A Robust Method to Update Local River Inundation Maps Using Global Climate Model Output and Weather Typing Based Statistical Downscaling

M. Bermúdez[1] · L. Cea[2] · E. Van Uytven[3] · P. Willems[3] · J.F. Farfán[2] · J. Puertas[2]

Abstract

Global warming is changing the magnitude and frequency of extreme precipitation events. This requires updating local rainfall intensity-duration-frequency (IDF) curves and flood hazard maps according to the future climate scenarios. This is, however, far from straightforward, given our limited ability to model the effects of climate change on the temporal and spatial variability of rainfall at small scales. In this study, we develop a robust method to update local IDF relations for sub-daily rainfall extremes using Global Climate Model (GCM) data, and we apply it to a coastal town in NW Spain. First, the relationship between large-scale atmospheric circulation, described by means of Lamb Circulation Type classification (LCT), and rainfall events with potential for flood generation is analyzed. A broad ensemble set of GCM runs is used to identify frequency changes in LCTs, and to assess the occurrence of flood generating events in the future. In a parallel way, we use this Weather Type (WT) classification and climate-flood linkages to downscale rainfall from GCMs, and to determine the IDF curves for the future climate scenarios. A hydrological-hydraulic modeling chain is then used to quantify the changes in flood maps induced by the IDF changes. The results point to a future increase in rainfall intensity for all rainfall durations, which consequently results in an increased flood hazard in the urban area. While acknowledging the uncertainty in the GCM projections, the results show the need to update IDF standards and flood hazard maps to reflect potential changes in future extreme rainfall intensities.

1 Introduction

Floods are the most common natural hazard worldwide. According to the global EM-DAT database, they represented nearly half of all weather-related disasters in the period 1995–2015 and affected more than 2 billion people (CRED and UNISDR 2015). Changes in storminess associated with global warming can modify the magnitude and frequency of extreme precipitation events (O'Gorman 2015) and exacerbate existing risks. For the 1.5 °C temperature rise target, the amount of people exposed to river flooding globally is estimated to increase by 50–60%, with direct flood damage rising in the range of 160% to 240% (Dottori et al. 2018).

Rainfall Intensity Duration Frequency (IDF) curves form the basis for quantifying extreme precipitation for various durations and return periods for water engineering planning and design. They are commonly used to create synthetic rainfalls that are then used in flood inundation models to obtain flood hazard maps. It is thus crucial that these curves reflect potential changes in future extreme rainfall intensities, as a first step towards obtaining hazard maps representative of future conditions. IDF curves currently in use, based on historical records, may no longer hold under an altered climate regime (Madsen et al. 2009; Peck et al. 2012; Singh et al. 2016).

In this context, climate change projections constitute another approach to historical records to update local IDF curves and flood hazard maps. This is, however, far from straightforward, given our limited ability to model the effects of climate change on the temporal and spatial variability of rainfall at small scales. Global Climate Models (GCMs) are typically run at rather coarse spatial resolutions (above 100 km) and daily time step. Processes that influence local rainfall such as convection operate at smaller scales and are thus not resolved but parameterized in GCMs (Fosser et al. 2015; Tabari et al. 2016). Additionally, local orography and surface characteristics that exert an influence on local rainfall distribution are also poorly represented at these scales (Maraun and Widmann 2015).

This creates a gap between the spatial and temporal scales of the GCM output and those needed to drive local impact models (van den Hurk et al. 2018), which is usually overcome by downscaling techniques, either statistical or dynamic. A key advantage of statistical downscaling methods is that they are comparatively cheap and computationally efficient (Fowler et al. 2007) to use them with multi-model ensemble predictions, which have become the standard paradigm for the characterization of future changes in hydrological impact studies (Hosseinzadehtalaei et al. 2017). Statistical downscaling methods are generally grouped into three categories (Fowler et al. 2007): (1) regression models which directly translate large atmospheric information to local-scale data (e.g., multiple linear regression, stepwise regression, and artificial neural networks), (2) weather generators, with input parameters modified according to scenarios from a GCM, that replicate the statistical attributes of a local-scale variable, and (3) weather classification schemes that classify the atmospheric circulation at the synoptic scale into a set of weather types (WT) and condition local weather on those large-scale WTs.

All the above statistical approaches rely on the assumption that the relationship established for the present climate will not vary over time (Salvi et al. 2016). From this perspective, methods that yield physically interpretable linkages between the large scale circulation and local surface climate are preferable. This is in fact one of the key advantages of using weather type-based approaches, which provide a greater understanding of the causal mechanisms that lead to weather events (i.e., the large-scale climatic environment associated to a given local weather condition), and provide a more reliable and objective framework for obtaining local

projections. Moreover, given the complexity of the relationship between the large-scale flow and local-scale weather, linear models that directly link predictor fields and predictands usually perform worse (Maraun and Widmann 2018).

The link between large-scale climate and local weather events, established by means of WTs, can also be potentially used to directly project future changes in flood occurrence (Hall et al. 2014; Merz et al. 2014). Several studies have analyzed the relationship between precipitation, which could serve as a proxy for flood occurrence, and WTs, and have explored the potential of this relationship to predict precipitation variability (Linderson 2001; Goodess and Jones 2002; Brisson et al. 2011; Cortesi et al. 2013). In regions where a strong link exists, it would be possible to evaluate future changes in WT frequencies as an indirect means of exploring future flooding. Projections of synoptic weather types under climate change can be obtained almost immediately from the output of GCMs, which are expected to correctly reproduce large scale atmospheric features (Räisänen 2007; Hargreaves 2010; Hargreaves and Annan 2014). A few works have indeed analyzed the ability of GCMs in reproducing circulation patterns, and explored changes in synoptic variability in the twenty-first century (Demuzere et al. 2009; Lorenzo et al. 2011; Åström et al. 2016; Otero et al. 2018).

The above strategies based on examining climate-flood connections are regarded as a promising complementary technique to the simulation of the complete flood hazard chain. The latter is currently the most widely used approach that begins with the downscaling of GCMs, followed by hydrological models to evaluate runoff generation. Model chains can also be extended to include hydraulic models for flood routing and inundation analysis, or even damage and loss models (Felder et al. 2018).

In this study, we combine both strategies to develop a robust method to update local flood hazard maps using GCM data. First, the relationship between large-scale atmospheric circulation, described by means of Lamb circulation type classification (LCT), and rainfall events with potential for flood generation in the studied area is analyzed. A broad ensemble set of GCM runs is used to identify frequency changes in LCTs, and to assess the occurrence of flood generating events in the future. In a parallel way, we use this WT classification and climate-flood linkages to downscale rainfall from the GCM climate projections, and determine IDF curves for the future climate. A hydrological-hydraulic modeling chain is then used to quantify the changes in flood discharge and inundation hazard maps induced by climate changes. It should be noted that the comparison between current and future conditions does not account for changes in land use or in initial soil moisture state.

2 Materials and Methods

2.1 Study Site and Rainfall Data

The proposed methodology was applied to estimate the impact of future climate change on precipitation extremes and flood hazard in the coastal town of Betanzos, located in a 440 km^2 basin in the NW of Spain (Fig. 1). The Mandeo River and its tributary, the river Mendo, flow through the town and discharge in the estuary of Betanzos (Fig. 1). Daily peak discharges measured since 2010 at two gauge stations (one on each catchment) managed by the Regional Water Administration (Augas de Galicia) are available. The urban area of Betanzos is vulnerable to flooding as a result of high precipitation and increased river discharge, and is classified as a high potential flood risk area by the regional authorities. Given its proximity to
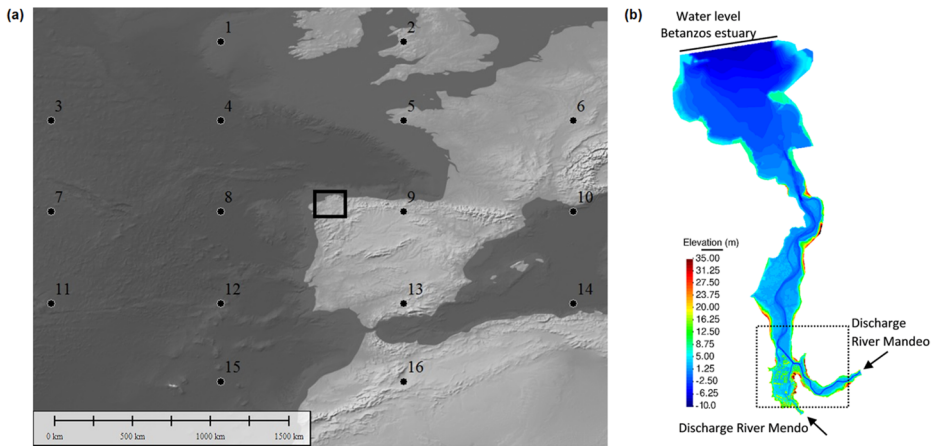

Fig. 1 **a** Location of the case study site (marked with a rectangle) and grid points for the calculation of WTs (1 to 16) (left). **b** Topography used in the flood inundation model with the location of the open boundaries and the urban area of Betanzos (dashed rectangle)

the sea, existing flood risks in this town could be aggravated not only by changes in precipitation but also through changes in sea levels. However, the scope of this evaluation is limited to the future changes in precipitation and their impact on flood hazard, without considering climate change effects on sea levels.

To characterize the maximum rainfall intensities in the study area, there are 11 rain gauges located around the catchments of the rivers Mandeo and Mendo, operated by the regional meteorological agency MeteoGalicia. The rainfall data registered by these pluviometers at 10-min time resolution were spatially interpolated using a natural neighbor interpolation, and then averaged over the whole catchment in order to obtain a basin-averaged time series of rainfall. More accurate rainfall interpolation methods, e.g., kriging with external drift (KED), could not be used because radar data is not available for the whole historical period. Nevertheless, as justified in Cea and Fraga (2018), at this study site the difference between natural neighbor and KED interpolation is not relevant for aggregation times larger than 1 h. The time series of rainfall obtained in this way covers a historical period of 18 years (2001–2018) at 10-min resolution. Although there are some gaps in the rainfall series of certain stations, the time series of basin-averaged rainfall is complete given the relatively high number of stations used in the interpolation. The average annual maximum 24-h rainfall depth during the historical period is 49 mm, while the average annual precipitation in the catchment is 1210 mm.

2.2 Classification of Atmospheric Circulation Patterns and Link to Rainfall Events

A large number of WT classification systems have been developed over the last decades (Philipp et al. 2010). Lamb WT classification, with the corresponding objective classification of Jenkinson and Collison (1977), has been prominently applied in mid-high latitudes (Otero et al. 2018). In this study, the Jenkinson Collision modified Lamb weather types (Jenkinson and Collison 1977; Trigo and DaCamara 2000; Philipp et al. 2010) were used to characterize the daily large-scale atmospheric circulation that affects the NW of Spain. It should be noted that the classification of Trigo and DaCamara (2000) was developed to study the precipitation regime in a region very close to the study site of this paper.

The atmospheric classification system considers the sea level pressure in a 16 point grid centred around the case study location (indicated by the rectangle in Fig. 1), and calculates flow and vorticity indices. The flow and vorticity indices are compared to define 26 different WTs that are then regrouped into 10 WTs. This regrouping is done by combining all the different cyclonic and anticyclonic WTs into just 2 WTs. Moreover, the hybrid WTs are equally divided over the complementary cyclonic or anticyclonic WT and directional WT (NE, E, SE, S, SW, W, NW and N).

Daily mean sea level pressure (SLP) to calculate historical LCTs frequency was extracted from the ERA Interim dataset (period 1979–2015) (Dee et al. 2011). A set of 123 GCM runs corresponding to the Coupled Model Intercomparison Project CMIP-5 for the four Representative Concentration Pathway (RCP) scenarios was used to assess the future LCTs' occurrence in the period 2071–2100. This far-future period is a common choice for climate change impact analysis, which allows comparability with other studies. The 123 GCM runs encompass 37 runs for RCP8.5, 16 runs for RCP6.0, 41 runs for RCP4.5 and 29 runs for RCP2.6.

The frequency of occurrence of each WT was calculated, and the number of historical storm rainfall events associated with a given WT was evaluated. In addition, the magnitude of the associated 24-h rainfall was explored for each rainfall event. For this purpose, high-intensity rainfall events were defined from the historical rainfall time series considering storm durations of 1, 3, 6, 12, 18 and 24 h. For each duration, the high-intensity rainfall events were defined as those with an average rainfall intensity higher than 30% of the average annual maximum rainfall for that specific duration. A minimum one week lag between events was also imposed to avoid statistical dependence, as previously used in Cea and Fraga (2018). These criteria produced 239 independent events in the period 2001–2015 (i.e., around 17 events per year).

2.3 Weather Type Statistical Downscaling Method

The downscaled projected precipitation time series were produced using the weather typing based statistical downscaling method SD-B-7 developed by Willems and Vrac (2011). Downscaling by this WT based method is performed in three steps. Firstly, an atmospheric classification system is applied to determine the historical and climate modeled Jenkinson Collision modified Lamb weather types, following the process described in section 2.2. In the second step, an analogue method is applied to the climate model output for the scenario period. More specifically, for each projected wet day in the scenario period (2071–2100), the historical wet day having a similar WT, occurring in the same season and best approximating the exceedance probability of the daily precipitation amount is defined as the analogue day. The projected precipitation time series is constructed by combining the precipitation amount sequences for the analogue days. The case study analyzed in this paper is focused on a small catchment where rainfall duration is typically shorter than a day. For larger catchments, the downscaling could be applied to rainfall events instead of on a day-by-day basis. In the last step of the downscaling process, the projected precipitation time series are rescaled following the Clausius-Clapeyron relation (CC relation). This relation assumes an intensification of extreme precipitation amounts by 7% per degree temperature increase. For each of the projected time series, the CC relation is defined at the annual time scale using the daily hydro-meteorological information. The precipitation scaling is performed using seasonal quantile based average daily temperature changes.

Following the above method, WTs and temperature were used as large-scale predictors, while the local-scale predictand was the daily precipitation accumulation. From the set of 123

GCM runs used to assess future LCTs' occurrence, a combination of 19 GCMs and 2 RCPs (i.e., a total of 38 GCM runs) was chosen to obtain projected precipitation time series based on data availability (required variables available from all 19 GCMs, and GCM projections available for both RCP scenarios).

2.4 Estimation of IDF Curves and Synthetic Hyetographs

IDF curves for the study catchment were estimated from the historical and projected basin-averaged precipitation time series. Using basin-averaged time series to evaluate the IDF curves avoids the need to apply generic Areal Reduction Factors (ARF) derived for other catchments or regions (Wright et al. 2014; Cea and Fraga 2018).

The basin-averaged time series of historical and projected rainfall were aggregated at durations of 1, 3, 6, 12, 18 and 24 h, obtaining thus six rainfall time series for each climate condition (historical, RCP 4.5 and RCP 8.5), each one with a different aggregation time step. Each register of the time series was classified according to its corresponding WT, and the annual maximum rainfall depth was obtained for each aggregation duration and WT. The exceedance probability of the sampled data was estimated using the formula of Gringorten (1963). A two-parameter Gumbel extreme value distribution was fitted to the data. The choice of the Gumbel distribution instead of the Generalized Extreme Value (GEV) distribution was made considering the relatively short length of the available time series (18 years). This was also the reason why the IDF curves were only computed for return periods up to 50 years. In this way, IDF relations were developed for each WT separately and then composed into a single IDF curve by summing for all WTs the product of their distribution function and their probability of occurrence. This was done for the historical precipitation data and for the future precipitation series obtained from each of the 38 GCMs runs corresponding to the RCP 4.5 and RCP 8.5. Thus, 19 IDFs were computed for each future climate scenario (one IDF per GCM run).

The basin-averaged IDF curves were used to build synthetic design hyetographs for different return periods (T = 2, 10, 25 and 50 years) and climate conditions (historical, RCP 4.5 and RCP 8.5). For that purpose, the median of the 19 IDFs available for each future climate scenario was used to characterize each RCP. The synthetic hyetographs were built with the Alternating Block Method using a block duration of 1 h. This is short enough compared to the estimated concentration time of the catchments (about 10 h). In whole 12 synthetic design hyetographs were obtained as the combination of 4 return periods and 3 climate conditions.

2.5 Hydrological and Hydraulic Models

The semi-distributed model HEC-HMS v4.2.1 (Scharffenberg and Fleming 2006) and its geospatial toolkit HEC-GeoHMS (Fleming and Doan 2009) were used to transform the synthetic hyetographs in flood hydrographs. The Mandeo (353 km^2) and Mendo (84 km^2) basins were subdivided into 34 and 24 subbasins, respectively, with areas ranging from 0.2 to 30 km^2. Effective rainfall was estimated using the SCS curve number method. A curve number (CN) corresponding to average antecedent soil moisture conditions (AMC) was assigned to each subbasin according to its Hydrologic Soil-Cover Complex (cover type, land treatment, hydrological condition, and hydrologic soil group). The SCS unit hydrograph was used to model rainfall-runoff transformation, using the TR55 method (USDA Soil Conservation Service 1986) to

compute the concentration time (Tc) of each subbasin, and the relation Tlag = 0.6 Tc to estimate the lag time (Tlag). Flow routing in the river stream network was modelled with the kinematic wave approximation. More specific details on the hydrological model can be found in Cea and Fraga (2018).

The 12 synthetic design hyetographs were introduced in the HEC-HMS model to compute the corresponding flood hydrographs, which were then used as boundary conditions in a two-dimensional hydrodynamic model to obtain the inundation hazard maps in the urban area of Betanzos for each climate condition and return period. The inundation model is based on the software Iber+ (Bladé et al. 2014; García-Feal et al. 2018), which solves the 2D depth-averaged shallow water equations with an unstructured finite volume solver. The model has been extensively validated and applied to river inundation studies (Garrote et al. 2016; Bermúdez et al. 2017; Sopelana et al. 2018; Areu-Rangel et al. 2019). Figure 1 shows the extension and topography of the numerical model, which includes the town of Betanzos (at the confluence of the rivers Mandeo and Mendo) and extends up to the ocean in order to correctly impose the tidal condition. The computational grid has about 126,000 elements, with a mesh size of the order of 5 m in the urban area. In the outer estuary the grid size increases to 50 m, which is enough to correctly propagate the tidal wave from the ocean to the urban area. The topography of the model was interpolated from a high-accuracy digital elevation model with a spatial resolution of 1 m (much finer than the mesh size). The only parameter of the model is the Manning bed roughness coefficient, which was specified considering six different land-use types. The flood hydrographs were imposed in the model as upstream boundary conditions, whereas the tidal level was imposed at the open sea boundary (Fig. 1). Since the study aims to evaluate the impact of increased extreme rainfall on flood hazard maps, a semi-diurnal tidal wave with a period of 12.42 h and an average tidal range of 2.5 m was used as the open sea boundary condition in all the inundation simulations.

3 Results and Discussion

3.1 Relationship between Atmospheric Circulation and Precipitation Events

From the analysis of the historical 36-year series of daily WTs (1979–2015), it can be observed that the anticyclone type (A in Fig. 2), with high pressures over the studied area, is dominant throughout the year and reaches its higher frequency during the summer months. Cyclone type (C in Fig. 2), associated with low pressures, also occurs consistently throughout the year, but its relative frequency is much lower, particularly in summer. Directional types N and NE show a seasonal behavior opposite to W and SW types, with maxima from April to September in the former case and from October to March in the latter. NW and E exhibit a similar frequency of occurrence throughout the year. The weather types with the lowest relative frequencies are directional types S and SE. These observations are consistent with the analysis of atmospheric circulation patterns performed by Lorenzo et al. (2008) in the same region, using a different reanalysis dataset and period of analysis.

The analysis of high rainfall events and WT frequencies showed that the majority of intense precipitation events in the catchment are associated with weather types W, SW and C (Fig. 3a). The overall number of high rainfall events occurring in winter (Oct-Mar)
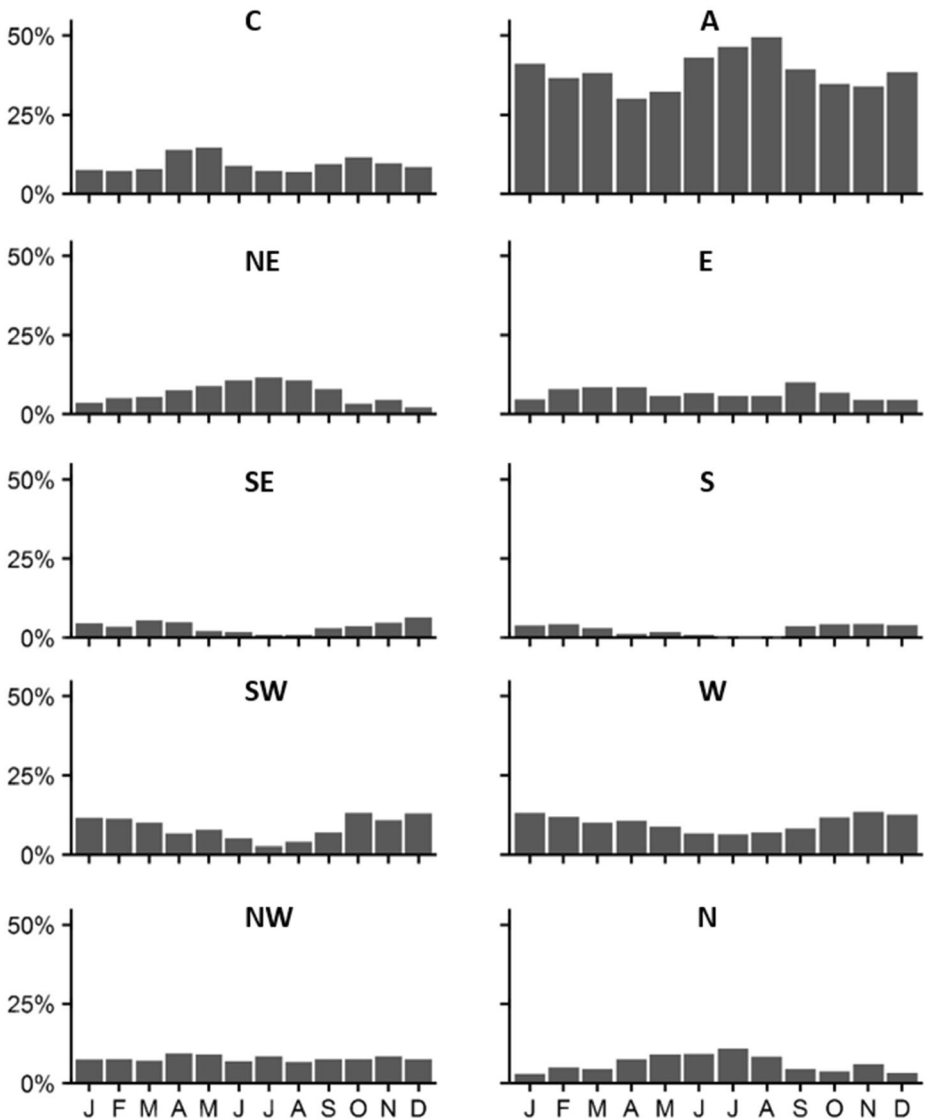

Fig. 2 Mean monthly relative frequency of the synoptic weather type based on the ERA Interim dataset (period 1979–2015). Note: Cyclonic (C), anticyclonic (A) and directional weather types (NE, E, SE, S, SW, W, NW, N)

is higher than in summer months (Apr-Sep) (138 vs. 101 events) (Fig. 3a), and its average magnitude is also higher (Fig. 3c). In winter, SW and W types, characterized by low-pressure systems over the North Atlantic, explain more rain events than C types. By contrast, C is the WT with the highest occurrence of high rainfall events in summer. Very few rainfall events occur during NE, E, SE and S types, characterized by high pressures over the British Isles, regardless of the season. Weather types C, W and SW alone explain 80% of all winter rainfall events and 60% of the summer ones. In addition, NE, E and SE rainfall events produce low rainfall magnitudes (Fig. 3b).
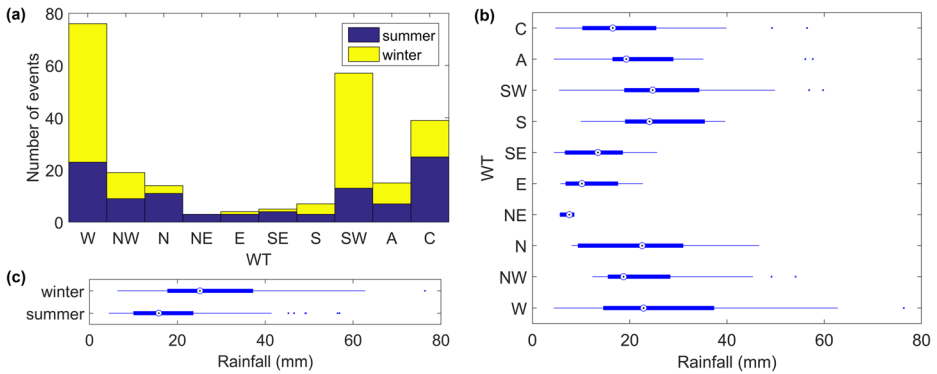

Fig. 3 **a** Absolute frequency of high rainfall events per weather type and season, based on data of 14 years (2001–2015), **b** Magnitude of accumulated daily rainfall per weather type in those events (both seasons), and **c** Magnitude of accumulated daily rainfall per season in those events. In the box and whisker plots, the central mark is the median, the box edges are the first and third quartile, the whiskers (lines) extend to the most extreme point within 1.5 times the interquartile range, and outliers are plotted as points beyond the whiskers

3.2 Future Changes in WT Frequencies

Future LCTs frequency was extracted from daily sea-level pressure projections from GCMs, as explained in section 2.2. Prior to conducting this analysis, the capability of the selected GCMs to reproduce current LCT frequencies was verified using the control runs (1961–1990). The comparison between the results obtained from the GCMs and those obtained from the historical reanalysis data are shown in Fig. S1 of the supplementary materials. The main discrepancies were found for westerly and anticyclonic types. The overestimation in the W frequency and underestimation of A frequency are well-known biases in the synoptic circulation simulated by GCMs in some regions (Addor et al. 2016; Otero et al. 2018). Overall, a reasonably good agreement was found.

Changes in frequency between the respective control runs (1961–1990) and the future period simulations (2071–2100) from the GCMs are shown in Fig. 4 for the WTs linked to high rainfall events (i.e., C, W and SW). The future LCTs estimated from the different GCM runs show a large spread in the frequency changes. The median predictions show a decrease in the C types throughout the year, and a slight increase of SW and W types in winter. For most of the seasons and LCTs, changes are stronger for higher RCP scenarios.

The link between the above weather types and high rainfall events shown in Fig. 3a suggests that there could be an increase in winter high rainfall events, which are usually associated with W and SW types. By contrast, the number of high rainfall events occurring in summer could decrease, since they are associated with C followed by W types, and both WTs are predicted to decrease in summer. These results corroborate the findings of Lorenzo et al. (2011), indicating a decrease in the future frequency of C, W and SW circulation types in the spring and summer months. Given that Lorenzo et al. (2011) used only three GCMs (CMIP-3 simulations), the work presented in this paper constitutes an updated analysis (CMIP-5 simulations) with a larger set of GCMs that provides insight into the uncertainties involved.

In spite of the relationship that exists between WTs and high rainfall events, it is obvious that WTs cannot be used alone as a proxy for rainfall occurrence. Other factors operating at smaller time and space scales than synoptic-scale phenomena explain the
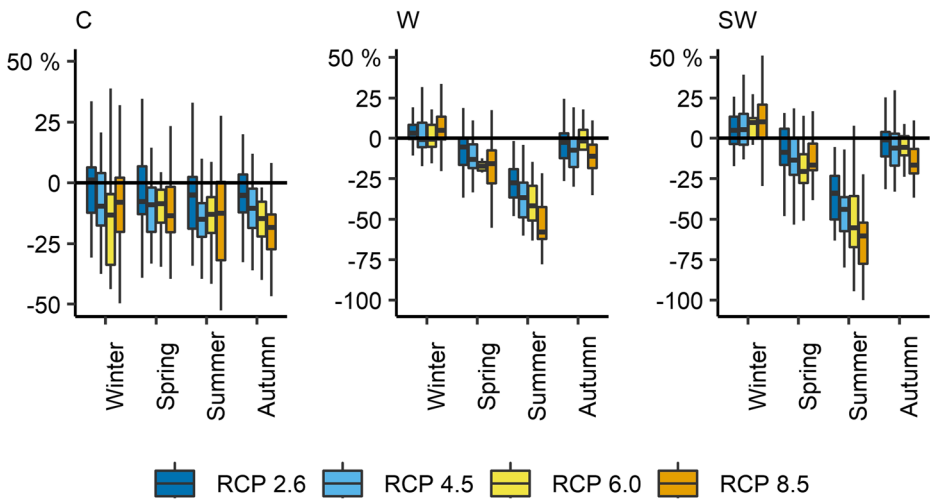

Fig. 4 Seasonal changes in the WT frequency of C, W and SW type for each of the four RCP scenarios, compared with the historical period. The box edges indicate the first and third quartile, the central mark in the box is the median and the whiskers (lines) extend to the 5th and 95th percentiles

occurrence of high rainfall. It is, however, an indirect means of gaining insight into the future rainfall change as a result of the synoptic variability changes, which are better simulated by GCMs than rainfall projections.

3.3 IDF Curves for Different Climate Conditions

The basin-averaged IDF curves computed for the historical and RCP 8.5 climate scenario are shown in Fig. 5. The IDF curves estimated from the RCP 4.5 projections can be found in the supplementary materials (Fig. S2). In the case of the RCP 8.5 scenario, the IDF computed from the 19 GCMs, as well as its median value, are shown in order to give a visual estimation of the variability of the downscaled GCMs projections. Figure 5 shows an increase in maximum rainfall intensity for all the return periods and rainfall durations. Moreover, all the GCMs predict an increase in maximum rainfall intensities, even though the ratio between projected and historical IDFs varies widely from one GCM to another.

The increase in the RCP 8.5 median IDF compared to the historical IDF is almost 25% for rainfall durations smaller than 12 h, which are the most relevant in the catchments of NW Spain, given their relatively small size. The ratio between RCP 8.5 and historical IDFs diminishes as the rainfall duration increases, being almost negligible for a 48-h rainfall. The most extreme rainfall projections give maximum differences up to 50% relative to the historical IDF, while the softer projections predict an increase in maximum rainfall intensities lower than 10% (Fig. 5).

It should be noticed when analyzing these results that any methodology that is driven by input from GCMs is dependent on the GCM skill in predicting the variables that form that input, in our case rainfall intensity. This limitation is shared by all downscaling techniques, including the more complex dynamic downscaling, which is dependent on boundary conditions obtained from GCMs.
Fig. 5 Basin-averaged IDF curves estimated from the historical rainfall and from the RCP 8.5 projected rainfall time series, for different return periods (2, 10, 25 and 50 years). The IDFs computed with all the GCM projections for the RCP 8.5 climate scenario are shown in addition to its median value

3.4 Flood Hydrographs

The basin-averaged IDF curves presented in Fig. 5 were used to build synthetic design hyetographs using the Alternating Block Method. Those hyetographs were then transformed to design flood hydrographs for both the Mandeo and Mendo rivers using the HEC-HMS hydrological model. In whole, 12 hyetographs and 24 flood hydrographs were computed, which correspond to the 4 return periods and the 3 climate conditions represented in Fig. 6. In the case of RCP 4.5 and RCP 8.5, the median IDF was used to build the synthetic hyetographs. The first thing that stands out is the relative increase in peak discharges, which is much larger than the increase in the peak rainfall intensities. This is because the differences in the peak of effective precipitation between climate conditions are much larger than the differences in total precipitation, even if the same values of CN were used in all the hydrological simulations. Even so, since the volume of the projected hyetographs is larger than the volume of the historical hyetographs, the infiltration capacity of the soil when the maximum rainfall intensity occurs is lower for the RCP 4.5 and 8.5 scenarios, producing much higher peaks of streamflow.

Compared to the historical flood hydrograph, the peak discharge computed for the RCP 4.5 is between 1.32 and 1.49 times higher, depending on the return period (please refer to
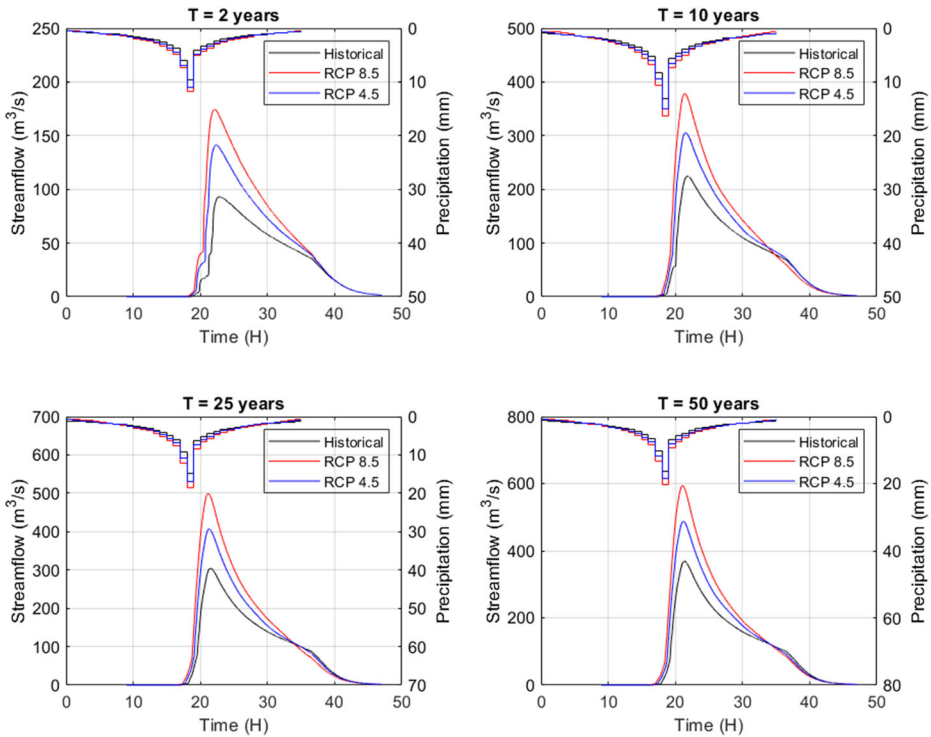

Fig. 6 Design synthetic hyetographs and hydrographs fo the different climate conditions (historical, RCP 4.5 and RCP 8.5) and return periods (2, 10, 25 and 50 years). The hydrographs shown correspond to the Mandeo river

supplementary materials - Table S1). Higher relative increments of runoff are obtained for the lower return periods. The same trend is observed for the RCP 8.5, although in this case the relative increment on peak discharge varies from 1.61 (for $T = 50$ years) to 1.85 (for $T = 2$ years). It is interesting to notice when comparing the historical and future climate conditions in Table S1 that the relative increase in the peak discharge is similar to the relative increase in the peak of effective precipitation intensity (except for $T = 2$), and higher than the relative increase in the effective precipitation depth. This effect can also be observed in the hydrographs presented in Fig. 6, where it is clearly shown that the relative difference in the peak of the hydrographs is higher than the difference in volume. Moreover, Table S1 shows that the differences between historical and future climate conditions are highly amplified when comparing peak discharges instead of total rainfall, even if potential future changes in land use and antecedent soil moisture conditions have not been considered in this analysis, in which the same values of CN have been used in all the hydrological simulations.

(a) Flood extent
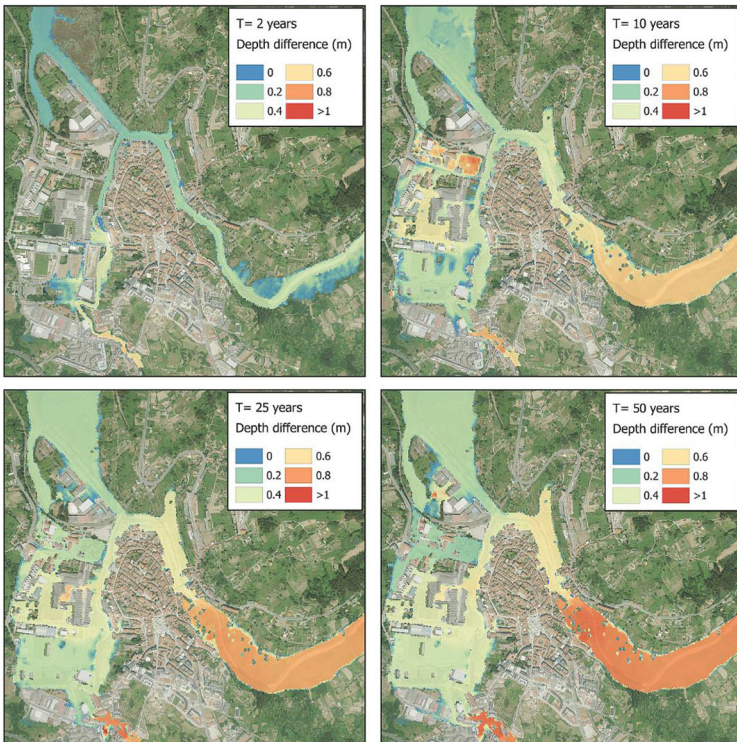

(b) Depth difference

3.5 Flood Maps

In this section, we estimate the extent and magnitude of flooding for the different climate conditions. The increased rainfall and runoff for future scenarios result in an increased flood extent in the urban area compared with current estimates for the same return period (Fig. 7a). For the T = 2 years storm event, the model results show that water stays in-bank in the historical conditions. However, in future scenarios, both the river Mandeo and Mendo overflow their banks in the upstream areas of the model domain for this return period. The flood extent is larger for RCP8.5 than RCP4.5, representing an increase from historical conditions of 60% and 20%, respectively (please refer to supplementary materials - Table S2).

The flood extent obviously increases with higher return periods (Fig. 7a). The water completely covers the floodplain for the design storm of T = 25 years in the historical scenario. In future scenarios, this situation is expected to occur more frequently, and as low as T = 10 years in RCP8.5. Comparatively, the relative increase in flood extent with respect to historical conditions is lower for the higher return periods (Table S2). The reason behind this is that the floodplains are constrained by the steep slopes of the surrounding terrain. Therefore, lateral flood expansion is limited and flood extent for all design storms with a return period above 25 years (i.e., once the floodplain is inundated in the historical conditions) is very similar.

For the higher return period events, the differences between the different simulations are mainly reflected in depth changes. The depth difference (90th percentile) with respect to historical conditions reaches 1.4 m for RCP8.5 and 0.71 m for RCP4.5 (Table S2). If these differences are plotted spatially (Fig. 7b), it can be seen that the largest differences are located in the upstream part of the River Mandeo, because of the narrow width of this floodplain in this area. The spatial distribution of maximum depth differences is very similar between scenarios RC4.5 and RCP8.5 (please refer to Fig. S3 in the supplementary materials for RCP4.5 results), but the magnitude of the differences is significantly higher for RCP8.5. The maximum depth differences with respect to historical simulations occur for T = 50 years, and reach up to 1.69 m for RCP4.5 and 2.34 m for RCP8.5.

Inundation levels in this coastal town are driven mainly by the river discharge. However, it is also important to be aware that, for low-return period discharges, sea level can also be responsible for high water surface elevations in the areas closer to the estuary (Sopelana et al. 2018; Bermúdez et al. 2019b). In this work, the average tide representative of normal conditions is imposed, so the potential role played by high sea levels on inundation levels is not considered. Future changes in mean sea level due to global warming are also not considered. Another important aspect regarding the limitations of the calculated flood maps is that they rely on the median IDF of all GCM runs. The calculation of flood maps using the individual IDF curves developed for each GCM run would be very computer-intensive for a detailed physically-based hydraulic model like the one used here, and would probably require the development of a fast surrogate model (Bermúdez et al. 2019a).

4 Conclusions

In this study, we developed a robust method to update local flood hazard maps using Global Climate Model (GCM) data. The LCT classification proved to be a valuable tool to analyze

possible changes in the probability of occurrence of high rainfall events and to generate local-scale rainfall projections in the studied area. The median of the future climate IDF curves, calculated from all the downscaled GCMs, show an increase in rainfall intensity for all studied rainfall durations. For durations below 12 h, which are the most relevant in the studied area due to the small catchment size, the increase in maximum rainfall intensity in RCP 8.5 median IDF is almost 25% compared to the historical IDF. The differences between historical and future climate conditions are highly amplified when comparing peak discharges instead of total rainfall (future peak discharges are between 1.32 and 1.85 times higher than in the historical hydrographs, depending on the RCP and return period considered).

The results show that existing IDF standards and flood maps need to be updated to reflect potential changes in future extreme rainfall intensities. Although the results presented use the best available information concerning future climate change, huge uncertainties remain. Therefore, besides updating IDF relations and flood maps, engineering design guidelines that incorporate climate change need to ensure that no regret solutions are being taken, and flexibility/adaptability to adjust to the uncertain future conditions.

A limitation of the methodology is that it does not account for potential changes in initial soil moisture conditions between present and future climate. There is no straightforward way to ascertain these potential changes in soil moisture in an event-based hydrological- hydraulic modelling approach like the one proposed here. To overcome this limitation, an alternative approach based on running a continuous mode hydrological model with future climate data could be considered. Future work should also consider potential changes in other sources of flooding (e.g., mean sea level rise associated with global warming) in regions with compound flooding potential.
