Abstract: Over the last decades and centuries, European mountain landscapes have experienced substantial transformations. Natural and anthropogenic LULC changes (land use and land cover changes), especially agro-pastoral activities, have directly influenced the spatial organization and composition of European mountain landscapes. For the past sixty years, natural reforestation has been occurring due to a decline in both agricultural production activities and rural population. Stakeholders, to better anticipate future changes, need spatially and temporally explicit models to identify areas at risk of land change and possible abandonment. This paper presents an integrated approach combining forecasting scenarios and a LULC changes simulation model to assess where LULC changes may occur in the Pyrenees Mountains, based on historical LULC trends and a range of future socio-economic drivers. The proposed methodology

considers local specificities of the Pyrenean valleys, sub-regional climate and topographical properties, and regional economic policies. Results indicate that some regions are projected to face strong abandonment, regardless of the scenario conditions. Overall, high rates of change are associated with administrative regions where land productivity is highly dependent on socio-economic drivers and climatic and environmental conditions limit intensive (agricultural and/or pastoral) production and profitability. The combination of the results for the four scenarios allows assessments of where encroachment (e.g. colonization by shrublands) and reforestation are the most probable. This assessment intends to provide insight into the potential future development of the Pyrenees to help identify areas that are the most sensitive to change and to guide decision makers to help their management decisions.

Reforestation; LULC Model

Introduction

Land use and land cover (LULC) change processes are an important part of global environmental changes affecting biodiversity, climate and environmental services (UNEP 2002; Lambin et al. 2006). In Europe, land use is dominated by agriculture and forestry which covers 45% and 36% of the EU-25 states, respectively (FAO 2003), with 34% of terrestrial area used for crop production and 14% for grassland (Verburg et al. 2006a). For centuries, agriculture has shaped a variety of landscapes across Europe as the result of various management strategies and policies, local human decision-making and physical factors.

In the last century, LULC of European mountains has experienced substantial transformations. Supporting competitive agriculture, the Common Agricultural Policy (CAP) has favored intensification and specialization of agriculture production neglecting less favored areas such as mountain lands (ACAP 2011). Moreover, constant modifications of regulations and management policies (e.g. CAP reforms, regulation measures for consumer and environment protection, quotas for food production, incentives for specific land management) have caused rapid changes in agricultural practices influencing land management. Concurrently, the decreasing number of agricultural employees and aging of farmers have led to agropastoral land abandonment and fewer farm holdings (Mottet et al. 2006). The socio-ecological and cultural richness of mountainous regions relies on an anthropogenic heritage, where landscapes were built and maintained by farmers and foresters. Thus, agropastoral and logging activities have historically played a key role in shaping and maintaining mountain landscapes (Mitchley 2006). The critical situation affecting agricultural sectors, combined with the recent introduction of competing activities (e.g. tourism, recreation activities), have raised major concerns for politicians, planners and local stakeholders (Busch 2006) dealing with mountain land use.

Over the next decades, many European regions will face major demographic, economic and technological modifications (Renwick et al. 2013). Many studies have proposed that rapid changes are to be expected, and predicted a massive decrease in agricultural areas (Rounsevell et al. 2005; van Meijl et al. 2006) and increase in encroachment (i.e. colonization by shrublands) and spontaneous reforestation on formerly open-lands (Garbarino et al. 2014). Such dynamics have been predominant in the French Pyrenees Mountain over the past 60 years and are expected to intensify at the expense of agro-pastoral lands in the upcoming decades (Métailié and Paegelow 2004; Galop et al. 2013).

However, LULC changes (Land Use and land Cover Change) processes in the Pyrenees are complex, occurring at various temporal and spatial scales, with interlinked environmental, societal and economic impacts (Houet et al. 2012; Grandjean et al. 2013). The extents of these changes are difficult to predict as are their impact on the environment, landscapes and rural societies. The uncertainties in future landscape evolution lie in the fact that they result from driving factors occurring at various spatial scales, affecting current and future landscape organization at different levels of intensity (Turner II et al. 1995).

Scenarios, representing a variety of potential future outcomes, have become popular tools in a number of research projects to inform spatially and temporally explicit models assessing LULC changes. Starting from a known initial situation and exploring the future to illustrate feasible trends of evolution, scenarios can help to understand the complexity of driving factors and distinguish their respective and combined effects on landscape evolution (Verburg et al. 2006b; Houet et al. 2010).

Scenario exercises exist at the global level and focus on the impact of anthropogenic activities on natural resources (IPCC 2000; UNEP 2002; MEA 2005). Using global drivers of change (e.g. demographic changes, economic growth and technological development) they describe alternative futures of the world for impact, adaptation and vulnerability assessments (Alcamo et al. 2006). However, because they are conducted at coarse spatial and temporal scales, they fail to provide insights into the consequences of changes at the landscape level. Concurrently, several

European projects focus on rural development and agricultural policies by downscaling quantitative indicators of change from a global extent to a spatial and temporal scale that is relevant for regional assessment studies (Klijn et al. 2005; Rounsevell et al. 2005; Verburg et al. 2006a). While investigating the impacts of economic trends and global climate/land-use changes on the potential vulnerability of Europe's ecosystems, such case studies remain limited for finer scale assessment (e.g. small regions or landscape) since most processes affecting global and regional changes are the consequences of local dynamics and policies (Veldkamp and Lambin 2001; Houghton 2003). Since these drivers are hard to comprehend and to model at larger scales, many local assessments have been developed over the years among various research themes (Gibon et al. 2010; Bourgoïn and Castella 2011; Marohn et al. 2013). These local assessments, primarily involving participatory approaches with local stakeholders, are usually centered on driving factors and policies representative of the studied area but do not depict processes and their impact at the regional level. Finally, even if a large number of studies have addressed the issue of LULC changes in Europe combining scenarios and LULC changes models, few have focused specifically on European mountains at a regional scale (Schneeberger et al. 2007; Zimmermann et al. 2010; Price et al. 2015).

The objective of this paper is to characterize

areas potentially affected by land abandonment in the future for the Pyrenees Mountains. We use a LULC change model accounting for landscape patterns to allocate the expected LUCC change for four contrasting scenarios. They are developed in order to account for past trends using LUCC analyses and regional specificities that have been already considered in existing sectorial narratives. Moreover, because conventional LUCC data (Corine Land Cover) underestimates observed changes occurring at finer scale (Verburg et al. 2006a), all these data are empirically used to refine future sub-regional LUCC changes. We hypothesize that using multiple scenarios will help to refine the identification of areas at stake for local and regional decision makers.

1 Materials and Methods

1.1 Study area

The French Pyrenees covers 18,000 km² and includes three regions (i.e. regional administrative organizational level): the Aquitaine, the Midi-Pyrenees and the Languedoc Roussillon (Figure 1). The climate varies regionally and ranges from oceanic humid (Aquitaine), continental humid (Midi-Pyrenees), Mediterranean dry (Languedoc-Roussillon), and mountainous (greater than 2000 m a.s.l.) climate. Because of its geographic position, orientation and geological structure, the Pyrenees

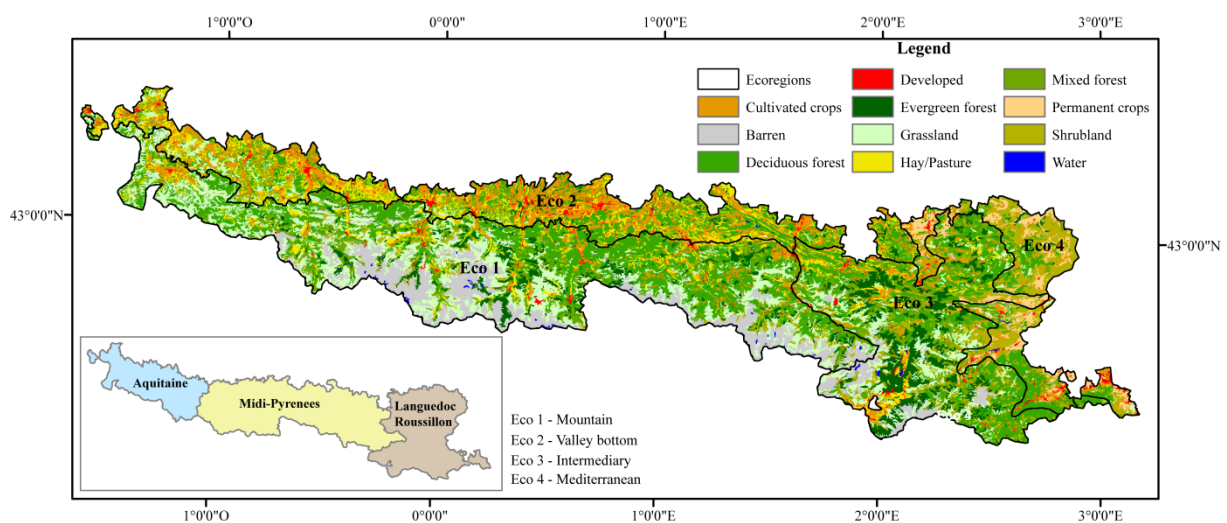

Figure 1 Land use and land cover map from 2006 (Corine Land Cover 2006) with ecoregions of the French Pyrenees. The study area is represented by three administrative regions (Aquitaine, Midi-Pyrenees and Languedoc-Roussillon).

Table 1 Ecoregions main characteristics

Ecoregions	Climate	Elevation	Mean annual temp.	Precipitation
Mountain	Mountain	65-3210 m	7-13°C	900-2000 mm
Valley bottom	Oceanic/Mountain	5-940 m	8-13°C	900-1500 mm
Intermediary	Mountain/Mediterranean	70-2900 m	8-12°C	640-1000 mm
Mediterranean	Mediterranean	0-1060 m	12-15°C	500-1000 mm

consist of contrasting ecological regions with variations in temperatures and an increase of precipitation positively correlated with the elevation.

Based on similar biogeographic factors (e.g. climate, geology, physiography), four homogeneous ecological regions are delineated by the French National Forest Inventory agency: the “Mountain” (Eco 1), “Valley bottom” (Eco 2), “Intermediary” (Eco 3) and “Mediterranean” (Eco 4). They each represent specific bioclimatic conditions for the survival and development of natural species and are used to assess past and future LULC changes (Table 1).

1.2 LULC-change model

A wide variety of spatially explicit LULC-change models have been developed over the past two decades. Literature reviews are available and offer an overview on the use of modeling tools and their assets for prospective studies (Verburg et al. 2004). For this study, the forecasting scenarios of land-use change (FORE-SCE) model (Sohl and Sayler 2008) is used for two main reasons: (1) it can deal with regional and sub-regional LULC dynamics (land demand) influenced by socio-economic drivers and (2) it can mimic observed landscape patterns detected from the analysis of LULC maps by uploading landscape metrics. It is assumed that landscape change patterns remain stable over time and the use of patch characteristics from observed LULC changes does not affect the validity of the outputs. Moreover, it has been widely used in the conterminous United States to spatially allocate LULC changes for various assessment studies (Sleeter et al. 2012; Sohl et al. 2012; Sohl et al. 2014).

The FORE-SCE model uses distinct “demand” and “spatial allocation” modules to partition the modeling of future land-use proportions (demand module) and the mapped location of future land-use change (spatial allocation module). Demand can be provided by a variety of sources, including

extrapolations of historical changes, economic models, quantitative scenario construction, or any other framework that provides regional-scale land-use proportions. The spatial allocation module uses suitability surfaces to guide where future landscape change occurs. Using a wide range of known drivers of LULC changes (e.g. topography, slope, climate, soil data) (Appendix 1), logistic regression is used to construct suitability-of-occurrence maps for each LULC type. It was used here to simulate LULC changes at 5-years intervals for the period 2006-2100. A patch-based allocation procedure is used to place change on the landscape (guided by the suitability surfaces) until the demand for each LULC type is reached. If there are no more possibilities for a given LULC class to be allocated (i.e. the demand cannot be respected), the FORE-SCE model stops allocating this particular class. Patch characteristics (e.g. mean and standard deviation for patch size) are derived from historical LULC data and are calculated in FRAGSTATS (McGarigal et al. 2002) to represent typical patch size distribution of each LULC type across the landscape and sub-regions. FORE-SCE model structure and function is extensively described in Sohl et al. (2008, 2014).

1.3 Scenario development and LULC modelling

This study intends to present possible future LULC changes under specific socio-ecological conditions using the combination of land-use scenarios and a LULC changes model. The methodological approach was initially based on the one proposed by Houet et al. (2010): (1) identifying past LULC trends (2) model calibration and validation, (3) developing scenarios and (4) modeling LULC change processes. It allows integrating data at multiple spatial and temporal scales, and taking into account all drivers affecting land-use change, while maintaining a manageable level of model complexity (Sohl et al. 2010). However, due to the lack of appropriate input

spatial data, this method was adapted. The scenarios (storylines) were firstly defined through the combination of existing reports focusing on future land uses over the study area. The method used is presented in section 1.3.1 and the storylines in section 1.3.2. Then, because the LULC changes provided by regional land cover maps are strongly under-estimated for two ecoregions compared to those observed at finer scales, future land changes were empirically modified and adapted accordingly to the storylines (section 1.3.3).

1.3.1 Defining the scenarios: methodology

The methodological approach for constructing the scenarios was based on existing storylines (i.e. qualitative and participatory assessment of alternate futures) made by regional and national institutions which have been adapted and downscaled for the various sub-regions. Since numerous studies have been developed by various national research communities over the last 20 years, there was a need to evaluate which ones were relevant and could serve as a basis for our scenarios. Four criteria were used to select and review existing sets of scenarios.

(1) Scenarios should fall within a global approach since global and regional scenarios represent large scale driving factors on LULC-changes. Global variables are usually used as a context for land-use changes at finer scales by defining and constraining socio-ecological conditions (Alcamo et al. 2006). This global context should include information regarding economic growth, energy cost and assumptions on world trade policies, since they are key driving forces for the Pyrenees production system;

(2) Regarding French development, the scenarios should contain national policies and management leanings, e.g. environmental and urbanization legislations, CAP orientations and public policies (financial support for agriculture

activities, and market interventions);

(3) The scenarios need to include local knowledge – through a participatory approach – since it provides a more detailed representation of LULC-changes by linking them to specific human decision-making and local physical factors;

(4) The scenarios have to present an exhaustive storyline regarding agricultural activities and have to assess forestry management strategies to estimate their impacts on LULC dynamics since they are the dominant land use types.

Among the six reports that were considered, four were selected as they provided information regarding at least one of the criteria mentioned above (Table 2). It appeared none of the above scenarios, considered independently, contained all the elements required to develop storylines that are believable, consistent and relevant to the actual environmental/socio-economic trends and policies for the Pyrenees as each serve a specific purpose in terms of agricultural, forestry and socio-economic analysis. However, elements of each scenario could be combined to fill thematic gaps and provide exhaustive storylines for the Pyrenees system. The Vert et al. (2013) scenarios offered the best starting point for its overall thematic veracity and its time frame. Additional elements from the three remaining reports (e.g. specific CAP orientations or forestry management strategies, quantitative projections given for example in Vert and Portet (2013), etc.) were integrated to fulfill each scenario of the Vert et al. (2013) report as long as they were relevant to the initial storyline. A summary of each report, illustrating their respective contribution to the definition of the storylines is given in Appendix 2. Thus, the scenarios developed are grounded on predefined storylines, each of which was then expanded based on additional information while making sure that they matched the initial scenario’s thematic scope.

Table 2 Review of reports selected for the French Pyrenees storylines and their level of detail for each criteria

Studies	Global context	National policies and management strategies	Participatory approach	Rich details about agricultural activities	Forestry management strategies
Vert et al. (2013)	++	+	++	++	+
Vert and Portet (2010)	++	+	+	+	○
CGAAER (2010)	+	++	+	○	–
Bourgau et al. (2008)	++	+	○	+	++

Notes: (++) Very high; (+) High; (○) Moderate; (–) Limited.

1.3.2 Scenario storylines

Four contrasting scenarios were developed and differentiated by their means of adaptation to different trajectories of socio-economic development and environmental disturbances (Figure 2). The means of adaptation translates the desire of the French government to support rural and/or logging production by applying particular public policies. Each storyline intends to emphasize a specific socio-economic paradigm which could influence land use changes in a major way.

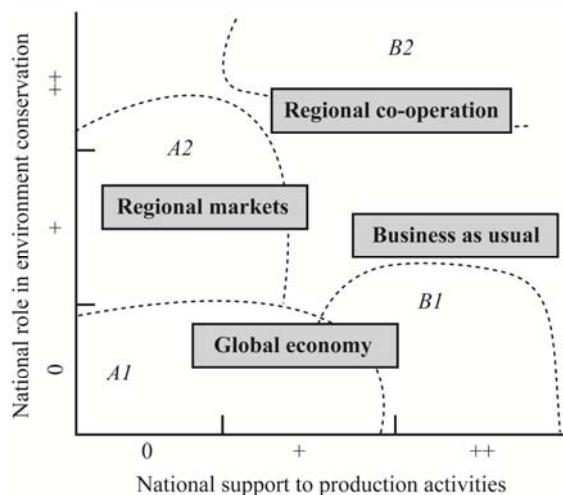

Figure 2 Socio-economic orientations prevailing in each of the scenarios and their position within the IPCC SRES scenarios framework.

Business as usual

This scenario is built on the assumption that there are no major changes in terms of global economy, public policy and land management. The CAP organization remains unchanged and offers the same financial supports to subsidize agricultural production in mountainous terrain. Current LULC trends observed for the recent past will continue into the future. Even if this scenario appears less realistic by avoiding an expected reform of the CAP, it provides a reference to which other scenarios can be compared.

Global economy

This scenario fits into a context of high economic growth and a liberalization of international trade. Economic development is a priority and environmental and rural issues are neglected by both national managers and society. The CAP is reformed and a drastic reduction of

agricultural financial aid causes the bankruptcy of many farms which strongly depend on policy-based agricultural support payments. To meet the global demand in goods and energy needs, the agroforestry sectors focus on production in higher quality production areas (e.g. accessible and profitable lands). Difficult lands to access in less favored areas are expected to be less intensively used and are assumed to be abandoned and reforested.

Regional markets

This scenario expects a major reconstruction of the agricultural sector under the influence of consistently high prices of fossil fuels and a reduction in international trade. Agricultural costs (e.g. fuel and fertilizers) are expected to increase, affecting farmers' profitability and as a result, prices for agricultural commodities. In the absence of national political interventions and high agricultural production costs, public policies are primarily implemented by regional authorities. This new autonomy leads the regions to implement contrasting management strategies to reinforce their own policies. The CAP is regionalized while the European Union, in a joint effort with the regions, favors local measures in terms of establishing plans to mitigate agricultural expenses.

Regional co-operation

This scenario is oriented toward a strong political and societal concern regarding energy, climate and environmental issues. Ambitious conservation policies are implemented at the European level. In response to the environmental requirements, the CAP architecture is modified to reduce the environmental impact of agricultural activities while optimizing production rates. CAP financial support policy is based on the quantity and quality of environmental services provided. There is a strong environmental consensus and a significant rallying of farmers, consumers and public authorities to support environmental conservation. A major energy and environmental transition is observed in the agroforestry sector to optimize land conservation.

1.3.3 Data and magnitude of future LULC changes

This study used the 2006 Corine Land Cover (CLC) data (CEC 2007) resampled to 125m

resolution as the starting land cover for the future scenario projections. Producing accurate, reliable and timely LULC mapping at a fine spatial resolution and a large spatial extent still remains a challenge for the global change community (Giri et al. 2013). Although there is ongoing work to map and characterize LULC in the Pyrenees (Ducrot et al. 2014), there are no historical LULC maps available providing a continuous record of LULC changes at the regional scale; CLC data remain the only usable database for this study. We used 1990 and 2006 CLC data to establish the initial demand for the “Business as usual” scenario. However, because of its spatial and temporal resolution, CLC data do not properly reflect landscape evolution trends (Verburg et al. 2006a) and underestimate LULC changes (Appendix 3), raising doubts of the validity of LULC change rates extracted from statistical analysis (Santini and Valentini 2011). To compensate for this effect and better characterize LULC trends, the annual demand of LULC changes was corrected for the mountain and intermediary ecoregions where LULC changes reach only $\pm 6\%$ of change based on the CLC database while they exhibit stronger rates at finer scale. To do so, we use results from a local research LULC change assessment: the MODE RESPYR project (Houet et al. 2012; <http://w3.mode-respyr.univ-tlse2.fr/>

[index.php](http://w3.mode-respyr.univ-tlse2.fr/index.php)). This project provided historical and statistical information on contemporary (1940-2000) LULC changes (e.g. gross, net, conversions) for three Pyrenean valleys (Sheeren et al. 2012; Vacquie et al. 2013). Based on this knowledge, change rates identified through CLC data between 1990 and 2006 were weighted by local trends observed over the past 60 years. It is assumed that LULC trends observed locally are representative of LULC changes in these ecoregions and these findings corroborate the LULC dynamics observed elsewhere in the Pyrenees (Cohen et al. 2011). Based on identified change rates, a LULC changes matrix was defined for the “Business as usual” scenario. Through an empirical approach based on expert knowledge, this scenario projects an overall decrease of agricultural land (-13% for crops, -6% for hay/pasture) and grassland (-20%) in all ecoregions (except for crops in valley bottom) compensated for by increasing forest (+20%) and shrublands (+14%).

For each of the “Global economy”, “Regional markets” and “Regional co-operation” scenarios, the quantity of change to be allocated corresponds to a proportional increase or decrease of measured change rates of the “Business as usual” matrix, balanced by socio-economic and/or bio-climatic conditions (Table 3a-d). In the “Global economy”

Table 3 Demand for each scenario by ecoregions and LULC classes (in $\pm\%/year$). Bold figures reflect the overall increase or decrease of the demand for the entire area. Forest includes deciduous, evergreen, and mixed forest classes; Dev. stands for developed.

Scenario	Crops	Hay, pasture	Grass	Forest	Shrub	Dev.	Water, barren
<i>(a) Business as usual</i>	-13	-6	-20	20	14	6	-1
Mountain ecoregion	-6	-11	-29	43	3	1	-1
Valley bottom ecoregion	-23	15	-14	-1	10	12	0
Intermediary ecoregion	-3	-26	-13	37	5	1	-1
Mediterranean ecoregion	-21	-1	-23	2	37	9	-2
<i>(b) Global economy</i>	-13	-6	-20	20	14	6	-1
Mountain ecoregion	-6	-11	-29	43	3	1	-1
Valley bottom ecoregion	-23	15	-14	-1	10	12	0
Intermediary ecoregion	-3	-26	-13	37	5	1	-1
Mediterranean ecoregion	-21	-1	-23	2	37	9	-2
<i>(c) Regional markets</i>	-10	-6	-19	18	14	5	-2
Mountain ecoregion	-2	-8	-28	31	10	2	-5
Valley bottom ecoregion	-23	15	-14	-1	10	12	0
Intermediary ecoregion	0	-21	-15	26	11	1	-2
Mediterranean ecoregion	-15	-9	-20	13	26	6	-2
<i>(d) Regional co-operation</i>	10	0	-4	-2	1	2	-8
Mountain ecoregion	10	2	-2	5	5	1	-21
Valley bottom ecoregion	5	14	-10	-9	-4	5	0
Intermediary ecoregion	15	-12	5	0	-3	1	-6
Mediterranean ecoregion	11	-3	-9	-4	7	3	-4

scenario, Vert and Portet (2010) find that given the economic difficulties farmers are facing, livestock are expected to decrease by 17% with a concurrent decrease of hay and pasture lands (i.e. between -3% and -5%). Grasslands are following similar trends and are expected to decrease by 22%. Assuming a $\pm 2\%$ margin, this scenario presents the same magnitude of change as the “Business as usual” scenario. However, additional reports assume a more intensive use of high quality production areas, submitting Less Favored Areas (LFAs) and precarious lands across the Pyrenees to more intensive changes. Thus, this scenario uses the same LULC change matrix as the “Business as usual” scenario but with a different spatial allocation of LULC changes. In the “Regional markets” scenario, Vert and Portet (2010) predict an overall decrease of hay/pastures (i.e. -6%) and crops in low lands (i.e. -23% in the valley bottom ecoregion) with associated impacts on the rest of the demand. Moreover, in a context where local political solutions are implemented to maintain the economic and environmental integrity of the Pyrenees, the magnitude of change is weighted by a longitudinal gradient favoring LULC changes in the Languedoc-Roussillon since the region is less agriculturally productive, and more sensitive to socio-economic and environmental changes. The “Regional co-operation” scenario presents relatively small changes due to policy assumptions that maintain agricultural production. According to Vert and Portet (2010), declines in agricultural and grassland areas are expected to be less in this scenario. They predict a stability of livestock which leads to a stability of hay/pasture lands and a 2% decrease of grasslands. Since grass land cover prevails in the mountain ecoregion, this decrease was favored in this ecoregion. Concurrently, a slow increase of crop yields is expected which translates into a 5% increase of crop lands in the valley bottom ecoregion. The increase of developed areas and decrease of water and barren land cover remain low compared to the magnitude of change in other LULC classes in all scenarios. Such contrasted scenarios, whether it is in terms of quantity of LULC change and/or in terms of spatial allocation, are expected to provide insights into a scope of potential futures of the Pyrenees Mountains and to help identify areas at stake, i.e. potentially concerned by land abandonment.

1.4 Scenarios’ comparison and assessment

Initial assessment of scenario results consists of comparing the allocation of LULC across scenarios. Results are compared between scenarios and administrative regions (i.e. Aquitaine, Midi-Pyrenees and Languedoc-Roussillon) which are more relevant to assess LULC changes in regard to specific socio-economic conditions. Since land abandonment dynamics is of importance in mountainous areas, the assessment of area at stake is made by overlaying the four scenarios. The resulting map highlights future uncertainty according to contrasted scenarios, i.e. where LULC changes inland abandonment is occurring in one or several scenarios (Verburg et al. 2010). Because land abandonment is made of encroachment and reforestation, a refined mapping approach is proposed. It is assumed that a pixel exhibiting encroachment in one scenario and reforestation in another scenario has a higher probability of being abandoned than a pixel with only encroachment or reforestation. In the same way, a pixel exhibiting reforestation and encroachment in two different scenarios has a lower probability of being abandoned than a pixel exhibiting reforestation in one scenario and encroachment in three scenarios since reforestation is expected to overcome encroachment.

2 Results

2.1 Comparison of the scenarios at the region administrative scale

The interaction between the demand for agricultural lands, forest, grassland/shrubland, spatial policies and land requirements results in highly variable land use dynamics across scenarios. Table 4 shows the percentage of land that is projected to change in each of the scenarios and indicates which part of the Pyrenees is expected to face the most change in LULC between 2006 and 2100. Due to the high rates of change observed in the past 60 years, the “Business as usual” scenario is the most dynamic with 24% of the total land area changing from one land use type to another. Of all thematic scenarios, the “Regional market” scenario presents the highest rates of landscape change resulting in an overall change of 18% of the total

study area followed by the “Global economy” with the conversion of 14% of the total area while only 8% of the Pyrenees are predicted to change under the “Regional co-operation” scenario. Regionally, high rates of change are typically associated with regions where land productivity is highly dependent on socio-economic drivers and where climatic and environmental conditions limit intensive production and profitability (e.g. conversion of 11% to 26% of the total area of the Languedoc-Roussillon region). Conversely, low rates of change are common in regions with high adaptability rates to socio-economic and climatic changes and where land resources are used at their highest intensity (e.g. conversion of 9% to 11% of the total area of the Aquitaine region).

2.2 Assessing land abandonment and reforestation dynamics

Of all changes in land cover, reforestation is the most important in term of net change (Figure 3). The largest amount of change is a net gain of 2.432 km² in the “Business as usual” scenario which equals an overall increase of forest of approximately 35%. The “Regional markets” and “Global economy” scenarios project a net forest gain of 1.850 km² (+25%) and 1.478 km² (+20%), respectively. Accounting for the largest portion of the landscape in 2006, covering approximately 41% of the total land area, the increase of forest lands has a significant impact on landscape patterns. For the “Regional markets”, “Global economy” and

“Business as usual” scenarios, it is between 9% and 14% of the total area of the Pyrenees that is expected to change due to reforestation alone and between 11% and 20% because of landscape enclosure (i.e. abandoned agricultural areas including those colonized by shrub and forest) (Table 5).

Land abandonment is the primary cause of this trend. Agro-pastoral land use and land cover (e.g. agriculture, hay/pasture and grasslands) have an overall net loss in the “Business as usual”, “Regional markets” and “Regional co-operation” scenarios equivalent to respective losses of 2.725 km², 1.723 km² and 1.480 km². Amongst those different LULC types, grasslands – used as summer pastures in high elevation areas - consistently change by the largest amount with a decrease ranging from 1.121 km² to 1.682 km² (-31% to -64%) depending upon scenario (Figure 4). On the whole, land abandonment counter balances reforestation dynamics and is directly responsible for the modification of 10% to 18% of the Pyrenean landscape (Table 5). As a consequence of incentives to maintain agricultural production, some agricultural areas expand in the “Regional co-operation” scenario leading to a reduction of forest and shrub land cover. The agricultural landscape remains stable with only 3.32% of the Pyrenees expected to change due to land abandonment and 1.20% due to reforestation (Table 5). A pattern of interest is the slight increase of hay/pasture in the Aquitaine region in all scenarios except for the “Business as usual”. This overall stability of

Table 4 Total area changed due to land use change across the Pyrenees for the different scenarios

Scenario	% of land area changed between 2006 and 2100			
	Entire Pyrenees	Aquitaine region	Midi-Pyrenees region	Languedoc-Roussillon region
Regional markets	18.59	11.09	16.50	26.35
Global economy	14.68	11.42	12.49	19.91
Regional co-operation	8.46	9.01	6.29	11.29
Business as usual	24.37	25.86	22.20	26.59

Table 5 Percentage of total area of the Pyrenees that is expected to change due to land abandonment, landscape enclosure and reforestation

Landuse types	Regional markets	Global economy	Regional co-operation	Business as usual
Land abandonment ^a	12.08	10.08	3.32	17.76
Landscape enclosure ^b	14.97	11.69	2.98	19.83
Reforestation	10.71	8.88	1.20	14.26

Notes: ^a This includes abandoned agricultural lands, e.g. crops, hay/pastures and grasslands colonized by shrubland or forest; ^b This includes any areas colonized by shrubland or forest.

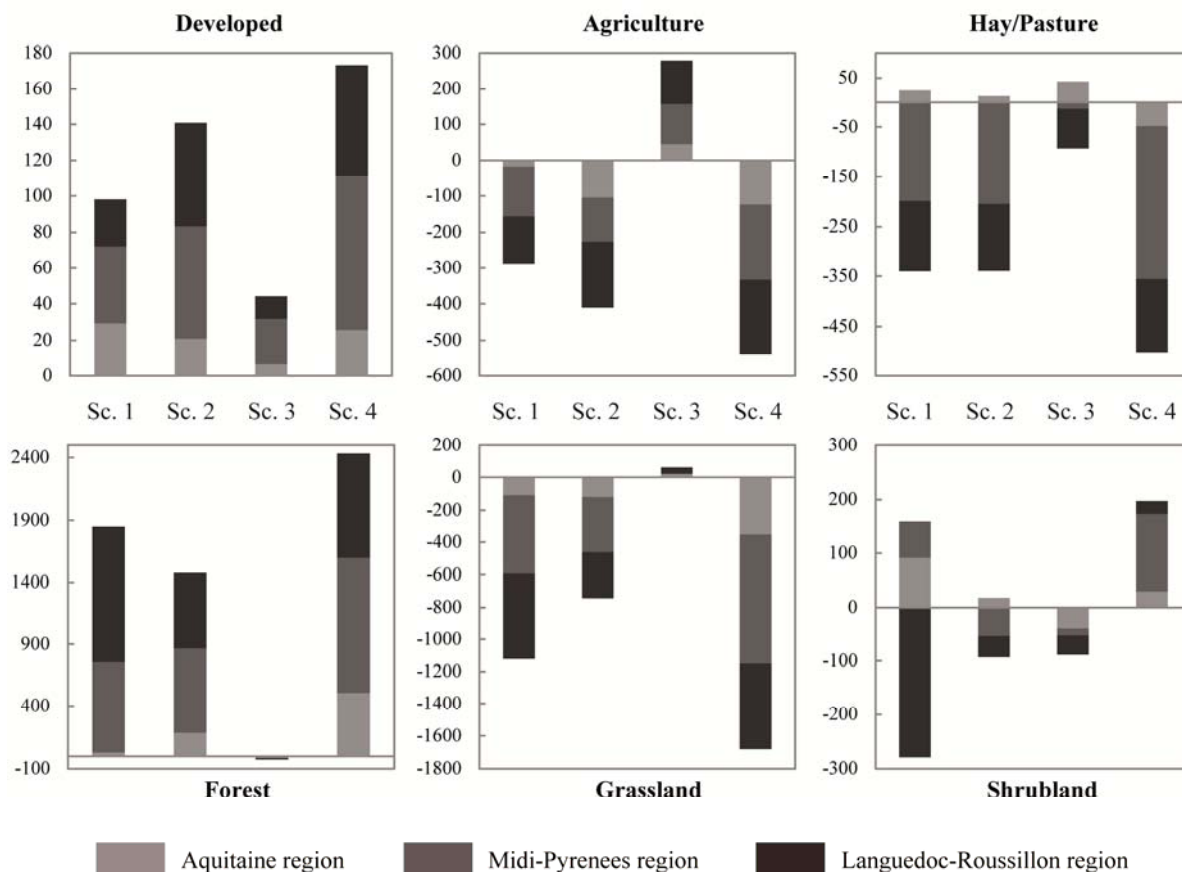

Figure 3 Projected net change in each of the 3 regions of the Pyrenees between 2006 and 2100 for each of the major land use (top row) and land cover (bottom). The vertical axis is in km². Scenario 1 is “Regional market”, scenario 2 is “Global economy”, scenario 3 is “Regional co-operation” and scenario 4 is “Business as usual”. Agriculture includes cultivated crops and permanent crops classes. Forest includes deciduous, evergreen and mixed forest classes.

pasturelands is consistent with the current and predicted dynamics of this region maintaining high pressure on available land resources.

Agricultural areas most sensitive to land abandonment and reforestation dynamics are typically found in LFAs and administrative regions with low production rates. Figure 4a shows that large parts of the agro-pastoral landscape are completely unaffected by future LULC change especially in the valley bottom and in the Aquitaine region where land abandonment dynamics remain low and scattered across the landscape. Although there are differences between allocations of LULC change between scenarios, some areas are projected to face abandonment, regardless of the scenario conditions, especially in the far eastern portion of the Midi-Pyrenees and in the Intermediary and Mediterranean ecoregions, e.g. areas with low production efficiency and low level of adaptability to socio-economic and

environmental changes. Moreover, the characterization of abandonment in terms of land-use and land-cover replacement can be used to identify alternate processes, e.g. encroachment versus reforestation dynamics. Areas that have the highest probability to be subjected to reforestation dynamics are mainly found at the geographic limits of existing forest areas in the Mountain ecoregion (Figure 4b) and to a lesser extent in the lower zones of the Intermediary and Mediterranean ecoregions (Figure 4c). Concurrently, encroachment dynamics are identified in the valley bottom and in the highest elevation slopes (e.g. above the tree line) where agro-pastoral lands have a higher probability to evolve into shrublands given the bio-climatic conditions. Climatic conditions are also relevant for the Mediterranean ecoregion where high temperatures and dry summers are more suitable for the development of shrublands (Figure 4c).

The spatial allocation of land abandonment in

relation to topography (i.e. elevation and slope) is also useful to identify the most sensitive areas to LULC changes. Figure 5a shows the proportion of pixels presenting a high probability of being abandoned (i.e. occurring in 3 of the 4 scenarios Figure 4b and 4c) for 50 meters altitude intervals. Values for each region are normalized by their respective area to make them comparable. Overall, the lower slopes of the Aquitaine region (i.e. 500-600 m a.s.l.) appear to be the most vulnerable to

land abandonment, similarly to the Midi-Pyrenees and Languedoc-Roussillon (i.e. 500-900 m a.s.l. and 900-1100 m a.s.l. respectively). In the latter region, the peak between 1500 m a.s.l. and 1660 m a.s.l. is representative of the LULC changes that have been occurring in the uplands (i.e. mountain summer pasture) abandoned since the 1950s and presenting a high probability for encroachment and reforestation with an upward shift of forest, also spreading at lower elevations (i.e. 900-1100 m

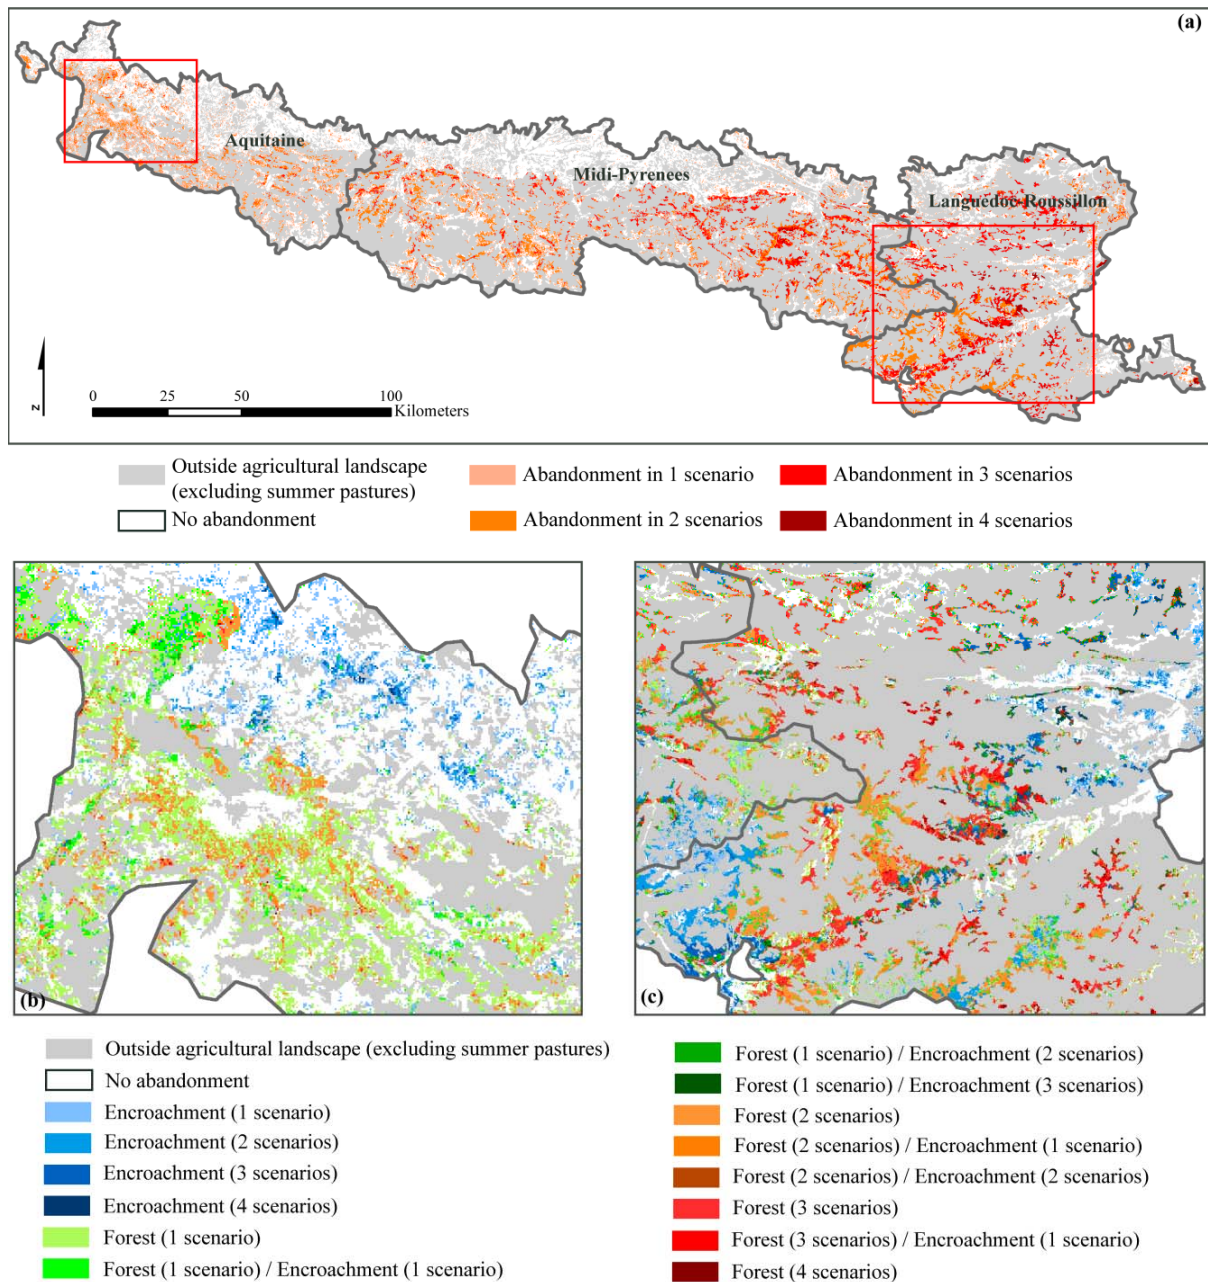

Figure 4 Frequency of simulated land abandonment within (a) the agro-pastoral landscape and (b-c) its corresponding LULC conversion at finer spatial scales.

Figure 5 Percentage of pixels presenting a 75% chance of being subjected to land abandonment based on (a) elevation (in meters) and (b) slope (in degrees) for each region of the Pyrenees Mountain.

a.s.l.). In the Aquitaine and Midi-Pyrenees regions the most vulnerable lands are located in the steepest areas (i.e. 25-30 degrees and 15-20 degrees respectively), while the opposite trend can be observed in the Languedoc-Roussillon region (i.e. lower than 10 degrees) (Figure 5b). This trend can be expected to occur gradually through the west as steepest areas were those primarily reforested in the Languedoc-Roussillon.

3 Discussion

3.1 Relevance of a multi-scale approach for building scenarios and simulating LULC changes

Houet et al. (2011) stated that it is from a comprehensive and explanatory picture of a complex system that a prospective study (i.e. scenario construction) can be implemented, accounting for interactions of multi-scaled drivers. However, the value of a phenomenon taking place within a specific landscape is generally dictated by causal processes at various spatial scales. Therefore, a clear and precise understanding of the processes occurring at both regional and local scales is essential to understand such complex systems. The current study integrates local knowledge from national assessment reports to refine each scenario during their construction and to reinforce their

plausibility and relevance. Information gathered at the local scale is used to explain dynamics at coarser spatial scales to obtain consistent patterns for the Pyrenees. Moreover, by basing the scenarios on pre-existing studies from national assessments and by accounting for regional structuring patterns, the procedure described in this paper has been successful at determining and constraining LULC change conditions at finer spatial scales. Overall, the approach used here comprises integrating the impacts resulting from local dynamics and the outcomes of regional trends. It puts in perspective global phenomenon and more local dynamics related to anthropogenic factors, and strengthens the observations made at different spatial scales by avoiding poor interpretations of LULC changes.

Since LULC change processes depend on the spatial scale considered, it is also essential to take into account the interdependence of spatial scales when quantifying relationships between LULC and their associated processes (Verburg et al. 2006c). Consequently, the spatial resolution of GIS data used to assess LULC changes has a significant influence on their quantification and spatial organization. In a landscape as complex as the Pyrenees, and in mountainous regions in general where driving factors of change are highly dependent on the spatial extent of the studied area considered, it is crucial to identify LULC changes in the most representative way. Many studies of LULC changes in other mountainous regions use

CLC data to conduct retrospective assessments and LULC evaluations (Verburg et al. 2006a; Santini and Valentini 2011). However, because of their spatial resolution and temporal horizon, they fail to precisely describe the landscape's evolution and correctly measure LULC changes. The unavailability of detailed and timely land classification maps at global and regional scales remains a major constraint for land-change mapping, monitoring, and modeling and calls for further improvements. To overcome this shortcoming, this study used local knowledge (i.e. LULC change observations in local study sites) to increase the relevance of retrospective statistical analysis since it provides a longer temporal horizon and a higher spatial resolution. While the validity of this approach can be argued by raising the question of the representativeness of the local sites compared to the Pyrenees, it does reflect evolution trends in a better way than would have been done without taking into account local knowledge. Moreover, as carried out by Santini and Valentini (2011) in the Italian Alps, the use of ancillary datasets (e.g. topography, socio-economic) is an effective way of compensating the restrictions induced by CLC data. One other way of increasing its validity would be to increase the number of local study sites along the Pyrenees to assess for local disparities as shown by Zimmermann et al. (2010).

3.2 Characterizing land abandonment dynamics

The procedure described in this paper has been successful in simulating LULC change in the Pyrenees by downscaling national assessments and integrating local knowledge. The land-use model accounts for spatial and temporal interactions and integrates specific driving factors (e.g. bioclimatic and geomorphological conditions, and socio-economic assumptions) for different ecoregions and scenarios. Specific LULC change dynamics emerge reflecting how both local management and national landscape drivers affect the landscape in different environmental and socio-economic contexts. The large declines of agro-pastoral lands observed across the Pyrenees are consistent with the ongoing trends observed over the past century in the Pyrenees (Mottet et al. 2006) and in many other mountainous regions across Europe (Prevosto et al. 2003; Price et

al. 2015). The results reflect global dynamics linked to national and European demographical and economical evolutions and relate to both natural and anthropogenic factors. Pyrenean production systems are highly dependent on bioclimatic conditions which determine the spatial distribution of livestock and the intensity of farming production – which are directly correlated to the dynamics of land abandonment and landscape enclosure. Consequently, even if similar dynamics (e.g. encroachment and reforestation) are observed across the Pyrenees, LULC change at the local level may differ due to local driving forces of landscape change.

An analysis of the results for the scenarios developed for this study reveals contrasting land abandonment processes. A latitudinal gradient guiding the establishment of either shrublands or forest can be observed along the Pyrenees Mountains. Hypothesis can be made whether it translates bioclimatic conditions (higher elevations not being a limitation in the Languedoc-Roussillon region due to higher temperatures compared to the Aquitaine region) and/or historical practices (abandoned lands in the Languedoc-Roussillon region are located at higher elevations because lands below 700 m a.s.l. have been abandoned earlier and are already reforested, contrary to the Aquitaine region). Overall, agro-pastoral abandonment is generally located in marginal areas bordering natural land covers. Thus, while the quantities and types of change differ across the Pyrenees, the spatial pattern of encroachment and reforestation follows similar processes and typically occurs at the margin of agro-pastoral land use as an extension of existing shrubland and forest land cover. Such areas are shown to be particularly sensitive to land abandonment in scenarios that project an increase in production efficiency or an overall decrease of agro-pastoral activities. Moreover, by translating the vulnerability of agro-pastoral lands, the characterization of land abandonment dynamics based on morphologic variables allows a finer identification of high stake areas. Overall, the lower slopes appear to be the most vulnerable to LULC changes, while the uplands of the Languedoc-Roussillon region also present a high probability of undergoing land abandonment. Concurrently, encroachment and reforestation are more

predominant on the steepest areas in the Aquitaine and Midi-Pyrenees regions than in the Languedoc-Roussillon. This could indicate that bioclimatic conditions are more binding than the accessibility of lands, especially in the Languedoc-Roussillon region, since areas at lower elevations and slopes are the most vulnerable. Such results intend to provide stakeholders with an insight into potential future evolution of the Pyrenees to improve their management and /or protection orientations.

3.3 Future perspectives

Although modelling should involve validation and uncertainty assessments of the simulation results, those issues are not addressed in this paper. It should be understood that the model outcomes are not predicting future LULC but are projecting LULC change based on socio-economic assumptions. In this respect, the purpose of model validation would not be to assess the model predictive capabilities but rather to demonstrate its ability to simulate realistic LULC changes. Validation could be a means to assess the uncertainty of the modeling procedure and estimate the level of reliability a user (e.g. modeler, local planner, etc.) can have in the model (Houet et al. 2014). However, a proper validation requires consistent LULC databases. Although the CLC database features changes in LULC between 1990 and 2006, it is not suitable for validation purposes since the LULC changes identified do not properly depict landscape patterns observed at local scales, as mentioned above.

Turley and Ford (2009) argue that uncertainties in simulation models can stem from the data or the model itself. While data validity remains an issue, a comparison of the outputs of simulations in various modeling platforms (e.g. CLUE, LCM, etc...) would contribute to an assessment of the validity and uncertainty of the simulation results, assuming they offer similar model calibrations. Concurrently, a multi-scale model assessment could serve a similar purpose. Downscaling the scenarios and comparing the outputs at different spatial scales would provide a means to identify uncertainty while accounting for specific (local) landscape processes. In the end, both approaches would serve a similar objective by identifying the redundant simulated abandoned

areas within various modelling platforms and/or various spatial scales to assess the model validity and reliability. For practical reasons, a multi-model assessment was not performed for this assessment. However, it should be emphasized that while data and model uncertainties certainly play a role in representing future landscape configurations, it is the variation in the scenarios themselves that is designed to capture overall uncertainties about the future.

4 Conclusion

The method presented in this paper focuses on the construction of socio-economic scenarios to forecast LULC changes using a spatially explicit model. The combined use of local and regional knowledge increases the relevance of retrospective analysis to simulate future LULC changes. The method results in the development of LULC maps providing insights into a range of alternative futures using a scope of socio-economic and environmental conditions. This analysis highlights the main trajectories of change and helps to identify areas that are most sensitive to change in order to guide decision makers of the concerned administrative region: medium sloped uplands are of concern in Languedoc-Roussillon while steep slopes nearby in the valley-bottom and in the uplands are the areas expected to be abandoned in the Midi-Pyrenees and Aquitaine regions. The assessment of LULC change trajectories reveals how agro-pastoral landscapes are projected to experience encroachment and reforestation dynamics, regardless of the scenarios. Furthermore, this work reveals how landscape enclosure is positively correlated to the degree of adaptability to socio-economic and climatic changes as well as the intensity of production activities. Remaining challenges are the validation of the model results through the implementation of each scenario into different modeling platforms applied at the regional scale or by comparing the model outputs at various spatial scales using different modeling tools.
