Abstract In this study, we focus on structural and thermodynamics properties, as well as phase stability of quinary CrFeCoNiMn and CrFeCoNiPd high-entropy alloys (HEA) for both equiatomic and non-equiatomic compositions. CrFeCoNiMn (Cantor alloy) is a widely studied fcc alloy, while CrFeCoNiPd is a newly reported fcc alloy, being synthesized by intentionally substituting Mn in Cantor alloy by Pd which has a markedly different atomic size and electronegativity from the other constituent elements and has been achieved the better mechanical properties than Cantor alloy in experiments. DFT-based integrated approaches are conducted on these two quinary systems to calculate the structural, electronic structure and magnetic properties at zero K, as well as the free energies as function of temperature including vibrational, configurational mixing entropy and thermal electronic effects. Various SOS models with about 200 atoms were created to simulate the equiatomic HEA and a special non-equiatomic HEA where a principal element has a rather high concentration while other four kinds of element have equal lower concentrations. Comparison between Mn- and Pd-HEAs in both equiatomic and non-equiatomic compositions shows that the stability of Mn- and Pd-HEAs at zero K and finite temperature are dominated by different mechanisms, this can explain the recent experimental observation that a pronounced spatial fluctuation in atomic fraction is much wider in Pd-HEA rather than in Mn-HEA.

Keywords HEA · CrFeNiCoMn/Pd HEAs · Thermodynamics · DFT

1 Introduction

High-entropy alloys (HEAs) have been attracting a great of interest because of their unconventional mixing of multiple principal elements (at least 4 or 5), resulting in attractive mechanical, magnetic and electronic, chemical, as well as other physical properties.^[1–5] The novel properties of HEAs have been shown comparable and sometimes superior to those of commercial and traditional metallic alloys. Also, the ability of tailoring those properties of HEAs by controlling their compositions or modifying their microstructures makes HEAs future candidates for material design and applications. Much works have been undertaken in order to realize the potential of HEAs in various fields such as superalloy, irradiation and corrosion resistances, superconductor, catalyst, etc. ^[4, 6–8]

Among hundreds of different HEA systems synthesized and investigated, the CrFeNiCoMn, formed from five 3d transition metal elements, so called Cantor alloy is one of the most interest. Objectives such as phase stability, local lattice distortion, microstructure, magnetic and electronic structure properties, and their effects on mechanical, elastic properties and others have been continuously studied and

This article is part of a special topical focus in the Journal of Phase Equilibria and Diffusion on the Thermodynamics and Kinetics of High-Entropy Alloys. This issue was organized by Dr. Michael Gao, National Energy Technology Laboratory; Dr. Ursula Kattner, NIST; Prof. Raymundo Arroyave, Texas A&M University; and the late Dr. John Morral, The Ohio State University.

actively discussed.^[4, 5, 9] Experimental characterization has demonstrated the Cantor alloy having a single fcc random solid solution phase at high temperature with remarkable combination of strength and ductility.^[10–12] Efforts to further enhance its mechanical properties are under way, focusing on modifying its compositions away from equiatomic center ^[13, 14] or by interstitial alloying.^[15, 16] Few studies concentrated on interdiffusion in CrFeNiCoMn alloy using classical theoretical model or high-throughput technique.^[17, 18] Yet for better understanding CrFeNi-CoMn alloy and building up a sufficient thermodynamic database which would allow its potential applications being more realistic, more investigations are required both experimentally and theoretically.

Recently, Ding et al. have reported a new fcc equiatomic CrFeNiCoPd alloy, which is synthesized by intentionally substituting Mn in Cantor alloy with the 4d element Pd which has a markedly different atomic size and electronegativity from the other constituent elements, showing that its strength is about 2.5 times higher than that of CrFeNiCoMn at similar grain size, and is comparable to that of advanced high-strength steels.^[19] Ouite interestingly, the authors had noticed a pronounced difference in the distribution of constituent elements between CrFeNi-CoMn and CrFeNiCoPd alloys: it is relatively random and uniform for the former, while it shows a great inhomogeneity and aggregation for the latter. Soon thereafter, Yin and Curtin have proposed a parameter-free model for random alloys which requires only solute misfit volumes, alloy elastic constants, and alloy lattice constant, capable of predicting CrFeNiCoPd strength in good agreement with the Ding et al.'s experimental finding.^[20] The model however cannot account for the different behaviors in the fluctuation in element distribution between CrFeNiCoMn and CrFeNiCoPd alloys. To this end, a closer look at atomistic, thermodynamic and energetic level for both equiatomic and non-equiatomic quinary CrFeNiCoPd alloys, as well as a detailed comparison with CrFeNiCoMn counterparts in a systematic manner are necessary. There are still only a few studies on CrFeNiCoPd HEAs compared to those on the Cantor alloy; and it is often that already investigated non-equiatomic compositions are not the same. Thus, a direct comparison between the two HEAs is somehow limited.

This work aims to reveal the similarities and differences between CrFeNiCoMn and CrFeNiCoPd HEAs in terms of structural, electronic structure and magnetic properties, as well as thermodynamics and energetics, and to investigate the Pd-sub-Mn substitution effect using the DFT-based integrated approaches. The usage of supercell approach including two equiatomic and two extreme non-equiatomic special quasirandom structures (SQSs) employed in the same manner for both CrFeNiCoMn and CrFeNiCoPd systems allows us to compare the two directly and systematically. Furthermore, two stability types identified in this work for CrFeNiCoMn and CrFeNiCoPd HEAs, going from equiatomic center toward non-equiatomic, gave an explanation to the Ding's experimental observation.

2 Models and Computational Methods

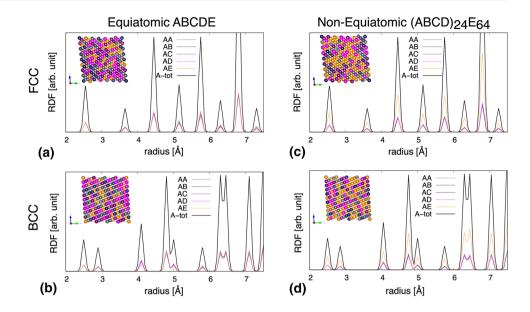

2.1 Models

Models of single phase solid-solution quinary HEAs were represented by Special Quasirandom Structures (SQSs)^[23] as shown in insets in Fig. 1. All these four equiatomic and non-equiatomic, fcc and bcc, SQS structures consist of the same number of atoms in supercell, 160, which is bigger than those used in Refs ^[24, 25] that claimed to be sufficient for modelling quinary HEA. The supercell lattice parameters of the starting fcc and bcc SQS structures, a*(1, b/a, c/ a) and (α, β, γ) (in degree), are a*(1, 1.00, 1.00) & (90, 106.3, 108.7) and a*(1, 1.00, 1.00) & (93.8, 93.8, 81.6), respectively. For the non-equiatomic quinary HEAs, a special composition (ABCD)₂₄E₆₄ was chosen in which an principle element E has highest atomic concentration of 40% (64 atoms, deviating from equiatomic composition by 20%), and all the rest having the same lower atomic concentration of 15% (24 atoms) (Fig. 1 c, d). We intentionally used the SQS structures to represent the situation of very strong fluctuation in local atomic fraction in CrFeNiCoPd HEA experimentally observed by Ding et. al ^[19]. All SOS structures used in this work were generated by the mcsqs code implemented in the Alloy Theoretic Automated Toolkit (ATAT) package.^[22]

Radial distribution functions (RDF) in Fig. 1 demonstrate how well our generated SQS structures are in representing the randomness characteristics of solid solution HEA. For the equiatomic SQS quinary HEAs, all RDF of pairs are nearly the same (Fig.1 a, b), while in the nonequiatomic (ABCD)₂₄E₆₄ SQS structures due to higher atomic concentration of E, it is the highest for AE pair and all the other RDF pairs are smaller and very similar (Fig.1 c, d).

2.2 Computational Methods

All total energy calculations at 0K temperature were carried out by spin-polarized DFT calculations using the projector augmented wave (PAW) method ^[26] as implemented in the Vienna Ab Initio Simulation Package (VASP).^[27-29] Also the generalized gradient approximation and the Perdew-Burke-Ernzerhof pseudo potential (GGA-PBE) ^[30, 31] were used in treating the exchange and correlation energy. An energy cutoff wavefunction was set **Fig. 1** Radial distribution functions of the equiatomic ABCDE (a) and (b), and nonequiatomic (ABCD)₂₄E₆₄ (c) and (d) SQS structures used in this work. Insets are fcc (a) and (c), and bcc (b) and (d) SQS structures as described in the main text

up at 400 eV and the Monkhorst-Pack k-point mesh $^{[32]}$ of 3x3x3 was used in the Brillouin-zone integrations. All SQS structures were fully relaxed until all force components smaller than 2 meV/Å.

The total Gibbs free energy as a function of temperature, $G_{tot}(T)$, can be calculated by summarizing the total energy of electrons E^{0K} at 0K and contributions of thermal vibration $F_{vib}(T)$, thermal electronic $F_{el}(T)$, and ideal mixing configurational entropy S_{config} , as follow:

$$G_{tot}(T) = E^{0K} + F_{vib}(T) + F_{el}(T) - T * S_{config}$$
(Eq 1)

To obtain the temperature dependent thermal vibrational free energy $F_{vib}(T)$, the quasiharmonic Debye-Grüneisen model was used as implemented in Gibbs2 code ^[33, 34] with modified Poisson ratio being of 0.34. The thermal electronic free energy $F_{el}(T)$ can be obtained using:

$$F_{el}(T) = E_{el} - T * S_{el} \qquad (Eq 2)$$

where:

$$E_{\rm el} = \int n(\varepsilon) f \varepsilon d\varepsilon - \int n(\varepsilon) \varepsilon d\varepsilon \qquad ({\rm Eq} \ 3)$$

$$S_{el} = -k_B \int n(\varepsilon) [flnf + (1-f)\ln(1-f)]d\varepsilon \qquad (Eq 4)$$

In Eqs (3, 4), *n* and *f* are electronic density of state and the Fermi distribution function, respectively, ε_F being Fermi energy. The thermal electronic free energy was also calculated with ATAT package.^[22]

Finally, the ideal configurational entropy of mixing can be expressed as:

$$S_{\text{config}} = -R \sum_{i=1}^{5} c_i \ln c_i$$
 (Eq 5)

where c_i is concentration of ith constituent element. This has been taken as a good approximation for the fully random system, and should be appropriate for multi-components HEA. Gao et. al. ^[43] have compared the configurational entropies for various equiatomic quaternary alloys (FCC, BCC, HCP) using DFT combining with Monte Carlo/Molecular Dynamic method and the entropy of ideal mixing and showed that the values of the ideal mixing entropy are fairly close to the values using more accurate methods.

3 Results and Discussions

3.1 Structural, Electronic Structure and Magnetic Properties

Using our generated SOS structures, two sets of quinary HEA structures have been considered by substituting dummy elements (A, B, C, D, E) by those of interest (Cr, Fe, Ni, Co, Mn, and Pd): Cr-Fe-Ni-Co-Mn, and Cr-Fe-Ni-Co-Pd. Hereafter, they are shortly abbreviated as CFNCM and CFNCP for the equiatomic quinary HEAs, respectively, while the non-equiatomic ones, such as (CrFeNiCo)₂₄Mn₆₄ for example, is denoted as CFNCM-Mn64 and so on. In total, there are 4 equiatomic SQS structures and 20 non-equiatomic SQS that have been fully relaxed. Table 1 summarizes structural and magnetic properties of all optimized SQS structures including supercell lattice parameters, volume per atom V₀, root mean square displacement (RMSD), as well as magnetic moment per atom for two systems. Details of the final relaxed SQS structures are shown in supporting information (SI) (Fig. S1).

relaxed SQS structures of fcc and bcc for Mn-HEAs and Pd-HEAs: supercell parameters $a(1, b/a, c/a)$ (Å) and (α, β, γ) (in degree), volume v_0 (Å ³ per atom), root mean	$MSD(Å)$ and magnetic moment $m_b(\mu_B \text{ per atom})$

We firstly focus on structural properties of the fully relaxed fcc structures. Our DFT calculations show that there are small cell distortions and ionic local displacements during the relaxations for both Mn- and Pd-sets of fcc SOS structures. The supercell lattice parameters of all the relaxed fcc SQS structures are very similar to each other, and the deviations from the pristine cells are found to be less than 1%. The calculated RMSD values of the Pdfcc set are obviously bigger than those of the Mn-set implying more lattice distortion for the Pd-HEA systems (see Fig. S1), but all of them are smaller than 0.2 Å. Okamoto and co-authors ^[21] have reported RMSD value of 0.05 Å for fcc CrMnFeNiCo in their 320-atoms SQS structure, which is comparable with our result (0.076 Å for CFNCM). The authors also confirmed that the difference between their theoretical and experimental results is very small, being only 0.017 Å. Although the values of atomic displacements in these HEAs are very small, it has been found that the mechanical properties of the HEAs relate to the averaged atomic displacement, and the yield strengths of some typical HEAs can be scaled and predicted using their RMSD values.^[21] We believe that introducing the large size element Pd into the 3d elements based solid solution results in the bigger average atomic displacement in Pd-HEAs, which might be the direct reason leading to its promising mechanical properties.

As demonstrated in Table 1, the difference in volume v_0 among considered structures in the fcc Mn-HEA set is minuscule, despite the fact that there is drastic difference in concentration of constituent elements. The biggest volume is found to be 11.25 Å³ for Ni-rich CFNCM-Ni64, which is only 0.18 Å³ bigger than the smallest Mn-rich CFNCM-Mn64. This is due to the well-known fact that the values of the atomic radii of the Cantor elements are very close.^[21] A similarity is also found in the fcc Pd-HEA set where the concentration of Pd is kept constant at 15%. Substituting Mn with Pd always results in bigger volume v₀ because of Pd having bigger atomic radius than Mn. The calculated values of v₀ for the equiatomic fcc CFNCM and CFNCP are 11.10 Å³ and 12.20 Å³ which can be converted straightforwardly to lattice constants of 3.54 and 3.65 Å, which is consistent with previous findings.^[35, 36] In the fcc Pd-HEA set, it is observed that v_0 decreases from 13.22 to 12.20 $Å^3$, and to 11.84 $Å^3$ as Pd concentration decreases subsequently from 40% (CFNCP-Pd64) to 20% (CFNCP), and to 15% (CFNCP-Co64) (see Table 1). This change in v₀ has been also reported for other Pd concentrations (Co₇Cr₇Fe₇Ni₇Pd₄, Co₆Cr₇Fe₇Ni₆Pd₆, Co₄Cr₈Fe₈Ni₄Pd₈, Co₅Cr₆Fe₆Ni₅Pd₁₀) by Calvo-Dahlborg et. al ^[35] using smaller fcc SQS structure of 32-atoms, where similar trend was found.

Our DFT calculations revealed a strong substitutional effect of Pd with Mn in simple bcc phase. Being very different from fcc structures, we could not stabilize any Pdcontaining bcc structures considered in this study even for systems containing high concentration of bcc-favoring components like Fe and Cr (CFNCP-Fe64, CFNCP-Cr64). The Pd- bcc set undergoes severe cell shape and lattice distortion during structural optimization. For instance, the angles between principal axes in the equiatomic CFNCP are (78.3, 78.3, 68.9) compared to the starting ones (93.8, 93.8, 81.6). The severe local lattice distortion can be pronouncedly seen in the non-equiatomic CFNCP-Ni64, CFNCP-Cr64, and CFNCP-Pd64 (see Fig. S1 i, k, l) where layers of atoms are regrouped or irregularly redistributed. As shown in Table 1, the calculated RMSD for the final bcc Pd-HEA structures are all greater than 0.62 Å and can reach up to 1.14 Å (CFNCP). The large RMSD values are consequence of distortion of both cell shape and lattice. Although the larger RMSD due to introducing inhomogeneous feature leads to better mechanical properties, it is also important to consider the trade-off between inhomogeneous and stability.

For the bcc set with Mn, similar phenomenon was found for the non-equiatomic bcc CFNCM-Ni64 and CFNCM-Co64 (see Table 1 and Fig. S1 c, d) where high concentrations in Ni and Co components are favoring fcc lattice rather than bcc. The other Mn-HEA compositions, equiatomic and non-equiatomic, can stabilize in bcc lattice and show a much smaller cell shape and ionic relaxations. Li et. al ^[37] had experimentally synthesized FeCoNi(MnAl)x HEAs and reported a Al-concentration dependence for formation of single fcc phase ($0 \le x \le 0.5$), a mixture of fcc and bcc structures (0.5 < x < 1.5), and bcc phase (x > 2.0). Other DFT calculations carried out by Feng et. al ^[38] have confirmed this observation. Also in Ref. ^[39] the authors using DFT-CPA approach concluded that adding Al to CrMnFeCoNi HEA can trigger the phase transformation from fcc to bcc. Therefore, we suggest that in order to stabilize quinary Pd-HEAs and other non-equiatomic Mn-HEAs in simple bcc phase, one needs to add certain amount of bcc stabilizer such as Al.

The radial distribution functions (RDFs) plotted in Fig. 2 and Fig. S2 further support our above conclusion that the Pd-containing HEAs and CFNCM-Ni64, CFNCM-Co64 considered in this study could not stabilize in bcc solid solution phase. RDFs of those undergoing great cell shape and lattice distortion completely lost the standardized RDF characteristics of bcc lattice (see Fig. 1 b, d as reference). Their peaks in RDF spectra are found relocating at positions that quite similar with those of fully relaxed corresponding fcc structures. More surprisingly, RDFs of *bcc* CFNCP, CFNCP-Fe64, and CFNCP-Co64 resemble exactly the same as for corresponding fcc ones (Fig. 2 b,

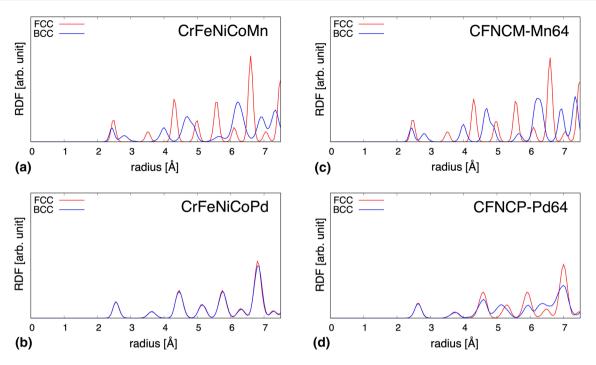

Fig. 2 Radial distribution function of the fully relaxed equiatomic CFNCM (a), CFNCP (b); and non-equiatomic CFNCM-Mn64 (c), CFNCP-Pd64 (d) SQS structures

Fig. S2 e, g). For the fcc Mn- and Pd- sets, in contrast, their RDFs show a lot of similarities with the perfect fcc lattice, excepted for the width of peaks. It is easily seen that all peaks in the fcc sets are broaden due to ionic relaxation. The RDF peaks for the Pd-HEAs are shifted to bigger radius compared to Mn-ones, and their widths are found to be also wider. The findings are in good agreement with other studies on equiatomic HEAs FeCoNiCrMn, FeCo-NiCrPd, and binary Ni₈₀Pd₂₀ alloy.^[40, 41] In addition, the authors have clearly demonstrated that RDF width broadening is because of the fluctuation in nearest-neighbor distances between metal atoms.

Figure 3 shows the renormalized total density of state (DOS) (per atom) and the most important d-orbital partial DOS of the equiatomic CFNCM and non-equiatomic CFNCM-Mn64 HEAs in comparison with the corresponding Pd-ones. All the rest can be found in Fig. S3. Despite of the difference in the (P)DOS shapes from system to system, we recognized some common features between them. Firstly, all shows the majority in spin-up PDOS for ferromagnetic elements Fe, Ni, Co, and Pd (fcc) in which their PDOS shapes could be different from those of corresponding pure elements. Pure fcc Mn is antiferromagnetic however in all considered fcc HEA systems the majority shows it in spin-up states as well. Other antiferromagnetic element Cr, on the orther hand, has majority in spin-down PDOS. Its local spin state is most likely preferred in opposite direction when surrounded by other ferromagnetic elements, and magnetic moment of HEAs

will be reduced as consequence. Secondly, replacing Mn with Pd tends to enhance the asymmetrical characteristics between up- and down- PDOS. Therefore, the magnetic property of the HEAs containing Pd can be improved, for instance, magnetic moment per atom of Pd-rich fcc CFNCP-Pd64 is about 1.5 times bigger than Mn-rich fcc CFNCM-Mn64 (see Table 1). Finally, we observed that in the stable Cr-rich fcc CFNCM-Cr64 and CFNCP-Cr64 systems the asymmetrical characteristics between up- and down- PDOS are reduced for Fe, Ni, Co, Mn and Pd (see Fig. S2 d, h) implying the reduction in magnetic moment of those constituent elements. Indeed, the magnetic moments of the fcc CFNCM-Cr64 and CFNCP-Cr64 systems are reported to be the lowest among our considered systems, being 0.27 and 0.31 μ_B , respectively (see Table 1). Above analysis suggests the possibility of tailoring the magnetic properties of HEAs using specific combination of composition elements.

3.2 Thermodynamics and Energetics

We furthermore investigated the thermodynamics and energetics of Mn- and Pd-HEAs. As already discussed in the previous section, since all Pd-HEAs in bcc structures are unstable due to a large structural distortion; following discussion focuses on the fcc phases of Mn- and Pdquinary HEAs only.

Displayed in Fig. 4 is the comparison for Mn-HEAs and Pd-HEAs of various finite temperature effects contributing

Fig. 3 Total and d-orbital partial density of states of the fully relaxed equiatomic CFNCM (a), CFNCP (b); and non-equiatomic CFNCM-Mn64 (c), CFNCP-Pd64 (d) SOS structures

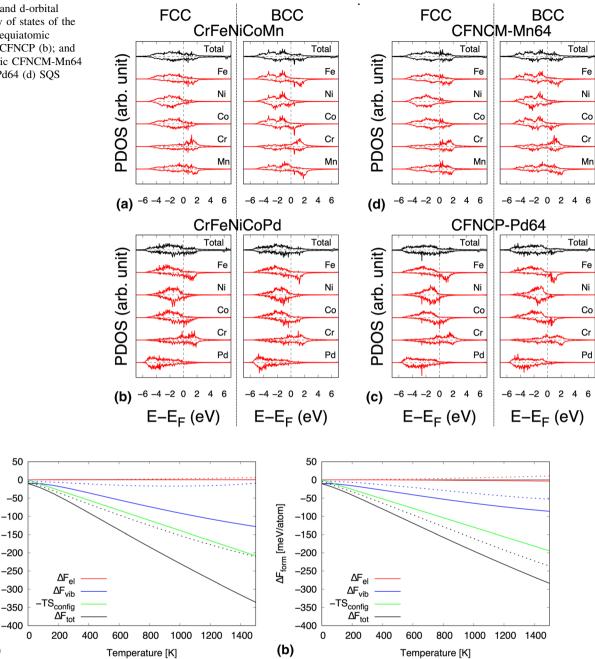

Fig. 4 Thermodynamic contributions to Gibbs formation free energies in the fully relaxed equiatomic CFNCM, CFNCP (a); and non-equiatomic CFNCM-Mn64, CFNCP-Pd64 (b) fcc SOS structures. Results for the fcc Mn-HEAs are in solid lines, and for the fcc Pd-HEAs are in dashed lines

to the Gibbs formation energy up to 1400K, including the lattice vibration ΔF_{vib} , thermal electronics ΔF_{el} , and ideal mixing configurational free energy $-TS_{config}$, in the equiatomic CFNCM, CFNCP and non-equiatomic Mn-rich CFNCM-Mn64, Pd-rich CFNCP-Pd64 HEAs. The contributions of vibrational and thermal electronic free energies are shown separately for all fcc Mn- and Pd- structures in Figs. S4 and S5. It is easily seen that the ideal configurational entropy term is the biggest contribution to free energies in both equiatomic and non-equiatomic systems. Since our specific setting of non-equiatomic $(ABCD)_{24}E_{64}$ SQS structure has 4 constituent elements with equal concentration (15%), it still maintains high-entropy effect. Indeed, at T = 1000K, the calculated configurational free energies -TS_{config} for the equiatomic CFNCM/P and nonequiatomic CFNCM/P-X64 are very close, e.g -139 and -130 meV/atom, respectively. Fig. 4 shows that the lattice vibrational contribution has stronger effect of stabilization in the relevant Mn-HEAs compared to the Pd- counterparts.

∆F_{form} [meV/atom]

(a)

In particular, the contribution of ΔF_{vib} is quite small in the fcc CFNCP and partially reduced by ΔF_{el} , making the total contribution ΔF_{tot} very close to the configurational contribution $-TS_{config}$, while there is bigger gap between the two in the fcc CFNCM.

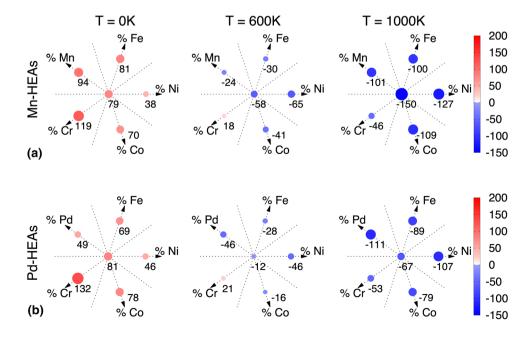

Combining all the finite temperature contributions allows us to visualize the Gibbs formation energy with increasing temperature as shown in Fig. 5. For each 2D plots in Fig. 5, the center circles represent for the equiatomic CFNCM and CFNCP HEAs, and the circles at the %X-axis, %Ni-axis in Fig. 5a for instance, represents for the Ni-rich non-equiatomic fcc CFNCM-Ni64 HEA. At 0K all the studied fcc HEAs have positive formation energies, reflecting the fact that they are not the ground states but the metastable ones. The computed values for the equiatomic CFNCM and CFNCP are very close to each other, 79 and 81 meV/atom, respectively, which are comparable with previously calculated values.^[6, 35, 42] Among our calculated structures, the fcc Ni-rich HEAs (CFNCM-Ni64, CFNCP-Ni64) and Pd-rich (CFNCP-Pd64) are found to be the relatively stable structures with the formation energies of being lower than 50 meV/atom. On the other hand, increasing the concentration of antiferromagnetic Mn and Cr elements is energetically unfavorable. The highest formation energy, 132 meV/atom, is found for the fcc CFNCP-Cr64.

When the temperature stabilization effect of configurational entropy and lattice vibration are considered, the Gibbs formation energies G_f of the fcc quinary Mn- and Pd-HEAs are decreased and change to negative. Indeed, at T = 600K almost all the fcc quinary Mn- and Pd-HEAs became stable, except for the Cr-rich CFNCM-Cr64 and CFNCP-Cr64 (see Fig. 5). The largest reduction in Gibbs 613

formation energy, $\Delta G_f = -137$ meV/atom, was found for the equiatiomic CFNCM. At $T = 1000K, G_f$ values of all computed systems are negative and the fcc Mn-HEAs are more stable compared to the corresponding Pd-ones. The fcc equiatomic CFNCM is the most stable structure, $G_f =$ -150 meV/atom, but when substituting Mn by Pd, the CFNCP HEA becomes one of the least stable ones. This big difference could be explained by comparing the contributions of vibrational and thermal electronic free energies for all the studied systems, see Figs. S4, S5, since the configurational mixing entropies are almost the same. Concerning the thermal electronic contribution ΔF_{el} alone, it shows the destabilization effect for all fcc Pd-HEAs and for some fcc Mn-HEAs (CFNCM, CFNCM-Ni64, CFNCM-Co64), but in overall $|\Delta F_{el}|$ is less than 15 meV/ atom over the whole range of considered temperature for all cases (see Fig. S4 b, S5 b) and can be neglected. The stabilization effect of vibrational free energy, on the other hand, is much more significant for all cases. The effect is maximized in the case of fcc equiatomic CFNCM. When Pd substituting Mn, ΔF_{vib} of the fcc CFNCP is always of the highest value for T > 600K, therefore cannot stabilize the CFNCP as much as for other HEAs.

In Fig.5, it is interesting to notice that the trends in the variation of the formation free energies with increasing temperature in Mn-HEAs and Pd-HEAs, respectively, and compare the two systems. In Mn-HEAs, the formation free energy of the equiatomic one (central circle) is getting more negative than the non-equiatomic ones (X%-axis), indicating that at finite temperature, the equiatomic Mn-HEA is more preferred than non-equiatomic ones. Whereas, the situation in Pd-HEAs is opposite. While the temperature is increasing, the value for central circle is

Fig. 5 Gibbs formation free energies at finite temperature of fcc Mn-HEAs (a) and Pd-HEAs (b). The radius of each circles is proportional to the absolute value of the formation energy

obviously smaller than those for all X%-axes, showing that in Pd-HEAs, various non-equiatomic systems tend to more stable than the equiatomic one. Such observation is consistent with the Ding et al.'s report ^[19], i.e., the existing big composition fluctuations in FeCoNiCrPd.

We are wondering what happens in Pd-HEAs and explored this phenomenon through following analysis using a hypothesis model for quinary HEAs where both equiatomic and non-equiatomic systems co-exist. Here we imagine a sample of CFNCY (Y=Mn, Pd) equal in constituent concentrations but consisting of 5 types of the nonequiatomic CFNCY-X64 in the same portion distributed randomly in the sample. So, the hypothesized CFNCY sample is equiatomic as average but inhomogeneous in local environment, which is taken as the model of hypothetical equiatomic quinary HEAs. For simplicity, the formation energy of the hypothetical equiatomic system is approximately equal to the average of the formation energies of all 5 types CFNCY-X64. Figure 6 shows the estimated Gibbs formation energies of both the hypothesized and of the real modeled equiatomic quinary fcc CFNCM and CFNCP as a function of temperature. It is obvious that for CFNCM, the real equiatomic fcc CFNCM has lower formation energy than the hypothesized one, such energetic preference implies that when one tries to fabricate a quinary CFNCM sample starting with equal atomic concentration of constituents, it is more likely that the equiatomic CFNCM HEA will form with homogeneous elements distribution. This is different for CFNCP, where the hypothesized equiatomic model is more stable than the real one, which leads to a high possibility that equiatomic CFNCP will form with inhomogeneous element distribution, even with a strong fluctuation in local atomic fraction.

This assumption is confirmed by the experimental results reported by Ding et.al. ^[19]. Using energy-dispersive X-ray spectroscopy the authors had investigated the atomic-scale element distribution in equiatomic fcc

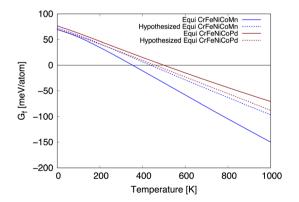

Fig. 6 Gibbs formation free energies as a function of temperature for the hypothesized (dashed lines) and real modeled (solid lines) equiatomic fcc CFNCM (blue) and CFNCP (dark-brown)

CrFeNiCoMn Cantor alloy, and also compared with fcc CrFeNiCoPd HEA. For the CrFeNiCoMn sample, they found a small fluctuation in local atomic fraction around the equiatomic line for all five elements. In contrast to the Cantor alloy, the atomic fraction lines of all five elements in CrFeNiCoPd alloy show a much wider fluctuation with the maxima reaching up to 58%. The fluctuations in both CrFeNiCoMn and CrFeNiCoPd samples seem to be random.

4 Conclusion

In this work, we carried out comprehensive DFT calculations combined with the quasiharmonic Debye-Grüuneisen approximation for both equiatomic and non-equiatomic compositions of CrFeNiCoMn Cantor and CrFeNiCoPd quinary HEAs based on SQS models. Similarities and differences between the two systems as consequences of Pd-to-Mn substitution effect have been highlighted in terms of structural, electronic structure, and magnetic properties, as well as thermodynamics and energetics. It has been found that substituting Mn with Pd in Cantor alloy introduced a inhomogeneous feature into the HEA, which increases the average atomic local displacement of the fcc CrFeNiCoPd to a moderate amount, consequently enhances the mechanical properties of the new HEA. It is also revealed that the stability of equiatomic/near-equiatomic composition is preferable than the extreme non-equiatomic in fcc CrFeNiCoMn HEAs, whereas the situation in fcc CrFeNiCoPd is reverted, that means the mixture of various non-equiatomic compositions is more preferred due to the local inhomogeneous feature, especially for Pd-rich and Ni-rich CrFeNiCoPd HEAs. These findings can explain some experimental observations reported recently. CrFe-NiCoMn and CrFeNiCoPd HEAs are among interesting multi-principal elements alloys representative for novel physical properties and with the potential for advanced applications; and more studies are needed to fully understand the systems. Our work is an effort to enrich the thermodynamic databases of CrFeNiCo(Mn/Pd) HEAs and could be useful for guiding material design and engineering, as well as for other future works.
