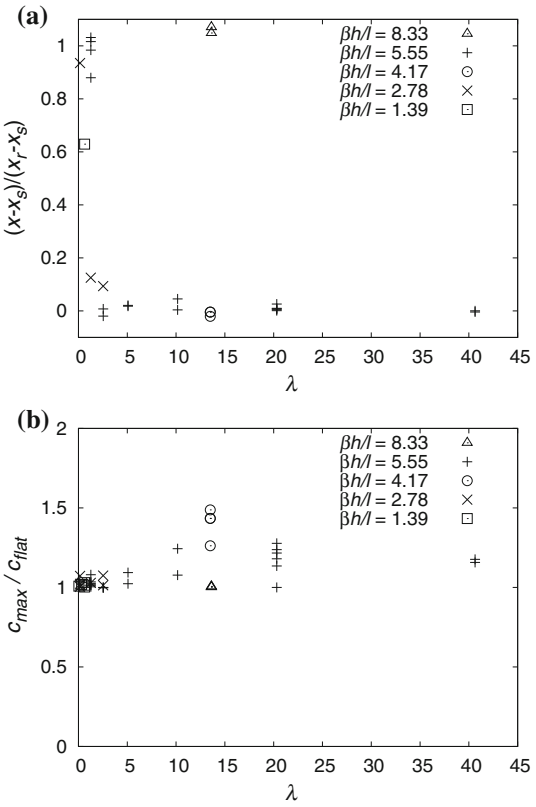

Fig. 3 **a** The non-dimensional location of the scalar maximum relative to the separation region $\xi = (x_{\mathrm{trmax}} - x_{\mathrm{s}})/(x_{\mathrm{r}} - x_{\mathrm{s}})$ where x_{trmax} is the location of the maximum surface tracer concentration, x_{s} is the location of the separation point and x_{r} is the reattachment point plotted against vertical velocity parameter, λ for different non-dimensional canopy depths $\beta h/l$. **b** The maximum tracer concentration normalized on the value within the equivalent flat canopy plotted against λ

point exhibits the highest concentration appears to be linked to the scale of the hill and the importance of vertical advection at canopy top. Smaller scale hills, where vertical advection is significant at canopy top, tend to exhibit minima of turbulent kinetic energy and eddy viscosity and maxima of tracer concentration at the separation point near the summit. Larger scale hills where canopy-top vertical advection is smaller show the minima of turbulent kinetic energy and eddy viscosity and the maxima of tracer concentration at the reattachment point near the foot of the hill.

The details of which separation point exhibits the maximum tracer concentration are sensitive to small differences in the induced flow, which lead to small differences in the turbulent kinetic energy and calculated eddy viscosity. The concentrations are therefore also likely to be sensitive to the details of the turbulence scheme. This is perhaps not surprising, but does mean that conclusions on the tracer concentrations in the deep canopy should be treated with some caution.

There are only a couple of simulations where the canopy is so shallow and sparse that no separation occurs at all. In these cases the maximum concentrations are observed near the foot of the hill similar to that observed in Fig. 2b. At this location the adverse pressure gradient over the lee slope generates the lowest wind speeds and hence the eddy viscosity is smallest. Above the canopy both the simulations in Fig. 2 exhibit horizontal variations in concentration. The scalar concentration isolines do not exactly coincide with the streamlines, suggesting that although advection plays an important role in modifying the scalar

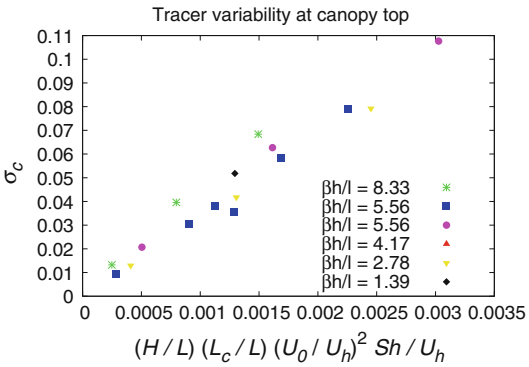

Fig. 4 The standard deviation of the tracer concentration at canopy top plotted against the scaling for tracer concentration from Eq. 12. Only experiments with $H/L < 0.1$ and $L/L_c \geq 50$ are included

concentrations over the hill, turbulent fluxes are also important. The horizontal variations are larger over the small hill, as expected, since the vertical velocities are larger. These general features are also reproduced in the other simulations (not shown). The analysis of Sect. 3 gives a scaling for canopy-top perturbations in tracer concentration. Here the magnitude of the canopy-top perturbations is characterized by the standard deviation of the canopy-top scalar concentration. Figure 4 shows the standard deviation of the canopy-top scalar concentration plotted against the scaling for the canopy-top tracer perturbation, c. Results are plotted only for simulations with $H/L < 0.1$ and $L/L_c \geq 50$, and so excludes the narrowest hills and steepest slopes where the Finnigan and Belcher (2004) model, and hence the tracer scaling, is not valid. Despite the fact that the analysis excludes the contribution to the variability from the deep canopy, the scaling is successful in collapsing the data from a wide range of simulations with different canopies and hills. This suggests that canopy-top variations in tracer concentrations may not be overly sensitive to the deep canopy solution, and hence may well be successfully predicted by a mixing-length turbulence closure scheme, unlike the deep canopy concentrations. For the narrower and steeper hills then vertical advection in the upper canopy plays an increasingly important role and the scaling appears no longer to hold (results not shown), with advection and the concentrations deeper in the canopy playing a bigger role.

Figure 5 shows the canopy top advection term for a number of different simulations. In Fig. 5a the advection is non-dimensionalized on the source term and results are shown for a fixed canopy ($\beta h/l = 5.56$, $L_c = 10\,\mathrm{m}$) and slope ($H/L = 0.02$) and only the scale of the hill is changed. For the widest hills advection is small compared to the source term, while for the narrowest hill ($L = 100\,\mathrm{m}$) the advection term at canopy top is comparable in magnitude with the scalar source term in the canopy and so advection plays an important role, as might be expected. The other interesting feature is that advection is particularly important over the lee slope in the recirculation region, which may be important for interpreting flux measurements over real forests. Figure 5b shows the advection over a range of different canopies and slopes for the widest hills ($L = 1600\,\mathrm{m}$). In this case advection is small compared to the source term and the scaling from (13) is expected to be valid. Results are shown non-dimensionalized on this scaling, which is reasonably successful in collapsing the results over the range of canopies and slopes. For a fixed canopy but different slopes the collapse is excellent ($\beta h/l = 5.56$ and $L_c = 10\,\mathrm{m}$ with $H/L = 0.02$ or $H/L = 0.00625$). For different canopies the scaling broadly predicts the magnitude of the advection terms, but there are some in magnitude and in the phase that reflect the fact that the scaling ignores the contribution to the advection from flow deep in the canopy. Nonetheless the scaling is a

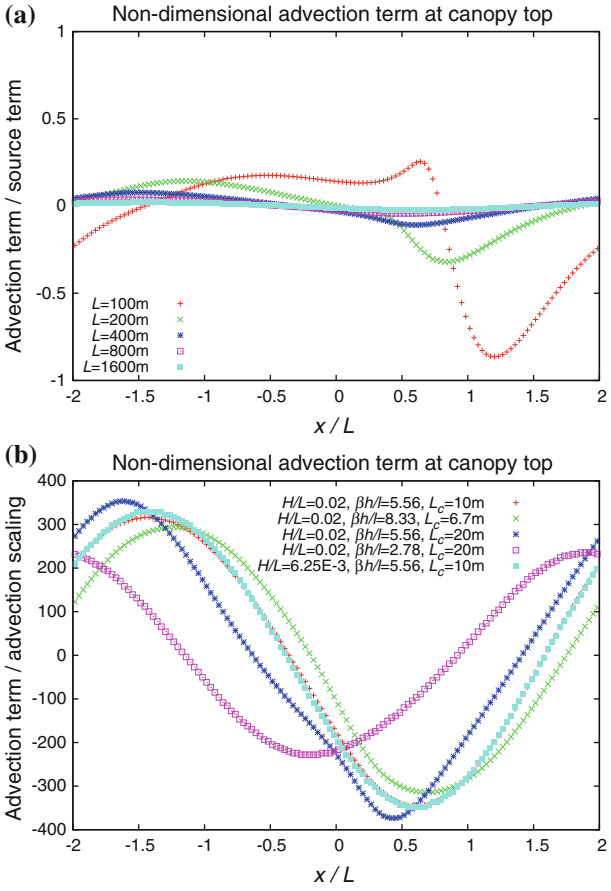

Fig. 5 Plots of the canopy top advection term as a function of non-dimensional distance across the hill for a number of different simulations. In **a** the slope and canopy are fixed ($H/L = 0.02$, $\beta h/l = 5.56$) and only the scale of the hill is changed ($L = 100-1600$ m). In **a** the advection term is scaled on the source term, S. In **b** a number of different simulations with fixed width $L = 1600$ m, but varying canopy and slope parameters are shown. The advection term is non-dimensionalized using the scaling in (13)

useful means of predicting the importance of scalar advection in these wide hill cases where advection is relatively weak. The scaling is less successful in the narrow hill regime where advection becomes large (not shown).

These simulations using the 1.5-order turbulence closure scheme and a fixed source of tracer within the canopy all demonstrate that advection can be important in modifying tracer concentrations over canopy-covered hills. In particular, wherever there is significant vertical advection at canopy top (small hills/dense canopies/deep canopies) transport is enhanced. This transport leads to lower mean concentrations within the canopy and significant horizontal variations in tracer concentration, which can actually lead to localized increases in tracer concentration. The horizontal variations are closely linked to flow separation and recirculation within the canopy and therefore scaling parameters that quantify these dynamical effects are also useful in explaining different regimes of behaviour in tracer concentrations. A simple scaling argument based on the analytical solution for flow over a forested hill successfully

collapses the observed tracer perturbations and also the tracer advection terms at canopy top over a wide range of simulations.

5 Large-Eddy Simulations

5.1 Large-Eddy Simulations over a Small Hill

Simulations with the 1.5-order closure scheme are useful because the scheme is simple and therefore the simulations are readily performed. This allows a wide range of parameter space to be investigated. Given the uncertainties over mixing-length closure schemes, and in particularly the sensitivity of tracer concentrations deep in the canopy to the turbulence scheme, then some form of validation of the results is however desirable. One way to address this is through the use of LES. Such simulations are significantly more computationally expensive and therefore a limited number of simulations are possible; however they can help to validate conclusions drawn from the simpler 1.5-order closure scheme results.

LES of flow over both a flat surface and a small hill ($H = 10\,\mathrm{m}$, $L = 100\,\mathrm{m}$) are presented. The model set-up is described in Sect. 2.1 and is identical to that used in Ross (2008) with the addition of a passive tracer. Ross (2008) demonstrated that, although some of the details of the flow, including the turbulence, were different between LES and mixing-length simulations, the mean flow and broad dynamic features were in good agreement. This is primarily because the flow is dominated by turbulence generated in the shear layer at canopy top and this is well represented in the mixing-length scheme.

Figure 6 shows profiles of the scalar concentration across the hill. Results from the LES over the hill (solid black line) are compared with results from simulations using the 1.5-order closure scheme over the same hill and from the LES model over flat ground. The canopy, hill and flow parameters are the same in both the LES and in the 1.5-order closure simulations. The 1.5-order results are presented for two different values of the empirical parameter β. The value $\beta = 0.30$ corresponds to the value assumed in Finnigan and Belcher (2004) and Ross

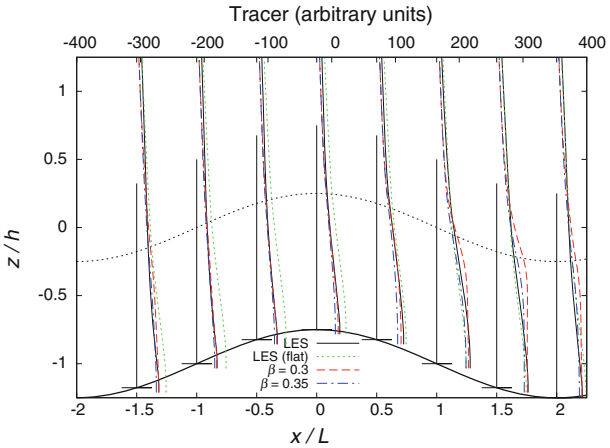

Fig. 6 Profiles of tracer (in arbitrary units) across a small hill from a LES simulation (*solid black line*), from a simulation using the 1.5-order closure scheme (*red dashed line*—$\beta = 0.3$ and *blue dot-dashed line*—$\beta = 0.35$). Also shown for comparison are the results from the LES over flat ground (*green dotted line*)

and Vosper (2005), while the value $\beta = 0.35$ was shown by Ross (2008) to better match the LES results in terms of the surface pressure field and wind-speed and shear-stress profiles. Here we see that all three simulations over the hill give very similar results in terms of scalar concentration profiles, suggesting that the scalar transport is not too sensitive to details of the turbulence scheme in this case. The results show small, but significant, differences from the results over flat ground. These differences are most noticeable over the upwind slope where mean-flow transport leads to lower concentrations deep in the canopy over the upwind slope compared to the flat case. Over the lee slope the concentrations in the recirculation region are slightly increased compared to the flat case, but the differences are smaller than over the upwind slope. Differences in the tracer profiles over the hill appear principally in the separation region over the lee slope. Again the value of $\beta = 0.35$ better reproduces the LES results, particularly near canopy top over the lee slope. Note that both values of β lie within the range of observed values from real forest canopies. These results are qualitatively similar to those observed using the 1.5-order closure scheme in Sect. 2. A closer examination of the tracer concentrations shows that the region of high tracer concentration over the lee slope has a lower maximum and is more spread out in the LES simulation compared to the mixing-length closure scheme. This is entirely consistent with Fig. 5b of Ross (2008), which showed that the LES predicted higher values for the turbulent kinetic energy in this region, and hence would be expected to exhibit more turbulent mixing. This probably reflects the fact that, although there is little mean flow in the deep canopy, there is significant variability in the flow and in the tracer concentrations resulting from the flow in the upper canopy and above penetrating downwards.

5.2 The Turbulent Schmidt Number

The first-order mixing length closure scheme assumes that the Reynolds shear stress, $\tau_{ij} = -\rho\overline{u_i' u_j'}$, and Reynolds-averaged turbulent tracer mixing term, $\overline{u_i' c'}$ are given by

$$\overline{u_i' u_j'} = K_\mathrm{m}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right), \tag{15a}$$

$$\overline{u_i' c'} = K_\mathrm{c}\frac{\partial c}{\partial x_i}. \tag{15b}$$

In the first-order turbulence scheme K_m is determined using a mixing-length closure. Ross (2008) examined the validity of this mixing-length approximation for K_m using the LES results. Implicit in the first-order mixing length closure is the assumption that the turbulent Schmidt number (the ratio of the turbulent diffusivities for momentum and scalar),

$$Sc \equiv \frac{K_\mathrm{m}}{K_\mathrm{c}} \tag{16}$$

is equal to 1, i.e. momentum and scalars are identically mixed by turbulence. Experimental observations in the atmospheric boundary layer do not necessarily satisfy Eq. 15b for all components, i. In general K_m and K_c are defined to ensure that this is a reasonable approximation in the direction of the dominant turbulent flux. To calculate K_m and K_c from the LES data the vertical components are taken so

$$K_\mathrm{m} = \frac{\overline{u'w'}}{\partial u/\partial z + \partial w/\partial x}, \tag{17a}$$

$$K_\mathrm{c} = \frac{\overline{w'c'}}{\partial c/\partial z}. \tag{17b}$$

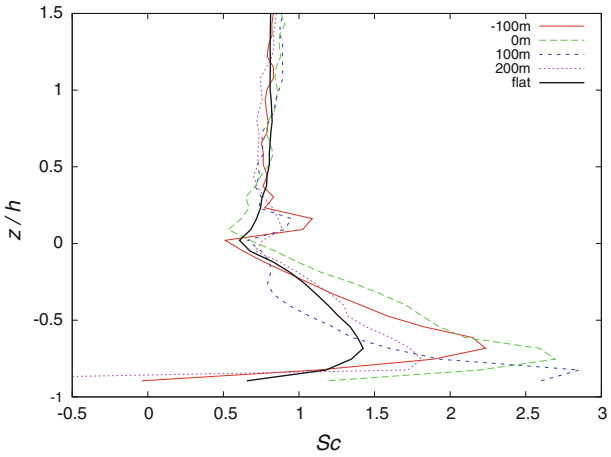

Fig. 7 Profiles of the turbulent Schmidt number on flat ground and at four locations over the hill derived from the LES. Canopy top is at $z/h = 0$

In the boundary layer the Schmidt number is generally close to 1, however observations in forest canopies show that the Schmidt number decreases to about 0.5 in the reduced surface layer that extends up to a few canopy heights above canopy top (Harman and Finnigan 2008). This is also observed in the LES simulations over flat terrain (see Fig. 7). Within the canopy the LES then demonstrates a sharp increase in the Schmidt number up to a maximum of about 2 at a height of 5m above the ground, before it then decreases again towards the surface. Variations in the Schmidt number within the canopy are perhaps unsurprising as mixing-length closure schemes are known not to perform particularly well there (see e.g. Ross 2008). From a dynamical point of view this has a relatively small impact since turbulent momentum fluxes are small deep within the canopy due to the small vertical wind shear. This is not necessarily the case for tracer fluxes, where there may still be significant gradients in tracer concentration.

Figure 7 also shows profiles of the Schmidt number derived from the LES at four different locations across the hill. These are slightly noisier, since averaging is only done in the lateral direction and over time on the hill, whereas streamwise averaging is also performed for the simulation over flat ground. All four profiles show similar trends to the results over flat ground with the Schmidt number decreasing from around 1 well above the canopy to a minimum near canopy top, and then increasing within the canopy to a maximum at about 5 m above the ground. There are however significant quantitative differences between profiles.

Well above the forest canopy results are similar for all profiles. Closer examination of the turbulent diffusivities in Fig. 8 shows that both K_m and K_c are enhanced over the hill, but by similar amounts. This is due to increases in both the horizontally averaged momentum and scalar fluxes. This is perhaps slightly surprising and may be due in part to starting the LES averaging before the simulation has settled to a statistically stationary state. What is surprising is that despite these differences the calculated values of Sc above the canopy vary little over the hill and compare very well with the results over flat ground. The values of K_m and K_c increase particularly above the recirculation region ($x = 200\,\mathrm{m}$) in what is likely to be a real dynamic effect due to the hill. Just above canopy top the systematic variations between K_m and K_c compared to the flat case are smaller but there are much more significant differences in the Schmidt number with lower values than over flat ground at the summit of

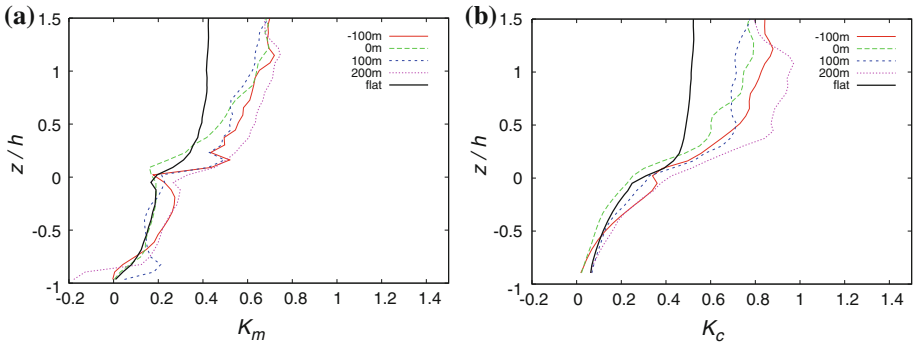

Fig. 8 Profiles of the turbulent diffusivity for **a** momentum, K_m and **b** tracer, K_c on flat ground and at four locations over the hill derived from the LES. Canopy top is at $z/h = 0$

the hill and larger values elsewhere over the hill. The larger values of the Schmidt number in this region, up to values of about 1, are principally due to enhanced values of K_m in this region compared to over flat ground. This suggests that increased shear and vertical advection at canopy top are important in modifying turbulent transport just above the canopy, which is entirely in accord with the scaling analysis of Sect. 3.

Within the canopy the Schmidt numbers over the hill exceed those over flat ground in most locations, and in particular the maximum values at low level are significantly larger, up to about 3. This is due to a combination of increased values of K_m over the lee slope (100 m) and in the valley (200 m) , and reduced values of K_c on the upwind slope (-100 m) and near the summit (zero height). The only place within the canopy where the Schmidt number is less over the hill than on flat ground is in the upper part of the canopy over the lee slope (100 m). This is in the recirculation region, and the low wind shear in this region leads to reduced values of K_m compared to other parts of the canopy, although the impact on K_c is less.

What these LES results show is that the relationship between K_m and K_c is not simple within and above forest canopies. This particular small hill, where vertical advection is significant, is likely to be an extreme case, however this variability in the Schmidt number potentially makes modelling of tracer transport using mixing-length closure schemes difficult. It would be possible to devise a scheme where Sc scaled with height to match results over flat ground, as done in Harman and Finnigan (2008), however these results suggest that even this approach might not be sufficient over hills. Having said this it is then perhaps surprising that the tracer profiles from the 1.5-order model agree so well with those from the LES in Fig. 1. Perhaps this suggests that tracer advection actually dominates in these cases and so errors in turbulent tracer fluxes are less important. This does seem to agree with the conclusions of the scaling analysis in Sect. 3 that the leading order perturbation in the turbulent fluxes is zero. This is clearly a topic for further research in terms of modelling scalar transport within and above forest canopies over complex terrain. In particular it would be interesting to make LES for much wider hills where advection is smaller and hence turbulent transport is more important.

6 Implications for Flux Measurements

Observations of carbon uptake by forests are frequently made using eddy-covariance flux measurements on a large tower (e.g. the FLUXNET project Baldocchi et al. 2001) and

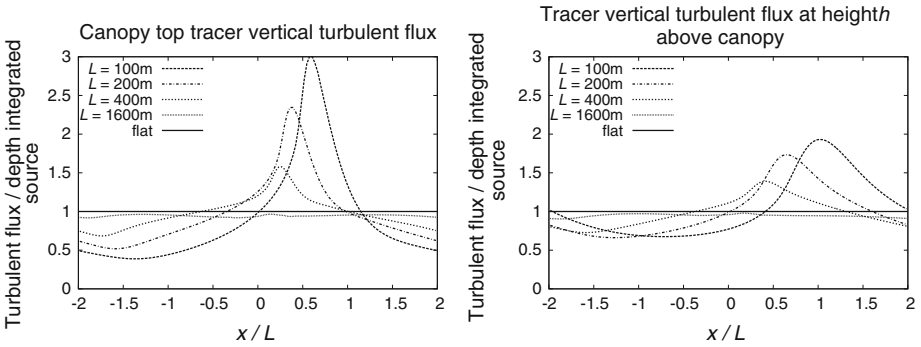

Fig. 9 Canopy-top turbulent scalar flux (normalized on the depth-integrated canopy source term) plotted against the position across the hill (non-dimensionalized on the hill width) for different hills (simulations 3, 5 and 7 in Sect. 2)

assuming that this is representative of a forest. Many forested sites are not truly flat though and so the assumptions of horizontal homogeneity are not exactly met. The potential impact of advection on the flux measurements has to be considered. Nighttime drainage flows on even gentle slopes are an often-cited source of errors in flux measurements (e.g. Wilson et al. 2002; Belcher et al. 2008), however this work shows that even under neutral, strong wind conditions advection may be non-negligible. There is evidence of this from the FLUXNET sites. The study of Wilson et al. (2002) demonstrated an average imbalance of around 20% in the energy balance, even in daytime conditions. The imbalance was observed even for well-mixed conditions (i.e. more neutral flow with stronger winds), although it increased for lower wind speeds and was much larger in nocturnal conditions. The advective effects demonstrated in our study, even for large hills with relatively small slopes, are certainly consistent with these observations. Figure 9 shows the turbulent scalar flux (non-dimensionalized on the depth integrated scalar source term) at canopy top and height h above the canopy for three different hills with the same slope ($H/L = 0.1$), but different scales ($L = 100, 200, 400, 1600$). In each case the canopy and the uniform scalar source term are the same ($\beta h/l = 5.55$, $L_c = 10\,\mathrm{m}$, $S = 10^{-2}\,\mathrm{m}^{-3}\,\mathrm{s}^{-1}$). For steady-state flow over flat ground the non-dimensional scalar flux has a value of one since production in the canopy is balanced by the turbulent transport at canopy top. For the widest hill, with relatively weak canopy-top vertical velocities, the canopy-top scalar fluxes only vary a small amount across the hill. Note that the total flux integrated across the hill is slightly less than the flat-ground case, suggesting that advection is responsible for a small net transport of scalar out of the canopy. As the scale of the hill decreases the variability in the canopy-top fluxes increases significantly. At some points over the smallest hill point measurements of the canopy-top turbulent flux vary by up to a factor of three compared to the source term. Variations at a height h above the canopy are qualitatively similar, but smaller in magnitude than those at canopy top. The increased height above the canopy smooths out some of the canopy-induced variability. For the smallest hill there is still a difference of up to a factor of two compared to the flat-ground case.

A further consideration when interpreting flux measurements is that the flow into and out of the canopy implies that streamlines are not parallel to the terrain or to canopy top, and therefore techniques that rotate sonic anemometer measurements into a mean flow coordinate system, or use a planar fit to the flow data as a coordinate system (see e.g. Lee et al. 2004), may not give the expected results. In particular, the lack of symmetry to a reversal of wind

direction means that even for an ideal symmetrical hill and ideal conditions the averaged wind data do not lie in a plane. For large-scale hills the effect is relatively small, but for smaller scale hills it may be significant.

Modelling studies such as these are not yet practical for correcting or scaling observational flux measurements for the effects of terrain, however they do provide important indications of the type and magnitude of errors that may be introduced through neglecting such effects. They may also provide guidance into the most suitable locations for making flux measurements that are truly representative of a larger area.

7 Conclusion

Our study provides a systematic investigation of the impact of hills on scalar concentration and transport within and above a forest canopy. With a fixed uniform source of scalar within the canopy the dynamics of the canopy–boundary-layer interactions (previously studied by e.g. Finnigan and Belcher 2004; Ross and Vosper 2005) dominate. Over hills the pressure field resulting from the presence of the hill drives flow into and out of the canopy and this dynamical process acts like a pump to remove scalars more efficiently from the canopy space; this reduces the mean concentration of scalar within the canopy for a fixed source term. This effect is particularly strong for small-scale hills where the canopy-atmosphere mean flow is largest. Although the overall effect is to reduce mean scalar concentrations in the canopy, there is a large spatial variability in concentrations in the canopy, with the maximum concentrations at a given canopy depth often exceeding those over flat ground. This is closely linked to flow separation in the lee of the hill trapping scalars in the canopy. In cases where there is moderately strong vertical advection at canopy top then the maximum concentrations occur near the separation point. Low wind speeds and shear in this region result in weak turbulent transport and long canopy residence times for the air, which both contribute to higher scalar concentrations. While these broad features are relatively robust it is likely that the details of tracer concentrations in the canopy are sensitive to the turbulence closure scheme. Canopy-top tracer variations can be successfully predicted using a simple scaling argument that neglects the deep canopy. This works well for relatively wide hills and suggests that in these cases first-order closure schemes may be more successful than anticipated in predicting tracer concentrations. Similar results for time-averaged scalar concentrations are seen for a LES of flow over a small hill based on the simulations in Ross (2008). The LES does highlight the unsteady and intermittent nature of the flow in the canopy. Calculations of the Schmidt number in the LES also suggest that the common assumption that momentum and scalars are transported in the same way is not valid within and just above the canopies, with significant variations in the Schmidt number in the vertical and across the hill. In principle at least some of this variability could be represented with a parametrization of the Schmidt number in the canopy, but whether this is the most significant source of uncertainty in mixing-length closure models for canopy flows remains to be studied.
