Abstract

Aim To evaluate the efficacy and safety of the restricted protein diet supplemented with keto analogues when applied in end-stage renal disease (ESRD).

Methods The Cochrane Library, PubMed, Embase, CBM and CENTRAL databases were searched and reviewed up to January 2017. Clinical trials were analyzed using RevMan 5.3 software.

Results Five randomized controlled trials were selected and included in this study according to our inclusion and exclusion criteria. Changes in serum albumin, PTH, triglyceride, cholesterol, calcium, phosphorus, hemoglobin, *Kt/v* and CRP before and after treatment were analyzed. Metaanalysis results indicated that, compared with normal protein diet, low-protein diet (LPD) supplemented with keto analogues (sLPD) could improve serum albumin (P < 0.00001), hyperparathyroidism (P < 0.00001) and hyperphosphatemia (P = 0.008). No differences in triglyceride, cholesterol, hemoglobin, *Kt/v* and CRP were observed between different protein intake groups.

Conclusion Restricted protein diet supplemented with keto analogues (sLPD) may improve nutritional status and prevent hyperparathyroidism in ESRD patients. The current data were mainly obtained from short-term, single-center

Introduction

End-stage renal disease (ESRD) represents the final stage of various causes of chronic kidney disease (CKD). With the development of economy, the prevalence of ESRD has received increasing focus as one of the leading public health problems [1-4]. Renal replacement therapy works as one of the most significant methods for ESRD patients; however, it cannot work as normal renal simulating physiological state absolutely [5]. Evidence tells that most ESRD patients who need maintenance dialysis suffer from malnutrition to some extent. Many researchers have attributed malnutrition to restricted protein diet which tends to moderate the symptoms of azotemia and acid-base disturbances. Some studies support restricted protein diet supplemented with keto analogues in the early stages of CKD patients helps gain smaller possibility of malnutrition in the following stage of maintenance dialysis [6, 7]. We previously conducted a metaanalysis with stage 3-5 CKD patients who did not enter the maintenance dialysis stage, and proved that restricted protein diet supplemented with keto analogues could delay the progression of CKD, prevent hyperphosphatemia, hyperparathyroidism and benefit blood pressure control without causing malnutrition [8]. However, whether it could still be available in ESRD patients remains unknown and that is why we carry out this study.

Methods

Search strategy

A literature search was performed in PubMed, Embase, Cochrane Library, China Biology Medicine (CBM) and China National Knowledge Infrastructure (CNKI). PubMed (1966–January 2017), Embase (1974–January 2017), the Central Register of Controlled Trials (1999–January 2017), the Cochrane Renal Group (1999–January 2017), CBM and CNKI were searched for the identification of relevant trials. The following search terms were used: keto acid, α -keto acid, keto analogue, ESRD (end-stage renal disease), ESKD (end-stage kidney disease), RRT (renal replacement therapy), dialysis, hemodialysis, peritoneal dialysis, low-protein diet, very low-protein diet, LPD, vLPD, sLPD and svLPD.

Inclusion criteria and risk of bias

Articles were selected and subsequently screened based on the patient problem intervention comparison outcome (PICO) principle. Five randomized controlled trials (RCTs) were finally selected. Inclusion criteria were: (1) study subjects were ESRD adults receiving maintenance dialysis therapy; (2) study subjects were treated with LPD/vLPD supplemented with keto analogues or free diet; (3) laboratory test indexes such as serum albumin (Alb), serum triglyceride (TG), cholesterol (CHO), calcium (Ca) and phosphorus (P) were clearly reported; (4) study subjects were followed up for at least 2 months. The exclusion criteria applied were as follow: (1) study subjects were children or animals; (2) old low-quality studies (before 1980); (3) studies without detailed observe indexes; (4) studies whose full texts are unavailable. Full texts of all potential articles were retrieved and reviewed independently by at least 2 investigators. Risk of bias tables recommended by Cochrane network was relied upon to assess the risk of bias.

Data extraction and management

Two reviewers independently assessed the eligibility of each article using standard data extraction forms, and any disagreement was further reviewed by a third party. For studies from which detailed data could not be extracted, the authors were contacted by emails. Basic information such as first author name, year of publication, study design, inclusion criteria, study sample size, basic characteristics of study subjects, intervention regimen, drug dosage, follow-up duration, outcome data and adverse effects was recorded for each study included. All authors reviewed the final list of articles and supervised the overall search process.

Statistical analysis

Meta-analysis was performed using Review Manager 5.3 software. Risk ratios (RR) and 95% CIs were used to express the results of dichotomous outcomes. Mean difference (MD) was used for results with continuous scales, and standardized mean difference (SMD) was used when different scales were used. Heterogeneity was analyzed using Cochran Q test (n - 1 df), with P < 0.05 denoting statistical significance and I^2 measuring the proportion of variation in efficacy estimates due to heterogeneity beyond chance. Random-effects analysis ($I^2 > 50\%$) and fixed-effect analysis ($I^2 < 50\%$) were performed in meta-analysis according to the protocol. Z test was conducted to analyze the overall effect, with P < 0.05 denoting statistical significance.

Study selection and trial characteristics

We identified 1790 articles during the first search. Of these, after careful examination of the title and abstract, 1778 articles were excluded because of duplicate references, reviews, case reports, basic researches, non-controlled studies, systematic reviews and meta-analyses. Full texts of the remaining 12 articles were retrieved for further selection. An additional 7 articles were excluded after further review because patients did not receive dialysis therapy in four studies and the other three studies were low quality (before 1980). Eventually, five studies were included in this meta-analysis and systematic review is described in Fig. 1.

Peritoneal dialysis was performed in the studies of Jiang and Chen [11, 12], and hemodialysis was applied in the other three studies [9, 10, 14]. In addition, protein and keto analogues intake level differed from each study, which may affect heterogeneity of studies. In the study reported by Li, the outcomes of some crucial indexes, such as albumin, calcium, phosphorus, mid-arm muscular circumference, were only shown as histograms without accurate data [13]. We sent an e-mail to the author enquiring the data about histogram, but there is no reply yet. Characteristics of the included studies are listed in Table 1. The risk of bias assessment was performed using a risk of bias table recommended by Cochrane (Table 2).

sLPD would not cause malnutrition in ESRD patients

In order to evaluate the nutritional status of ESRD patients with restricted protein diet, we analyzed nutritional factors in this study. Comparison of serum albumin level (Alb) between sLPD and regular diet group included 4RCTs. Meta-analysis was performed using a fixed-effect model because tests for heterogeneity indicated $I^2 = 28\%$

 Risk of bias summary

Review of the authors' judgments about each risk of bias item for each included study

+: Good quality (low risk of bias), -: low quality (high risk of bias), ?: unclear quality (unclear risk of bias)

Result suggested a significantly higher serum albumin level in sLPD group than that in control group (MD 3.84, 95% CI 2.61, 5.06, P < 0.00001). Comparison of cholesterol (CHOL) included 3 RCTs. A fixed-effect model was applied to compare CHOL level in 3RCTs because $I^2 = 41\%$. Result suggested no significance between two groups (MD - 0.21, 95% CI - 0.52, 0.11, P = 0.20). Comparison of triglyceride (TG) included 3 RCTs. The randomized-effects models were used because heterogeneity tests indicated $I^2 = 85\%$. No significant difference was observed between two groups (MD 0.04, 95% CI – 0.28, 0.36, P = 0.81) (Fig. 2). Moreover, Li's study assessed arm muscle circumferences, skin-fold thicknesses, BMI and Mini-Nutritional Assessment (MNA, Nestlé Nutrition

Institute). Results showed that all of these indexes were within the normal range, and no remarkable changes could be observed before and after treatment [13]. In Chen's study, comparison of mid-arm circumference (MAC) and triceps skin-fold thickness (TSF) revealed no difference between sLPD and control group. However, the level of leptin was decreased in sLPD group after treatment (P < 0.01) which may refer to the reduction in energy wasting and improvement of nutrition status [12].

sLPD could ameliorate MBD in ESRD patients

Two RCTs were included in the comparison of serum phosphorus (P) level between sLPD and regular food treatment groups. Meta-analysis using random-effects models ($I^2 = 85\%$) indicated significantly lower serum phosphorus level in sLPD group (MD – 0.37, 95% CI – 0.64, – 0.09, P = 0.008). Two RCTs involved in the comparison of serum calcium (Ca) level, fixed-effect model ($I^2 = 0\%$) analysis suggested better outcome in sLPD group (MD 0.1, 95% CI 0.09, 0.11, P < 0.00001). Comparison of serum PTH level was performed using random-effects models with 2 RCTs, which showed significant effect of sLPD in preventing

hyperparathyroidism (MD – 212.35, 95% CI – 294.28, – 130.42, *P* < 0.00001) (Fig. 3).

Effects of sLPD on anemia, *Kt/v* and inflammatory biomarkers in ESRD patients

Assessment of hemoglobin, *Kt/v* and CRP included 2 RCTs, respectively. No significant difference was observed between sLPD and regular food groups in the present meta-analysis (Fig. 4). Li's study also suggested that C-reactive protein (hsCRP) was similar between treatment group and control group [13]. Furthermore, in the study by Chen, the comparison of interleukin-1 α (IL-1 α), interleukin-6 (IL-6) and tumor necrosis factor- α (TNF- α) indicated lower levels in sLPD group, but only the change in CRP level reached statistical significance (P < 0.01) [12]. This result may suggest reduced inflammatory status in sLPD group.

Discussion

Nowadays, ESRD has become one of the most vital threats to health. Not only primary kidney disease induced ESRD,

but also obesity, diabetes, hypertension or other cardiovascular disease contribute to the increasing prevalence of ESRD [15, 16]. The adjusted incidence rate of ESRD, which includes both dialysis and transplant patients, remains at 352 per million per year [4]. Moreover, ESRD associated morbidity is rising gradually every year in both developing and developed countries [1–4, 17]. More and more researches suggested that hyperphosphatemia, CKD-MBD and other complications remarkably increased the mortality of ESRD patients. Considering that application of sLPD/sVLPD in early stage CKD patients could delay the progress of disease and prevent severe complications such as anemia, hypertension, hyperphosphatemia, hyperparathyroidism and malnutrition [8], researchers began to think it may also be helpful for ESRD patients receiving dialysis.

Although it is worried that restricted protein diet may lead to malnutrition because of inadequate nutrient intake, clinical trials and observational studies relieved this problem. In the current study, assessment of serum albumin level (Alb) showed significantly higher level in sLPD group and comparison of cholesterol (CHOL) and triglyceride (TG) showed no difference between two groups, suggesting that sLPD could improve nutritional status of ESRD patients. The mechanism of this effect may lie in the fact that several other factors such as metabolic acidosis, uremic toxin accumulation, chronic inflammation, insulin resistance, hyperparathyroidism and oxidative stress are also contributive to ESRD-related PEW (protein-energy wasting) [6, 18]. Several investigations have pointed that restricted protein diet may reduce amino acid oxidation, decrease protein degradation and prevent metabolic acidosis. Therefore, it is helpful to maintain a better nutrition status and prevent PEW in dialysis patients [19–23]. It was previously reported that sLPD treatment led to clear amelioration of protein synthesis in peritoneal dialysis (PD) patients and maintained lower transport rates [24–26]. Hence, several studies suggested that sLPD is safe in CKD patients and would not increase mortality [7, 26].

Hyperphosphatemia is the leading cause of CKD-MBD and is associated with increased risk of cardiovascular diseases as well as mortality rates in CKD patients [14, 27]. Our earlier study reported that restricted protein diet supplemented with keto analogues could decrease serum phosphorus and PTH levels in patients of stage 3–5 CKD

[8]. For ESRD patients undergoing maintenance dialysis treatment, the current study confirms that sLPD could be beneficial to mineral bone disease by decreasing serum phosphorus, PTH level and avoiding hypocalcemia. Long-term prospective cohort study also indicated that sLPD may improve the primary outcomes of native AVF, reduce the vascular stiffness and calcification, possibly by preserving vascular wall quality through a better serum phosphorus and inflammatory reaction control [28].

Although some cohort studies indicated that sLPD may ameliorate anemia, improve dialysis adequacy and inflammatory status [12, 29], our meta-analysis does not show apparent differences between protein restrict group and regular food group. It was previously reported that sLPD could prevent the loss of muscle mass, block the activation of autophagy/mitophagy and decrease inflammation in skeletal muscle in 5/6 nephrectomized rats [30]. Based on this evidence, it is suspected that suboptimal adherence and low patient compliance may be the reasons of compromised nutrition status observed in several studies.

Furthermore, it was reported that sLPD was safe in pregnant patients with advanced CKD and may improve fetal outcomes [31]. Several small sample case reports have suggested that restricted protein diets may favor chronic dialysis discontinuation [32], although the mechanism was still unknown.

Our study had several limitations. The data analyzed in the present meta-analysis were obtained from shortterm, small sample sizes, single-center studies. Only 5 RCTs were included in this meta-analysis. And we failed to obtain individual patient and original data, some nutritional status indexes like BMI, mid-arm circumference (MAC) and triceps skin-fold thickness (TSF) were only in one study and some data were presented only as histograms, which may compromise our results. Additionally, our meta-analysis contained heterogeneity in actual protein intake levels which may have an impact on the reliability of our results. Therefore, long-term, large sample, multicenter RCTs are needed to confirm the efficacy and safety of restricted protein diet in ESRD patients.

Conclusion

Our meta-analysis indicated that restricted protein diet supplemented with keto analogues may improve nutritional status and prevent hyperparathyroidism in ESRD patients. However, long-term, large sample, multicenter RCTs are needed to confirm these results in the future. **Author contributions** Wei Qin planned the study, analyzed data and assisted in article preparation. Zheng Jiang and Yi Tang searched the literature, selected articles, extracted data, analyzed data and composed the article. Lichuan Yang and Xuhua Mi contributed to the concept, data collection and analysis of this study.
