At heterointerfaces between complex oxides with polar discontinuity, the instability-induced electric field may drive electron redistribution, causing a dramatic change in the interfacial charge density. This results in the emergence of a rich diversity of exotic physical phenomena in these quasi-two-dimensional systems, which can be further tuned by an external field. To develop novel multifunctional electronic devices, it is essential to control the growth of polar oxide films and heterointerfaces with atomic precision. In this article, we review recent progress in control techniques for oxide film growth by molecular beam epitaxy (MBE). We emphasize the importance of tuning the microscopic surface structures of polar films for developing precise growth control techniques. Taking the polar  $\text{SrTiO}_3$  (110) and (111) surfaces as examples, we show that, by keeping the surface reconstructed throughout MBE growth, high-quality layer-by-layer homoepitaxy can be realized. Because the stability of different reconstructions is determined by the surface cation concentration, the growth rate from the Sr/Ti evaporation source can be monitored in real time. A precise, automated control method is established by which insulating homoepitaxial  $SrTiO<sub>3</sub>$  (110) and (111) films can be obtained on doped metallic substrates. The films show atomically well-defined surfaces and high dielectric performance, which allows the surface carrier concentration to be tuned in the range of  $\sim 10^{13}/\text{cm}^2$ . By applying the knowledge of microstructures from fundamental surface physics to film growth techniques, new opportunities are provided for material science and related research.

## <span id="page-0-0"></span>**1 Introduction**

Transition metal oxides (TMOs) have attracted extensive research interest owing to their rich phase diagram and unique properties. At TMO heterointerfaces, owing to the presence of broken symmetry, reduced dimensionality, and spatial confinement, even more exotic behaviors emerge that are related to, but distinct from, those in the bulk forms [\[1](#page-8-1)[–4](#page-8-2)]. This offers great opportunities for next-generation all-oxide electronics because the low-dimensional electron systems hosted by TMO heterointerfaces are highly sensitive to external fields [\[5](#page-8-3)[–8](#page-8-4)]. The essential basis of this field is precise control of the growth of TMO heterointerfaces. For example, it was reported that a two-dimensional electron gas (2DEG) appears at the interface between insulating  $LaAlO<sub>3</sub>$  and  $SrTiO<sub>3</sub>$  (STO) only when the STO substrate is terminated by a  $TiO<sub>2</sub>$  layer [\[2\]](#page-8-5). Further, both the electron density and electron mobility in the 2DEG are closely related to the quality of the heteroepitaxial films [[9](#page-9-0)[–11](#page-9-1)].

Great efforts have been made to obtain TMO films with precise stoichiometry [[12–](#page-9-2)[17\]](#page-9-3). Compared to the metal cations, the oxygen concentration is especially challenging to control due to its high vapor pressure and low adhesion efficiency, as well as the difficulty of *in situ* monitoring and post characterization. The oxygen concentration in TMO films is significantly influenced by the oxidant species  $(0, 0<sub>2</sub>, or 0<sub>3</sub>)$  and the corresponding partial pressure, the substrate temperature, and the annealing process. By carefully adjusting these growth parameters, the effect of oxygen vacancies (VOs) on the film properties has been investigated [\[18](#page-9-4)[–24](#page-9-5)]. However, macroscopic tuning of the average chemical concentration cannot lead to a clear understanding of the underlying physics because in some cases VOs form clusters [\[25](#page-9-6)] and even induce phase separation in the system [[26,](#page-9-7) [27](#page-9-8)]. It was also reported that lattice site occupation of cations affects the TMO properties [[28–](#page-9-9)[30\]](#page-9-10). In brief, it is ex-

 $d_2$ 

 $(a)$ 

 $(b)$ 

 $\overline{z}$ 

tremely important to control the growth of TMO films at the atomic scale.

As typical correlated electron systems, many TMOs possess polarized bands with multiple degrees of freedom. Accordingly, different orders can be formed in the material when the electron density is varied. By exploiting the charge modulation at TMO heterointerfaces, multifunctional oxide devices can be realized [\[31](#page-9-11)[–36](#page-10-0)]. One important issue is the investigation of polar TMO surfaces. As schematically shown in Fig. 1, the bulk truncated surface along the polar direction of an oxide is unstable. Dipoles are formed in adjacent layers with aligned orientation; thus, the electrostatic potential diverges with increasing thickness [Fig.  $1(a)$ ]. The macroscopic polarity can be canceled by modifying the charge density on both surfaces of the material as  $\sigma' = \sigma d_2/(d_1 + d_2)$  [Fig. 1(b)]. Several mechanisms can change the surface charge density and compensate for the polarity, such as the formation of surface reconstruction and the adsorption of charged particles. At the interface between two oxides with different charge density in each layer, i.e., with polar discontinuity, charge transfer occurs, and the charge redistribution may reduce or even cancel the surface polarity. Most importantly, the density of the transferred charge can be extremely high (on the order of  $10^{14}/\text{cm}^2$ , corresponding to *∼* 1 electron per unit cell). Compared to tuning of the electric field in gate structures, the field can be tuned in a broad range at the atomic scale using heterointerfaces with polar discontinuity.

However, it is quite challenging to precisely control the growth of TMO heterostructures with polar dis-

 $\overline{c}$ 

 $\sqrt{2}$ 

 $\overline{a}$ -0 continuity. In addition to the typical interfacial issues, e.g., chemical intermixing, elemental segregation, or defect trapping, polar instability often inhibits high-quality two-dimensional film growth. There have been reports that reconstructions can be formed on polar TMO surfaces during film growth by molecular beam epitaxy (MBE) [\[37](#page-10-1)[–41](#page-10-2)]. Therefore, the polarity can be effectively compensated for and layer-by-layer growth enabled.

This article reviews relevant studies on the growth control of polar TMO films and heterointerfaces. Different reconstructions on the polar STO (110) and (111) surfaces and their stability are determined by the relative concentrations of Sr and Ti cations on the surface. Therefore, by keeping the film surface reconstructed during growth, the chemical stoichiometry can be monitored *in situ* and in real time by reflective high-energy electron diffraction (RHEED), which reveals not only the surface morphology but also the microstructure. Precise control techniques for MBE growth can be developed accordingly. The recent development of pulsed laser deposition (PLD) growth, which enables control of the growth kinetics of TMO heterointerfaces, is also introduced briefly.

## <span id="page-2-0"></span>**2 Control techniques of chemical stoichiometry in oxide MBE**

MBE has been employed to grow complex oxide films for 30 years, with the expectation of the same great success as that obtained for conventional semiconductors [[42,](#page-10-3) [43](#page-10-4)]. However, unlike the self-regulated growth of GaAs, in which only one low-vapor-pressure element is involved and thus stoichiometry can be realized [[44,](#page-10-5) [45](#page-10-6)], MBE growth of complex oxide films involves multiple metals with low vapor pressure, and precise control of each evaporation source is required. The quartz crystal microbalance (QCM) and atomic absorption spectroscopy (AAS) have been widely used for *in situ* calibration of the flux rates of metal evaporation beams. AAS usually supports composition control with better than 1% precision. However, it is not a real-time technique and cannot deal with random fluctuations during growth. Moreover, for some elements such as Ti, the absorption signal is too weak to detect, and the precision is far from satisfactory [\[12](#page-9-2), [45](#page-10-6)]. Regarding the QCM, a large discrepancy might be introduced by the different adhesion coefficients of the quartz crystal and substrate owing to their different temperatures, chemical environments, and geometries with respect to the evaporation source.

In oxide MBE growth, the flux rate of a metal evaporation source varies in an uncontrolled way owing to its oxidation during growth (in oxygen ambient at high temperature). A specially designed geometry of the evapora-

tion source and pumping scheme may reduce the change in the source rate [\[15](#page-9-12), [46,](#page-10-7) [47\]](#page-10-8). A hybrid MBE technique, in which the metal sources are replaced by volatile metalorganic precursors, e.g., titanium tetra-isopropoxide or vanadium oxytriisopropoxide for Ti or V, respectively [\[48](#page-10-9), [49\]](#page-10-10), has also been introduced to avoid the oxidation problem. Nevertheless, the impurities introduced by the metal-organic precursor have not been investigated carefully yet, nor have the special growth dynamics and kinetics of hybrid MBE, which may cause phase limitation.

An *in situ*, real-time monitoring technique is imperative for control of the chemical stoichiometry in MBE growth. Indeed, RHEED has been demonstrated as an ideal tool, as its intensity responds sensitively to the morphology of the growing surface and reveals the growth mode and rate. Moreover, RHEED provides information on the surface microscopic structure and chemical concentration [\[12](#page-9-2), [50–](#page-10-11)[52\]](#page-10-12), because the scattering matrix is determined by the mass and spatial arrangement of the scattering centers. By analyzing the fine structure of the RHEED intensity evolution during MBE growth of a STO (001) film, the cation stoichiometry can be optimized with a precision of 1% [[12\]](#page-9-2). Recently, a particularly important control technique was developed on the basis of RHEED monitoring of the evolution of surface reconstructions with the cation concentration [\[37](#page-10-1)[–39](#page-10-13), [53](#page-10-14)– [55](#page-10-15)]. Cation stoichiometry with a precision of *±*0*.*3% was achieved in an STO (001) film grown on Si [\[37](#page-10-1)], and a precision of *±*0*.*1% was demonstrated in a homoepitaxial STO (111) film [\[54](#page-10-16)]. With the advanced use of RHEED, control of oxide film growth can benefit dramatically from detailed knowledge of surface reconstructions.

## <span id="page-2-1"></span>**3 Reconstructions of polar SrTiO<sup>3</sup> surfaces and their stability**

Polar oxide surfaces exhibit high reconstruction instability [[56\]](#page-10-17). Figure 2 shows two typical polar oxide surfaces, STO (110) and (111). Along the [110] direction, STO consists of stacks of alternating  $(SrTiO)^{4+}/(O<sub>2</sub>)^{4-}$ atomic layers, whereas along the [111] direction, it consists of stacks of  $(SrO<sub>3</sub>)<sup>4</sup>$  –  $/(Ti)<sup>4+</sup>$  atomic layers. Both surfaces are unstable owing to the aligned dipoles along the perpendicular direction. In the following, different reconstruction phases of polar STO surfaces and their evolution with the surface cation concentration will be introduced.

#### <span id="page-2-2"></span>3.1 Reconstructions on  $\text{SrTiO}_3$  (110)

A wide variety of reconstructions have been observed on the STO (110) surface, such as  $(n \times 1)$   $(n = 3, 4, 6)$ ,

**Fig.** 2 Schematic drawings of the structures of bulk-truncated (a) SrTiO<sub>3</sub> (110) with  $(SrTiO)^{4+}$  and  $(O_2)^{4-}$  terminations, and (b) SrTiO<sub>3</sub> (111) with  $(SrO<sub>3</sub>)<sup>4−</sup>$  and  $(Ti)<sup>4+</sup>$  terminations. The surface unit cells are labeled, respectively.

 $(2 \times 5)$ ,  $(3 \times 4)$ ,  $(4 \times 4)$ ,  $(4 \times 7)$ ,  $(6 \times 4)$ ,  $(5 \times 2)$ , and  $c(2 \times 6)$ , depending on the preparation conditions [\[57–](#page-10-18) [61](#page-11-0). Taking the  $(4\times1)$  reconstruction as an example (top panel of Fig. 3), a scanning tunneling microscopy (STM) image shows periodic stripes along the  $[1\bar{1}0]$  direction separated by dark trenches. This reconstructed structure corresponds to  $(SrTiO)^{4+}$  termination [\[62](#page-11-1)]. Further study by STM combined with density functional theory (DFT) calculations, as discussed in detail below, resolves the atomistic structure, in which an adlayer of  $TiO<sub>4</sub> tetrahedra atop the (SrTiO)<sup>4+</sup> plane shares the$ corner oxygen that forms the  $(4 \times 1)$  reconstruction on the STO (110) surface [[57,](#page-10-18) [63\]](#page-11-2). The nominal chemical formula is  $Ti_{1.5}O_4$  per  $(1 \times 1)$  area on the topmost layer, which exhibits an extra charge of 2*<sup>−</sup>* that satisfies the polar compensation criterion without varying the chemical valence of Ti.

Reconstructions of  $(5\times1)$ ,  $(4\times1)$ ,  $(2\times8)$ , or  $(6\times8)$  can be obtained on STO  $(110)$  by  $Ar^{+}$  sputtering followed by annealing in vacuum [[62,](#page-11-1) [64\]](#page-11-3). As the sputtering dose is increased, the surface reconstruction is transformed gradually from SrTiO-terminated  $(5 \times 1)$  to  $(4 \times 1)$ , then to O-terminated  $(2 \times 8)$ , and to  $(6 \times 8)$ , as shown in Fig. 3. Characterization of the nominal composition near the surface region by X-ray photoemission spectroscopy indicates a corresponding increase in the Ti/Sr concentration ratio. Note that these reconstructions are not oxygen-deficient; the oxygen concentration is higher than that on the cleaved STO (001) surface [\[64](#page-11-3)].

Alternatively, the reconstruction phases on STO (110) can be changed by Sr or Ti deposition followed by annealing [[64\]](#page-11-3). The relative area ratio of adjacent phases can be continuously tuned by adjusting the deposition dosage, and monophased reconstructions can be obtained (see Fig. 3). For example, given the monophased  $(5 \times 1)$  reconstruction as the starting surface, depositing a small amount of Ti (followed by annealing) induces the formation of  $(4 \times 1)$  patches. With increasing Ti deposition

dosage, the area of (4*×*1) is enlarged until a monophased (4*×*1) surface is obtained when 0.15 monolayer (ML) Ti is deposited on the  $(5 \times 1)$  surface. The sharp fractional RHEED patterns shown in the bottom panel of Fig. 3 clearly indicate the phase transformation. As the Ti deposition dosage increases further,  $(2 \times 8)$  and  $(6 \times 8)$ reconstructions are developed sequentially. Further, this phase evolution can be reversed by depositing Sr with a dosage equivalent to that of Ti between adjacent phases in the opposite direction. The phase diagram of the STO (110) surface is shown in Fig. 3. All of the reconstruction phases are Ti-enriched. Owing to the hightemperature annealing (800*◦*C), thermodynamic equilibrium is reached on the surface at any Sr/Ti concentration. Therefore, it is concluded that the stability of each

**Fig. 3** The reversible transformation of different reconstruction phases on STO (110). Top panel (from left to right): STM images (30 nm *×* 30 nm, 20 pA/1.5 V) of (5*×*1), (4*×*1), (2*×*8), and (6*×*8). Middle panel: The phases diagram of STO (110) depending on the sputtering dose or the surface cation concentration. Bottom panel (from left to right): RHEED patterns along  $[1\bar{1}0]$  (upper) and  $[001]$  (lower) directions  $[63]$  $[63]$ .

reconstruction phase is determined by the cation concentration. Importantly, as observed by RHEED, a reconstruction with long-range periodicity can be formed even at a high annealing temperature [\[38](#page-10-19)].

#### <span id="page-4-0"></span>3.2 Reconstructions on  $SrTiO<sub>3</sub>$  (111)

On another typical polar surface of STO, STO (111), a series of reconstructions have been observed, such as  $(n \times n)$   $(n = 3-6)$ ,  $(\sqrt{7} \times \sqrt{7})$ –R19.1<sup>°</sup>, and  $(\sqrt{13} \times \sqrt{13})$ – R13.9<sup>°</sup>, depending on the treatment conditions [[65](#page-11-4)[–70](#page-11-5)]. Similar to those on the STO (110) surface, the reconstructions on STO (111) can also be reversibly modulated by Sr or Ti deposition followed by annealing [\[71](#page-11-6)]. Note that STO (111) is annealed under oxygen ambient with  $P_{O2} = 5.5 \times 10^{-6}$  mbar, whereas STO (110) is annealed under ultrahigh vacuum (UHV). The reconstructed STO (111) surface can evolve from  $(4 \times 4)$  to  $(6 \times 6)$  and then to  $(5 \times 5)$  reconstruction by increasing the Ti deposition dosage on the surface. Further, this evolution can be reversed by increasing the Sr deposition dosage. STM height analysis and the optimal evaporation dosage suggest that the  $(4 \times 4)$  reconstructed structure corresponds to  $SrO<sub>3</sub>$  termination, whereas (6  $\times$  6) and  $(5 \times 5)$  correspond to Ti termination.

As shown in the top panel of Fig. 4, the  $(4 \times 4)$  reconstruction features bright three-blade shapes with chirality arranged in the  $(4 \times 4)$  hexagonal lattice. The unit cell of the  $(6 \times 6)$  reconstruction is composed of a bright triangle and a bright dot. Similarly, the  $(5 \times 5)$ reconstruction also consists of two triangular parts; one exhibits a bright dot in the center, and the other shows a dark center.

Although Russell and Castell have classified the (4*×*4),  $(6 \times 6)$ , and  $(5 \times 5)$  reconstructions into a single family of  $(n \times n)$  reconstructions [\[70](#page-11-5)], the three reconstructions may have different polar compensation mechanisms, and their absorption behaviors are quite different. A clean  $(4 \times 4)$  reconstruction is difficult to obtain; i.e., it is always covered by triangular adsorbates (a minimum of *∼* 28% in area). These disordered adsorbates might contribute to polar compensation along with reconstruction. In contrast, the monophased  $(6 \times 6)$  reconstruction can be obtained, indicating that the  $(6 \times 6)$  reconstruction itself is polar-compensated. For the  $(5 \times 5)$  reconstruction, Russell and Castell obtained a flat surface; however, Feng *et al*. found that it tends to form three-dimensional islands, because it may be unstable in oxygen ambient, and thus the surface tends to be rough [[71\]](#page-11-6).

Notably, just as in the case of STO (110), both the evolution of the reconstructions on STO (111) and their stability depend on the Sr/Ti ratio, and these reconstructions can form at high temperature. The RHEED patterns shown in the bottom panel of Fig. 4 distinctly reveal the reconstruction evolution among  $(4\times4)$ ,  $(6\times6)$ ,

**Fig. 4** The reversible transformation between different reconstructions on STO (111) surface. Top panel (from left to right): STM images (40 pA/2.3 V) of the reconstructions of (4*×*4) (12 nm *×* 12 nm), (6*×*6) (10 nm *×* 10 nm), and (5*×*5)  $(15 \text{ nm} \times 15 \text{ nm})$ , respectively. Middle panel: The surface evolution of STO (111) depending on the deposition dosage of Sr or Ti. The shaded area in the (4*×*4) region indicates the existence of the triangular adsorbates, while the shaded area in the  $(5 \times 5)$  region indicates the existence of multilayered islands. Bottom panel (from left to right): RHEED patterns along  $[1\overline{1}0]$  (upper) and  $[211]$  (lower) directions.

<span id="page-4-1"></span>and  $(5 \times 5)$  induced by Ti or Sr deposition.

#### 3.3 Atomistic structures resolved by a combination of experiments and calculations

The atomistic structures of reconstructions on polar STO (110) surfaces can be resolved by a combination of STM and *ab initio* calculations using DFT. As proposed by Enterkin *et al.* [\[57](#page-10-18)], the  $(3 \times 1)$  reconstruction consists of rings of six or eight corner-sharing  $TiO<sub>4</sub>$  tetrahedra. The structure can be extended to a homologous series of  $(n \times 1)$  atomistic reconstruction structures  $(2 \leq n \leq 6)$ and  $n = \infty$ ). The size of the large ring consisting of TiO<sub>4</sub> tetrahedra is enlarged by inserting an extra tetrahedron as *n* increases. Further, all the (*n×*1) reconstructions are charge-compensated with nominal surface compositions of  $[\text{Ti}_{(n+2)/n}\text{O}_{(3n+4)/n}]^{2-}$  per  $(1\times1)$  unit cell. Compared with the experimental results, the  $(4 \times 1)$  reconstruction agrees well with such atomistic structural model, as shown in the left panel of Fig. 5. However, the simulated STM images of the (5*×*1) reconstruction based on this model are not fully consistent with the experimental features. To fit the experimental results, as shown in Fig.  $5(b)$ , TiO<sub>4</sub> tetrahedron 1 should be shifted from the linear chain along [001] to the middle of the zigzag chain along  $[1\overline{1}0]$  [[63\]](#page-11-2). The simulated STM image of the

![](_page_5_Figure_1.jpeg)

**Fig. 5 (a)** Structural model of the  $(n \times 1)$  reconstruction with  $(4 \times 1)$  on the left and  $(5 \times 1)$  on the right. **(b)** The modified structural model of  $(5 \times 1)$ . The upper panels are the top view while the lower panels are the side view. **(c, d)** and **(e, f)** The simulated and experimental STM images of  $(4 \times 1)$  and  $(5 \times 1)$ , respectively [[63](#page-11-2)].

structure after relaxation reproduces the experimental characteristics excellently [Figs. 5(e) and (f)].

Studying the atomistic structure is helpful for quantitative analysis of the RHEED patterns and their intensity at the level of the scattering matrix [[39\]](#page-10-13). Furthermore, learning the energy configuration of different reconstructions is also essential to establishing the growth control method. In oxides, specifically, the oxygen chemical potential is related to, or even determined by, the energy configuration of cations in thermodynamic equilibrium. If the metal stoichiometry is well controlled during growth, one can obtain high-quality films even when VOs are eliminated at a low growth rate and high temperature [[72–](#page-11-7)[76\]](#page-11-8).

Calculations of the formation energy of VOs on different layers of STO (110) show that, owing to the energy configuration associated with surface reconstruction, all of the VOs are confined within a few subsurface layers. On the other hand, thermodynamics and kinetics studies of the atomistic surface processes during film growth indicate that the cation diffusion barrier to form reconstructions on the surface is much higher than that of oxygen diffusion toward the surface. Therefore, STO (110) polar films with high quality and low VO density can be grown by MBE even in UHV [\[77](#page-11-9)]. Moreover, a quasitwo-dimensional VO-doped region forms, similar to the case of *δ*-doping in conventional semiconductors. The charge density of such a  $\delta$ -doping layer can be precisely controlled because the total VO population can be tuned using the oxygen chemical potential during preparation.

Similarly, reconstructions on the STO (111) surface such as the  $(n \times n)$   $(2 \leq n \leq 4)$  reconstructions are also considered as a network of  $TiO<sub>4</sub>$  tetrahedra on the  $(110)$  surface residing on octahedral TiO<sub>5</sub> with a vacant oxygen site and  $TiO_6$  octahedra in the second layer [[78\]](#page-11-10). The anatase  $TiO<sub>2</sub>$  (101) surface exhibits a similar characteristic [\[79](#page-11-11)]. These results open a new way to resolving the difficulty in controlling or minimizing the VO density to obtain an oxide surface or other low-dimensional structure with ideal stoichiometry.

## <span id="page-5-0"></span>**4 Precise control of film growth by monitoring the evolution of surface reconstructions**

Because the stability of reconstructions on polar STO surfaces is determined by the cation concentration, and the reconstructions can be detected *in situ* and in real time at high temperatures, monitoring their evolution may provide a signal for precise control of MBE growth of high-quality films. The presupposition is that the thermodynamics should play an important role. Of course, it is also a critical issue whether the cation nonstoichiometry exists only on the surface. For  $BaTiO<sub>3</sub>$  films grown on a  $SrRuO<sub>3</sub>$  substrate, the reconstruction of  $SrRuO<sub>3</sub>$ was considered to be buried under the  $BaTiO<sub>3</sub> film [80]$  $BaTiO<sub>3</sub> film [80]$ . However, for other oxides such as STO, a transmission electron microscopy (TEM) study and DFT calculations verified that the reconstruction can exist only on the surface [\[61](#page-11-0)].

Homoepitaxial STO (110) films have been grown by coevaporating Sr and Ti in oxygen under precise control [\[38](#page-10-19)]. Although the flux rates of the source metals were calibrated by a QCM before MBE growth, the RHEED intensity oscillation faded out after the growth of a few layers, indicating failure of high-quality twodimensional growth. On the other hand, it is observed that the RHEED patterns evolve from "1*×*" to weak " $8\times$ " [Figs. 6(a)–(c)]. These results demonstrate that the evaporation rates of the Sr and Ti sources are not exactly the same, and the discrepancy accumulates on the top few layers of the growing film. This accumulation, which is reflected by the RHEED patterns, provides high sensitivity that enables precise control of the polar film growth *in situ* and in real time. In this case, one can adjust the flux rate by varying either the source temperature or evaporation time until the RHEED pattern remains unchanged during extended growth. Thus, stable layer-by-layer growth is realized, as demonstrated by the significantly improved RHEED oscillations [Figs. 6(d)– (f)]. The high quality of the film is revealed by STM and high-resolution cross-sectional TEM images [Figs.  $6(g)$ , (h)]. As shown in Fig. 6(h), the interface between the

![](_page_6_Figure_1.jpeg)

The inset shows the high resolution image. **(h)** Cross-sectional TEM image of the homoepitaxial STO (110) film. The interface is indistinguishable and it is determined by counting atomic layers from the film surface [[38](#page-10-19)].

substrate and the homoepitaxial film cannot be identified, suggesting that the film lattice is perfect. The precision of the cation stoichiometry is better than 0.5%, as determined by energy dispersion spectroscopy [\[38](#page-10-19)]. Note that the accumulation effect is important for improving the precision of stoichiometry control. Owing to the limited RHEED sensitivity, it takes a long time to accumulate a detectable discrepancy in the cation concentrations; i.e., as the calibration duration increases, the precision of the stoichiometry could increase.

An automatic control technique with atomic precision has been further developed for MBE growth of STO (110) films [[39\]](#page-10-13). Instead of the fractional RHEED patterns, of which the intensity variation becomes detectable as stoichiometric drift accumulates, the integral patterns are monitored and taken as the control signal. By using a kinematic model in the single-scattering limit [\[51](#page-10-20), [81](#page-11-13)] and taking the atomistic structural model of STO  $(110)-(n \times 1)$  from DFT calculations and the atomic scattering factor [\[81](#page-11-13)], the dependence of the

integral RHEED patterns of the surface reconstruction or roughness on the incident angle of the electron beam  $(\theta_i)$  is analyzed. When  $\theta_i \approx 1.8^\circ$ , the RHEED intensity is much more sensitive to the surface reconstruction (i.e., the surface cation concentration) than the roughness (at the scale of unit cells). Technically, the incident angle of the electron beam can be adjusted within the grazing range, so the variation of the surface chemical concentration is sensitively represented by the intensity change of the integral RHEED patterns, which is monitored as the automatic feedback control signal to switch the status of the source shutter in real time. When the RHEED intensity drops (indicating that the growing surface becomes Sr-rich) by a certain amount, the shutter of the Sr source is closed automatically, whereas when the RHEED intensity increases, it is opened. Homoepitaxy can be achieved by keeping the reconstruction evolution within the reversible range. This precise method eliminates the uncontrollable fluctuation of the source flux and can be used to grow films with a desired thickness.

To maintain the reconstructions on polar surfaces, the oxide MBE method generally requires a high growth temperature. Consequently, in most cases, the oxygen pressure during growth also needs to be high to prevent decomposition of oxide materials and to obtain the expected phase [[82,](#page-11-14) [83\]](#page-11-15). Although this might raise the risk of inducing cation interdiffusion across the interface [\[84](#page-11-16)[–86\]](#page-11-17), there have been examples of its successful application to heteroepitaxy. Li *et al*. obtained high-quality heteroepitaxial  $LaTiO<sub>3</sub>$  (110) films by keeping the growing surface reconstructed in  $(2 \times 16)$  [[87\]](#page-11-18). The intensity of the RHEED patterns, either the integral or fractional patterns, exhibits behavior quite similar to that in homoepitaxial growth. The only difference from homoepitaxy is that 2 ML La and Ti should be deposited first onto the STO (110) substrate surface to form the  $(2\times16)$ reconstruction as the initial surface.

Polar oxide surfaces along the [111] direction offer even more flexible tunability of the physical properties [\[88](#page-12-0), [89](#page-12-1)]. The double-perovskite structure  $A_2BB'O_6$  can be artificially constructed as the [111]-oriented superlattice AO3/B/AO3/B*′* . Further, the six-fold symmetry might lead to the formation of novel quantum states such as half-metallic ferromagnetism or the quantum anomalous Hall effect [\[90](#page-12-2)[–96](#page-12-3)]. Dielectric STO (111) films have been homoepitaxially grown on metallic Nb-doped STO substrates by a similar feedback control method, as described above [\[54](#page-10-16)]. The films, which have atomically well-defined surfaces, show high dielectric performance, and the charge density is tunable in the range of  $2 \times 10^{13}/\text{cm}^2$  with a back gate voltage lower than 0.2 V. Figure 7(a) shows a schematic of the setup for dielectric property measurement. The leakage current density of films at different electric fields is shown in

![](_page_7_Figure_1.jpeg)

**Fig. 7 (a)** The schematic drawing of the Au/Cr/STO/Nb-STO capacitor structure. **(b)** The leakage current density at different electric field, **(c)** the capacitance at different bias, and **(d)** the charge density modulation range with different gate voltage measured at 6 K, respectively [[54\]](#page-10-16).

Fig. 7(b). It remains extremely low  $(< 1 \mu A/cm^2)$  until the electric field reaches the breakdown value. The capacitance measured at various gate voltages is displayed in Fig. 7(c), where the charge modulation  $\Delta n$  can be determined. Figure 7(d) shows the dependence of ∆*n* upon the gate voltage, which must be below the breakdown field, suggesting that  $\Delta n$  can be effectively enhanced by reducing the VO concentration. The STO (111) film with an atomically well-defined surface and remarkable dielectric properties provides an ideal platform for epitaxy of novel quantum materials as well as control of the electronic properties of their device structures.

## <span id="page-7-0"></span>**5 Control of the growth kinetics in pulsed laser deposition**

By the method described above, complex polar oxide films can be epitaxially grown by MBE under precise control. However, as mentioned above, this requires a very high substrate temperature for the formation of surface reconstructions, which inevitably enables chemical intermixing and might degrade the sharpness of the heterointerface. It is essential that the growth kinetics play a more important role than the thermodynamics during the growth of these artificial low-dimensional systems. Increasing the growth rate is apparently an effective method. Unlike the case of growth by MBE, where the growth rate is limited by the use of metal sources with low vapor pressure, the growth rate is much more flexible in growth by PLD.

Recently, PLD in UHV chambers has been combined with RHEED, making it a powerful technique for precisely controlled growth of TMO films [\[1](#page-8-1), [2,](#page-8-5) [97](#page-12-4)]. Although it is commonly believed that PLD provides nearly stoichiometric composition transfer from the target to the film [[98\]](#page-12-5), the growth of polar films is still a challenge. A simple method to consider is to circumvent the polar catastrophe, i.e., to grow polar films with continuous polarity at the interfaces. For example, selecting a suitable substrate or growing a buffer layer with the same polarity as the polar films can efficiently prevent the electronically active multivalent ions from changing the valence [\[99](#page-12-6)]. Because electronic reconstruction facilitates polar compensation without necessitating intermixing, introducing a metallic screening layer would also be effective. Using a conducting buffer layer on the polar substrate surface, Blok *et al*. succeeded in epitaxially growing  $BiFeO<sub>3</sub>$  and  $CaTiO<sub>3</sub>$  films on  $SrTiO<sub>3</sub>$  and  $LaAlO<sub>3</sub>$ , respectively [\[100](#page-12-7)]. Similarly, Mukunoki *et al*. deposited a very thin, oxygen-deficient homoepitaxial STO (110) layer before heteroepitaxy so that the VOs in the initial buffer layer could compensate for the charges transferred between the film and substrate [\[101](#page-12-8)].

A general control method for PLD growth of polar TMO films and heterointerfaces was developed by Koster *et al.* [\[102](#page-12-9)]. They used a rather high laser frequency (as high as 100 Hz) to deposit one ML's worth of material in a very short time and then used a much longer interval to rearrange the film lattice. Using this socalled interrupted growth method, they obtained STO homoepitaxial films and  $[\text{BaCuO}_2/\text{SrCuO}_2]_n$  superlattices. Chakhalian's group succeeded in achieving layerby-layer growth of nickelates. As the pulse frequency increases to 30 Hz, it exhibits a quasi-constant state with an average high flux. During the short deposition intervals, only small islands are formed owing to the high supersaturation. As the average radius of the islands decreases, nucleation of the islands becomes less probable. Supersaturation is far from the equilibrium state, and the nucleation barrier is overcome only during the long intervals of rearrangement, resulting in rapid nucleation from the supercritical vapor [[103\]](#page-12-10). Consequently, the substrate temperature in interrupted growth can be low, which prevents interdiffusion across the heterointerface. This interval growth technique is unique to PLD; no other technique can combine very high deposition rates with intervals of no deposition in a fast periodic sequence [\[102](#page-12-9)].

Last but not least, it has been determined that the growth parameters of PLD, e.g., the laser energy density, growth temperature, and oxygen pressure, do affect the film stoichiometry. For example, one cannot obtain stoichiometric films if the laser energy density is below a threshold fluence value [[104](#page-12-11)]. In this regard, keeping the surface reconstruction, which can be monitored by RHEED, unchanged throughout the growth process might also be critical for precise control of the stoichiometry and high-quality layer-by-layer growth of polar oxide films by PLD. Indeed, high-quality heteroepitaxy has been achieved on the reconstructed surface [\[105](#page-12-12)].

## <span id="page-8-0"></span>**6 Conclusions**

Research on emergent phenomena at heterointerfaces between complex oxides with polar discontinuity is a rapidly advancing field. Exploiting and understanding the underlying physics are necessary for precise growth control of polar films. We review recent progress in control techniques for polar oxide film growth by MBE. Although MBE is a typical kinetic growth process, it somehow allows the thermodynamics to play an important role. We highlight the importance of knowing the microscopic surface structures on polar films for establishing reliable precise growth control techniques. Taking the STO (110) and (111) surfaces as examples, we show that the surface polarity can be compensated for by the formation of reconstructions. Therefore, high-quality twodimensional growth of polar films is realized by keeping the surface reconstructed throughout the growth process. Further, the fact that the stability of different reconstructions is determined by the surface cation concentration enables real-time monitoring of the growth rate of each metal source. A precise, *in situ*, and automated control method has been developed, and high-quality homoepitaxial layers of STO (110) and STO (111) have been obtained on doped metallic substrates. By applying the knowledge of microstructures from fundamental surface physics to film growth techniques, new opportunities for designing complex superlattices and heterointerfaces with rich controllable functionalities become available.
