REVIEW

Animal Models in Bariatric Surgery—A Review of the Surgical Techniques and Postsurgical Physiology

Raghavendra S. Rao · Venkatesh Rao · Subhash Kini

Abstract Bariatric surgery is considered the most effective current treatment for morbid obesity. Since the first publication of an article by Kremen, Linner, and Nelson, many experiments have been performed using animal models. The initial experiments used only malabsorptive procedures like intestinal bypass which have largely been abandoned now. These experimental models have been used to assess feasibility and safety as well as to refine techniques particular to each procedure. We will discuss the surgical techniques and the postsurgical physiology of the four major current bariatric procedures (namely, Roux-en-Y gastric bypass, gastric banding, sleeve gastrectomy, and biliopancreatic diversion). We have also reviewed the anatomy and physiology of animal models. We have reviewed the literature and presented it such that it would be a reference to an investigator interested in animal experiments in bariatric surgery. Experimental animal models are further divided into two categories: large mammals that include dogs, cats, rabbits, and pig and small mammals that include rats and mice.

Keywords Bariatric surgery · Animal models · Roux-en-Y gastric bypass · Gastric banding · Biliopancreatic diversion · Sleeve gastrectomy

Introduction

Obesity is a rapidly growing worldwide problem. Bariatric surgery is the most effective method of obtaining weight loss in a morbidly obese person (NIH Consensus 1991). A remarkable advantage of these operations is that they can induce resolution of associated metabolic disorders especially type 2 diabetes. The use of animal models is an excellent way of developing and learning bariatric surgical techniques as well as understanding the postsurgical physiology. We are presenting a review of the anatomy and physiology of the animal models and also the surgical techniques and postsurgical physiology of the four main bariatric surgical procedures in various animal models (Table 1).

We have included only those articles which have significantly contributed to the development of modern bariatric surgery in terms of development of techniques as well as understanding the postsurgical physiology.

Overview of Animal Models: Anatomy and Physiology

Pigs

Anatomy

Due to their large body structure, surgical techniques in pigs can be performed to simulate those done in humans. Although the pig stomach is similar to the human stomach, there are a few differences—the cardia is exaggerated [1], the fundus is large [2], the diverticulum ventriculi is a small partially isolated pocket present within the fundus 4 cm distal to the cardia [3], thickened perigastric membranes, and a small lesser sac is present [1, 4]. Unlike the human

small intestine, the pig counterpart has a variable length with an intraperitoneal duodenum [5], smaller caliber, fragile nature [5], and mesenteric vascular arcades in the subserosa [6]. The colon is the same caliber as the small bowel, is supported to the dorsal abdominal wall by the mesocolon, has a spiral course, has a left-sided cecum [2], and lacks a proper transverse mesocolon and appendix [3] (Fig. 1 and 2).

Physiology

Electrical Activity of Intestine In the gastrointestinal tract, the tissue continuity allows coordinated propagation of pacemaker potentials generated by the interstitial cells of Cajal (ICC) network on the neighboring smooth muscle cells, which enables them to generate spike potentials and contract in an organized manner. A natural intestinal pacemaker is located in the duodenum, which controls the intestinal motility [7]. Groner et al. [8] and Zabielski [9] reported that in young pigs, the antral and duodenal electrical control activity frequencies were similar to values in human adults and that the migrating motor complex cycle duration was only slightly shorter.

Dogs

Anatomy

The stomach lies distal to the liver. It is C-shaped with the lesser curvature facing the liver and the greater curvature facing the rest of the abdominal wall. The stomach is very similar to the human stomach having four parts: cardia, around entry of the esophagus; fundus, adjacent to the left
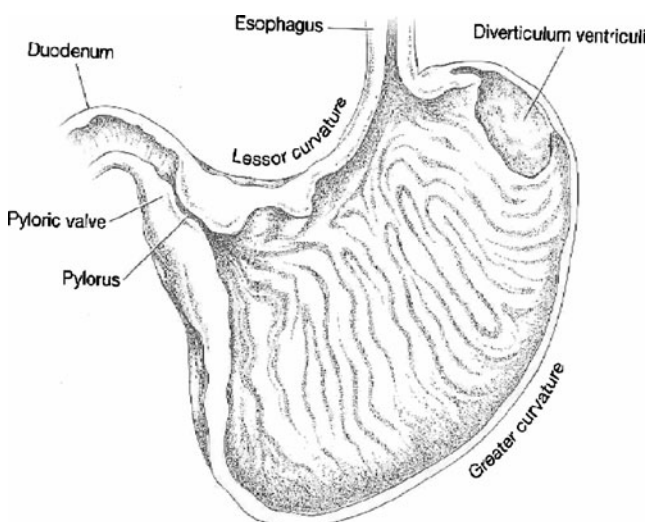

abdominal wall; body, the largest part; and pylorus, adjacent to the right abdominal wall which continues as the small intestine (Fig. 3).

The duodenum has a cranial and a caudal duodenal flexure with an interposed descending duodenum. The caudal flexure is followed by the ascending duodenum which in turn continues as the jejunum, the longest part of dog intestine (Fig. 4). Unlike in humans, the dog ileum is only 15–20 cm long [10].

There is a 5×2-cm-sized [11] short spiral bent [12] tortuous cecum [10] which is puckered [12]. It has no appendix [11]. The ileum does not communicate with the cecum [11]. The large intestine does not differ much in caliber from the small intestine [12] (Fig. 4). The entire colon except the cecum has a mesentry [12].

Rats

Anatomy

In spite of the small size of the organs of the rat, the anatomy of the rat GI tract is strikingly similar to humans (see Figs. 5 and 6).

The esophagus opens into the lesser curvature of the stomach. The rat stomach has a cardia or forestomach which is continuous with the esophagus and is lined by squamous epithelium. It is thinner and relatively non-motile. The fundus and pylorus (glandular stomach) have a similar anatomy as humans [13]. The forestomach and the pylorus are separated by a band of tissue called margo plicatus (limiting ridge) [14]. The greater and lesser omentum and mesentery have a similar anatomy as humans. The liver has four lobes [13].

Unlike the human intestine, the jejunum has the greatest length but cannot be easily distinguished from the other two segments. The ileum is recognized by the presence of large lymph nodes which appear as small bumps on its surface [13].

Given the small organs of the rat, one needs to use microsurgical instruments and techniques.
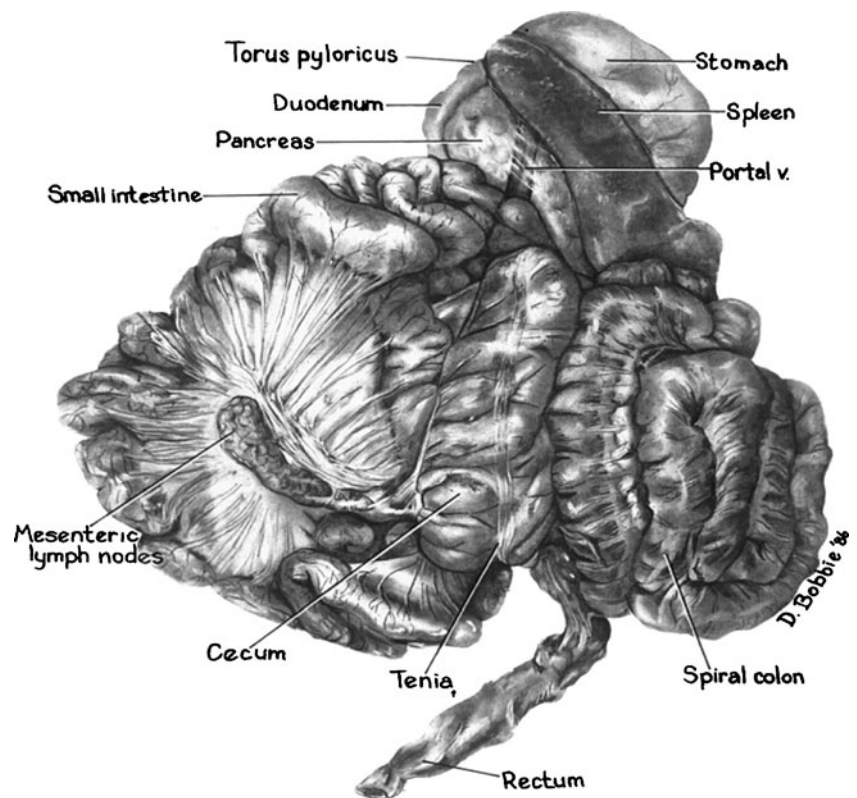

Physiology

The physiological characteristics of the rat models used to study bariatric surgery have been summarized in Table 2:

Given that 10–13 days in a rat's life is equal to one human year, it is possible to learn about long-term physiological changes of bariatric surgery not currently studied in humans.

Two kinds of controls are used: a sham-operated group where the bowels are just exposed after a laparotomy for the same time as the standard operation. The sham-operated group can also be pair fed.

Fig. 1 Anatomy of pig stomach [3] (reproduced with permission from Bluedoor, LLC)

Roux-en-Y Gastric Bypass

Pigs

Pigs have played a leading role as an experimental model in
the development of the surgical technique of Roux-en-Y
gastric bypass (RYGB). In the early 1990s, with the advent
of advanced laparoscopy, several investigators used these
animals to test the safety and feasibility of laparoscopic
RYGB.

The technique of RYGB in pigs is very similar to the
technique in humans, with a few differences due to
anatomical differences (described earlier).

Surgical Technique A 10- to 30-ml gastric pouch is created
using a linear cutting stapler. The pouch can be created using a
Baker's tube [5]. A V-shaped pouch can also be created taking
advantage of the small lesser sac [1]. Since it is difficult to
identify the ligament of Treitz, the duodenum can be followed
to the point where it passes behind the colon. The Roux limb

Fig. 3 Anatomy of dog gastro-
intestinal tract (hand-drawn by
authors)

Fig. 4 The rat stomach (reproduced with permission from Elsevier) [15]

can be positioned either antegastric or retrogastric, but it cannot be retrocolic as there is no proper transverse mesocolon [5]. The gastrojejunostomy can be hand-sewn or stapled. Due to the variable length of the intestine, it is better to calculate the length of the Roux and afferent limbs as a fraction of the total intestinal length [1]. The jejunojejunostomy can be done intracorporeally or extracorporeally and can be either hand-sewn or stapled. Gastrostomy, to avoid gastric dilation, and jejunostomy, for postoperative feeding, have been used by some investigators [28]. Also, the staple lines frequently need to be reinforced with sutures due to the thick stomach wall and perigastric membranes. The fragile nature of intestine causes frequent complications due to leakage—this has to be taken into account when using the pig as a survival model. Awareness of the liver and spleen anatomy is also necessary to avoid complications during retraction [5].

Postsurgical Physiology Flum et al. [1] have studied postsurgical physiology of pigs after RYGB. They found that after RYGB, there was an increase in both the fasting and postprandial ghrelin levels, but no change in fasting and postprandial peptide YY (PYY) levels. They also evaluated food intake and reported that the "limited feeding time" approach produced more weight loss than ad libitum feeding in their pig model.

Kiciak et al. [29] compared "uncut" Roux procedure and RYGB. They reported that there were more ICC in upper jejunum and there was an earlier return of the migrating motor complex in the uncut group than in the RYGB group. They attributed the decrease in postoperative adhesions in the uncut group to this. There is preservation of the natural pacemaker function in the duodenum in an "uncut Roux" technique, whereas ectopic pacemakers develop in the Roux limb, causing retrograde peristalsis and thus slowing intestinal transit.

Rats

Surgical Technique A 20% residual volume stapled gastric pouch is created. The stomach is better divided to avoid gastro-gastric fistulas. The lengths of the biliopancreatic limb, alimentary limb, and common channel used by Meguid et al. are 16, 10, and 34 cm, respectively. Very similar lengths were also used by Aprahamian et al. Increasing the biliopancreatic channel to 30 cm and

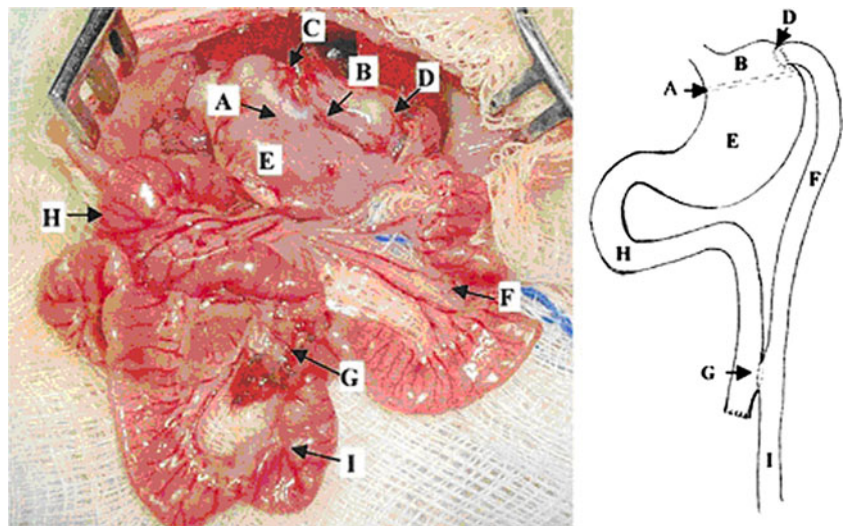

Fig. 5 Rat gastrointestinal tract (reproduced with permission from Elsevier) [15]. *Please note that the limiting ridge in the stomach is shown delimiting the forestomach from hindstomach

Fig. 6 Gastric bypass with Roux-en-Y operation in the rat. **a** Staple line; **b** pouch; **c** gastroesophageal junction; **d** gastrojejunostomy; **e** stomach; **f** Roux-en-Y limb; **g** jejunojejunostomy; **h** afferent limb; **i** efferent limb [32] (reproduced with pemission from Elsevier)

reducing the common channel to 18 cm produces more sustained weight loss [30, 31].

Postsurgical Physiology Rat models of RYGB have been used to study mainly the metabolic aspects of the surgery. Various parameters are affected by RYGB, all of which ultimately contribute to weight loss and resolution of type 2 diabetes mellitus (DM). A review of those parameters is presented in Table 3:

Dogs

Surgical Technique Dogs have mainly been used to study the electrical activity of the stomach and its role in producing weight loss. The operation on the control group consists of implantation of three pairs of electrodes of the cardiac pacemaker type in the serous membrane along the greater curvature of the stomach at the level of fundus, body, and antrum. The electrodes are fixed with sutures to prevent dislocation. The operation done on the experimental group consists of an RYGB; the width of both the gastrojejunostomy and jejunojejunostomy being 5 cm, the latter was placed 25 cm from the former. Paired gastric electrodes are then implanted on the greater curvature of the excluded stomach at the fundus, body, and antrum and fixed with sutures. The electrodes are brought to the exterior and fixed to the abdominal wall. The records of the

Table 2 Types of rats used as models for bariatric surgery

Type of rat	Metabolic profile
Wistar rats	Non-obese, non-diabetic. Also susceptible to obesity, diabetes, and related metabolic disorders when fed a high-fat diet [16]. Specific components of the Western diet can influence development of obesity and in these rats [17].
Sprague–Dawley	Non-obese, non-diabetic. But when fed a high fat diet they develop obesity and impaired glucose tolerance [18, 19].
Zucker fatty rats (fa/fa)	Obese and non-diabetic. They have a mutation of hypothalamic leptin receptors and also profound hepatic insulin resistance [20]. The hyperinsulinemia reaches peak at the 18th week [21], though they have impaired glucose tolerance they do not develop frank diabetes.
Zucker diabetic fatty (ZDF)	Obese and diabetic. They have peripheral insulin resistance due to mutation of GLUT-4 receptors in skeletal muscle and adipose tissue. They also have impaired glucose induced insulin release due to mutation of GLUT-2 receptors in β cells and apoptosis of β cells [22]. But the females can increase insulin production to overcome insulin resistance [23], thus capable of acting as controls.
Goto–Kakizaki	Non-obese diabetic rat model. Have a defect of development of β-cells due to absence of growth factors and defective proliferation of β-cells due to glucotoxicity. Also have hepatic insulin resistance [24, 25].
Fisher-344 (F-344)	Non-diabetic and non-obese. But prone to obesity when fed high-calorie diet [26]. Young rats also develop insulin resistance and increased triglycerides when fed high calorie diet [27].

GLUT glucose transporter

Table 3 Postsurgical changes in rat models after RYGB

Parameter	Postsurgical change after RYGB in rat models
Weight	Decrease [32–37]
Change in adipose tissue	Decreased weight of subcutaneous abdominal, retroperitoneal [33], and mesenteric fat [38]
Food intake	Decrease [32, 35]
Glucose	Decrease [30, 40]
Insulin	Decrease [32]
Ghrelin	Decrease [39]
PYY[a]	Increase [37, 39]
Leptin	Decrease [37, 40, 41]
PYY/Leptin ratio	Increase. Failure to maintain ↑ ratio results in failure of RYGB [31]
GIP and GLP-1	No change in GIP. Increased postprandial GLP-1 [77]
Adiponectin	Initially increased, normalized over time [37]
Endocannabinoids: anandamide and 2-arachnidoglycerol	Decreased at 4 weeks [37]
Cholecystokinin (CCK)	Though it is increased postoperatively levels normalized over time [39, 40]
Gene expression profiles:	Changes in gene expression profiles in arcuate nucleus and subcutaneous fat tissue occuring after RYGB. These genes are related to carbohydrate, fat, protein metabolism and action of neuropeptide and cytokines [43]. Meguid et al. [31] have also studied the changes in expression of genes (like AMPK, UCP-2 and others) in subcutaneous adipose tissue after RYGB
Inflammatory markers	Decrease in inflammation as measured by TNF-α, IL-6, corticosterone and gene profiling [38]

PYY protein YY; *GIP* gastric inhibitory insulinotropic polypeptide, *GLP* glucagon-like peptide, *AMPK* adenosine monophosphate kinase, *UCP-2* uncoupling protein-2

electrical signals are processed by a hardware unit and appropriate software [44].

Postsurgical Physiology Electrical control activity (fasting and postprandial) and electrical response activity were studied to detect any difference in the electrical activity of controls and the experimental groups for each gastric segment on one hand and the different gastric segments of each group on the other [44].

Gastric Banding

Pigs

Surgical Technique Coelho et al. [45] first investigated the technique of placing gastric bands in pigs by laparotomy. With the advent of laparoscopic surgery, there was a need to develop a gastric band which could be placed laparoscopically. Belachew et al. [46], through a series of experiments on their pig model, developed a band that could be placed laparoscopically. They also worked out the method and appropriate instrumentation required for a safe retrogastric dissection.

Postsurgical physiology after gastric banding has not been studied in pigs.

Rats

Surgical Technique Due to anatomical differences, it is very difficult to perform a gastric banding operation equivalent to that in humans [47]. Many techniques of placing bands in rats have been successfully tested. One of them is to place the band between the upper and the lower parts of the stomach after incising the stomach at the boundary between the forestomach and the pylorus (see Fig. 6) [47]. To facilitate appropriate positioning of the pouch, a balloon embolectomy catheter can be inserted into the stomach and pulled against the cardia after inflating the balloon. The band is placed around the lower part of the stomach just below the gastroesophageal junction. To prevent band slippage, the separated stomach is fixed just above the band. The band has also been placed around the glandular stomach without the incision mentioned above [48] by just developing an opening in the greater and lesser curvatures [49]. The forestomach can also be inverted [50]. Different types of bands have been used, but it is relevant here to only mention about adjustable bands which are widely used in humans. The adjustable gastric band used in the rat model is a commercially available (In Vivo Metric, CA, USA) vascular occluding device consisting of a silicone ring (8-mm width, 14-mm diameter) with an inflatable inner lining and a tube which can be

omentum, the greater curvature, and the entire fundus are removed (70–80% of total stomach, which includes 90% of the forestomach and 70% of the glandular stomach). A gastric tube is created with vascular clamps from the antrum to the fundus across both the forestomach and the glandular stomach and closed in three layers with non absorbable suture, starting from the distal antrum (1.5–2 mm from the pylorus) to the angle of His (Fig. 9).

Postsurgical Physiology The changes in the postsurgical parameters have been summarized in Table 5. Pereferrer et al. [58] reported that physiological changes depend on the rat model chosen.

Biliopancreatic Diversion

Pigs

Surgical Technique: Biliopancreatic Diversion with Duodenal Switch (BPD-DS) After attachments of the stomach to the greater curvature are transected, a sleeve gastrectomy is performed. The duodenum is divided just distal to the pylorus, and the anvil of the circular stapler is passed along with an orogastric tube and brought out of the proximal duodenum. After the bowel is transected 250 cm (or 40% of the length of intestine from ileocecal valve to the ligament of Treitz) from the ileocecal valve using a linear cutting stapler, an end-to-side duodenoenterostomy is created between the gastro-duodenal pouch and upper segment of the Roux limb. Then, a side-to-side enteroenterostomy is fashioned between the end of the biliopancreatic limb and a point on the small bowel 100 cm from ileocecal junction. A

Fig. 9 *Top figure* intact rat stomach, *bottom figure* stomach after sleeve gastrectomy (reproduced with permission from Elsevier [14])

Table 5 Postsurgical physiology after sleeve gastrectomy in rats

Parameter	Postsurgical change
Weight	Decrease [14, 58]
Food intake	Decreased [58]
Plasma cholesterol and triglycerides	Decrease [14, 57]
Insulin	Normalized [14, 58]
Glucose	Decrease * [14, 58].
Ghrelin	Controversial [14, 58]
GLP-1	Decrease. Please see ref for details. [58]
Hypothalamic growth hormone secretagogue receptor 1a	High [51]

methylene blue testing of the sleeve gastrectomy and duodenoenterostomy is done. The authors reported that frequent leakage at the duodenoenterostomy site was due to the thin-walled nature of the swine duodenum and that the thickness of the pig stomach requires staples of greater height [59].

Postsurgical physiology after biliopancreatic diversion has not been studied in pigs.

Dogs

Surgical Technique Scopinaro et al. [60] evaluated the feasibility of biliopancreatic diversion in dogs in 1979. The procedure consisted of a three quarters gastric resection, closure of distal duodenum, division of the jejunum 20 cm distal to the ligament of Treitz, an antecolic anti-peristalitic, a gastroentero anastomosis using the distal end of the transected jejunum, and an end-to-side jejuno-ileal anastomosis using the proximal end of the jejunum. The distance of the latter anastomosis from the ileocecal valve was varied in the original experiment by different fractions of the total intestinal length (footnote of Table 6) and was found that a common channel of one sixth of the intestinal length was optimal for allowing adequate weight loss without medical complications.

Postsurgical Physiology Please refer to Table 6 [60].

Rats

Surgical Technique: BPD-DS The bowel is transected 50 cm from the ileocecal valve, and the distal part of the transected intestine is anastomosed end to side with the duodenum 1–1.5 cm from the pylorus. The duodenum is closed distal to this anastomosis with a titanium clip. Though the limb lengths are representative of the human operation, the duodenum is not divided due to technical

Table 6 Postsurgical physiology after BPD-DS in dogs

Parameter	Group 1[a]	Group 2[b]	Group 3[c]	Group 4[d]

[c] Lengths of common channels in different groups as a fraction of total intestinal length: 1/12

[d] Control

reasons. A vertical gastrectomy is performed by excising the entire fibrous membrane, thus removing two thirds of the gastric capacity. Then, a side-to-side enteroenterostomy is fashioned between the end of the biliopancreatic limb and a point on the small bowel 20 cm from ileocecal junction (the alimentary limb being 30 cm and the common limb 20 cm) [61]. But different investigators have used different limb lengths. For example, a common limb of only 5 and 10 cm were created by Zeron et al. and Borg et al., respectively [62, 63] (Fig. 10).

Postsurgical Physiology Various investigators like Jiminez et al., Zeron et al., Borg et al., Nadreau et al., and Evrard et al., have designed rat models for biliopancreatic diversion. All of them have reported reduced weight in their respective animal models [61–65]. The changes in other physiological parameters have been summarized in Table 7.

The cat and rabbit models have not contributed a great deal to our understanding of modern bariatric surgery [66, 67].

Other large animals including non-human primates have not been used to experiment bariatric surgical techniques.

Mouse

Though they are not widely used to study bariatric surgery, these animals have been extensively used as models for obesity and may be useful to study postsurgical physiology of bariatric surgeries. Liu et al. [68] designed a mouse model of RYGB and type 2 DM using the C57BL/6 strain. They used three groups: duodeno-jejunal bypass (DJB), long limb DJB, and sham-operated. They were the first to design a mouse model for bariatric surgery and reported that mouse had several advantages over rats, including being more cost-effective, having quicker postoperative recovery time, and providing greater opportunities for genomic and proteomic manipulations in future research. Also, the C57BL/6 strain

of mouse has already been widely used for diabetes research. In the future, application of the bariatric surgical techniques in knockout or transgenic mice may help in the understanding of the physiological mechanisms of type 2 DM resolution.

Troy et al. [69] studied the physiological effect of gastric banding and RYGB in mice and reported that increased intestinal gluconeogenesis acting through

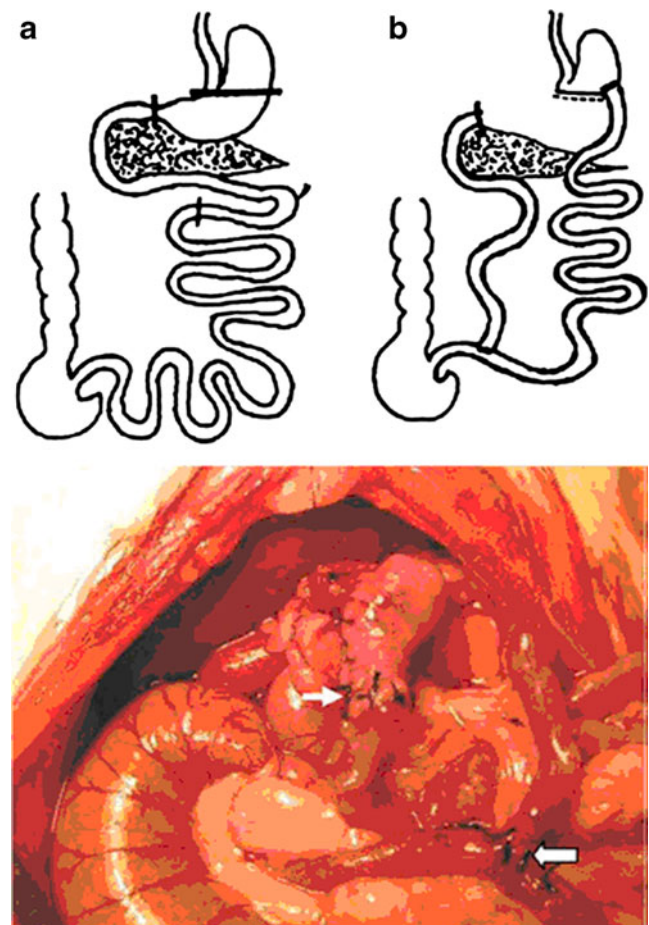

Fig. 10 Rat model of biliopancreatic diversion—duodenal switch (reproduced with permission from Springer) [63]. *Upper* and *lower arrows* indicate gastrojejunostomy and enteroenterostomy, respectively

Table 7 Postsurgical physiology after BPD in rats

Parameter	Postsurgical change
Food intake	Decreased, increased in frequency [61, 62]. Weight loss is maintained irrespective of food intake [63].
Fecal energy density and protein fecal energy	Increased [61]
Adipose tissue	Decreased white epididymal, inguinal, retroperitoneal and brown adipose tissues [61]
PYY	Increase [62]
GLP-1 and GLP-2	Increase [62]
Triglycerides and cholesterol	Decrease [65]
Histology	Increase in surface area of the mucosa and musularis of the common limb [61] due to hyperplasia and hypertrophy [62]
Neurobiologic changes	Increase NPY and AgRP expression in brain [61].

NPY neuropeptide Y, *AgRP* Agouti-related protein

GLUT-2 receptors was responsible for decreased food intake and resolution of glucose intolerance in RYGB-treated rats.

This strain has been used to create genetically modified mouse strains, e.g., ob/ob mouse. C57BL/6J mice fed a high-fat diet develop obesity, mild to moderate hyperglycemia [70], hyperinsulinemia, and hyperlipedemia [71]. Also, obesity developed after high-fat diet tends to be maintained even after switching to regular chow [72]. C57BL/6J mice fed an atherogenic diet (1.25% cholesterol, 0.5% cholic acid, and 15% fat) for 14 weeks develop atherosclerotic lesions. The cytokines and adipokines associated with obesity have been studied in this mouse model [73].

A new mouse model C57BL/6J-Nmf15/+with a dominant mutation has been characterized which develops complications related to the metabolic syndrome (MS) and would be an excellent model for the same and especially for MS-related cardiomyopathy.

Transgenic mice can be maintained by breeding them with C57BL/6 mice. For example, transgenic ob/ob mouse strains with human islet amyloid polypeptide (hIAPP) overexpression have been created and have been proven to develop extensive islet amyloid and higher glucose concentrations [74, 75]. On pathological examination of C57BL/6 mice with diet-induced obesity, islets show no extracellular amyloid, but there is aggregation of amyloid fibrils in the β-cell secretory granules and no reported decrease in β cell mass. Extracellular amyloid is found only in the hIAPP transgenic mice [76]. They are the most widely used lab mouse strain due to the availability of congenic strains, easy breeding, robustness, and their relationship to genetically modified mouse models, making them ideal controls. C57BL/6J was the DNA source for the international collaboration that generated the first high-quality draft sequence of the mouse genome.

Choice of Animal Model

Obviously, surgical techniques are better developed and learnt with the help of large animals. Pigs have been extensively used for this purpose. The physiological changes after these surgeries are better studied using small animals, especially rats. Rats are also useful in developing and learning the surgical techniques to some extent. The choice of the rat model again depends on whether the investigator needs to study the anatomical aspects or the postsurgical physiology. The effects of bariatric surgeries on diabetes are obviously better studied using Zucker diabetic fatty or the Goto–Kakizaki rats. The Sprague–Dawley and Wistar rats have been used extensively to study RYGB and gastric banding, respectively. With a few mouse models being developed more recently, even these could be useful in the future for the study of physiology of bariatric surgeries and especially metabolic surgery.

Conclusion

The efficacy and safety of most novel techniques are better studied in animal models even before pilot studies are performed in humans. The choice of the animal model depends on whether the surgical technique or the postsurgical physiology needs to be studied. Pigs and rats have extensively been used to study various aspects of bariatric surgery. The mouse model for bariatric surgery has been developed recently. Dogs have been widely used to study the electro-physiological aspects of bariatric procedures. Other large mammals have not been used in the recent past to study bariatric procedures. This article is meant to provide a reference and guidance for researchers in bariatric surgery.
