Cardiac fibroblast (CF) differentiation into myofibroblasts is a crucial cause of cardiac fibrosis, which increases in the extracellular matrix (ECM) stiffness. The increased stiffness further promotes CF differentiation and fibrosis. However, the molecular mechanism is still unclear. We used bioinformatics analysis to find new candidates that regulate the genes involved in stiffness-induced CF differentiation, and found that there were binding sites for the POU-domain transcription factor, POU2F1 (also known as Oct-1), in the promoters of 50 differentially expressed genes (DEGs) in CFs on the stiffer substrate. Immunofluorescent staining and Western blotting revealed that pathological stiffness upregulated POU2F1 expression and increased CF differentiation on polyacrylamide hydrogel substrates and in mouse myocardial infarction tissue. A chromatin immunoprecipitation assay showed that POU2F1 bound to the promoters of fibrosis repressors IL1R2, CD69, and TGIF2. The expression of these fibrosis repressors was inhibited on pathological substrate stiffness. Knockdown of POU2F1 upregulated these repressors and attenuated CF differentiation on pathological substrate stiffness (35 kPa). Whereas, overexpression of POU2F1 downregulated these repressors and enhanced CF differentiation. In conclusion, pathological stiffness upregulates the transcription factor POU2F1 to promote CF differentiation by inhibiting fibrosis repressors. Our work elucidated the crosstalk between CF differentiation and the ECM and provided a potential target for cardiac fibrosis treatment.

### INTRODUCTION

Cardiac fibrosis is a typical pathological process that occurs in various heart diseases, including myocardial infarction (MI), aortic stenosis, and cardiomyopathy, and it ultimately leads to the progression of heart failure (Li et al., 2018). Cardiac fibrosis is characterized by excessive accumulation

of extracellular matrix (ECM) proteins in the cardiac interstitium (Feng et al., 2018; Kong et al., 2014; Segura et al., 2014). ECM proteins are mainly synthesized and secreted from myofibroblasts (Gyongyosi et al., 2017; Herum et al., 2017; Hinz et al., 2007; van Putten et al., 2016), and myofibroblasts are primarily differentiated from cardiac fibroblasts (CFs), one of the most abundant cell types in the heart (Souders et al., 2009). The accumulation of ECM proteins during cardiac fibrosis increases in the stiffness of cardiac tissue. However, the increased stiffness can further promote

the process of cardiac fibrosis (Herum et al., 2017; Zhao et al., 2014), and ECM stiffness has been reported to induce CF differentiation (Elson et al., 2019; Engler et al., 2006; Zhao et al., 2014). Our group previously found that CFs displayed a nonmonotonic elasticity variation with an increase in substrate stiffness (Shi et al., 2011). However, the mechanism by which matrix stiffness promotes CF differentiation has not been fully elucidated. It is important to clarify the mechanism, as gaining this knowledge may lead to significant progress in blocking cardiac fibrosis and the progression of heart failure.

Several distinct pathways have been studied for their role in the mechanosensing of ECM stiffness in CFs. On the plasma membrane, integrin, toll-like receptors, and syndecans are reported to sense ECM stiffness (Li and Chaikof, 2002; Scheibner et al., 2006; Taylor et al., 2004; Zaidel-Bar et al., 2007). In the cytoplasm, the TGF $\beta$  (Huelsz-Prince et al., 2013; Jenkins, 2008; Rahaman et al., 2014; Robertson et al., 2015; Song et al., 2014; Yang et al., 2016; Zilberberg et al., 2012), ROCK (Driesen et al., 2014; Ni et al., 2013; Xie et al., 2014) and Hippo signaling pathways (Aragona et al., 2013; Codelia et al., 2014; Dupont et al., 2011) respond to stiffness and induce fibrosis. In addition, HSP, IL1 $\alpha$ , NF $\kappa$ B, and HMGB1, which are involved in the MAPK signaling pathway and the AGE-RAGE signaling pathway, contribute to the stiffness-induced release of ECM proteins (Strand et al., 2015; Tian et al., 2007; Turner, 2014; Vabulas et al., 2001). In the nucleus, the LINC (linker of nucleoskeleton and cytoskeleton) complex, including NESPRINs, SUN and LAMINs, was reported to be involved in mechanotransduction (Herum et al., 2017). In addition, transcription factors in the nucleus were also regulated by stiffness (Wang et al., 2009). Nonetheless, the crosstalk and the shared regulatory mechanism of these distinct signaling pathways are still incompletely understood. It is unknown whether there is a core factor in the regulation of these multiple pathways involved in ECM stiffness-induced CF differentiation.

Here, to investigate the core factor regulating substrate stiffness-induced CF differentiation, we used published RNA-seq data to identify the differentially expressed genes (DEGs) in CFs cultured on substrates with different levels of stiffness. Bioinformatics analysis was used to predict the transcription factors of these genes and to identify a transcription factor that can regulate the largest number of DEGs. The analysis results suggested that POU domain class 2 transcription factor 1 (POU2F1, also known as Oct-1) is a crucial candidate whose binding sites were found in 50 DEGs. POU2F1 expression was found to change in CFs cultured on pathological substrates with different levels of stiffness and was additionally found to have a role in the regulation of CF differentiation. This research will improve our understanding of the role of substrate stiffness in CF differentiation and will provide a potential target for the

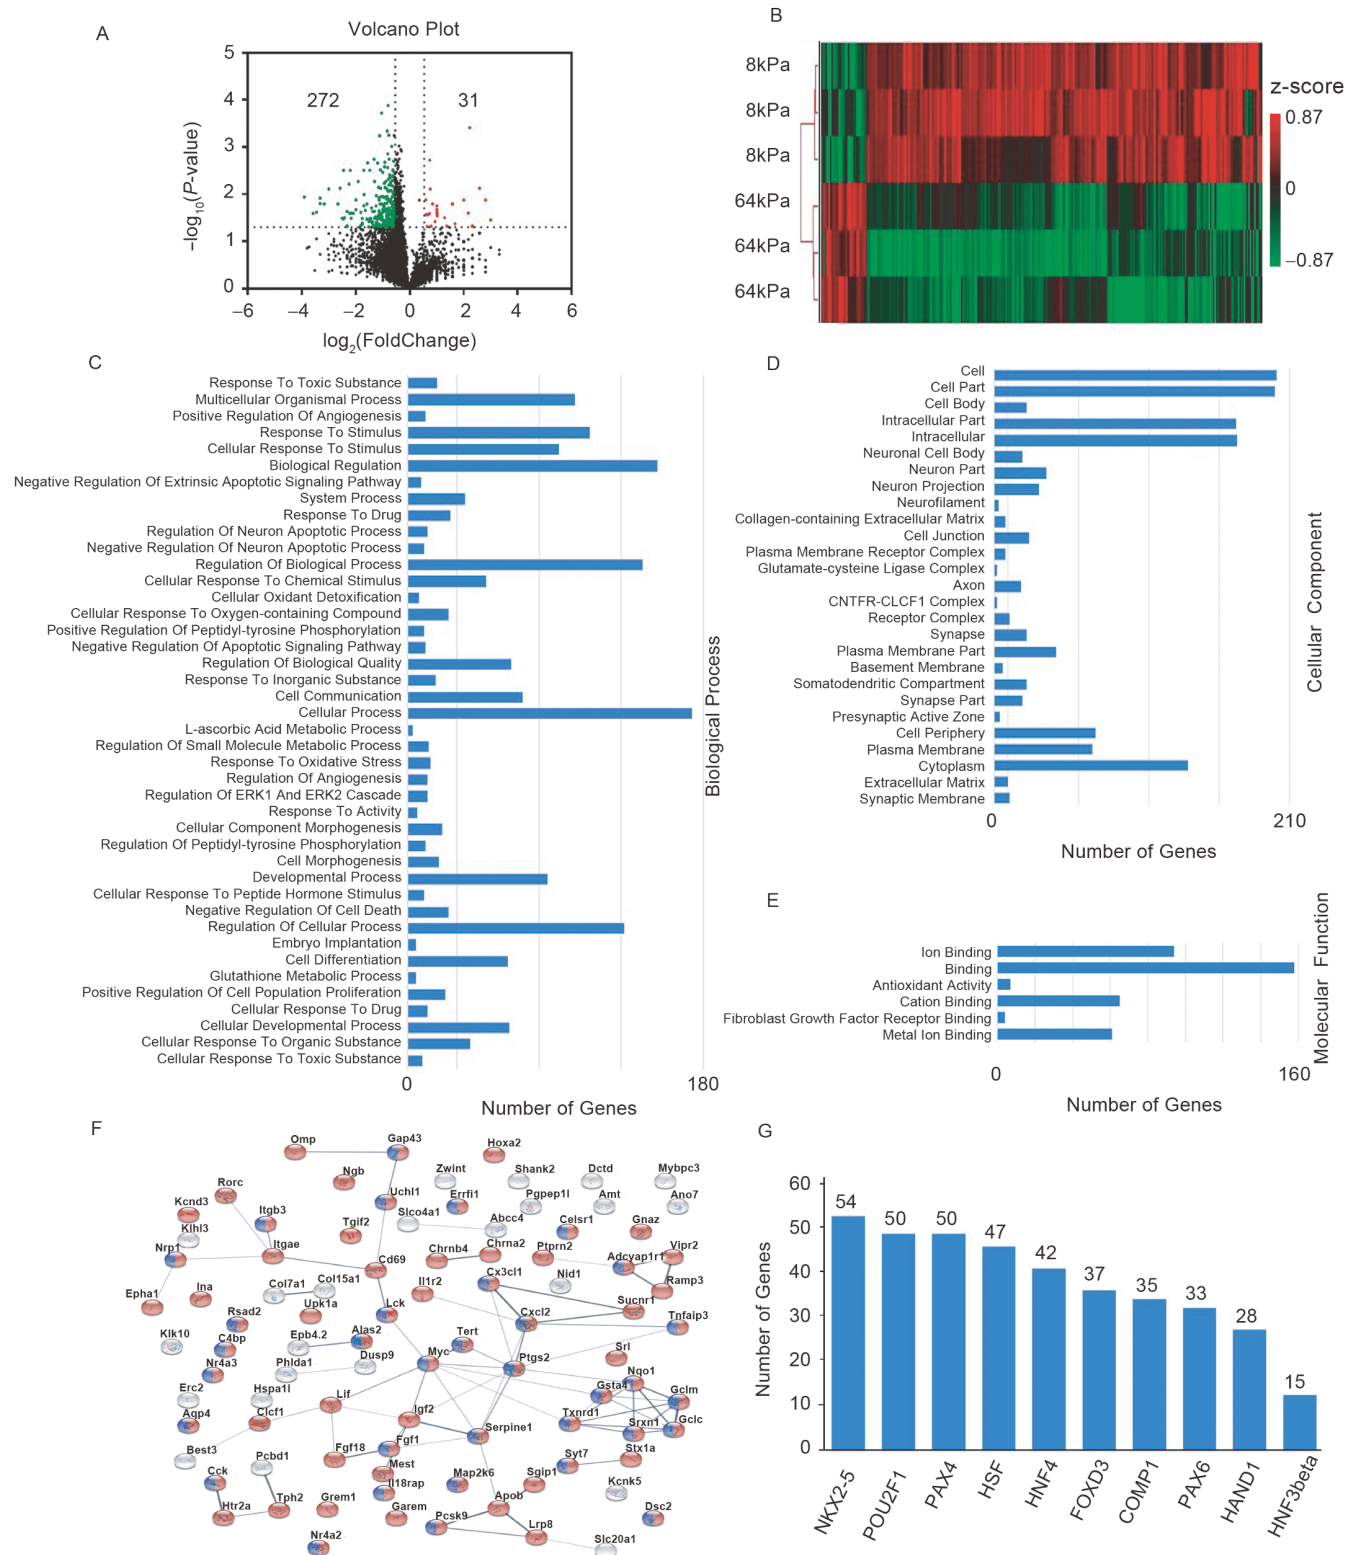

treatment of cardiac fibrosis.

## RESULTS

### Transcriptome change in CFs under different substrate stiffness

To identify candidates that regulate multiple downstream genes responding to substrate stiffness, we conducted bioinformatics analysis. The global transcriptional profiles of CFs cultured on substrates with different stiffnesses were obtained from the NCBI's Gene Expression Omnibus database (GSE113277) (Yu et al., 2018). Compared with gene expression in CFs on the softer substrate (8 kPa), 303 DEGs (filtering criteria  $P < 0.05$ , fold-change  $> 2.0$ ) were identified in CFs on the stiffer substrate (64 kPa) (Table S1 in Supporting Information). These genes included 272 downregulated and 31 upregulated genes (Figure 1A and B). Gene Ontology (GO) enrichment was listed based on the annotation of three categories: molecular function, cellular component, and biological process (Figure 1C–E; Table S2 in Supporting Information). The levels of 111 DEGs responding to the stimulus changed when the cells were cultured with the stiffer substrate (GO: 0050896). Sixty-one DEGs were involved in cell differentiation (GO: 0030154). The DEGs (172 genes) are mainly involved in the intracellular systems (GO: 0044424). The analysis emphasized that the DEGs with the ion binding (GO: 0043167) ability played important roles in response to substrate stiffness. Ninety-one of the 303 genes have been previously reported to be associated with fibrosis in the PubMed database (Table S3 in Supporting Information). STRING analysis (Szklarczyk et al., 2011) also revealed that the functional links of 67 of these 91 DEGs were associated with responding to stimulus (GO: 0050896), and 34 of these 91 DEGs participated in responding to stress (GO: 0006950) (Figure 1F; Table S3 in Supporting Information).

The position weight matrix algorithm in TRANSFAC was used to predict the potential transcription factors of the 91 DEGs that have been reported to be involved in fibrosis. The top 10 transcription factors that were predicted to bind to the greatest number of DEGs are listed in Figure 1G and Table S4 (in Supporting Information). Nkx2-5 was predicted to bind to the most DEGs (54 DEGs). A previous study reported that Nkx2-5 regulates CF differentiation and fibrosis (Dritsoula et al., 2018). The putative binding site for the transcription factor POU2F1 was predicted in the promoter regions of 50 DEGs (Figure 1G). Among the 50 DEGs, five were upregulated and 45 were downregulated. In these 50 DEGs, there were 41 DEGs related to the “physiological response to stimulus (GO: 0050896)”, 20 DEGs related to the “response to stress (GO: 0006950)”, and 11 DEGs related to the “regulation of cell differentiation (GO: 0045595)”

(Table S5 in Supporting Information). This information indicates that POU2F1 plays a crucial role in sensing the stiffness and inducing CF differentiation.

### The protein level of POU2F1 was upregulated in response to substrates with pathological stiffness

POU2F1 is a new potential target identified in the present study, and its role in stiffness-induced cardiac fibrosis has not been reported. Before we studied the expression of POU2F1 in response to different substrate stiffness, we first cultured CFs on polyacrylamide hydrogels with different stiffnesses and assessed the morphological change in CFs by characterizing the F-actin distribution; these assessments were performed to ensure that this *in vitro* substrate stiffness system was effective. The stiffness of 7.5 kPa is similar to the stiffness of the infarct region (Herum et al., 2017); 13 kPa is comparable to that of the healthy myocardium (Hinz, 2009); both 19.5 kPa and 35 kPa mimic the stiffness in fibrotic myocardium and in scar tissue of the infarct region (Herum et al., 2017). Consistent with previous reports, CFs exhibited a round and elongated form on softer hydrogels, and they had a greater extent of cell spreading and were star-shaped when cultured on stiffer hydrogels (Figure S1 in Supporting Information).

We examined the distribution and expression of POU2F1 in response to different substrate stiffnesses. POU2F1 was predominantly located in the nucleus (Figure 2A). The expression pattern of POU2F1 was the lowest in CFs cultured on a physiological stiffness (13 kPa) substrate. Compared with physiological stiffness (13 kPa), the softer and stiffer pathological stiffness resulted in a higher protein expression level of POU2F1 in CFs on the substrate (Figure 2A and B). The POU2F1 mRNA level also increased in CFs cultured on the softer or stiffer substrate (Figure 2C), suggesting that the expression of POU2F1 was regulated by different substrate stiffness at the transcriptional level. To gain insight into the *in vivo* relevance, we detected the protein level of POU2F1 in different phases of the MI model. The protein level of POU2F1 in the infarct region was significantly upregulated within 1 day (3 kPa), 4 days (stiffer than physiological tissue), and 7 days (close to 30 kPa) after MI. As a reference, there was no apparent change in the protein level of POU2F1 in the remote region (the stiffness was similar to that in healthy tissue, Figure 2D). Collectively, these results indicated that pathological stiffness upregulated POU2F1 expression both *in vitro* and *in vivo*.

The differentiation of CF into myofibroblasts is characterized by an increase in the expression of fibronectin and  $\alpha$ -smooth actin ( $\alpha$ SMA) (Hinz et al., 2007; Pankov and Yamada, 2002). Immunofluorescent staining showed that the protein levels of fibronectin and  $\alpha$ SMA in CFs were the lowest on 13 kPa (physiological stiffness) polyacrylamide

hydrogels. Both softer and stiffer substrates induced an increase in the protein levels of fibronectin and  $\alpha$ SMA (Figure 2E). Consistently, Western blotting revealed that fibronectin and  $\alpha$ SMA were upregulated on the 19.5 kPa substrate and further increased on the 7.5 kPa and 35 kPa substrates, compared with the 13 kPa substrate (Figure 2F). These results indicated that fibroblast differentiation was induced by pathological stiffness.

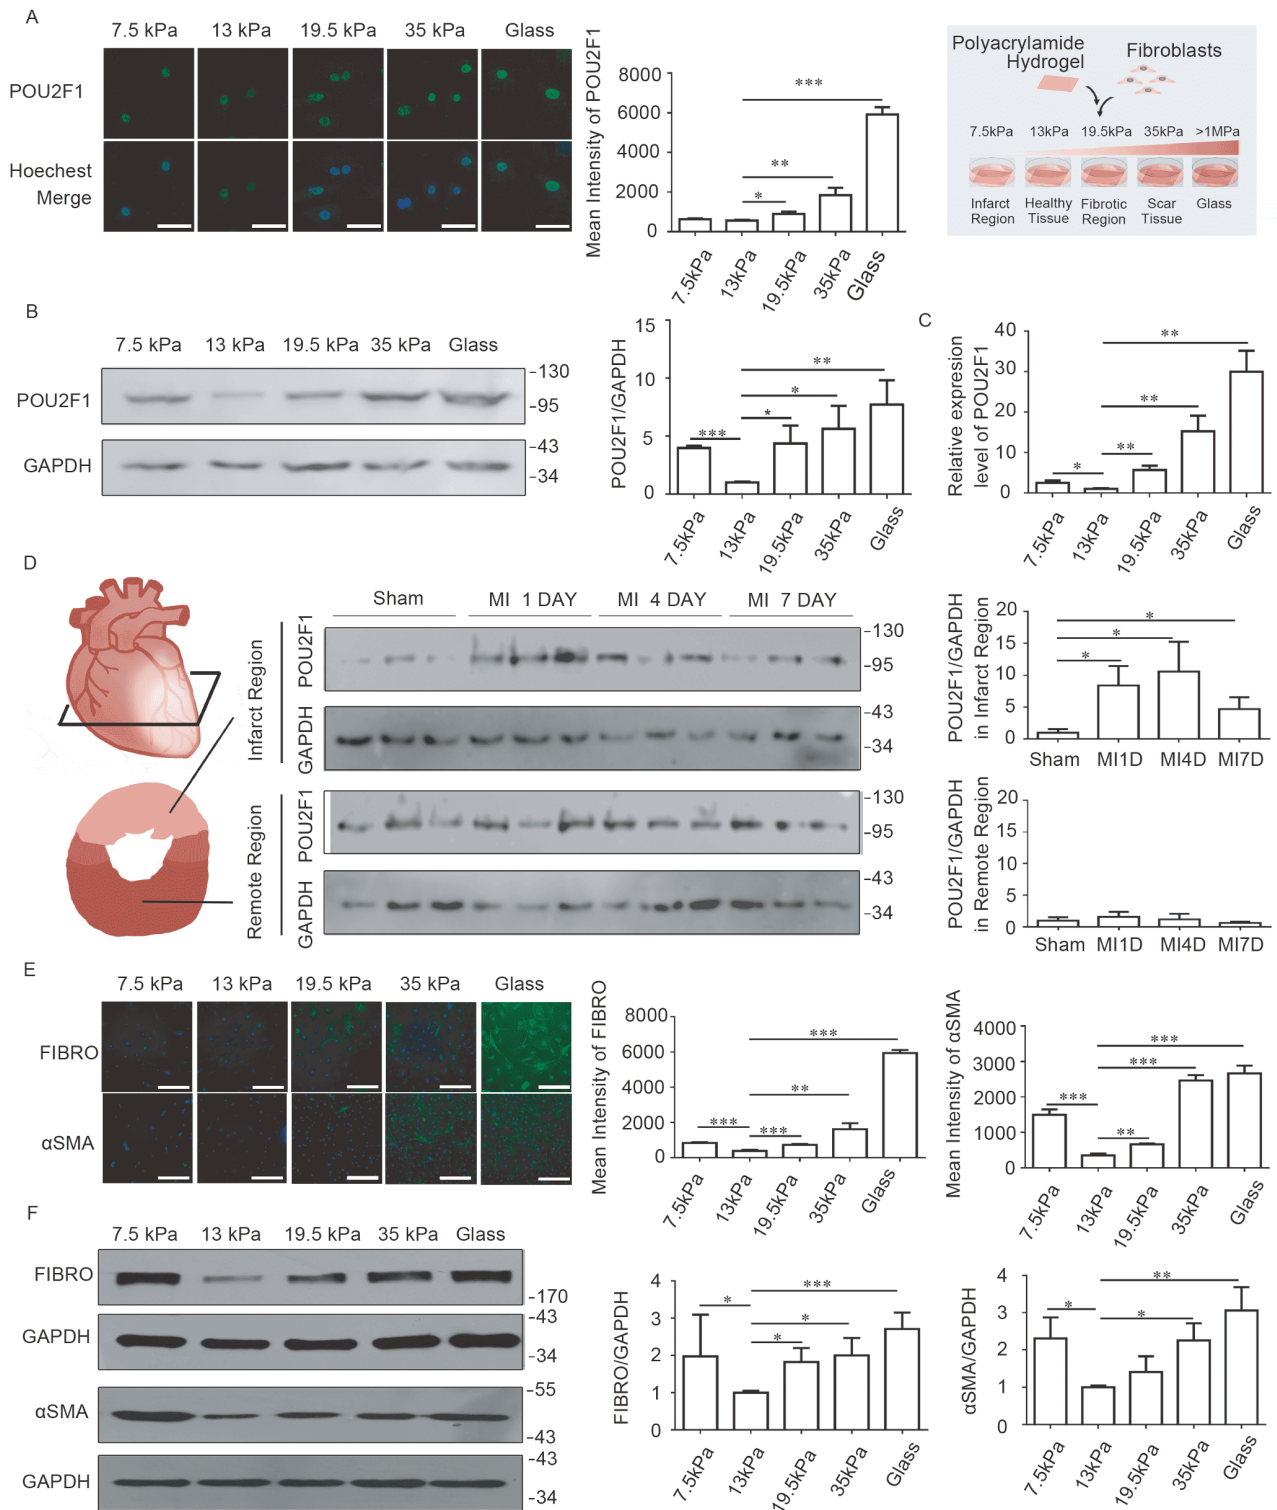

### POU2F1 bound to the promoter of the predicted downstream genes

To validate whether POU2F1 can bind to the promoter of the predicted target genes, we selected three candidate genes from the TRANSFAC bioinformatics analysis, IL1R2, CD69, TGIF2. They were chosen as representatives because they not only have the putative POU2F1-binding site, but they are also reported to play similar roles in inhibiting cardiac fibrosis. The putative POU2F1-binding sites were predicted in the promoter region of these three genes (Figure 3A–C). The chromatin immunoprecipitation (ChIP) assay revealed that the fraction containing the IL1R2, CD69 and TGIF2 promoters was significantly higher than that containing the control regions, suggesting that POU2F1 bound to the three gene promoters (Figure 3D–F). Compared with CFs cultured on a physiological substrate (13 kPa), the expression pattern of all three genes was downregulated in CFs cultured on a pathological substrate (35 kPa) (Figure 3G–I). These results indicated that pathological stiffness regulated the gene expression of IL1R2, CD69 and TGIF2 and may be associated with POU2F1 binding to their promoters.

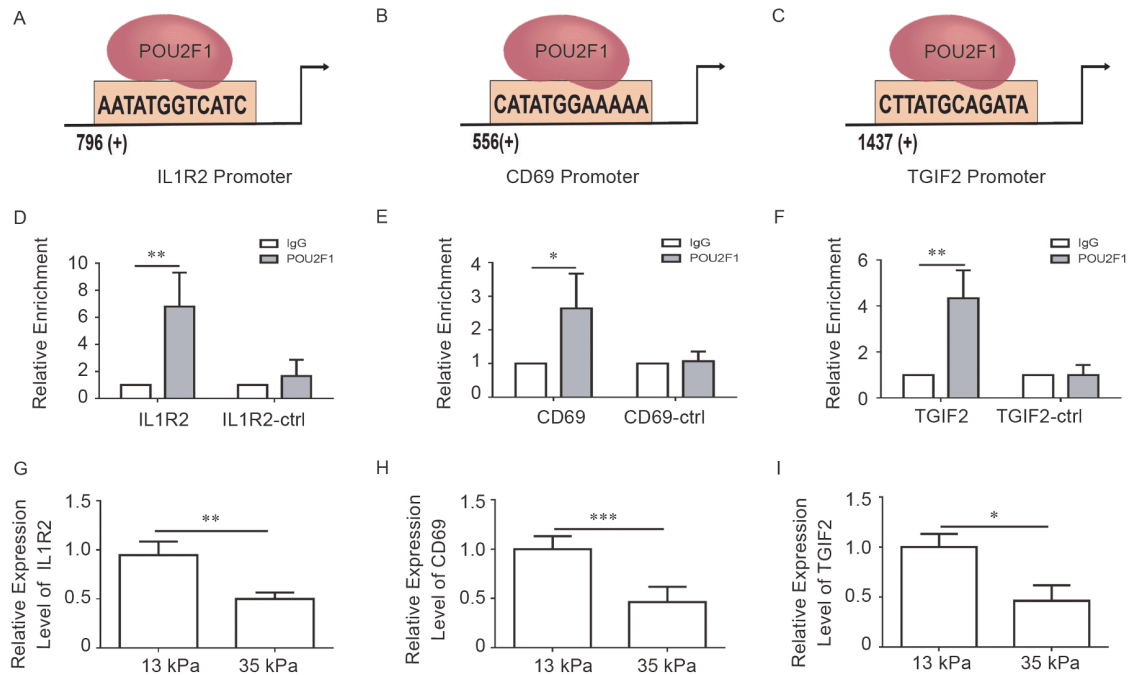

### POU2F1 suppressed the expression of IL1R2, CD69 and TGIF2 in CFs on a substrate with pathological stiffness

To determine the role of POU2F1 in the expression of the candidate genes involved in stiffness-induced CF differentiation, we knocked down POU2F1 and determined the expression of IL1R2, CD69 and TGIF2 on pathological stiffness (35 kPa) substrate by qRT-PCR and Western blotting. The mRNA and protein levels of POU2F1 were significantly reduced in the POU2F1 knockdown group (Figure 4A and B). The expression levels of IL1R2, CD69 and TGIF2 significantly increased following POU2F1 knockdown on the 35 kPa substrate (Figure 4C–H). We also investigated whether POU2F1 overexpression decreases IL1R2, CD69 and TGIF2 expression. Mouse POU2F1 expression cassette in the pAdeasy adenoviral vector was constructed (Figure 4J). The protein level of POU2F1 was significantly increased in the ad-POU2F1 infected group (Figure 4I). As expected, the protein levels of IL1R2, CD69 and TGIF2 were decreased in POU2F1 adenovirus-infected CFs (Figure 4K–M). Thus, POU2F1 inhibited the expression

of the three fibrosis repressors in CFs on pathological stiffness substrate.

### Substrate stiffness modulated CF differentiation through POU2F1

To verify the function of POU2F1 in pathological stiffness-induced CF differentiation, the protein level of myofibroblast markers in POU2F1-knockdown CFs was detected on pathological stiffness (35 kPa) hydrogels by immunofluorescent staining and Western blotting. The green fluorescence of fibronectin and  $\alpha$ SMA became weaker in POU2F1-knockdown CFs (Figure 5A and B). Western blotting also showed that the protein levels of fibronectin and  $\alpha$ SMA significantly decreased after knockdown of POU2F1 (Figure 5C). In contrast, the protein levels of fibronectin and  $\alpha$ SMA increased in POU2F1 overexpressed CFs (Figure 5D). These results indicated that POU2F1 promoted pathological stiffness-induced fibroblast differentiation.

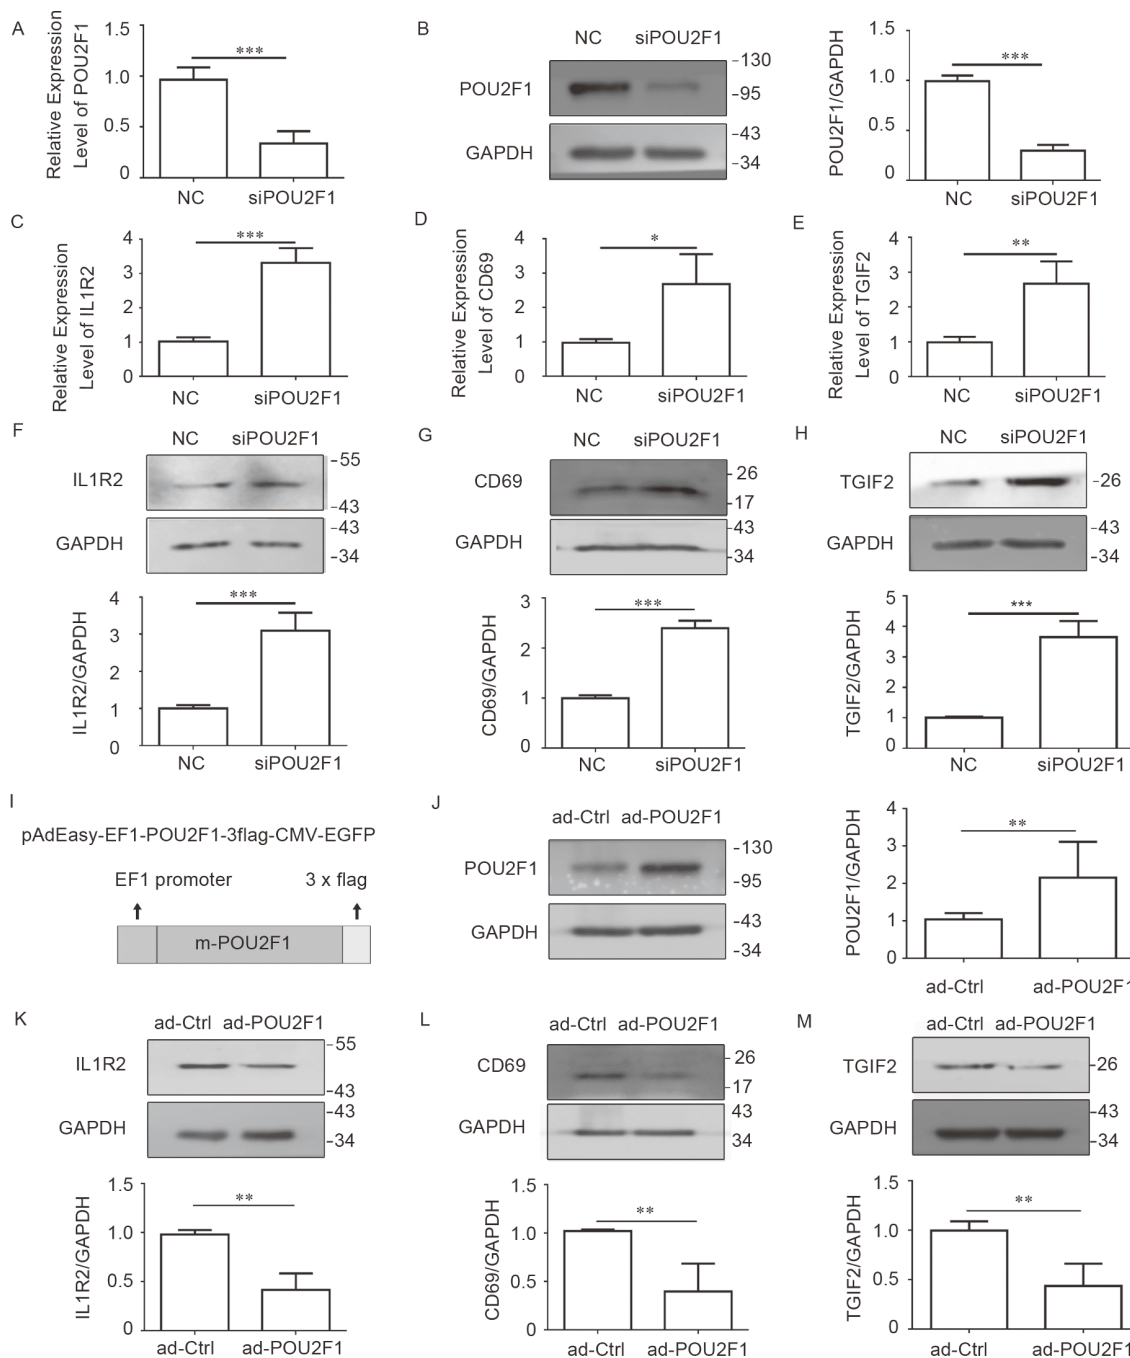

## DISCUSSION

The present study first found that the transcription factor POU2F1 plays a crucial role in the crosstalk between ECM stiffness and CF differentiation. POU2F1 was upregulated by pathological substrate stiffness and promoted CF differ-

entiation by inhibiting fibrotic repressors, including IL1R2, CD69 and TGIF2. Our findings have provided a new core link between ECM stiffness and CF differentiation and suggested POU2F1 as a potential therapeutic target for cardiac fibrosis (Figure 6).

POU2F1 is the only widely expressed member of the POU factor family (Hinz et al., 2007; Pankov and Yamada, 2002). About half of the members in the family display a substantial affinity for an 8 bp DNA site termed the octamer motif, and hence POU2F1 is also known as Oct-1. POU2F1 associates with different cofactors to mediate either transcriptional activation, repression, or gene poising (Shakya et al., 2011; Zhang et al., 1999). The mRNA and protein levels of POU2F1 significantly increase in various cancers (Shakya et al., 2011; Zhang et al., 1999). Initially, POU2F1 was described to target genes associated with proliferation and immune modulation (Vazquez-Arreguin and Tantin, 2016). Recent studies identified that its targets are also associated with oxidative and cytotoxic stress resistance, metabolic regulation, stem cell function and other unexpected processes (Borlak and Thum, 2002; Boulon et al., 2002; Cairns et al., 2011; Kang et al., 2009; Kang et al., 2013; Maddox et al., 2012; Magne et al., 2003). However, the role of POU2F1 in the heart is not fully understood, especially in cardiac fibrosis.

We analyzed the transcriptome data of fibroblasts on different stiffness (8 and 64 kPa) as a clue for investigating the

underlying mechanism of stiffness-induced fibrosis. It indicated that POU2F1 is the possible key regulatory factor. The stiffness range of normal heart under physiological conditions is estimated as 10–20 kPa, and 20–100 kPa for the

fibrotic myocardium (Berry et al., 2006; Conrad et al., 1995; Engler et al., 2008; Torres et al., 2018; Wu et al., 2000). The physiological cardiac stiffness (13 kPa) in the present study was chosen according to the above-mentioned knowledge

**Figure 5** Roles of POU2F1 in fibroblast differentiation. A and B, CFs were transfected with POU2F1 siRNA or negative control (NC) and cultured on a substrate with a stiffness of 35 kPa. **Figure 6** Schematic summary of the role of POU2F1 in pathological stiffness-induced CF differentiation. During the pathological process, the abnormal alteration in stiffness of substrates, both stiffer or softer, upregulates POU2F1. POU2F1 inhibits the transcription of fibrosis repressors, IL1R2, CD69 and TGIF2, which results in the differentiation of CFs to myofibroblasts.

and our group's previous publication (Shi et al., 2011). According to these studies, we selected the substrate stiffness (7.5, 13, 19.5 and 35 kPa) to investigate the effect and mechanism of stiffness on CF differentiation in the present study.

Following MI, the infarct region showed softer stiffness initially (within 1 day), and the stiffness continuously increased to higher stiffness than normal after the acute phase. In the present study, we found that both softer and stiffer substrate stiffness could promote POU2F1 expression and CF differentiation. The softer stiffness-induced fibrosis, which occurs in the early phase following myocardial infarction, is considered protective against heart rupture (Talmán and Ruskoaho, 2016). Hence, POU2F1 may be important for cardiac repair during the acute phase by promoting softer stiffness-induced CF differentiation. However, in the later phase, the cardiac tissue gradually becomes stiffer than physiological condition. The fibrosis enhanced by stiffer stiffness is deleterious and can promote pathological cardiac remodeling. Exaggerated fibrosis leads to impairments in cardiac function and ultimately heart failure (Talmán and Ruskoaho, 2016). During this process, cardiac fibrosis results in an increase in matrix stiffness, which will further aggravate fibrosis (Herum et al., 2017). Thus, we focused on the stiffer stiffness-induced CF differentiation

and chose 35 kPa to study the mechanism how stiffer substrate regulates CF differentiation. The present study suggests that POU2F1 is a newly identified crucial factor in this vicious cycle, which will finally result in heart failure. In addition, the heart failure marker beta-myosin heavy chain is reported as the downstream target gene of POU2F1 (Allen et al., 2005; Lakich et al., 1998). Therefore, POU2F1 is critical to the regulation of cardiac fibrosis and may be a potential target for the treatment of cardiac fibrosis and heart failure.

Both the mRNA and protein levels of POU2F1 were up-regulated during stiffness-induced CF activation. Several studies identified elevated levels of POU2F1 mRNA and protein in cancer compared with normal tissues (Vazquez-Arreguin and Tantin, 2016). But the upstream regulative mechanism of POU2F1 expression has not been extensively investigated. It is reported that POU2F1 is modified by ubiquitylation, but the ubiquitin ligase(s) and deubiquitinases are still unknown (Kang et al., 2013). Focal adhesion kinase (FAK) acts as a mechanosensor by modulating cell proliferation in response to changes in tissue compliance (Thomas et al., 2019). Matrix stiffness regulates cell differentiation through FAK signaling pathway (Thomas et al., 2019). FAK promotes protein degradation through ubiquitination, leading to cell growth and proliferation (Zhou et al., 2019). It is possible that FAK may be involved in stiffness-induced POU2F1 expression. Overall, how pathological stiffness upregulates POU2F1 needs further study in the future.

IL1R2, CD69 and TGIF2 were identified as the target genes of POU2F1. They are known as fibrotic suppressors. IL1R2 is a decoy receptor that inhibits IL-1 signal and fibrosis (Shimizu et al., 2015). It interacts with IL1R1 to inhibit the activity of its ligands (IL1A and IL1B) (Borthwick, 2016; Palomo et al., 2015). IL-1 cytokine families are potent activators of classical NF- $\kappa$ B signaling (Vallabhapurapu and Karin, 2009). Activated NF- $\kappa$ B signaling pathway promotes fibroblast differentiation (Tian et al., 2015). IL1R2 may function as an inhibitor of the IL-1/NF- $\kappa$ B pathway to inhibit fibroblast differentiation (Tian et al., 2015). CD69 controls tissue fibrosis by regulating Th17-mediated inflammation (Liappas et al., 2016). CD69 suppresses mTOR signaling (Notario et al., 2018). The abrogation of the mTORC2-Akt signaling axis impeded fibroblast differentiation (Kim et al., 2019). Thus, CD69 may suppress fibroblast differentiation by down-regulating the mTOR signaling pathway. Both of these proteins participate in the MAPK/PI3K/AKT signaling pathway. The transcriptional repressor TGIF2 is critical in TGF $\beta$  signaling to mediate the antifibrotic effect (Melhuish et al., 2016; Sharma et al., 2015). TGF $\beta$  is the most well-known inducer of fibroblast differentiation (Carthy, 2018). It is possible that TGIF2 represses fibroblasts differentiation through negatively regulating the TGF $\beta$  signaling pathway. Within the 50 DEGs that were predicted to have POU2F1

binding sites, some of these genes belong to the reported signaling pathway involved in the mechanosensing of ECM stiffness. In the PubMed database, 27 DEGs were associated with the TGF $\beta$  signaling pathway, 13 DEGs were associated with the ROCK signaling pathway, 4 DEGs were associated with the Hippo signaling pathway, 37 DEGs were associated with the MAPK signaling pathway, and 3 DEGs were associated with the AGE-RAGE signaling pathway (Table S6 in Supporting Information). All of these signaling pathways were reported to participate in stiffness-induced CF differentiation (Herum et al., 2017). These bioinformatics data suggest the core position of POU2F1 in this process.

In conclusion, pathological substrate stiffness promotes the differentiation of CFs into myofibroblasts. The underlying mechanism is that pathological stiffness upregulates expression of POU2F1, resulting in decreased expression of the fibrosis repressor genes IL1R2, CD69 and TGIF2, and consequently contributes to CF differentiation. The present study clarified the role of POU2F1 in pathological substrate stiffness-induced CF differentiation and provided a new target for the treatment of cardiac fibrosis.

## MATERIALS AND METHODS

### Isolation and culture of CFs

All experiments conformed to the US National Institutes of Health Guide for the Care and Use of Laboratory Animals (NIH Publication No. 85-23, revised 2011). Animal experiments were approved by the Committee of Peking University on Ethics of Animal Experiments (LA 2016018) and were conducted in accordance with the ARRIVE (Animal Research: Reporting *In Vivo* Experiments) guidelines and the Guidelines for Animal Experiments, Peking University Health Science Center.

CF cells were isolated and cultured from the hearts of 8- to 10-week-old male C57BL/6 mice as previously described with minor modifications (Takeda et al., 2010). The heart was isolated and digested with 0.1% collagenase type II (300U, 17101-015, Gibco, USA) at 37°C. After centrifugation at 1,000 r min<sup>-1</sup> for 5 min, the supernatant was removed, and the obtained cells were transferred to 10-cm dishes and cultured in DMEM (12800-058, Gibco, USA) supplemented with 10% fetal bovine serum (15140-122, Gibco, USA) in a humidified atmosphere at 37°C and 5% CO<sub>2</sub>. Cells of the second passage were seeded onto substrates with different stiffness for further investigation. CFs were grown on hydrogels for one day and were then subjected to assays.

### Mouse MI model

Ten-week-old male C57BL/6 mice were used in the MI model. The mice were randomly assigned to either the MI

group (surgery to induce MI by occlusion of the left coronary artery) or the sham group (same operation but without left coronary artery occlusion). The surgical procedures were performed after the righting reflex disappeared under anesthesia with 1%–2% isoflurane.

### Preparation of polyacrylamide hydrogels

Polyacrylamide (PA) hydrogels were prepared following the previous protocols (Minisah et al., 2016). Briefly, 25 mm × 25 mm glass microscope slides were treated with NaOH, 3-aminopropyltrimethoxysilane, and glutaraldehyde in a step-by-step manner. After the slides were extensively washed with distilled H<sub>2</sub>O, the slides were ready to support the polyacrylamide gels. Four prepolymer solutions with different acrylamide/bisacrylamide percentage (w/v) ratios were prepared to achieve elastic moduli of 7.5 kPa (10% acrylamide and 0.03% bisacrylamide), 13 kPa (10% acrylamide and 0.07% bisacrylamide), 19.5 kPa (10% acrylamide and 0.13% bisacrylamide), and 35 kPa (10% acrylamide and 0.26% bisacrylamide) and similar porosity. After polymerization, the gel surface was derivatized with the hetero-bifunctional cross-linker Sulfo-SANPAH (Thermo Fisher Scientific, USA) and UV irradiation. Rat-tail collagen (Sigma, USA) was diluted in PBS at 100 µg mL<sup>-1</sup>, spread onto each coverslip and incubated for 18 h at 4°C. The hydrogels on coverslips were rinsed with PBS and sterilized by UV before the cells were seeded. CFs were grown on different gels for one day and then subjected to assays.

### Western blotting

Cell lysates were subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis and blotted on nitrocellulose membranes. The membranes were then incubated with antibodies against fibronectin (ab2413, Abcam, USA), αSMA (ab32575, Abcam, USA), POU2F1 (ab178869, Abcam, USA), IL1R2 (sc-376247, Santa Cruz Biotech, USA), CD69 (ab202909, Abcam, USA), TGIF2 (ab190152, Abcam, USA), and GAPDH (2118S, CST). The bands were visualized with SuperSignal West Dura Extended Duration Substrate (Thermo Fisher Scientific, USA). Band intensity was quantitated using NIH ImageJ software (Wu et al., 2019).

### Chromatin immunoprecipitation (ChIP)

Formaldehyde (1%) was used to crosslink proteins and their bound DNA in live CFs. The lysates were then collected and sonicated to shear DNA into fragments of 500–600 bp in length. An antibody against POU2F1 (ab178869, Abcam, USA) and a rabbit IgG antibody were used for immunoprecipitation. The primers used to detect the binding of

POU2F1 to the POU2F1 binding sites in the promoters of mouse IL1R2, CD69, and TGIF2 are listed in Table S7 in Supporting Information.

### Quantitative real-time PCR (qRT-PCR)

Total RNA was extracted from fibroblasts by using TRIzol Reagent (Invitrogen, USA) according to the manufacturer's protocol. cDNA was synthesized in a 20 µL reverse transcription reaction system (M-MLV Reverse Transcription System, Promega Corporation, USA). qRT-PCR was performed on the Mastercycler ep Realplex2 Real-Time PCR System (Eppendorf, Germany) using SYBR Green Mix (TransGen Biotech, Beijing, China). The expression levels of the POU2F1, IL1R2, CD69, and TGIF2 genes were expressed as ratios to that of GAPDH, a housekeeping gene. The sequences of the gene-specific primers are as follows: POU2F1 forward: 5'-GTAAGCTCTGCCTCCTGGTG-3', POU2F1 reverse: 5'-GCTGTCGTTCTCCTGTAGCC-3'; IL1R2 forward: 5'-GAATACACAGCTCCAGGCTCC-3', IL1R2 reverse: 5'-CTGGAGATGTCGGAGTGAGG-3'; CD69 forward: 5'-TGTGTGGAATAGAGCGGAGA-3', CD69 reverse: 5'-AACTAGGTCAAGCCAGGCAA-3'; TGIF2 forward: 5'-TCAAAGATGGTGTCCCTCGC-3', TGIF2 reverse: 5'-ACATCCGGTCCATGGTGAAC-3'; and GAPDH forward: 5'-TCCTGGTATGACAATGAA-TACGGC-3', GAPDH reverse: 5'-TCTTGCTCAGTGTC-CTTGCTGG-3'.

### siRNA transfection of fibroblasts

Fibroblasts were transfected with POU2F1 siRNA (sc-36120, Santa Cruz Biotech, USA) or control siRNA (sc-37007, Santa Cruz Biotech, USA) at 80 nmol L<sup>-1</sup> with Hi-PerFect Transfection Reagent (301705, QIAGEN, USA). Experiments were performed 24 h (for mRNA) or 72 h (for protein) after the cells were transfected.

### Adenovirus expressing POU2F1

Adenovirus expressing POU2F1 (ad-POU2F1) and vector-containing adenovirus (ad-GFP) were purchased from Han-Bio Co., Ltd. (Shanghai, China). The adenoviral vector ad-GFP was used as a control (ad-Ctrl). CFs were infected with ad-POU2F1 or ad-Ctrl followed by the collection of cellular samples.

### Immunofluorescence and imaging

The cells were fixed with 4% paraformaldehyde for 15 min in PBS, permeabilized with 0.2% Triton X-100, blocked with 5% BSA and then stained with primary antibodies against αSMA (ab32575, Abcam, USA), fibronectin (ab2413, Ab-

cam, USA), and POU2F1 (ab178869, Abcam, USA), followed by Alexa Fluor 488 secondary antibodies. The cells were incubated with Hoechst (Invitrogen, USA) for 8 min at room temperature to stain the nuclei. Cells were then incubated with rhodamine phalloidin dye (R415, Invitrogen, USA) for 20 min at room temperature to stain F-actin. For high-content screening imaging, stained cells were visualized and analyzed by a Cellomics ArrayScan VTI HCS Reader (Thermo Fisher Scientific, USA) with the Morphology Explorer BioApplication. For confocal imaging, stained cells were visualized using a laser scanning confocal microscope (LSM780, ZEISS, Germany) with a 20× or 63×/1.4NA oil immersion objective lens and excitation wavelengths of 405 or 488 nm. The images were acquired and analyzed using ZEN 2012 software.

### Bioinformatics

Transcriptomic data were downloaded from NCBI's Gene Expression Omnibus (GEO). We used data from GSE113277 (Yu et al., 2018), RNA-seq data from comparing samples from CFs cultured on 2D 8 kPa (softer) and 64 kPa (stiffer) substrates. Differential expression analysis was performed with the R package edgeR (<https://www.rproject.org>) (Robinson et al., 2010). Cutoff values with a fold-change greater than 2 and a *P* value less than 0.05 were considered significant. Data were log-transformed before analysis. DAVID was used to conduct GO analysis (<https://david.ncifcrf.gov/>). Terms with a *P* value <0.05 were considered. STRING analysis (Szklarczyk et al., 2011) was used to predict protein relationships. The position weight matrix algorithm in TRANSFAC (Wingender et al., 1997) was used to predict potential transcription factors.

### Statistical analysis

All experiments were repeated at least 3 times. The results are expressed as the mean±SD. Statistical analyses were performed using SPSS statistical program or GraphPad Prism 5.0. For parametric data, Student's *t*-test or analysis of variance (ANOVA) combined with Tukey's post hoc test was used to analyze the differences among groups if the data were normally distributed. For data with unequal variances, Welch's *t*-test or ANOVA with Games-Howell post-hoc test was used. For non-parametric data, the Mann-Whitney U-test with the exact method was used to analyze the differences between two groups. The Kruskal-Wallis ANOVA combined with post hoc Dunn's multiple comparison test was performed when more than two groups were evaluated. Differences were considered statistically significant at *P* values <0.05.

**Compliance and ethics** The author(s) declare that they have no conflict

of interest.
