# **ESTIMATION OF VECTORS SIMILARITY BY THEIR RANDOMIZED BINARY PROJECTIONS**

**D. A. Rachkovskij** UDC 004.22 + 004.93'11

**Abstract.** *We analyze the estimation of the angle, scalar product, and the Euclidean distance of real-valued vectors using binary vectors with controlled sparsity. Transformation is carried out by projection using a binary random matrix with elements*  $\{0,1\}$  *and the output threshold transformation. We also provide a comparative analysis of the error obtained while estimating the similarity measures of input vectors by some similarity measures of output binary vectors based on their scalar product.*

**Keywords:** *binary random projections, sparse binary representations, estimate of vector similarity.*

## **INTRODUCTION**

Vectorial data representation seems to be the most popular in information technologies. Many search methods using similarity, classification, regression, clustering, as well as methods of estimating quantities based on measurements are intended for vector data handling. At the same time, the amount of complex-structured data, for example, XML structures or oriented acyclic graphs of knowledge bases in KIF, CycL languages, including representations of episodes in models of analogical reasoning [1–11] increase. However, methods of handling complex-structured data are computationally difficult. To increase handling efficiency, they are transformed into vectors, which allow us to estimate the characteristics important in the context of the problem being solved (for example, similarity measures) and to use these estimates to solve the original problem (see [7, 12] and references therein).

The complexity of handling vector data is proportional to the dimension and number of vectors. To deal with large arrays of large-dimensional vectors, a number of approaches are used. The most obvious is application of the brute force method, which is a powerful computing resource. For example, efficient implementation of vector operations is supported by vector (co)processors and, moreover, these operations are naturally parallelized. This allows using parallel computing tools: multi-core processors, parallel computers, and high-performance computing clusters and distributed computing systems (see [13–15] and references therein).

Another approach to increasing the efficiency of vector data handling is based on the fact that many applications do not require exact results of operations over original vectors (for example, calculation of scalar products, distances, etc.), an approximate but fast estimate is enough. For example, in similarity search problems it is often more important to quickly determine approximate "nearest neighbors" than to search for exact ones for a long time. To implement this approach, a number of methods of transformation of vector arrays is developed.

The methods reducing vector dimension [16, 17] can be adjusted for the special features of their basis used as a training sample. Methods of supervised and unsupervised training (adaptation) are applied.

Methods of unsupervised training detect the most informative (according to the given criteria) new coordinates in the data and reduce the dimension by eliminating some of them. The similarity measures of the original vectors can be distorted. For example, principal component analysis (PCA) reveals orthogonal directions in the data, which minimize the distortion of

International Scientific and Training Center of Information Technologies and Systems, National Academy of Sciences and Ministry of Education and Science of Ukraine, Kyiv, Ukraine, *dar@infrm.kiev.ua*. the Euclidean distances between vectors. This reduces distance estimate, and the error increases with the number of eliminated measurements.

In a number of supervised dimension reduction methods, the similarity of resultant vectors reflects the "semantic similarity" of input data [18]. Obtaining this information involves a lot of labor on estimating the similarity of original objects, usually done by an expert.

A common disadvantage of many supervised dimension reduction methods is the computing complexity of the solution of their optimization problems, for example, singular value decomposition or gradient descent procedures (with possible local minima). Moreover, application of some methods involves difficulties in transformation of new data that were not used in training. Obtaining their reduced short representations can demand repeated training or estimation of the similarity with a considerable part of the training sample.

The shortcomings of supervised dimension reduction methods have caused the development of the approach to transformation of vector data without adaptation, so-called random projection [19–27]. In this method, to transform input vectors into output ones, multiplication by a random matrix is carried out; elements of the matrix are randomly generated and then fixed numbers from some distribution. In a number of studies (for example, [19, 20, 26]), the accuracy of estimates of some similarity–distinction measures is analyzed when random matrices of certain form are used. For example, it is shown in [26] that transformation by a simple (from the point of view of generation and application) binary random matrix with elements  ${0, 1}$  allows estimating the Euclidean distance, norm, and scalar product of input vectors using output vectors.

Some approaches and methods require specialized algorithms for storage and handling of vector data in a certain format (representation). Sparse [28, 29] (with a small share of nonzero components) binary vectors are used, for example, in associative-projective neural networks [30, 31] and in the efficient binary version [32–34] of distributed associative memory [10, 11, 35–38]. format (representation). Sparse [28, 29] (with a small share of nonzero components) binary vectors are used, for exar<br>in associative-projective neural networks [30, 31] and in the efficient binary version [32–34] of distr ez<br>se<br>ty

The formation of binary output vectors with controlled sparsity, which can be used to estimate the similarity (angle value) of real-valued input vectors, is considered in [25] for a ternary random matrix with elements from  $\{-1, 0, +1\}$ , and in [27] for a binary matrix. In the present paper, we will analyze the estimates of the angle, Euclidean distance, and scalar product of input vectors based on a series of similarity characteristics of binary output vectors when a random binary matrix is used for the transformation.

## **PROJECTION BY A RANDOM BINARY MATRIX AND ESTIMATE OF SIMILARITY MEASURES USING BINARY VECTORS**

Similarly to [26, 27], we consider projection of vectors by a random binary matrix **R** with elements  $r_{ij}$  from the set  $\{0, 1\}$ . Random variables (r.v.) whose realization are elements of **R** (ones and zeros) are independent and have identical **distribution (i.i.d.).** Each  $r_{ij}$  takes the value 1 with probability *q* and value 0 with probability 1-<br>distribution (i.i.d.). Each  $r_{ij}$  takes the value 1 with probability *q* and value 0 with probability 1distribution (i.i.d.). Each  $r_{ii}$  takes the value 1 with probability q and value 0 with probability  $1-q$ . Denote by **x** and **y** input Similarly to [26, 27], we consider projection of vectors by a random binary matrix **R** with elements  $r_{ij}$  from the set {0, 1}. Random variables (r.v.) whose realization are elements of **R** (ones and zeros) are independe Similarly to [26, 27], we consider projection of v<br>{0, 1}. Random variables (r.v.) whose realization are el<br>distribution (i.i.d.). Each  $r_{ij}$  takes the value 1 with proba<br>real-valued vectors of dimension *D* and by  $\mathbf{$ real-valued vectors of dimension *D* and by  $\mathbf{u} = \mathbf{R} \mathbf{x}$  and  $\mathbf{v} = \mathbf{R} \mathbf{y}$  the results of their projection (intermediate vectors of dimension *d*). Hence, the dimension of **R** is  $(d \times D)$ . bility q and<br> **r r r x**<br> **r r x**<br> **r r x**

The standardization of  $u_i$  is carried out by subtraction of expectation (2)  $q \sum x_j$ *j D*  $\sum x_i$  (centering) and dividing by the root 1  $\frac{1}{a^2}$ 

mean square deviation  $||x||_2 \sqrt{q-q^2}$  (square root of (3)). The distribution of the standardized r.v.  $u_i$  converges to the Gaussian one with zero mean value and unit variance. The convergence rate of  $u_i$  is analyzed in Gaussian one with zero mean value and unit variance. The convergence rate of  $u_i$  is analyzed in [27] (for the review of the convergence problem for the general case see [39, 40]).

The binary output vector is formed by the binarizing threshold transformation of the intermediate vector  $\mathbf{u} \to \mathbf{z}$ :

$$
z_i = 1 \text{ for } u_i > t_i; \ z_i = 0 \text{ otherwise, } i = 1, \dots, d,
$$
 (4)

where  $t_i$  is the threshold value for the  $i$ th component of the output vector. We will use identical threshold values for all the components,  $t_i \equiv t$ . The given probability *p* of the unit component *z* of the binary output vector **z** is determined the components,  $t_i \equiv t$ . The given probability *p* of the unit component *z* of the binary out by choosing the appropriate threshold  $t_p$ . The random variable  $k = \langle z_1, z_2 \rangle$  has binomial distribution [25]:  $P(k) = \beta(k, d, p_{join})$  with the expectation *E*{ $k$ } =  $dp_{join}$  and variance  $V$ { $k$ } =  $dp_{join}$  (1 –  $p_{join}$ ). Therefore,<br>  $E$ { $p_{join}^*$ } =  $E$ { $k/d$ } =  $p_{join}$ ,<br>  $V{p_{join}^*}$ } =  $V$ { $k/d$ } =  $V$ { $k$ }  $d^2$  =  $p_{join}$  (1 –  $p_{join}$ )/ d *E* binomial distribution [25]<br>*P<sub>join</sub>* ). Therefore,<br> $E\{p_{join}^*\} = E\{k/d\} = p_{join}$ ,

$$
E\{p_{join}^{*}\} = E\{k/d\} = p_{join},
$$
  

$$
V\{p_{join}^{*}\} = V\{k/d\} = V\{k\}/d^{2} = p_{join} (1 - p_{join})/d.
$$
  
(9)  
with (9), we write (8) as  

$$
E\{\theta_{join}^{*}\} = f_{join}(p_{join}), V\{\theta_{join}^{*}\} = (f_{join}'(p_{join}))^{2} p_{join} (1 - p_{join})/d.
$$
 (10)

Taking into account  $(9)$ , we write  $(8)$  as

Taking into account (9), we write (8) as  
\n
$$
E\{\theta_{join}^*\} = f_{join}(p_{join}), V\{\theta_{join}^*\} = (f_{join}'(p_{join}))^2 p_{join} (1-p_{join})/d.
$$
\n(10)  
\nTo estimate the value of the derivative  $f_{join}'(p_{join}) \equiv \theta'(p_{join})$  using the known value of probability  $p_{join}$ , we can

use the tabulated function (5), having found the nearest value in the table from  $p_{join}$  and the angle corresponding to it  $\theta$ , and  $E{\theta_{join}}^* = f_{join}(p_{join}), V{\theta_{join}}^* = (f_{join}(p_{join}))^2 p_{join}(1-p_{join})/d.$  (10)<br>To estimate the value of the derivative  $f_{join}'(p_{join}) \equiv \theta'(p_{join})$  using the known value of probability  $p_{join}$ , we can<br>use the tabulated function (5), having found the ne the found and adjacent cells of the table, respectively. Hence, if  $\theta$  is known, to find the "analytical" expectation and the variance of its estimate using  $p_{join}^*$ , we will find in the tabulated (5) using  $\theta$  the respective probability  $p_{join}$  and having calculated  $\Delta\theta/\Delta p$ , where  $\Delta\theta$  and  $\Delta p$  is the difference of the values of angles and probabilities between the value in the found and adjacent cells of the table, respectively. Hence, if  $\theta$  is known, to fin

Along with the estimate of the angle with respect to the empirical probability  $p_{join}$ , we will analyze its estimate with respect to the empirical conditional probability  $p_{cond}$  of the coincidence of unit components of output binary vectors, and also with respect to the empirical probability *pequ* of the coincidence of values of their components (both unit and zero). *p* conditional probability  $p_{cond}$  of the coincidence of unit components of output binary vectors, and mpirical probability  $p_{equ}$  of the coincidence of values of their components (both unit and zero).<br> *p<sub>rond</sub>* in terms

Let us express  $p_{cond}$  in terms of  $p_{join}$ . For binary vectors with identical probability  $p$  of the unit component we have

$$
p_{cond} \equiv p(z_{1,i} = 1 | z_{2,i} = 1) = p(z_{1,i} = 1, z_{2,i} = 1) / p(z_{2,i} = 1) = p_{join} / p.
$$
\n(11)

 $p_{cond} = p(z_{1,i} = 1 | z_{2,i} = 1) = p(z_{1,i} = 1, z_{2,i} = 1) / p(z_{2,i} = 1)$ <br>We will find the dependence of  $p_{cond}$  on the angle by dividing (5) by *p*. *and* on the angle by dividing (*c*,<br>, where  $|z_2|$  is the number of<br> $E \{p_{cond}^* \} = E \{k/(pd)\} = p_{cond}$ ,

Having found  $p^*_{cond} = \langle \mathbf{z}_1, \mathbf{z}_2 \rangle / |\mathbf{z}_2|$ , where  $|\mathbf{z}_2|$  is the number of unit components of  $\mathbf{z}_2$ , we can calculate

Having found 
$$
p_{cond}^* = \langle \mathbf{z}_1, \mathbf{z}_2 \rangle / |\mathbf{z}_2|
$$
, where  $|\mathbf{z}_2|$  is the number of unit components of  $\mathbf{z}_2$ , we can calculate\n
$$
E\{p_{cond}^*\} = E\{k/(pd)\} = p_{cond},
$$
\n
$$
V\{p_{cond}^*\} = V\{k/(pd)\} = V\{k\}/(pd^2) = p_{cond}(1 - p_{cond})/(pd),
$$
\n(12)\nsince no more than *pd* unit components can coincide. We will find the values of  $f'(p_{cond}) \equiv \theta'(p_{cond})$  from the

tabulated  $p_{cond}$  similarly to  $p_{join}$  and obtain  $[ed]$ } =  $V\{k\}$  / ( $pd^2$ ) =  $p_{cond}$ <br>coincide. We will find to  $E\{\theta^*_{cond}\} = f_{cond}(p_{cond})$ ,

components can coincide. We will find the values of 
$$
f'(p_{cond}) \equiv \theta'(p_{cond})
$$
 from the *E* { $\theta^*_{cond}$ } =  $f_{cond}(p_{cond})$ ,

\n $V\{\theta^*_{cond}\} = (f'_{cond}(p_{cond}))^2 p_{cond}(1 - p_{cond})/(pd)$ .

\n(13)

\n $p_{equ} \equiv p(z_{1,i} = z_{2,i}) = 1 - p(z_{1,i} \neq z_{2,i}) = 1 - (p(z_{1,i} = 1))$ 

For  $p_{equ}$  we write

For 
$$
p_{equ}
$$
 we write  
\n
$$
p_{equ} = p(z_{1,i} = z_{2,i}) = 1 - p(z_{1,i} \neq z_{2,i}) = 1 - (p(z_{1,i} = 1)
$$
\n
$$
+ p(z_{2,i} = 1) - 2p(z_{2,i} = 1, z_{2,i} = 1)) = 1 - (2p - 2p_{join}).
$$
\n(14)  
\nWe will find the dependence of  $p_{equ}$  on the angle using  $p_{join}$  (5) and  $p$ .  
\nHaving found  $p_{equ}^* = 1 - z_1 \oplus z_2 / d$ , where  $\oplus$  is the component-wise "exclusive OR" operation, similarly to (9), (10),

(12), and (13) we obtain *E equ* on the angle using  $p_{join}$  (5) and  $p_2 / d$ , where  $\oplus$  is the component-wise "exclusiv<br> $E\{p_{equ}^* \} = p_{cond}$ ,  $V\{p_{equ}^* \} = p_{equ} (1 - p_{equ}) / d$ *E*  $\{p_{equ}^* \} = p_{cond}, V\{p_{equ}^* \} = p_{equ} (1 - p_{equ})/d,$ <br> *E*  $\{p_{equ}^* \} = p_{cond}, V\{p_{equ}^* \} = p_{equ} (1 - p_{equ})/d,$ <br> *E*  $\{\theta_{equ}^* \} = f_{equ} (p_{equ}), V\{\theta_{equ}^* \} = (f_{equ} (p_{equ}))^2 p_{equ} (1 - p_{equ})/d$ 

$$
E\{p_{equ}^* \} = p_{cond}, \ V\{p_{equ}^* \} = p_{equ} (1 - p_{equ})/d, \tag{15}
$$

$$
E\left\{\theta_{equ}^{*}\right\} = f_{equ}\left(p_{equ}\right),\ V\left\{\theta_{equ}^{*}\right\} = \left(f'_{equ}\left(p_{equ}\right)\right)^{2}\,p_{equ}\left(1 - p_{equ}\right)/\,d.\tag{16}
$$

As shown in [25], the probability *p join* of the coincidence of unit components of the output binary vectors monotonically decreases as the angle  $\theta$  increases. According to (11) and (14), this is also true for  $p_{cond}$  and  $p_{equ}$ . Hence, the estimates of these probabilities  $p_{join}^*$ ,  $p_{cond}^*$ , and  $p_{equ}^*$  can be useful as the measures of similarity of input vectors (without using them to calculate angle estimates).

**Estimate of the Scalar Product and Euclidean Distance.** As was mentioned above, the standardization of  $u_i$  to obtain binary output vectors requires the Euclidean norms of original vectors  $||\mathbf{x}||$  and  $||\mathbf{y}||$  to be known. The norm is calculated once for one vector and the obtained number is saved. This information, together with the angle estimate  $\theta^*$ **Estimate of the Scalar Product and Euclidean Distance.** As was mentioned above, the standardization of  $u_i$  to obtain binary output vectors requires the Euclidean norms of original vectors  $||\mathbf{x}||$  and  $||\mathbf{y}||$  to be obtain binary output vectors re<br>is calculated once for one vecto<br>with respect to binary output ve<br>Euclidean distance  $||\mathbf{x} - \mathbf{y}||^{2^*}$ : and number is saved. #### **EXPERIMENTAL ANALYSIS**

We analyzed the behavior of the error of estimate of the angle between input vectors, scalar product, and the Euclidean distance between them. The estimates were found from the output binary vectors of different sparsity. As the error of angle estimate, we used the variance  $V$ ; the error of the estimate of scalar product and distance was measured by the or angle estimate, we used the variance  $V$ ; the error or the estimate or scalar product and distance was measured by the variation coefficient  $V^{1/2}/E$ . The results of the dependence of the error of angle estimate on th output vectors are presented in [27], where the dependence of the error on the angle between input vectors was analyzed. a<br>fi(<br>si

To transform input real-valued vectors **x** and **y** into intermediate ones **u** and **v**, random matrices with binary { } 0 1, and  $t$  for standardized values of components of intermediate vectors  $u_i$  was selected to maintain the probability of unit component  $p = \{0.5, 0.1\}$  in output binary vectors, i.e.,  $t_p = \{0.0, 1.282\}$ . ternary  $\{-1, 0, +1\}$  elements were used; the probability of a nonzero element of matrices is  $q = \{0.5, 0.1\}$ . The threshold value t for standardized values of components of intermediate vectors  $u_i$  was selected to main component  $p = \{0.5, 0.1\}$  in output binary vectors, i.e.,  $t_p = \{0.0, 1.282\}$ .<br>Input vectors with  $D = 1000$  and output binary vectors with  $d = 1000$  were used. The similarity was varied by the concatenation of vectors **a** 

are zero, we obtain identical vectors **b** of dimension *d*, and if the dimension of **b**is zero, we obtain different vectors **a** and **c** of Input vectors with  $D = 1000$  and output binary vectors with  $d = 1000$  were used. The similarity was va<br>concatenation of vectors **a**, **b**, and **c**: **x** = (**a b**) and **y** = (**c b**) of different dimensions. For example,  $\frac{1}{3}$  as eq.  $[D, +D]$ . Since the concatenation of vectors **a**, **b**, and **c**: **x** = (**a b**) and **y** = (**c b**) of different dimensions. For example, if the dimensions of **a** and **c** are zero, we obtain identical vectors **b** of dimension *d*, and if the are zero, we obtain identical vectors **b** of dimension *d*, and if the dimension of **b** is zero, we obtain different vectors **a** and **c** of dimension *d*. The components of **a**, **b**, and **c** were generated randomly from u dimension d. The components of **a**, **b**, and **c** were generated randomly from uniform distribution in  $[-D, +D]$ . Since the dimensions of input vectors  $(D = 1000)$  are big, their norms are close. A typical value of the angle dimensions of input vectors ( $D = 1000$ ) are big, their norms are close. A typical value of the angle between random vectors is approximately 90°, i.e., random vectors are almost orthogonal. For random vectors with uniform imately 90°, i.e., random vectors are almost orthogonal. For random vectors with uniformly distributed positive nents, the angle is usually 40° to 45°. For such vectors, the orthogonality can be attained for nonintersecti almost orthogonal. For random vectors with uniformly distributed positive and vectors, the orthogonality can be attained for nonintersecting parts<br> $\frac{1}{2}$  the velue of  $(7, 7)$  d can exceed the greatest possible velue  $\sum_{j=1}^{n}$ 

components, the angle is usually 40° to 45°. For such vectors, the orthogonality can be attained for nonintersecting parts of vectors  $\mathbf{x} = (\mathbf{a} \ 0)$  and  $\mathbf{y} = (0 \ \mathbf{b})$ .<br>For the estimates of joint probability  $p_{join}$ used for the case  $p_{join}^* > p_{join}^{max}$ , and the obtained value of the angle was considered negative.  $y = ($ <br>tes of<br>onder

The results were averaged over 10,000 realizations of a random matrix.

The experiments have shown that values of errors for the analyzed parameters are close for binary and ternary random matrices. Therefore, we will present the results for binary matrix.

Fig. 1. Dependences of the error of estimate of the angle  $\theta$  between output

Figure 1 shows the dependences of error *V* of the estimate of angle  $\theta$  between the input vectors on its value. The estimates are found from  $p_{join}^*$ ,  $p_{cond}^*$ , and  $p_{equ}^*$ ; the notation T corresponds to the values obtained from (10), (13), and (16), and E to experimental results. Figure 1 shows the dependences of error *V* of the estimate of angle  $\theta$  between the input vectors on its value. The es are found from  $p_{join}^*$ ,  $p_{cond}^*$ , and  $p_{equ}^*$ ; the notation T corresponds to the values obtained  $P_{cond}$ , and  $P_{equ}$ , the notation T corresponds to the values obtained from (10), (1.

Angle estimates with respect to  $p_{join}^*$  have the greatest error (its value decreases as the angle increases), with respect to  $p_{equ}^*$ the least error, and with respect to  $p_{cond}^*$  the error is intermediate. Zero error for zero angle is obtained for  $p_{equ}^*$  and  $p_{cond}^*$ . For  $p = 0.5$ , the analytical values of the errors of angle estimates are close to the respective experimental values. The value of error grows with the angle. (Zero angle was not used in the above-mentioned experiments.) estimates with respect to  $p_{join}^*$  have the greatest error (its value decreases as the angle increases), with respect to  $p_{equ}^*$  at error, and with respect to  $p_{cond}^*$  the error is intermediate. Zero error for zero angl ngie is obiai

errors of angle estimates are close to the experimental ones corresponding to them for  $p_{cond}^*$  and  $p_{join}^*$  in the whole range of angles. The error of angle estimate with respect to  $p_{cond}^*$  is still less than the error with respect to  $p_{join}^*$  with the greatest As one would expect, for  $p = 0.1$  the errors exceed the respective values for  $p = 0.5$ . The analytical values of the errors of angle estimates are close to the experimental ones corresponding to them for  $p_{cond}^*$  and  $p_{j$ strongly differ from the case *p* = 0.5: if the angle is greater than 50°, its value exceeds the error with respect to *p*<sub>rond</sub> with the difference for 0° and with approximately equal values for 90°. The values of the er  $_{cond}^*$ , and if difference for 0° and with approximately equal values for 90°. The values for 90°, it exceeds the error with respect to  $p_{join}^*$  the angle is greater than 60°, it exceeds the error with respect to  $p_{join}^*$  $\phi_{\text{ioin}}^*$ ; moreover, the analytical values of the error become less than experimental ones, i.e., approximation  $(7)$  does not hold. Thus, the angle estimate with respect to  $p_{cond}^*$  is preferable, and the range of applicability of estimates with respect to  $p_{equ}^*$  is restricted by small angles and decreases as the share of unit components in output vectors decreases.

Figure 2 shows the dependences of the error  $V^{1/2}/E$  (variation coefficient) of the estimate of the scalar product of input vectors with respect to (17) on the value of angle  $\theta$  for the angle estimates obtained with respect to  $p_{join}^*$ ,  $p_{cond}^*$ , and  $p_{equ}^*$ . The notation T corresponds to the values of error obtained from (19) and from the angle estimates from (10), (13), and (16), and E corresponds to the experimental results.

Fig. 2. Dependence of the error of estimate of scalar product on the angle  $\theta$ 

For all the analyzed combinations of parameters, the values of errors of the estimate of scalar product for  $p = 0.1$ . For all the analyzed combinations of parameters, the values of errors of the estimate of scalar product for  $p = 0.1$  exceeds the respective values for  $p = 0.5$ ; as the angle between input vectors increases, the error grow For all the analyzed combinations of parameters, the values of errors of the est<br>exceeds the respective values for  $p = 0.5$ ; as the angle between input vectors increases, t<br>angle is greater than 50°. Similarly to the angl estimate of scalar product for  $p = 0.1$ <br>s, the error grows especially fast if the<br> $\frac{a}{p}$  also has the least error for  $p = 0.5$ , For all the analyzed combinations of parameters, the values of errors of the estimate of scalar product for  $p = 0.1$  exceeds the respective values for  $p = 0.5$ ; as the angle between input vectors increases, the error grow analytical and experimental values of errors for  $p_{equ}^*$  is noticeable, for other cases these results are close. Thus, the greatest  $\mathbf{I}$ accuracy of the estimate of the scalar product is attained for small values of angles between input vectors: for  $p = 0.5$  it is necessary to use the estimate with respect to  $p_{equ}^*$ , and for sparse output binary vectors the best results are attained for the but for  $p = 0.1$  the error becomes the greatest if the angle is greater than 60°. For greater angle values, a difference between estimate with respect to  $p_{cond}^*$ .

Figure 3 shows the dependences of the error  $V^{1/2}$  / E (variation coefficient) of the estimate of squared Euclidean e between input vectors with respect to (18) on the value of angle  $\theta$ , the analytical values of the e distance between input vectors with respect to (18) on the value of angle  $\theta$ , the analytical values of the error are obtained from (20); the notation in the description is similar to that in Figs. 1 and 2. Figure 3 shows the dependences of the error  $V^{-2}/E$  (variation coefficient) of the estimate of squared Euclidean distance between input vectors with respect to (18) on the value of angle  $\theta$ , the analytical values of the

distance between angles grows with the angle between vectors, the value of the relative error analyzed in the paper decreases, and this compensates for the growth of the variance of angle as the angle increases for  $p_{cond}^*$  and  $p_{equ}^*$ . As a distance fo result, the error estimate of the squared distance with respect to  $p_{cond}^*$  (and even with respect to  $p_{equ}^*$ ) varies insignificantly s not grow but decreases as the a in all the analyzed range of angles. The greatest error (and discrepancy between the analytical and experimental results) can be obtained for  $p_{join}^*$  for small angles since the variance of angle estimate is maximum for this case. The variation coefficient is unstable in the neighborhood of zero, and hence it cannot be applied for an adequate error estimate for angles close to zero. As we mentioned above, the error estimate of angle with respect to  $p_{equ}^*$  grows very fast as the angle be obtained for  $p_{join}^*$  for small angles since<br>coefficient is unstable in the neighborhood of *z*<br>close to zero. As we mentioned above, the *a*<br>approaches to 90° for sparse binary vectors.

Fig. 3. Dependence of the error of estimate of the squared Euclidean distance<br>on the angle  $\theta$  between vectors with  $D = 1000$ ,  $d = 1000$ , and  $q = 0.1$ .<br>Thus, for  $p = 0.5$  estimates of the distance with respect to  $p_{equ}^*$ Fig. 3. Dependence of the error of estimate of the squared Euclidean distance

the best results are attained for estimates with respect to  $p_{cond}^*$  and with respect to  $p_{equ}^*$  (for  $p_{equ}^*$  if the angle is not too close Thus, for  $p = 0.5$  estimates of the distance with respect to  $p^*_{cond}$  and to 90°); for small angle the distance error estimate grows fast.

For estimates of the angle between input vectors with respect to output binary vectors and for scalar product and Euclidean distance between input vectors with respect to the obtained angle estimate and known norms of input vectors in their application in similarity search problems, it is of interest to analyze a hybrid approach, where the similarity is estimated based on the angle for small angles and on the distance for large ones.

#### **CONCLUSIONS**

We have analyzed the estimates of similarity measures of real-valued vectors with respect to binary ones, obtained by projection by a random binary matrix with elements  $\{0, +1\}$  and output threshold transformation, which allows the control of the sparsity (share of unit components) of binary vectors. The similarity of the latter was estimated using the measures We have analyzed the estimates of similarity measures of real-valued vectors with respect to binary ones, obtained by projection by a random binary matrix with elements  $\{0, +1\}$  and output threshold transformation, whic We have analyzed the estimates of similarity measures of real-valued vectors with respect to binary ones, obtained by<br>projection by a random binary matrix with elements  $\{0, +1\}$  and output threshold transformation, whic  $\frac{3}{x}$ <br>er<br>io respectively, and  $|z|$  is the number of unit components in the binary vector  $\bar{z}$ . These measures are natural estimates of the similarity of the original real-valued vectors **x** and **y**: their values monotonically decrease as the angle  $\theta$  between the vectors increases and allow estimating its value. The estimate of angle  $\theta$  for known values of the Euclidean norms  $1 - z_1 \oplus z_2 / a = 1 - (|z_1| + |z_2| - 2 |z_1 \wedge z_2|) / a$ , where  $\oplus$  and  $\wedge$  are the operations of component-wise XOK and AND, respectively, and  $|z|$  is the number of unit components in the binary vector z. These measures are the similarity of the original real-valued vectors :<br>the vectors increases and allow estimating its value  $||\mathbf{x}||$  and  $||\mathbf{y}||$  has also allowed estimating the s<br> $||\mathbf{x} - \mathbf{y}||^* = (||\mathbf{x}||^2 + ||\mathbf{y}||^2 - 2||\mathbf{x}|| ||\mathbf{y}$ 

We have analyzed, analytically and experimentally, the dependences of error of the estimate of angle, scalar product, and Euclidean distance between input real-valued vectors on the angle between them. The dependences substantially differ for the analyzed three similarity measures of binary vectors and for estimates of the scalar product and Euclidean distance. This allows using the estimates with the least error in different ranges of angles.

For binary and ternary random matrices, the values of error are close for the analyzed values of parameters. However, implementing the transformation by means of a binary random matrix is computationally simpler.

A promising subject of the further studies is the analysis of the influence of modifications of the proposed methods on the accuracy of similarity estimates, for example: instead of the probability of unit element in the matrix, using the actual share of unit elements in the entire matrix and in its rows and columns; using random matrices with fixed number of randomly arranged unit elements in the entire matrix and in its rows and columns; taking into account the actual share of unit components in output binary vectors in the angle estimate based on their scalar product.

Output binary vectors, where not the semantics of separate components is important but their reflection of the similarity of represented objects, are an example of randomized distributed representations [1–11, 30, 31, 35, 36, 42–45]. Distributed representations can also be formed in inner layers of multilayer networks in the course of training [46–48]. Distributed representations are used to represent semantic similarity [18, 42, 49–51], sequences [29–31, 43, 51–54], complex hierarchically structured objects [1, 2, 4–11, 30, 31, 35, 36, 42–45, 55–57] required for models and systems of artificial intelligence [3, 31, 35, 36, 57–59].
