## Abstract

It is assumed that clay soil with high Fe contents as its main ingredient was used in the red pigment layers on the surfaces of the Neolithic Age Red Painted pottery and the Red Burnished pottery in the Bronze Age that were excavated from the southern areas of the Korean peninsula. A variety of phases of iron oxides that form pigment layers were identified through X-ray diffraction analysis, Raman spectroscopy and Mössbauer spectroscopy in this study. In particular, although previous studies focused only on hematite as a pigment mineral, the Mössbauer spectra of pigment layers in this study showed a higher spectrum area ratio of sextet by ferrihydrite than that by hematite, implying that ferrihydrite in reddish-brown might have played a significant role in developing its color. In addition, as it can be seen in each specimen showing a different area ratio by site in the Mössbauer spectrum, compositions of Fe-containing minerals were different. It is assumed to have been caused by different ionic forms of iron in the soil materials and unstable firing atmosphere during Pit firing.

**Keywords** Mössbauer spectroscopy · X-Ray Diffraction analysis · Raman spectroscopy · Red Burnished Pottery · Fe phase

## Introduction

Potteries are used as indicators of ages as their shapes and manufacturing techniques were developed following respective eras. In particular, red-painted potteries manufactured during the prehistoric age are found worldwide, most of which were designed for rituals and buried.

The use of earthenwares in Korea was at least from 8,000 B.C., in accordance with the relics in Gosan-ri site, Jeju. From the Neolithic Age, the Red Painted pottery, which is called *Juchil* (in Korean, red-painted) pottery, was made with red pigment applied to the outer surface, and a burnishing

technique for polishing the surface of earthenware was introduced [1]. It is known that the surface is semi-dry during burnishing process and flattened using various tools such as pebbles and leaves to enhance the coloration and polish effect [1, 2]. The burnishing technique reduces absorption by fine-tuning the surface, and was used as a common method of making even surfaces of prehistoric earthenware. The neolithic red painted pottery and the red burnished pottery were excavated mainly in the southern part of the Korean Peninsula.

A prior study of the Neolithic Age Red Painted pottery and the Red Burnished pottery on the Korean Peninsula has confirmed that iron (Fe) is the main element of pigmentation [3, 4]. In addition, some studies conducted X-ray diffraction analysis of samples of red painted pottery and red burnished pottery, and hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ) was identified to present red iron as the main source of coloration of the red pigmentation layer [4]. Estimates of materials in the pigmentation layer were based on microscopic observance and SEM–EDS analysis, and minerals were directly analyzed using XRD analysis in few reaserches, but only a weak peak of hematite was identified, and Phase analysis of iron oxides forming the red pigment layer was insufficient.

Mössbauer spectroscopy is an ionic phase analysis method using gamma-ray resonance, and the study of pottery using Mössbauer spectroscopy confirms that the phase analysis of the mineral that consists the pottery is possible [5–10]. The studies have been conducted on the phase transition of minerals according to the firing atmosphere. Since the phase of the Fe-containing minerals in the red painted pottery and the red burnished pottery depends on the raw materials and firing conditions used to produce the red color, it can provide crucial information on the production techniques.

Therefore, room temperature Mössbauer spectroscopy using Fe-57 was applied on a trial basis to analyze the crystalline phase of the Fe-containing minerals in the pigment layers of ancient earthenware excavated from the Southern Korean Peninsula. Prior to the Mössbauer spectroscopy analysis, Fe content was analyzed using SEM–EDS and elemental distribution on the cross-section of the pigment layer was verified through elemental map. Crystal structure analysis using XRD and Raman spectroscopy confirmed the existence of iron oxides, the most influential composition of the pigment layer, and the results of different analysis methods were cross-validated.

## Experimental

### Sample preparation

For the analysis of excavated specimens, the samples with well-preserved surfaces and no traces of conservation treatment were selected from the collection of the National Jinju Museum. Additional samples were provided with good surface preservation with the help of other institutions and related researchers. The three Neolithic Age Painted pottery and the five Red Burnished pottery were analyzed Table 1, Fig. 1 and Fig. 2. The Red Burnished pottery JJ-1 and other Bronze Age pottery

Fig. 1 Location of the archaeological sites for study

samples excavated from Sancheong were provided by Jinju National Museum. Kyungnam University Museum provided the Red Burnished pottery JJ-7, and the Neolithic pottery samples from Geoje and Tongyeong were provided by Gimhae national Museum. The Neolithic pottery sample UJ-1 excavated from Jukbyeon-ri site was provided by Samhan Institute of Cultural Properties.

### Color

The surface colors of potteries are affected by the chemical composition of raw materials and firing conditions. Therefore, the firing intensity and conditions can be inferred by the color information, and chromaticity was measured to understand the correlation between iron oxide phases and

| GJ-1   |               |                           | Daepo Shell Midden, Geoje        |

colors. The external chromaticity of all specimens was measured by a portable Chroma meter (CR-400, Minolta, Japan) after the specimens were dried entirely. To reduce measurement error, average values of 3 measurements were used. The measurement results were displayed in  $L^*$ ,  $a^*$ , and  $b^*$  chromatic systems.

### Elemental composition: SEM–EDS

For the composition analysis of excavated potteries, an energy dispersive X-ray spectrometer attached to a scanning microscope was used. The surfaces of the potteries made as mounting specimens were magnified to 300 $\times$ , and elemental mapping was performed to check the Fe content of the surface pigment layer.

### Constituent minerals: XRD and raman spectroscopy

To identify compositional minerals, crystal structures were analyzed with an X-ray diffraction spectroscopy (Miniflex600, Rigaku, Japan). After contaminated surfaces of specimens were washed with distilled water, red pigment layers were extracted from the surfaces using a scalpel to prevent mixing with clay, powdered, and completely dried at  $100 \pm 5^\circ\text{C}$  for over 24 h. The analysis condition was set to 40 kV, 15 mA,  $5^\circ$ – $80^\circ$ , scan step of  $0.02^\circ$ , and scan speed of  $1^\circ/\text{min}$ .

The pottery surfaces were further analyzed using a micro-Raman spectrometer (LamRAM Aramis, Horiba, Japan) with a laser of 785 nm, 10 $\times$  objectives. The data of the Raman spectrum was compared to the hematite ( $\alpha\text{-Fe}_2\text{O}_3$ ), magnetite ( $\text{Fe}_3\text{O}_4$ ), and goethite ( $\alpha\text{-FeO(OH)}$ ) spectral data analyzed using 785 nm laser in the RRUFF Project website. However, the analysis was expected to be challenged as iron oxides are easily denatured by laser, and it occurs even faster when the crystallinity is not high in a natural state [11]. Thus, specimens with the well preserved surface pigment layer were selected for the analysis, observed for any changes in spectrums before and after the analysis, and then verified any discoloration through microscopic images.339A

### Phase of Fe ion: mössbauer spectroscopy

Mössbauer spectroscopy was conducted by the Department of Physics of Kookmin University, to verify crystalline characteristics of iron oxides in red layers. The measurement was carried out at room temperature through an electrodynamic constant-acceleration Mössbauer spectrometer using a single light source of Co-57 at 50 mCi dispersed on Rh metal of FAST (MR-31, driving unit). The specimen

used as an absorber was applied as a thin layer between Al foils of 1 inch diameter, and both sides were blocked and fixed with 0.125 inches thick Be plates. The fixed specimen was secured on a specimen holder made of Cu to maintain consistent temperature across the specimen during the measurement.

## Results and discussion

### Color and elemental composition of the pigment layer

The iron oxide content of the pigment layers measured by SEM–EDS analysis was compared to the intensity of the red color of the specimen surfaces to illustrate a regression line passing through the center point and 95% confidence interval Fig. 3. The degree of scattering is determined by various phases of iron oxide generated by differences in the firing conditions of the pigment layers. It seems that the pigmentation was affected by the conservation status and mineral composition of the pigment layers. However, as thinner and poorly preserved pigment layers mean less shield from the clay material, the chromaticity value may reflect the color of the clay material. As an example of color change due to the change in Fe phase, the previous research verified that while only  $a^*$  value increases when the phase is changed from ferrihydrite to goethite, both  $a^*$  and  $b^*$  values increase simultaneously when it is changed to hematite [12].

### Constituent minerals

Figure 4. The peaks of hematite of the (140) planes appeared at  $33^\circ$  and near  $35.7^\circ$  where its (110) planes. As for the  $\gamma$  phase, the peak of maghemite near  $35.6^\circ$  of the (311) planes and near  $30.2^\circ$  of the (220) planes, overlaps with the peak of

Fig. 2 the red painted pottery sherds analyzed in this study

**Fig. 3** Iron oxides content analyzed by SEM–EDS vs.  $a^*$  value of the pigment layer, regression line and the line at the endpoints of the 95% confidence intervals

feldspar group, did not appear. Also, the peak of magnetite did not appear near  $30.1^\circ$  on the (220) planes.

On the other hand, ferrihydrite shows a two-line or a five-line pattern in the X-ray diffraction analysis, but as it has X-ray amorphous characteristics, it is difficult to identify when analyzed along with crystalline material. Although the main peak of lepidocrocite is relatively easy to identify in XRD, it was not identified in the analysis result.

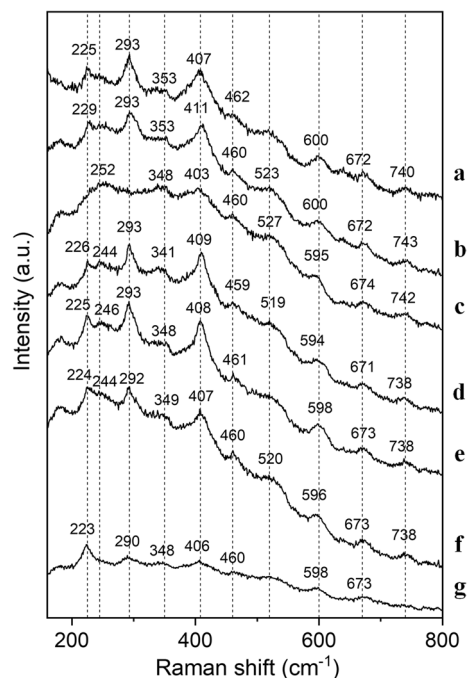

Raman spectra of the pigment layers showed that hematite had a  $403\text{--}411\text{ cm}^{-1}$  peak due to Fe–O bending and a  $594\text{--}600\text{ cm}^{-1}$  peak due to Fe–O stretching along with a broad peak near  $1310\text{ cm}^{-1}$  Fig. 5. In addition, it was confirmed that magnetite had a  $671\text{--}674\text{ cm}^{-1}$  peak due to asymmetric stretching and a  $520\text{--}240\text{ cm}^{-1}$  peak due to Fe–O asymmetric bending. The Raman band of the pigment layers did not show any goethite, which is relatively common in soil, like the XRD diffraction pattern. Although it can be a relative difference in contents in the pigment layer, it is assumed that the phase of most goethite of the raw material was changed to hematite as it went through the firing process.

### Phase of Fe ion

In the Mössbauer spectra of the pigment layers, a sextet by  $\alpha\text{-Fe}_2\text{O}_3$ , 2 sextets by  $\text{Fe}_3\text{O}_4$ , and a doublet by ferrihydrite or  $\gamma\text{-FeO(OH)}$  were overlapped for all the specimens Fig. 6. Table 2 shows the hyperfine field (Hhf), the quadrupole

splitting ( $\Delta E_Q$ ), the isomer shift ( $\delta$ ), and the area ratios of spectrum by site.

In the Mössbauer spectrum measured at room temperature, it is challenging to distinguish hematite ( $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>) on  $\alpha$ -phase from maghemite ( $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>) on  $\gamma$ -phase. However, considering that the results of X-ray diffraction analysis and Raman spectroscopy showed a stronger peak of hematite and that the particle size effect might have reduced the values in the hyperfine field, the sextets of 501.75–511.66 kOe identified in each specimen are likely to have been generated by  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>. It has been reported that  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> measured at room temperature has a sextet with a wide range of values around

the hyperfine field of 518 kOe, the isomer shift of 0.37 mm/s, the quadrupole splitting of −0.2 mm/s [12].

The X-ray diffraction analysis did not show any peak of ferrihydrite or lepidocrocite, while the Mössbauer analysis showed a very high spectrum area ratio of 33.55–59.84%. At room temperature, lepidocrocite is identified as a doublet having values of the isomer shift of 0.37 mm/s and the quadrupole splitting of 0.53 mm/s, and has a similar resonance absorption line to ferrihydrite. However, it is characterized by a lower quadrupole splitting and narrower line width [13, 14]. The sample measured in this study resulted in the quadrupole splitting value of 0.72–0.8 mm/s, which is somewhat

**Fig. 6** Mössbauer spectra of the red pigment layers. The black dots represent the raw data collected as Mossbauer spectra. The green lines refer to  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, and red and blue lines to each A site and B site of Fe<sub>3</sub>O<sub>4</sub>, respectively. Pink lines refer to ferrihydrite

higher than that of lepidocrocite, and a wider line as well. Therefore, it was identified as ferrihydrite.

Lepidocrocite forms maghemite in a semi-stable state at approximately 473–553 K during firing at oxidizing atmosphere [14], and it goes through a phase transition to hematite at about 873 K as the temperature rises [15].

Soil contains abundant  $\alpha$ -phase goethite [ $\alpha$ -FeO(OH)], which forms hematite when fired at 530–600 K [7, 14]. The Red Burnished pottery is assumed to have been fired at 873 K or higher, so most of the iron hydroxide in soil was expected to have gone through a phase transition to hematite immediately after firing.

As for an inverse spinel structure of magnetite (Fe<sub>3</sub>O<sub>4</sub>), in a cell unit of the face-centered cubic, Fe<sup>3+</sup> ions occupy 8 A sites with tetrahedron symmetry, and 8 Fe<sup>2+</sup> ions and 8 Fe<sup>3+</sup> ions occupy 16 B sites with octahedron symmetry. The Mössbauer spectrum of Fe<sub>3</sub>O<sub>4</sub> at room temperature shows two sextets overlapped with each other because of the presence of the two different grid sites []. Reduction firing generates magnetite via reaction to carbon monoxide, while oxidized firing generates hematite.

Comparison of spectrum area ratios for each site in the Mössbauer spectrum showed a complete inverse proportional relationship where the area ratio of ferrihydrite

decreases as the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phase increases, and ferrihydrite increases as the area of the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phase decreases Fig. 7. Area ratios of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>3</sub>O<sub>4</sub> tend to increase or decrease concurrently, but they do not show increase/decrease curves that are perfectly consistent. Therefore, an increase/decrease in the area ratios of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and Fe<sub>3</sub>O<sub>4</sub> is inversely proportional to ferrihydrite. Fe<sub>3</sub>O<sub>4</sub> detected in specimens after firing implies a possible presence of different iron oxyhydroxides from the soil. If some lepidocrocite existed in the soil, maghemite, which is an intermediate product of lepidocrocite and hematite, was potentially existed in the specimens as well, considering the firing reaction. In this case, the spectrum might have been overlapped with hematite. Since iron oxides may exist in various phases, an additional Mössbauer measurement needs to be conducted at a lower temperature (4.2 K) for accurate assessment in the further study.

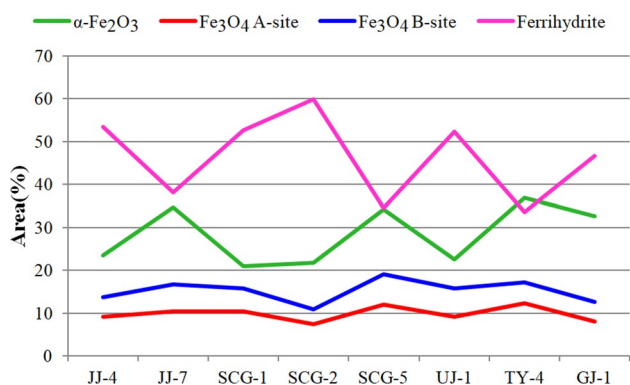

In order to understand the effect of iron content in pigment layers forming hematite during oxidized firing and the oxidation–reduction of Fe ions on the chromaticity, the relationship between the spectrum area of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> and the chromaticity value is illustrated on a 2-dimensional plane and the stoichiometry Fe(II)/Fe(III) for each specimen was calculated Table 3. The following formula was used with relative area ratios of A site and B site sextets to obtain the stoichiometry ratio of Fe ions within Fe<sub>3</sub>O<sub>4</sub> [16].

$$[\text{Fe}(\text{II})/\text{Fe}(\text{III})]_{\text{Fe}_3\text{O}_4} = (0.5 \times \text{Fe}_{\text{Oh}}) / (0.5 \times \text{Fe}_{\text{Oh}} + \text{Fe}_{\text{Td}})$$

The comparison between the  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> area ratio and the chromaticity did not show any relations between the increase in  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> area ratio and the increase/decrease in certain chromaticity value Fig. 8. The area ratio of ferrihydrite phase increase/decrease shows an inverse proportion to  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> phase and Fe<sub>3</sub>O<sub>4</sub> phase, implying that the black Fe<sub>3</sub>O<sub>4</sub> affected the increase/decrease in the chromaticity value. However, if pottery contains red  $\gamma$ -FeO(OH) that can only be identified via measurement at a lower temperature (4.2 K), they might collectively influence on of the pigment layers. The higher the Fe(II)/Fe(III) value, the more

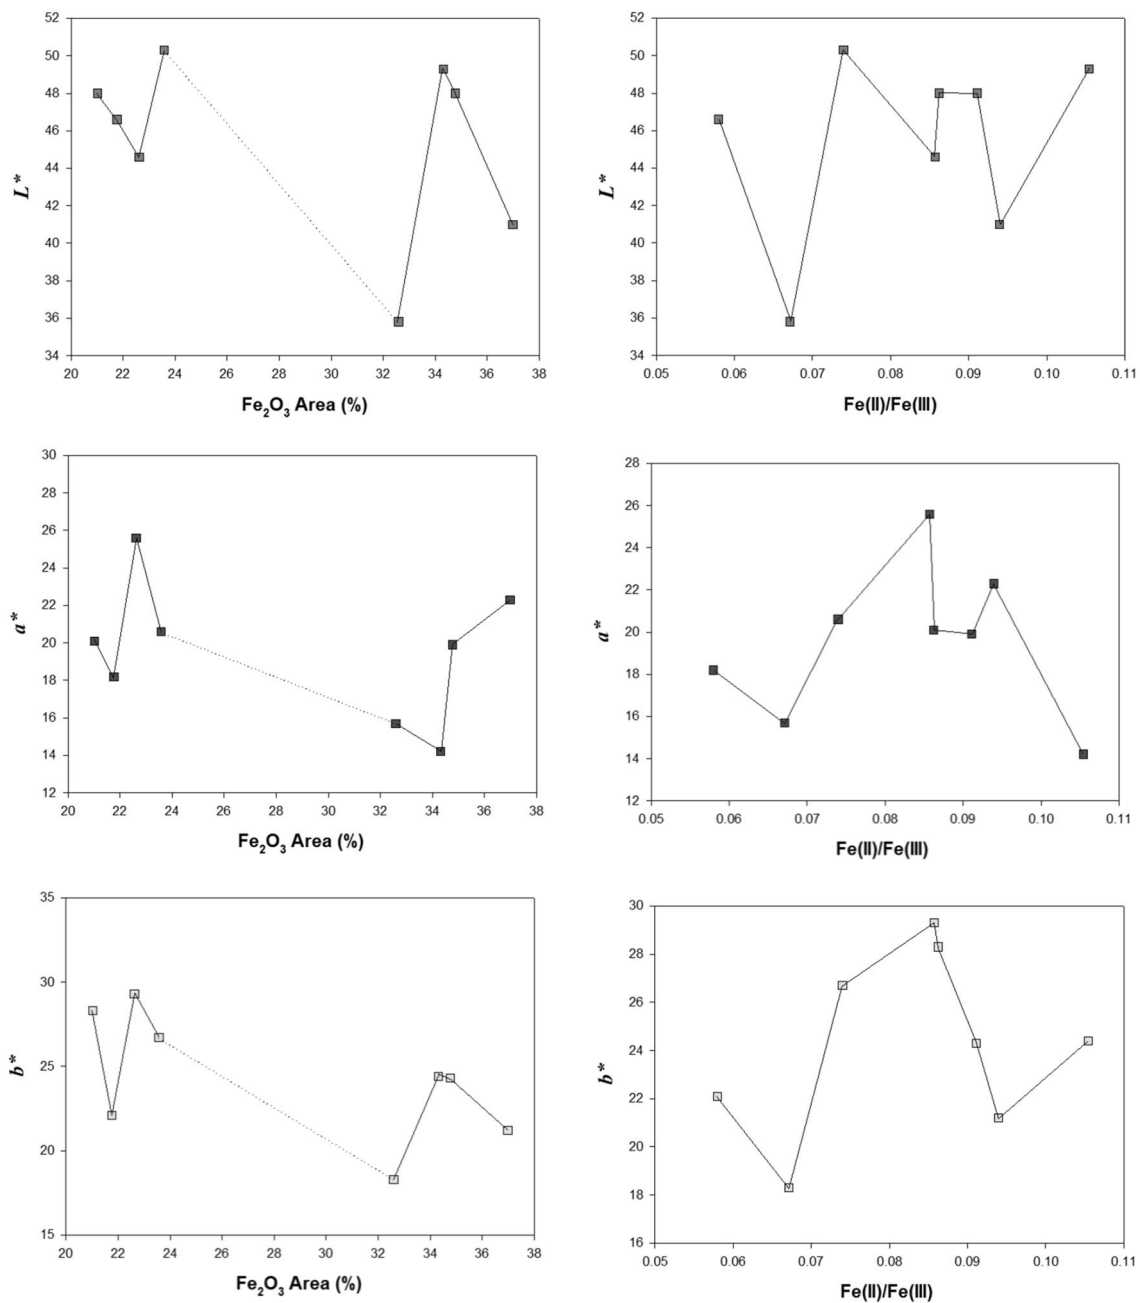

**Fig. 7** Area ratio of the Mössbauer spectra collected from pigment layers

intense the reduction atmosphere is likely to be established. Accordingly, The analyzed potteries in this study showed the Fe(II)/Fe(III) values between 0.06 and 0.11, which is significantly lower than those of celadon glaze (2.5 – 7) fired at a reducing atmosphere [17]. Although the area ratio of Fe(II)/Fe(III) and chromaticity did not show any distinct relationship between the two, it might have been affected by the texture of the surfaces or particle sizes.

## Conclusions

Previous studies argued that hematite  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>, which was identified in X-ray diffraction analysis, led the pigmentation of Neolithic and Bronze Age potteries excavated in the Korean peninsula. However, Raman spectroscopy and Mössbauer spectroscopy used in this study identified various phases of iron oxides that previous studies failed to detect or identify due to very weak peaks. In particular, the Mössbauer spectrum showed that the Fe<sub>3</sub>O<sub>4</sub> phase affected the pigmentation, and the spectrum area ratio of the sextets generated by the phase assumed as ferrihydrite (some might be lepidocrocite) was significantly higher than that of hematite, indicating that ferrihydrite might have contributed to the pigmentation. In addition, each specimen had different area ratio of each site in the Mössbauer spectrum, demonstrating different content of minerals including iron. This can be attributed to the Fe phases in soil and the unstable firing atmosphere during open pit firing. There was difficulty in obtaining specimens with different colors and iron oxide contents due to the characteristics of the excavated artifact. However, this study demonstrated strengths of the Mössbauer method in analyzing ferruginous mineral pigments, which have been used since the ancient times. The specimen produced through its reproduction experiment will allow scientific interpretation of the relationships between generated iron oxides, chromaticity and firing atmosphere.
