## Abstract

This study focused on O<sub>3</sub> variations and the titration effects of NO<sub>x</sub> during nighttime at urban, industrial, sub-urban and background sites. Nighttime O<sub>3</sub> concentration variations and the presence of high particles with an aerodynamic diameter of less than 10 μm (PM<sub>10</sub>) were examined because haze disturbs the photochemical reactions of O<sub>3</sub>. Hourly data on O<sub>3</sub>, NO<sub>2</sub>, NO and PM<sub>10</sub> concentrations provided by the Air Quality Division of the Department of Environment were divided into two groups of daytime and nighttime and analysed. The maximum O<sub>3</sub> concentrations during daytime were generally observed during noon. At nighttime, the concentration of O<sub>3</sub> decreased, indicating that destruction activities occurred mainly via titration. The retention of O<sub>3</sub> during daytime caused the nighttime O<sub>3</sub> during haze events to be higher than that during normal days. Apparent fluctuations in nighttime O<sub>3</sub> concentrations were observed in the urban site (20 ± 13 ppb) during haze events. The NO<sub>2</sub>/NO ratio in the urban site during haze was higher than that on normal days; amongst the sites, the urban one had the highest value (6.6). Results indicated that during haze, the reactions between NO and O<sub>3</sub> were enhanced at nighttime, leading to low nighttime NO concentrations. The low nighttime NO concentrations led to low nighttime NO titration rates, which enabled O<sub>3</sub> to persist in ambient air. Nighttime O<sub>3</sub> was not completely absent due to anthropogenic sources. This condition accelerated NO titration to NO<sub>2</sub>, thus promoting O<sub>3</sub> production even during haze.

## Introduction

O<sub>3</sub> exists as a secondary pollutant in the lower atmosphere, where its formation and destruction highly depend on UV radiation and the intensity of its precursors, such as NO<sub>x</sub> (Ainsworth et al. 2012; Hassan et al. 2013; Alghamdi et al. 2014). Aside from being a secondary pollutant that requires UV light to complete its photochemical reactions, O<sub>3</sub> is a noxious air pollutant and recognised as the second most significant air pollutant in Malaysia (Rahman 2013). O<sub>3</sub> is toxic to humans and vegetation

at the ground level due to its capability to oxidise biological tissues (Brimblecombe 2009; Pugliese et al. 2014).

The transformational characteristics of O<sub>3</sub> during haze are crucial for understanding the role of this air pollutant in such an event. Haze conditions may trigger high O<sub>3</sub> photochemical reactions, which intensify the effects of high particulate events resulting from large increments in ambient particulates and O<sub>3</sub>. McNaught and Wilkinson (1997) explained that haze is a phenomenon where the readings of an environmental application programme interface consecutively exceed 100 within a 72-h period or longer. They measured the level of visibility interference in the atmosphere by using the coefficient of haze. Quan et al. (2014) reported that stagnation weather, which is generally characterised by low wind speeds and decreased planetary boundary layer height, is the dominant factor in haze events, followed by high particulate emission. Wildfires or biomass burning from the open burning of agricultural residues and forest fires are the major sources of haze, especially in Southeast Asia (Velasco and Rastan 2015; Ahmed et al. 2016). Haze also originates from anthropogenic sources, which are mainly contributed by growing urbanisation and expanding economic activities (Rahman 2013).

In Malaysia, the high frequency of large-scale biomass burning adversely affects air quality. Several researchers have reported that the long-range transport of air pollution from Sumatera (Ashfold et al. 2017; Kusumaningtyas and Aldrian 2016; Dominick et al. 2015; Khan et al. 2016; Latif et al. 2012) and the prolonged dry weather in Southeast Asia reduce the air quality in Peninsular Malaysia and other neighbouring countries; for example, Singapore experienced extensive haze in June 2013 (DOE 2013; Rahman 2013). Awang et al. (2018) found that light scattering influences the amount of sunlight that penetrates the Earth and the formation of ground-level ozone. Given that ozone requires precursors for their formation, the frequent occurrence of haze as indicated by elevated air pollution index (API) levels essentially represents the rate of transformation of ozone in the atmosphere (Awang et al. 2018).

Theoretically, the O<sub>3</sub> concentration in daytime is higher than that in nighttime because photochemical reactions could occur with the availability of insolation (Alghamdi et al. 2014; Kumar et al. 2015; Reddy and Pfister 2016). The absence of solar radiation during nighttime decreases the O<sub>3</sub> photochemical reaction rate and O<sub>3</sub> concentrations due to continuous chemical destruction by NO and titration (Ghosh et al. 2013). NO<sub>2</sub> does not photolyse at night; as a result, the chemistry of the NO<sub>x</sub> family at night is entirely different from that during daytime. The steady state of O<sub>3</sub> concentration is directly proportional to the NO<sub>2</sub>/NO ratio (Clapp and Jenkin 2001; Han et al. 2011). Han et al. (2011) reported that O<sub>3</sub> concentration build-up is high in the presence of small values of [NO<sub>2</sub>]/[NO] and reaches stable conditions when the O<sub>3</sub> concentration exceeds 90 ppb. However, during nighttime, NO<sub>2</sub> and NO cease to be O<sub>3</sub> precursors and become O<sub>3</sub> reduction agents (Awang and Ramli 2017). Any NO present at night reacts rapidly with O<sub>3</sub> (Eq. (1)). As a result, almost all NO<sub>x</sub> at night is converted to NO<sub>2</sub>, which reacts with O<sub>3</sub> to produce a nitrate radical (NO<sub>3</sub>) (Eq. (2)) (Brown and Stutz 2012) and subsequently removes nighttime O<sub>3</sub> concentration from ambient air.

Nighttime processes considerably influence the next day's photochemistry and refine our understanding of the role of heterogeneous processes (reaction between gas- and particulate-phase constituents) occurring at night (Brown and Stutz 2012). Studies have found that up to 50% of freshly emitted NO<sub>x</sub> within a 24-h period in urban areas can be removed through nighttime processes (Stutz et al. 2010). NO<sub>x</sub> from anthropogenic sources, especially vehicle exhaust, is broken down during nighttime and form NO<sub>3</sub>, which is naturally destroyed at night (IDA 2010). Awang et al. (2015) recorded high nighttime O<sub>3</sub> concentrations in Kemaman, Terengganu (Malaysia), due to inefficient removal

mechanisms. Ineffective removal or depletion mechanisms cause high O<sub>3</sub> concentrations to remain in the atmosphere and could exert negative effects. Awang and Ramli (2017) emphasized that NO and NO<sub>2</sub> play essential roles in O<sub>3</sub> elimination. Their results confirmed that high nighttime NO concentrations further enhance the destruction of nighttime O<sub>3</sub> concentrations. Dey et al. (2017) found that the diurnal variation of O<sub>3</sub> during nighttime is higher than that during daytime in an industrial site in Golgapur, India. According to Kulkarni et al. (2013), increased nighttime O<sub>3</sub> concentration is associated with prevailing meteorological conditions and transport processes because the photochemical production of O<sub>3</sub> ceases with the absence of sunlight. This explanation could be valid only when the supply of NO<sub>2</sub> at night is constant.

Studies on nighttime O<sub>3</sub> fluctuation during high particulate events (haze) are scarce in Malaysia. Previous studies have confirmed that aerosol particles affect the surface O<sub>3</sub> concentration in Tianjin (Gu et al. 2010; Han et al. 2011). Recently, Awang et al. (2018) reported that haze disturbs the photochemical reactions of O<sub>3</sub>. The present study aims to assess variations in nighttime O<sub>3</sub> concentrations during normal days and haze events in Malaysia.

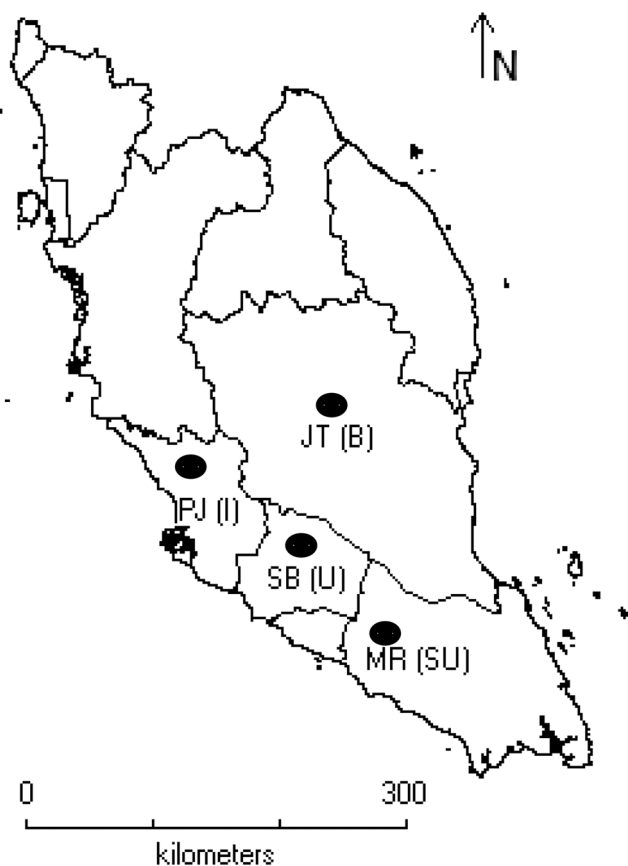

## Material and methods

### Sampling sites

This study was conducted in four continuous air quality monitoring stations in Malaysia; these stations represent different categories of urban (Seremban (SB)), industrial (Petaling Jaya (PJ)), sub-urban (Muar (MR)) and background (Jerantut (JT)) sites located in Peninsular Malaysia, as shown in Fig. 1. The occurrence of haze for over 24 h was the primary criterion for selecting the study areas because haze is considered to occur once the API value exceeds 100 for 24 h. Figure 2 shows the differences in the trends of PM<sub>10</sub> concentrations during normal days and haze events.

### Sampling measurements

The data for this study, including hourly O<sub>3</sub>, NO<sub>2</sub>, NO and PM<sub>10</sub> concentrations, were obtained from the Air Quality Division of the Department of Environment, Ministry of Natural Resources and Environment of Malaysia. These variables (NO<sub>2</sub>, NO and PM<sub>10</sub> concentrations) were selected because of their relationship with O<sub>3</sub> production (Clapp and Jenkin 2001; Ahamad et al. 2014). The haze events in three consecutive years (2013, 2014 and 2015) were regarded as the baseline of nighttime ground-level ozone variations during normal days and haze events. The occurrence of haze for over 24 h was the main criterion for selecting the study areas. Meanwhile, data for normal days refer to the remaining data

**Fig. 1** Location of the study areas at urban, industrial, sub-urban and background sites

for a particular month of the year. Daylight hours (daytime) were defined as the complete hours that fall between sunrise and sunset (Clapp and Jenkin 2001). Nighttime hours ranged from 7 p.m. to 7 a.m. (12 h), as used by Mohammed et al. (2013), Awang et al. (2015) and Awang and Ramli (2017) for the observation of nighttime  $O_3$  diurnal characteristics in Malaysia.

**Fig. 2**  $PM_{10}$  concentrations at urban, industrial, sub-urban and background sites during normal days and haze events

Hourly  $O_3$  concentration was measured with a UV absorption ozone analyser (Model 400E). The device was operated using the Beer–Lambert Law, which is based on the internal electronic resonance of  $O_3$  molecules with the absorption of 254 nm UV light for measuring low ranges of  $O_3$  concentration in ambient air (Ghazali et al. 2010; Mohammed et al. 2013).  $NO_2$  and  $NO$  concentrations were determined using a  $NO/NO_2/NO_x$  analyser (Model 200A) (Ghazali et al. 2010; Latif et al. 2014).  $PM_{10}$  concentration was determined with a BAM-1020 continuous particulate monitor (Met One Instruments, Inc., USA), a high-resolution equipment that can measure  $PM_{10}$  concentrations that are as low as 4.8 and  $1.0 \mu g m^{-3}$  for 1 and 24 h, respectively (Latif et al. 2014).

## Results and discussion

### Nighttime and daytime ozone measurements

During haze, SB had the highest mean daytime and nighttime  $O_3$  concentrations with a mean value  $\pm$  standard deviation of  $41 \pm 16$  ppb and  $20 \pm 13$  ppb, respectively, as shown in Table 1. During normal days, given that photochemical reactions occur during daytime, the  $O_3$  concentration was higher than that at nighttime. The nighttime  $O_3$  concentrations observed at this site are higher than the values reported for other cities, such as Kemaman (Awang et al. 2015, 2016), Kolkata (Ghosh et al. 2013) and Portugal (Kulkarni et al. 2013) on a typical day (14, 12 and 10 ppb, respectively). Usually, the lack of human activities at night reduces  $NO$ , which eventually leads to low titration (Yusoff et al. 2019).

During haze, the nighttime  $O_3$  concentrations were higher than those on normal days because the efficiency rate of  $NO_x$  photochemical reactions increased due to daytime  $O_3$  retention. The variations in nighttime  $O_3$  concentrations in all the sites suggested that the  $O_3$  concentrations during haze were higher than those during normal days. High  $O_3$  concentrations are likely to be found in cities due to high emissions of  $O_3$  precursors (Dufour et al. 2010; Ran et al. 2012) and high occurrence frequency of haze (Awang et al. 2018).

The mean nighttime  $O_3$  concentrations ranged from 10 to 20 ppb. The minimum concentrations were observed from 4 to 6 a.m. Similar to the findings of He et al. (2012), the mean concentrations ranged from 6 to 12 ppb. Saxena and Ghosh (2011) reported that the lifetime of tropospheric  $O_3$  with minor amounts of  $NO_x$  is approximately 4–5 days to 1–2 weeks, and hydrocarbons act as an  $O_3$  sink. Meanwhile, at the atmosphere, the lifetime of  $O_3$  is very short (typically hours), especially at high  $NO_x$  concentrations (Young et al. 2013). These low concentrations of  $O_3$  are due to the absence of photochemical reactions that directly convert  $O_3$  precursors into  $O_3$  (Awang et al. 2015). In the current study, JT (background site) showed the lowest concentrations during normal days

**Table 1** Variations in daytime and nighttime O<sub>3</sub> (mean ± standard deviation)

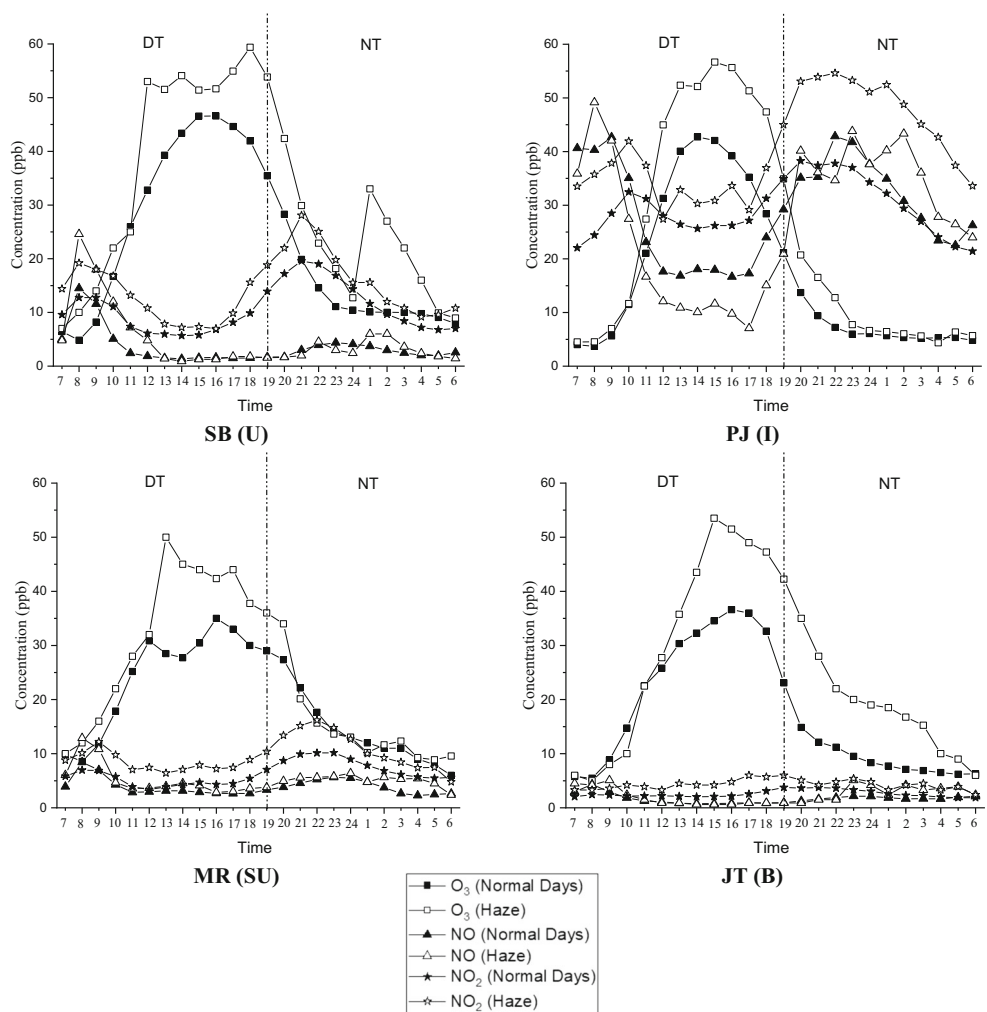

Station (category)	Condition	Daytime O <sub>3</sub> concentration (ppb)	Nighttime O <sub>3</sub> concentration (ppb)
SB (urban)	Normal days	32 ± 14	12 ± 14
	Haze	41 ± 16	20 ± 13
PJ (industrial)	Normal days	31 ± 11	15 ± 6
	Haze	36 ± 12	17 ± 9
MR(sub-urban)	Normal days	26 ± 7	13 ± 7
	Haze	34 ± 12	15 ± 8
JT (background)	Normal days	23 ± 11	10 ± 7
	Haze	36 ± 13	12 ± 7

and haze, with mean nighttime O<sub>3</sub> concentrations of 10 ± 7 ppb and 12 ± 7 ppb, respectively.

### Diurnal variation in O<sub>3</sub>, NO, NO<sub>2</sub> and PM<sub>10</sub>

Sunlight induces O<sub>3</sub> photochemical reactions at daytime. Hence, the maximum O<sub>3</sub> concentrations are recorded at noon-time in all the sites, as shown in Fig. 3. Meanwhile, during

nighttime, O<sub>3</sub> concentrations are theoretically supposed to be zero due to the absence of photochemistry reactions and other destruction processes. However, in this study, high nighttime O<sub>3</sub> concentrations were observed early at night (7 p.m.) and began to decrease until 10 p.m., suggesting that destruction activities occurred mainly through titration. Particles influenced the interaction of O<sub>3</sub> and solar radiation, similar to the results of previous modelling experiments (Li et al. 2011; Péré

\*Bold with significant value at  $p < 0.05$

et al. 2015) that showed that particles decrease daytime O<sub>3</sub> concentrations by 2–17%. The O<sub>3</sub> nighttime chemistry is a new piece of the air quality puzzle. According to Brown and Stutz (2012), nighttime cleansing is slowed down by 7% by the effects of light pollution in Los Angeles, thus increasing O<sub>3</sub> formation the next day by up to 5%. Similarly, nighttime O<sub>3</sub> variation was observed in the current study during haze, and the concentration recorded during haze was higher than that during normal days at all sites. The nighttime O<sub>3</sub> concentrations during haze were influenced by the rate of removal reactions but were unchanged even under high NO<sub>x</sub> reactions.

During daytime, the NO<sub>2</sub> peaks occurred about 1–2 h after the NO peak, and the O<sub>3</sub> peak emerged 6 h after the NO peak (Han et al. 2011; Banan et al. 2013). At nighttime, the NO<sub>2</sub> peaks usually occurred 3 h before the NO peak and about 2 h after the O<sub>3</sub> peak in all the sites. This pattern may be due to the

nocturnal planetary boundary layer, where the surface emissions of NO are retained under this inversion and cause the hourly NO<sub>x</sub> concentration to increase during nighttime. In many instances, these variations depend on site location, local emission of precursor gases (An et al. 2015; Wang et al. 2017; Zhao et al. 2018) and meteorological conditions (Yusoff et al. 2019; Reddy and Pfister 2016; Li et al. 2017).

NO and NO<sub>2</sub> during nighttime in the current study exhibited the same trend as those in the work of Han et al. (2011), Awang and Ramli (2018) and Awang et al. (2018). They began increasing with the destruction of O<sub>3</sub>. The variations during normal days and haze were similar, and NO<sub>2</sub> was always higher than NO. Two peaks (i.e. 8–9 a.m. and 9–10 p.m.) were observed in all the sites, and the maximum NO<sub>2</sub> mean concentrations ranged from 5 to 47 ppb. The fluctuation in the urban site was clearer than that in the industrial,

**Fig. 4** Ratio of NO<sub>2</sub>/NO and O<sub>3</sub>/NO

sub-urban and background sites during haze. This finding is similar to that obtained by Awang et al. (2018), who reported that urban sites have higher PM<sub>10</sub> concentrations than other sites.

Table 2 shows the Pearson correlation results of nighttime O<sub>3</sub> concentrations with NO, NO<sub>2</sub>, PM<sub>10</sub>, temperature, relative humidity and wind speed. During nighttime, temperature exerted a direct effect on O<sub>3</sub> formation (positively correlated). During haze, O<sub>3</sub> and PM<sub>10</sub> were positively correlated. The highest association was recorded in the background site (JT with 0.86), and the urban site (SB) exhibited the lowest association of 0.52. Meanwhile, a negative correlation between O<sub>3</sub> concentration and NO, NO<sub>2</sub> and relative humidity was found during normal days and haze in all the sites. Thus, the production of O<sub>3</sub> during nighttime could be associated with the decrease in NO, NO<sub>2</sub> and relative humidity. High relative humidity could enhance O<sub>3</sub> cleansing through wet deposition. Similar findings were obtained by Toh et al. (2013) and Awang et al. (2015).

### Nighttime NO<sub>2</sub>/NO and O<sub>3</sub>/NO ratio

Figure 4 shows the mean ratios of NO<sub>2</sub>/NO and O<sub>3</sub>/NO for all the sites. The concentrations of O<sub>3</sub> increased as the ratio of NO<sub>2</sub>/NO increased. All sites showed higher NO<sub>2</sub>/NO ratios during haze than during normal days, and the urban site (SB) had the highest value (6.6). These results suggest that haze enhanced the reactions between NO and O<sub>3</sub>, resulting in reduced nighttime NO in air. Atkinson (2000) indicated that during nighttime, NO reacts with O<sub>3</sub> and produces NO<sub>2</sub>, which in turn produces NO<sub>3</sub> and N<sub>2</sub>O<sub>5</sub>. Evidently, net production of O<sub>3</sub> still occurs after these conversions.

In the present study, a high NO<sub>2</sub> was recorded in the urban site (SB) due to the contribution of anthropogenic sources, particularly from the downtown site, during haze. Given that NO titration is limited during haze (Awang et al. 2018), the conversion of NO into NO<sub>2</sub> is also limited. This observation is supported by the findings of Khalil et al. (2018). They studied nighttime O<sub>3</sub>

concentrations in Makkah and found that nighttime activities in all cities cause high NO<sub>2</sub> and NO concentrations and contribute to the high O<sub>3</sub> concentration at night. Low nighttime NO titration rates could reduce nighttime O<sub>3</sub> (Banan et al. 2013), thus enabling O<sub>3</sub> to persist in ambient air.

### Conclusions

This study revealed fluctuations in nighttime O<sub>3</sub> concentrations, especially in urban sites (SB). The mean nighttime O<sub>3</sub> concentrations ranged from 10 ± 7 ppb to 20 ± 13 ppb. The minimum levels during daytime were observed from 4 to 6 a.m., with the mean levels ranging from 6 to 12 ppb. The daytime O<sub>3</sub> level affected the nighttime O<sub>3</sub> level even during haze but at different magnitudes; the value during haze was higher than that during normal days in all the sites. All of the sites showed higher NO<sub>2</sub>/NO ratio during haze than during normal days, with the urban site (SB) having the highest recorded value (6.6). Increased NO may result in high levels of nighttime O<sub>3</sub>. During haze, the enhanced reactions between NO and O<sub>3</sub> at nighttime lead to low nighttime NO concentrations. Thus, we suspect that additional anthropogenic sources accelerate NO titration to NO<sub>2</sub> and directly increase the O<sub>3</sub> concentrations during nighttime in haze events.
