

# Viscosity of Blast Furnace Type Slags

NORITAKA SAITO, NAOTO HORI, KUNIHICO NAKASHIMA, and KATSUMI MORI

The effect of MgO, TiO<sub>2</sub>, or Fe<sub>2</sub>O<sub>3</sub> on the viscosity of 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> (mass pct) slags has been measured by the rotating crucible viscometer. Viscosity of these quaternary slags decreased with an increase in the content of additive oxide. At the same content of additive oxide, the viscosity decreases from MgO, TiO<sub>2</sub> to Fe<sub>2</sub>O<sub>3</sub>. In addition, the effect of SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub> on the viscosity of 26.1CaO-73.9Fe<sub>2</sub>O<sub>3</sub> (mass pct) (CF) and 14.9CaO-85.1Fe<sub>2</sub>O<sub>3</sub> (mass pct) (CF<sub>2</sub>) slags has been measured. Viscosity of calcium ferrite slags increased with increasing SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub> content. Al<sub>2</sub>O<sub>3</sub> was found to be more effective for increasing the viscosity at the same content of the additive oxide.

## I. INTRODUCTION

VISCOSITY of molten slag changes in wide range depending on temperature and composition. Several of factors in a blast furnace process, such as the rate of various reactions and the fluid flows, are affected by the properties of molten slag. Among them, it is well known that the viscosity is an important physical property for understanding the network structure of slag melts and for simulating the rate of various phenomena in high-temperature metallurgical processes. Numerous viscosity measurements have been carried out for binary or ternary slags in the last several decades.<sup>[1-7]</sup> Although practical slags related to the iron-making process are multicomponent systems, there are few data available on their viscosities. Furthermore, errors in the values of viscosity depending on published data range within  $\pm 25$  to 50 pct.<sup>[8]</sup> Thus, the accuracy of measurements in viscosity for multicomponent slag and flux is strongly required for understanding of the reaction behavior in the iron-making process.

In recent years, the amount of demanded sinters in the blast furnace process has been increased to achieve high productivity. It is important to clarify the role of the liquid slag during the sintering process of ores, for the formation of liquid slags, and its flow controlling the strength and the reducibility of sinters in a blast furnace. However, there is no viscosity data available for this slag.

Here, the effect of adding MgO, TiO<sub>2</sub>, or Fe<sub>2</sub>O<sub>3</sub> on the viscosity of 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> (mass pct) slags relating to blast furnace was investigated. In addition, the effect of adding SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub> on the viscosity of calcium ferrite melts, 26.1CaO-73.9Fe<sub>2</sub>O<sub>3</sub> (mass pct) (CF) and 14.9CaO-85.1Fe<sub>2</sub>O<sub>3</sub> (mass pct) (CF<sub>2</sub>) relating to liquid-phase sintering of ore, was also measured.

This article is based on a presentation given in the Mills Symposium entitled "Metals, Slags, Glasses: High Temperature Properties & Phenomena," which took place at The Institute of Materials in London, England, on August 22-23, 2002.

## II. EXPERIMENTAL

### A. Apparatus for Viscosity Measurement

Figure 1 presents the schematic diagram of the outer cylinder rotating viscometer, which consists of a rotating system, a heating system, and a measuring system.<sup>[9]</sup> An electric resistance furnace with six U-shape MoSi<sub>2</sub> heating elements was employed for heating and melting. The differential transformer, as shown in Figure 1(a), was developed by improving a commercially available rotation angle detector. A crucible and a bob, both with Pt-20Rh (mass pct), were used in the experiments. The dimensions of the crucible and the bob are given in Figure 1(b).

The viscometer was calibrated using four silicone oil standards with viscosities of 0.001 to 10 Pa·s at room temperature before each measurement. Figure 2 shows examples of the calibration line. This figure reveals a linear relationship between the viscosity of silicone oil and the detected voltage by the differential transformer. Calibrations of the viscometer were also made in the temperature range 1523 to 1823 K using reference slags (SRM2 type slags<sup>[8]</sup>). The compositions of the reference slags are given in Table I. As shown in Figure 3, the results of high-temperature calibration fitted in with the recommended value<sup>[8]</sup> and had reproducibility. The experimental conditions used in this study are summarized in Table II.

### B. Sample Preparation

Samples for viscosity measurement were prepared from reagent grade SiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, MgO, TiO<sub>2</sub>, Fe<sub>2</sub>O<sub>3</sub>, and CaCO<sub>3</sub> powders (Sigma-Aldrich, Japan). These reagents were precisely weighed to form given compositions (*cf.* Table III), and mixed in an alumina mortar thoroughly. The sample was premelted in a resistance furnace using the Pt crucible for an hour. Then, the sample was crushed into powder and used for measurements.

### C. Viscosity Measurements

The crucible filled with slag powder was placed in a crucible supporter in the furnace and heated to 1873 K. After then, the molten slag was kept at that temperature until the detected voltage value (viscosity) became constant. The measurements were carried out 3 times at every 50 K interval

Fig. 1—Schematic illustration of the apparatus for viscosity measurement.

on cooling. Thereafter, the measurements were repeated at the same temperature on heating. The thermal equilibration time at each temperature setting point was chosen to be 30 minutes. The average value of these six measurements was used for the measured potential difference. An apparent viscosity was calculated based on the reference relationship between the viscosity and the potential difference, which was obtained by using various silicone oils beforehand (*cf.* Figure 2). Thereafter, these values were corrected for the thermal expansions of the crucible and the bob using the following equation:

$$\eta = \eta' / (1 + \alpha T)^3 \quad [1]$$

where  $\eta$ ,  $\eta'$ ,  $\alpha$ , and  $T$  are viscosity, apparent viscosity, thermal expansion coefficient, and absolute temperature, respectively.

The scatter of the measured values between on cooling and on heating and the repetitive error of measurements were both within  $\pm 3$  pct. Table III shows the initial slag compositions and the summary viscosity data.

### III. RESULTS AND DISCUSSION

#### A. Effect of Holding Time on Isothermal Viscosity

Figure 4 shows an example of the variation of viscosity with different holding times, and reveals the decrease of viscosity with holding time. It required no less than 8 hours

to become constant for the viscosity of 13.4CaO-76.6Fe<sub>2</sub>O<sub>3</sub>-10SiO<sub>2</sub> (mass pct) slag. CF<sub>2</sub>-SiO<sub>2</sub> slags required a fairly long holding time to become constant value for viscosities, especially 11 hours for CF<sub>2</sub>-15 mass pct SiO<sub>2</sub>, 8 hours for CF<sub>2</sub>-10 mass pct SiO<sub>2</sub>, and 5.5 hours for CF<sub>2</sub>-5 mass pct SiO<sub>2</sub>. In other calcium ferrite slags and CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-(MgO, TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub>) slags, a similar tendency can be seen, as shown in Figure 4, and holding times of 3 and 1.5 hours are required to become constant value for viscosities, respectively. Generally, it will take several hours to stabilize the viscosity value due to the time required for complete homogenization and thermal equilibration of melts.<sup>[10]</sup>

On the other hand, Nagata and Hayashi<sup>[11]</sup> have recently investigated the change of the oxygen coordination structures of both iron ions, Fe<sup>3+</sup> and Fe<sup>2+</sup>, in calcium-silicate (40CaO-40SiO<sub>2</sub>-20Fe<sub>2</sub>O<sub>3</sub> (mol pct)) slag during the equilibration process at various temperatures. And they have reported that the fraction of Fe<sup>3+</sup> ions in octahedral symmetry to the total Fe<sup>3+</sup> ions increased with holding time and became constant within 2 hours at 1773 K after equilibration operation. This result suggests that the decrease of the viscosity, as shown in Figure 4, is probably due to the increase in Fe<sup>3+</sup> ions in octahedral symmetry with holding time, as Fe<sup>3+</sup> ions in octahedral symmetry play the role of network modifier. Since calcium ferrite slags measured in this study contain a greater amount of Fe<sub>2</sub>O<sub>3</sub> than slags used in their investigation, a much longer holding time would be necessary for stabilization of structures, particularly. Also, Al<sup>3+</sup> and Ti<sup>4+</sup> ions will have various oxygen coordination

structures in CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-(MgO, TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub>) slags. Therefore, in the case of amphoteric oxides containing slag melting, it might be expected that they require a considerably long holding time for the homogenization and the equilibration of coordination structures.

### B. The Viscosity of 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub>-(MgO, TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub>) Quaternary Slags

Figures 5 through 7 show the temperature dependence of the viscosity in 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub>-(MgO, TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub>) quaternary slags, respectively. The present result for 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> (mass pct) slag is in good agreement with the results reported by Machin *et al.*<sup>[12]</sup> and Kozakevitch.<sup>[13]</sup>

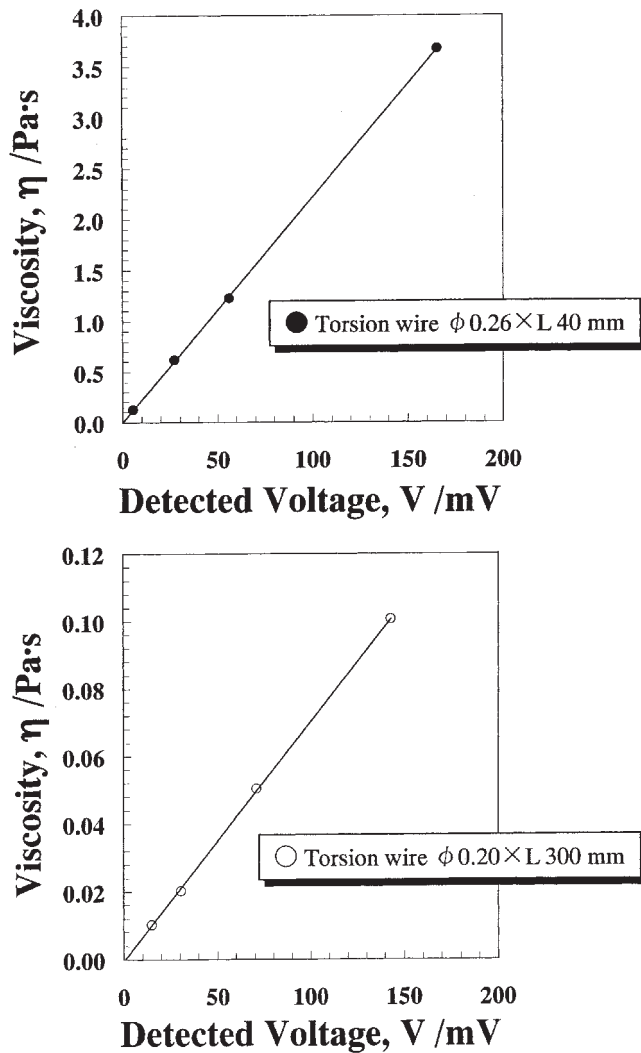

Fig. 2—Calibration curves for the evaluation of viscosity value.

Table I. Chemical Composition of SRM2 Type Slags for Calibration at High Temperature

|        | SiO <sub>2</sub> | Al <sub>2</sub> O <sub>3</sub> | Li <sub>2</sub> O | K <sub>2</sub> O | Na <sub>2</sub> O | MgO   | CaO   | TiO <sub>2</sub> | P <sub>2</sub> O <sub>5</sub> |
|--------|------------------|--------------------------------|-------------------|------------------|-------------------|-------|-------|------------------|-------------------------------|
| SRM2   | 63.7             | 14.4                           | 20.6              | 0.130            | 0.400             | <0.1  | 0.400 | <0.1             | <0.01                         |
| Slag 1 | 63.0             | 14.3                           | 20.2              | 0.630            | 0.550             | 0.140 | 0.380 | —                | —                             |
| Slag 2 | 62.5             | 15.2                           | 21.3              | 0.500            | 0.630             | 0.140 | 0.390 | —                | —                             |

The viscosity data can be described by an Andrade equation over the entire temperature region in this study.

$$\eta = A \exp\left(\frac{E_\eta}{RT}\right) \quad [2]$$

where  $A$ ,  $E_\eta$ ,  $R$ , and  $T$  are a constant, the apparent activation energy of viscous flow, the universal gas constant, and absolute temperature, respectively.

Figure 8 illustrates the effect of adding oxide (MgO, TiO<sub>2</sub>, or Fe<sub>2</sub>O<sub>3</sub>) on the viscosity of 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> (mass

pct) slags at 1873 K together with our previous data<sup>[9]</sup> for 50CaO-50SiO<sub>2</sub> (mass pct) slags. The horizontal axis shows the molar concentration of additive oxides. The viscosities of these quaternary slags decrease with increasing content of additive oxide. At the same content of additive oxide, the viscosity decrease from MgO, TiO<sub>2</sub> to Fe<sub>2</sub>O<sub>3</sub>. These vari-

ations of decreasing viscosity isotherm are similar to the previous work<sup>[9]</sup> for 50CaO-50SiO<sub>2</sub> slags.

It is known that Al<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, and Fe<sub>2</sub>O<sub>3</sub> are amphoteric oxide<sup>[3,14-16]</sup> and their behavior depend on the basicity of slags to which they are added.

Fig. 8—Effect of additive oxide on the viscosity of CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> and CaO-SiO<sub>2</sub> slags at 1873 K.

In the case of the mole ratio  $Al_2O_3/RO < 1$  (RO: basic oxide),  $Al_2O_3$  would behave as acid oxide (network former), as described in References 14 and 17. Moreover, the viscosity of 50CaO-50SiO<sub>2</sub> (mass pct) slag increased linearly with increasing  $Al_2O_3$  content.<sup>[9]</sup> These results indicate that  $Al_2O_3$

will behave as a network former in the present 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> (mass pct) slag.

Morinaga *et al.*<sup>[18]</sup> have investigated the electrical conductivity of the CaO-SiO<sub>2</sub>-TiO<sub>2</sub> system. And they have suggested that, in the case of silicate melts with the ratio CaO/SiO<sub>2</sub> = 1, the percentage of Ti<sup>4+</sup> ion in octahedral symmetry to the total Ti<sup>4+</sup> ions is about 50 pct. Moreover, decreasing the ratio CaO/SiO<sub>2</sub> leads to increasing the percentage of Ti<sup>4+</sup> ion in octahedral symmetry to the total Ti<sup>4+</sup> ions, as described in Reference 18. Also, Morinaga *et al.*<sup>[15]</sup> and Sumita *et al.*<sup>[19]</sup> have reported that the oxygen coordination structure of Fe<sup>3+</sup> ion can be determined by the ratio RO/Fe<sub>2</sub>O<sub>3</sub> (RO: basic oxide). In this study, the structural analysis of quenched slag has not been done. It is expected that TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub> would behave as a network modifier in 40CaO-40SiO<sub>2</sub>-20Al<sub>2</sub>O<sub>3</sub> slag. Therefore, the viscosity of these quaternary slags decreases with increasing TiO<sub>2</sub> or Fe<sub>2</sub>O<sub>3</sub>.

Since Fe<sup>3+</sup> ion has a smaller cation-oxygen attraction<sup>[20]</sup> than that of the Ti<sup>4+</sup> ion, at the same contents of TiO<sub>2</sub> and Fe<sub>2</sub>O<sub>3</sub>, the viscosity of CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-Fe<sub>2</sub>O<sub>3</sub> slags was lower than those of CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub>-TiO<sub>2</sub> slags.

There are few data available on the viscosity and the structural analysis for the slags with multiple amphoteric oxides coexisting. Further investigation of structural analysis is required.

When MgO behaves as a network modifier in Na<sub>2</sub>O-SiO<sub>2</sub>-MgO and CaO-SiO<sub>2</sub>-MgO slags, the viscosity decreases<sup>[17]</sup> and the electrical conductivity increases<sup>[14]</sup> with increasing MgO content, respectively. As such, it is natural that MgO will behave as a network modifier and decrease the viscosity of slag.

Figure 9 shows the relationship between the content of additive oxide and the apparent activation energy of viscous flow calculated according to Eq. [1]. The horizontal axis shows the molar concentration of additive oxides.

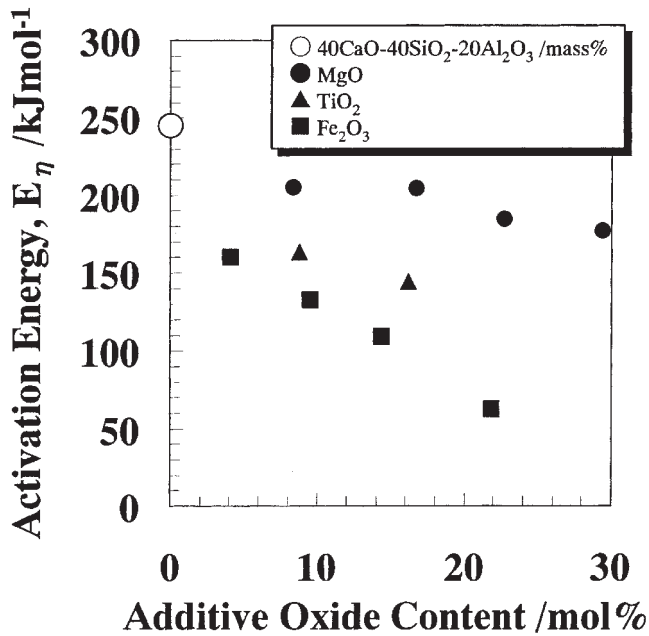

Fig. 9—Effect of additive oxide on the apparent activation energy of viscous flow of CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> slags.

Fig. 10—Temperature dependence of the viscosity of CF-SiO<sub>2</sub> slags.

The apparent activation energy of viscous flow decreases with increasing content of additive oxide in any system. This result also indicates that the structural unit for viscous flow of slags becomes smaller with increasing MgO, TiO<sub>2</sub>, or Fe<sub>2</sub>O<sub>3</sub> content.

### C. The Viscosity of CF-(SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub>) and CF<sub>2</sub>-(SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub>) Ternary Slags

Figures 10 through 13 show the temperature dependence of the viscosity of CF-SiO<sub>2</sub>, CF-Al<sub>2</sub>O<sub>3</sub>, CF<sub>2</sub>-SiO<sub>2</sub>, and CF<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> ternary slags, respectively. The present results of CF

Fig. 11—Temperature dependence of the viscosity of CF-Al<sub>2</sub>O<sub>3</sub> slags.

Fig. 12—Temperature dependence of the viscosity of CF<sub>2</sub>-SiO<sub>2</sub> slags.

and CF<sub>2</sub> are not in good agreement with the results reported by Sumita *et al.*<sup>[19]</sup> Generally, the errors in values of viscosity depending on published data range within  $\pm 25$  to 50 pct<sup>[8]</sup> In the case of rotating crucible viscometer, several instrumental factors cause errors,<sup>[21]</sup> *i.e.*, the lean of rotating axis, the variation of immersion depth, and so on. However, their work with the experimental conditions is not published; the difference in values between our result and reported results is, in part, due to the holding time, as mentioned earlier.

Fig. 13—Temperature dependence of the viscosity of  $\text{CF}_2\text{-Al}_2\text{O}_3$  slags.

Fig. 14—Effect of additive oxide on the viscosity of  $\text{CaO-Fe}_2\text{O}_3$  slags at 1873 K.

The viscosity data can be described by an Andrade Eq. [1] over the entire temperature region in this study, as shown in Figures 10 through 13.

Figure 14 illustrates the effect of adding oxide ( $\text{SiO}_2$  or  $\text{Al}_2\text{O}_3$ ) on the viscosity of CF and  $\text{CF}_2$  slags at 1873 K. The horizontal axis shows the molar concentration of additive oxides. The viscosity of these calcium ferrite slags increases with an increase in the content of additive oxide. At the same content of additive oxide,  $\text{Al}_2\text{O}_3$  is more effective for

Fig. 15—Effect of additive oxide on the apparent activation energy of viscous flow of  $\text{CaO-Fe}_2\text{O}_3$  slags.

increasing the viscosity than other additions. Kou *et al.*<sup>[22]</sup> have investigated the viscosity of  $\text{Na}_2\text{O-SiO}_2\text{-Al}_2\text{O}_3$  and  $\text{CaO-SiO}_2\text{-SiO}_2$  systems using a rotating crucible viscometer. They have reported that, in the case of melts with high basicity,  $\text{Al}^{3+}$  ion formed oxygen tetrahedron like  $\text{Si}^{4+}$  ion, and the value of  $\text{SiO}_2$  equivalence of  $\text{Al}_2\text{O}_3$  was about 1.65. In this study, the basicity of CF and  $\text{CF}_2$  slags will be fairly high, it is very natural that almost all of the  $\text{Al}_2\text{O}_3$  added would behave as a network former in calcium ferrite slag. Therefore, the viscosity of  $\text{Al}_2\text{O}_3$  containing slag is higher than that of  $\text{SiO}_2$  containing slag.

Figure 15 shows the relationship between the content of additive oxide and the apparent activation energy of viscous flow based on Eq. [1]. The horizontal axis shows the molar concentration of additive oxides. The apparent activation energy of viscous flow decreases with increasing content of additive oxide in any systems. However, the viscosity increases with an increase in the addition contents. At this point, it is difficult to estimate the structure of these calcium ferrite slags solely from the data of viscosity.

Further investigations such as spectroscopy, density, and surface tension measurements are required for the clarification of structure of calcium ferrite slags.

#### IV. CONCLUSIONS

The effect of adding  $\text{MgO}$ ,  $\text{TiO}_2$ , or  $\text{Fe}_2\text{O}_3$  on the viscosity of  $40\text{CaO-40SiO}_2\text{-20Al}_2\text{O}_3$  (mass pct) slags and that of adding  $\text{SiO}_2$ ,  $\text{Al}_2\text{O}_3$ , or  $\text{MgO}$  on the viscosity of CF (Mono calcium ferrite  $26.1\text{CaO-73.9Fe}_2\text{O}_3$  (mass pct)) and  $\text{CF}_2$  (Hemi calcium ferrite  $14.9\text{CaO-85.1Fe}_2\text{O}_3$  (mass pct)) have been measured by the outer cylinder rotating viscometer.

1. Slags shortly after melting showed some higher values of viscosity, but the viscosity decreased with the holding

time and became constant in 1.5 to 11 hours depending on slag compositions.

2. Viscosity of CaO-SiO<sub>2</sub>-Al<sub>2</sub>O<sub>3</sub> slags decreased with increasing MgO, TiO<sub>2</sub>, or Fe<sub>2</sub>O<sub>3</sub>. At the same content of additive oxide, the viscosity decreases in order of Fe<sub>2</sub>O<sub>3</sub>, TiO<sub>2</sub>, and MgO. The apparent activation energy of viscous flow decreases with increasing the content of additive oxide in any systems.
3. The viscosity of calcium ferrite slags increased with increasing the content of SiO<sub>2</sub> or Al<sub>2</sub>O<sub>3</sub>. At the same content of additive oxide, Al<sub>2</sub>O<sub>3</sub> is effective for increasing the viscosity more than others. The apparent activation energy of viscous flow decreased with increasing the content of additive oxide in any systems.
