# **Abstract**

An optimization approach for black-and-white and hinge-removal topology designs is studied. To achieve this motive, an optimal topology allowing grey boundaries is found firstly. When a suitable design has been obtained, this solution is then used as a starting point for the follow-up optimization with the goal to free unfavorable intermediate elements. For this purpose, an updated optimality criterion in which a threshold factor is introduced to gradually suppress elements with low density is proposed. The typical optimality method and new technique proposed are applied to the design procedure sequentially. Besides, to circumvent the one-point hinge connection problem producing in the process of freeing intermediate elements, a hinge-removal strategy is also proposed. During the optimization, the binary constraints on design variables are relaxed based on the scheme of solid isotropic material with penalization. Meanwhile, the meshindependency filter is employed to ensure the existence of a solution and remove well-known checkerboards. In this way, a solution that has few intermediate elements and is free of one-point hinge connections is obtained. Finally, different numerical examples including the compliance minimization, compliant mechanisms and vibration problems demonstrate the validity of the proposed approach.

## **1. Introduction**

By means of the method of topology optimization, general topology optimization problems, such as the compliance minimization, compliant mechanisms and vibration problems, can be posed as material distribution problems. During the process of solving, the design domain is usually divided into a certain number of finite elements. Subsequently, to determine the optimal placement of a given isotropic material in the design space, a numerical optimization cycle is needed. For reasons of the manufacture, a black-and-white (0-1) structural topology is classically desired, whereas it requires mathematical programming that can handle lots of discrete 0-1 design variables, such as simulated annealing [1, 2], genetic algorithm [3, 4], sequential integer programming methods [5, 6], dual method [7, 8], and methods for global optimization [9, 10], and so on. However, it is computationally prohibitive to solve the optimum problem using these methods. Thus, the most common approach to circumvent solution difficulties is still to relax design variables, i.e. replace the integer variables with continuous variables [11-21], so that the material distribution problem can be solved using most mathematical programming with continuous design variables. Among the relaxation methods, two major approaches, namely microstructure based and power law based, are used in the field of the topology optimization. The homogenization technique [11, 12], which determines the optimal material distribution by designing the size parameters of microstructures, is a representative microstructure method. This technique is effective for a large class of elasticity problems, but it commonly needs a lot of design variables and results in topologies with micro perforations, checkerboards and one-point hinge connections. As an alternative, SIMP (solid isotropic material with penalization) method has thereby become increasingly popular due to its advantages in computation efficiency and conception simplicity. This method directly treats the material density of each element as a design variable, which reduces the size of the optimization problem to a large extent [13-19], whereas it is noteworthy that the SIMP method could produce topologies with intermediate elements. It is very impractical and of high cost to produce structural elements with varied densities. This means that the intermediate values of this artificial material model should be penalized in some manner to make them uneconomical. In past works, researchers usually ensured continuous design variables to be forced towards a black and white solution by applying a penalization on the density of element as  $\rho^p$ ,  $(p > 1)$  [13-18]. But this penalization method is

prone to lead to checkerboards and one-point hinge connections. This necessitates applications of some restriction methods, such as the perimeter [22], local gradient [23] and meshindependency filter [24, 25]. By exerting a length scale on the variable variation, these methods can make checkerboards and one-point hinge connections to be arbitrarily weak, but grey band could thus be brought around the topology again, as reviewed in Refs. [20] and [26]. Another method is to employ a specified threshold value to obtain elements with normalized densities equivalent to either 1.0 or 0.0 [27, 28]. However, it is not evident how to choose the threshold value appropriately in where  $\rho_{\min}$  is a positive lower bound and taken the value of these works. In order to relieve intermediate elements in the resultant topologies, explicit penalization terms are also proposed to either append to the objective function [29] or impose as a separate constraint [30]. However, it is also possible for the extra penalization terms to cause difficulties for the optimization software in finding a feasible solution. In addition to the above methods, other methods include a simple heuristic for gray-scale suppression by the modification of the optimality criterion statement by Groenwold et al. [19], a method combing a separate constraint and a post-processor based on the sequential linear integer programming by Werme [31], filtering techniques based on image processing by Sigmund [32] and Wang et al. [33], a hybrid SINH method by Bruns [34], evolutionary structural optimization method by Chu et al. [35], complex-shaped beam element and graph-based optimization by Sauter et al. [36], A hybrid methodology combining simulated annealing and SIMP by Garcia-Lopez et al. [37], standardized elements by Jang et al. [38], curve-based methods by Luo et al. [39], James et al. [40], Wang et al. [41] and Zhou et al. [42].

In this paper, an optimization approach for black-and-white and hinge-removal topology designs is studied. To achieve this motive, an optimal topology allowing grey boundaries is found firstly. When a suitable design has been obtained, this solution is then used as a starting point for the follow-up optimization with the goal to free unfavorable intermediate elements. For this purpose, an updated optimality criterion in which a threshold factor is introduced to gradually suppress elements with low density is proposed. The typical optimality method and new technique proposed are applied to the design procedure sequentially. Besides, to circumvent the one-point hinge connection problem producing in the process of freeing intermediate elements, the hinge-removal strategy is also proposed. During the optimization, the binary constraints on design variables are relaxed based on the scheme of solid isotropic material with penalization. Meanwhile, the meshindependency filter is employed to ensure the existence of a solution and remove well-known checkerboards. In this way, a solution that has few intermediate elements and is free of one point hinge connections is obtained. Finally, different numerical examples including the compliance minimization, compliant mechanisms and vibration problems demonstrate the validity of the proposed approach.

design variables. In the present appr

$$
\mathbf{K}^0 = \int_{V_s} \mathbf{B}^T \mathbf{D} \mathbf{B} dV \tag{3}
$$

where  $V_e$  is the material volume of a solid element, **B** is the strain matrix of a point of a solid element. On the other hand, the element mass matrix  $M_e$  in the vibration problem is also the function of the element density and can be written as: **s** is hxet at  $p = 3$  to naster the optimization con-<br>
genee,  $K^0$  is the stiffness matrix of an arbitrary solid ele-<br>
and can be written as:<br>  $K^0 = \int_{V_c} B^T DBdV$  (3)<br>  $\int_{V_c} B^T DBdV$  (3)<br>  $\int_{V_c} B^T DBdV$  (3)<br>  $\int_{V_c} B^T DBdV$ ere  $V_e$  is the material volume of a solid element, *B* is the<br>in matrix of a point of a solid element. On the other hand,<br>element mass matrix  $M_e$  in the vibration problem is also<br>function of the element density and can

$$
M_e = \rho_e^q M^0 \tag{4}
$$

where *q* is a penalization factor, normally  $q = 1$  is chosen [43],  $M^0$  represents the element mass matrix of an arbitrary solid element and can be written by using the shape function matrix  $N_s$  and the material density  $\rho_{\text{mat}}$  as:

$$
\boldsymbol{M}^0 = \int_{V_c} \rho_{\text{mat}} \boldsymbol{N}_s^T \boldsymbol{N}_s dV. \tag{5}
$$

Note that localized eigenmodes may occur in subregions of the design domain with low values of the material density  $(e.g., \rho_e \le 0.1)$  [43, 44]. For this reason,  $M_e$  is thus rewritten as [43]: mass matrix  $M_e$  in the vibration problem is also<br>of the element density and can be written as:<br>(4)<br>a penalization factor, normally  $q = 1$  is chosen<br>presents the element mass matrix of an arbitrary<br>t and can be written by on of the element density and can be written as:<br>  $P_e^g M^0$  (4)<br>
is a penalization factor, normally  $q = 1$  is chosen<br>
represents the element mass matrix of an arbitrary<br>
nent and can be written by using the shape function of the element density and can be written as:<br>
(4)<br>
(4)<br>
penalization factor, normally  $q = 1$  is chosen<br>
resents the element mass matrix of an arbitrary<br>
and can be written by using the shape function<br>
the material densit

$$
\boldsymbol{M}_e = \begin{cases} \rho_e \boldsymbol{M}^0 & (\rho_e > 0.1) \\ 10^5 \rho_e^6 \boldsymbol{M}^0 & (\rho_e \le 0.1) \end{cases}
$$
 (6)

From Eqs. (2) and (6), the global stiffness matrix *K* and mass matrix *M* can be formulated as:

$$
K = \sum_{e} K_{e}, \quad M = \sum_{e} M_{e} \tag{7}
$$

#### *2.2.2 Compliant mechanism problems*

A compliant mechanism should be flexible so that it can easily deform to achieve given mission, but it should also be stiff to provide an adequate mechanical advantage and working stability [20, 21, 45]. Usually, the strain energy and mutual potential energy are respectively formulated as measures for removal strategy is proposed in the present study. Specifically, the overall stiffness and flexibility of a compliant mechanism. Assuming that active load  $F_{in}$  is specified, again assuming unit dummy load  $F_{out}$  is applied at output point in the direction of the output displacement, the compliant mechanism problem can be defined in terms of these two conflicting objectives as [45-51] or with zero, and origines of incredibition of the minut and solutions during the<br>

sens, as plotted in F

$$
\begin{cases}\n\rho_{e_{11}} \leq \delta_1 \\
\rho_{e_{21}} \leq \delta_1 \\
\rho_{e_{31}} \geq \delta_2 \\
\rho_{e_{41}} \geq \delta_2\n\end{cases}
$$
\n(13)

with  $\delta_1 < \delta_2$ ,  $\rho_{e_1}$ ,  $\rho_{e_2}$ ,  $\rho_{e_3}$  and  $\rho_{e_4}$  are respectively den-<br> $\ldots$ , N sities of elements  $e_{11}$ ,  $e_{21}$ ,  $e_{31}$  and  $e_{41}$ . If the condition in Eq. (13) holds true, one can determine that elements  $e_{11}$ ,  $e_{21}$ ,  $e_{31}$ and *e*41 constitute a potential patch of the one-point hinge con nection, as shown in Fig. 1(a) or Fig. 1(b). Of these, elements  $e_{11}$  and  $e_{21}$  are ones with relatively low density, while elements *e*<sup>31</sup> and *e*41 are ones with relatively high density. In order to cure the hinge patch checked, densities of elements  $e_{11}$  and  $e_{21}$ are then modified by using ones of elements *e*<sup>31</sup> and *e*<sup>41</sup> as

Fig. 1. The cases of one-point hinge connection: (a)  $H = 1$ ; (b)  $H = 1$ ; (c)  $H = 1$  and  $H = 2$ ; (d)  $H = 1$  and  $H = 3$ ; (e)  $H = 1$  and  $H = 4$ .

$$
\hat{g}(\rho_e) = \frac{1}{2} (\rho_{e_{31}} + \rho_{e_{41}})
$$
\n(14)

where  $\hat{g}(\rho_e)$  is the modified density of element *e*, *e* respresents low-density element  $e_{11}$  or  $e_{21}$  possessed by a potential onepoint hinge patch. To including all cases shown in Figs. 1(c)- (e), Eq. (14) is thus rewritten as:  $e_e$ ) =  $\frac{1}{2}(\rho_{e_{31}} + \rho_{e_{41}})$  (14) by<br>  $\hat{g}(\rho_e)$  is the modified density of element *e*, *e* respresents<br>
msity element *e*<sub>11</sub> or *e*<sub>21</sub> possessed by a potential one-<br>
impge patch. To including all cases shown i

$$
g(\rho_e) = \frac{1}{H} \sum_{h=1}^{H} (\hat{g}(\rho_e))_h
$$
 (15)

where  $g(\rho_e)$  is the modified density of low-density element *e* patches, *h* is the number of the one-point hinge patch.

## **4. Numerical implementation**

For simplicity, assume that  $Q_d$  is the set of the elements with relatively low density in all patches of the one-point hinge connection in the design domain. One can define the modified density of element *e* of set *Ω*\*Ω*<sub>*dl*</sub> as:

$$
g(\rho_e) = \rho_e \qquad e \in \Omega \setminus \Omega_d \tag{16}
$$

For all elements in the design domain, the modified densities Eqs. (15) and (16) are used to replace the original values in the stiffness matrix *K* and mass matrix *M*. where  $V(\rho)$  is the volume of the optimized topology. Clearly, the emergence of the one-point hinge patch will lead to an increase in the complexity of the sensitivity calculation of the objective function. Nevertheless, by using the hinge-removal strategy proposed, one-point hinge connections can be found and circumvented promptly, which avoids the reproducing of this problem in the same location in subsequent iterations. where  $\partial f/\partial \rho_e$  is the sensitivity of the overall objective func-Moreover, considering that the one-point hinge problem often tion in Eqs.  $(17) - (19)$ ,  $\gamma$  is a Lagrange multiplier, which is produces in the process of freeing intermediate elements, the hinge-removal strategy will be implemented only in the follow-up optimization. Further,  $\delta_1$  is chosen as a small value for  $\sim$ most cases in this work such that a smaller number of potential one-point hinge connections can be expected. As a result, computational effort on the cure of the one-point hinge problem would be greatly reduced. Especially for the case where no one-point hinge connection is found, the implementation of the hinge-removal strategy has little influence on the CPU time. Therefore, the proposed hinge-removal strategy will be applied in the three problems mentioned above.

#### **5. Optimality criterion**

#### *5.1 Typical optimality criterion*

In the proposed approach, an optimal topology with grey boundaries is found firstly. Therefore, the typical optimality criterion (OC) method with continuous design variables is employed to update element densities. Following Bendsøe and Sigmund [20] and considering the hinge-removal strategy, a heuristic updating scheme for density variables in the above design problems can be formulated as: the entropy the Cure of the temperature plus-<br>

function of which is to inhibit elements with intermediate densities. The reasons to adopt Eq. (34) as an updated criterion include the following aspects. Firstly, because the optimal topology with grey boundaries is used as an initial design for the follow-up optimization, what should be removed are only intermediate elements. Thus, during the *k*+1 *th* iteration, those elements whose densities are  $\rho_{\text{max}}$  in the *k th* iteration remain unchanged. Secondly, from the stiffness matrix and mass matrix of the finite element, it can be seen that elements with high density have larger contribution to the design problem than the ones with low densities. high density have larger contri preferable effect to remove intermediate elements, a continuation scheme similar to that developed by Sigmund [32] is thus used to determine parameter  $\alpha$  in this study. That is, parameter  $\alpha$  should be specified as a relatively small positive number initially and then increased gradually during the iteration until that the ideal 0-1 topology is obtained. Of course, it should also be noted here that for the continuation scheme a relatively large iteration number to achieve convergence may be required, as observed in Ref. [32]. However, because of the easy formulation by slightly modifying OC, the updated optimality criterion itself doesn't increase the complexity of the sensitivity calculation of the objective function. By integrating the hinge-removal strategy with the updated optimality criterion, it can be seen that the proposed approach only requires calculation complexity as low as possible. The increase in the CPU time with the present optimization approach would thus be moderate. From this perspective, the proposed approach is meaningful and feasible for black-and-white and hingeremoval topology designs.

## **6. Sensitivity filter**

During the whole optimization process, in order to ensure the existence of a solution and remove the well-known checkerboards, we employed the popular mesh-independency filter, which works by modifying the element sensitivities as [25]: gy designs.<br> **ii e** either<br>

$$
\frac{\partial \hat{f}}{\partial \rho_i} = \frac{1}{\rho_i \sum_{e \in NE_i} \hat{H}_e} \sum_{e \in NE_i} \hat{H}_e \rho_e \frac{\partial f}{\partial \rho_e} \qquad i = 1, ..., N
$$

where  $NE_i$  is the neighborhood of element *i*, which is defined by the elements having centers within a given filter radius *R* of the center of element *i*. Let  $x_e$  is the center location of element *e*, one has [25]

$$
NE_i = \left\{ e \middle\| \mathbf{x}_e - \mathbf{x}_i \middle\| \le R \right\} \tag{36}
$$

And  $\hat{H}_e$  is a convolution operator decaying linearly with the  $\epsilon$ distance from element *i*, i.e. [25]

$$
\hat{H}_e = R - \left\| \mathbf{x}_e - \mathbf{x}_i \right\| \tag{37}
$$

During the whole optimization, the modified sensitivities Eq. (35) are used to replace the original values in Eqs. (17)  $-$  (19).

More specifically, a decrease in *ε* will lead to an increase in the termination value  $1e - \theta$  (where  $\theta$  is a positive integer) and be modified as follows: if there exist intermediate elements in the final topology adhering to the volume constraint, which indicates that the termination value of  $\alpha$  is too small, one should attempt to decrease *ε* appropriately. With this implicit adjustment, desired black-and-white topology design satisfying the volume constraint can be obtained. On the other hand, hinge detection parameter  $\delta_2$  ideally takes the value of 1 to ensure the continuity of the resultant material. Also, computational experience shows that purely black-and-white topologies are often obsteps 2-9 unin a solution win volume preserving and rew<br>

In the first example, the popular MBB beam which previ-<br>
Secon that grey boundarics i seen that grey boundaries inevitably appear in the topology plot, as seen in many topology design problems [20]. Subses quently, this solution is used as a starting point and then the follow-up optimization is implemented. To free unfavorable intermediate elements, the updated optimality criterion is thus employed to update design variables. And the hinge-removal strategy is also employed to check and circumvent potential one-point hinge connections. A set of optimal topologies with corresponding parameters are obtained, as shown in Fig. 5. Numerical solutions to the MBB beam are also listed in Table 1, wherein all the CPU time is based on a desktop computer with Intel(R) Core(TM) i7 870 processor of 2.93 GHz clock speed (the same hereinafter). Comparing Fig. 5 with Fig. 4, it can be seen that all final optimal topologies are markedly different from the initial one. Unfavorable grey regions are effectively removed and all members in topology solutions are plotted with a clear black-and-white and hinge-removal design

Fig. 6. Design domain of a force inverter.

pattern. The reason for this is that the updated optimality criterion formulated by slightly modifying OC enforces intermediate elements to be progressively removed from low to high density such that material can be added to the high-density elements. On the other hand, there is no one-point hinge con nection to be found by tracking the optimization process. However, the implementation of the hinge-removal strategy has little influence on the CPU time. This is because the sensitivity calculations of the objective function become simple in proposed approach with different meshes: (a)  $120 \times 60$  mesh; (b) this case.

Simultaneously, it can also be seen that final topologies in Fig. 5 and objective function values in Table 1 are relatively consistent and preserving the volume constraint. These show that the proposed approach is feasible for compliance minimum problems. Meanwhile, one can find that the continuation on *α* may result in a relatively large iteration number to achieve convergence. However, the increase in the total CPU time is moderate. This is because the present approach only requires computational complexity as low as possible.

## *8.2 A compliant force inverter*

has been studied by Sigmund [32], is also employed to check 180×90 mesh,  $\alpha_0 = 0.25$ ,  $\Delta \alpha = 0.05$ ; (e) 120×60 mesh, the performance of the proposed approach for the black-and-<br> $\alpha_0 = 0.4$ ,  $\Delta \alpha = 0.02$ ; (f) 180×90 mesh,  $\alpha_0 = 0.4$ ,  $\Delta \alpha = 0.02$ . white and hinge-removal topology design. OC and the hinge-removal strategy is used to prevent the one point hinge connection. Fig. 8 and Table 2 depict the corresponding optimal topologies and numerical results with differ ent meshes and varying parameters. As shown, black-and white designs with appropriate parameters are obtained. Further, these topology layouts are free of one-point hinge con nections and the minimum size of hinges is one-element-thick. Without doubt, black-and-white designs are contributed to the action of the optimality criterion formulated by slightly modifying OC. At the same time, the hinge-removal strategy can find the potential one-point hinge connections producing in the topologies and always circumvent them promptly. Besides, by combining Fig. 8 and Table 2, it can be seen that the optimal solutions are preserving the volume constraint and fairly consistent in both the resultant topologies and objective function values for the fixed mesh. These suggest that the proposed approach is also feasible for compliant mechanism problems. Moreover, one can find that the continuation on *α* requires a large iteration number to achieve convergence as

Fig. 9. Optimal topologies of the inverter with different meshes from

Fig. 10. Freely vibrating thin-plate structures (40 mm×40 mm×1 mm): (a) four edges clamped and concentrated mass *m* at the center of the structure ( $m = 0.3$   $m_s$ ,  $m_s$  the total structural mass of the plate); (b) four corners supported and concentrated mass *m* at the center of the structure  $(m = m<sub>s</sub>)$ ; (c) one edge clamped and concentrated mass *m* attached at the mid-point of the edge opposite to the clamped one  $(m = m<sub>s</sub>)$ .

well, whereas the increase in the total CPU time is still moderate, thanks to the low computation complexity of the proposed algorithm.

On the other hand, we compare the present approach with the bilateral density filtering proposed by Wang and Wang [33] for this example. The convergence criterion in Ref. [33], i.e.  $|f^{k+1} - f^k| < 10^{-5}$  or  $|(\rho^a)^{k+1} - (\rho^a)^k| < 10^{-6}$  (where  $\rho^a$  is f (a)<br>

Fig. 11. The initial optimal of control of the contracted mass *m* at the center of the (c) one edge clamped and  $m = 0.3$  *m<sub>i</sub>*, the total structural m adopted. Note that continuation strategies in which parameters *σ<sup>d</sup>* and *σr* are chosen with relatively large values initially and then slowly decreased until the black-and-white optimum is obtained are used in their work. However, no specific details are given. Here, these two parameters are thus initialized as 1 and then gradually diminished until convergence with the fixed step  $\Delta\sigma$  of  $-0.002$ ,  $-0.005$  and  $-0.01$ , respectively. The final optimal topologies and numerical results from the bilateral density filtering are shown in Fig. 9 and Table 3. Comparing them with Fig. 8 and Table 2, respectively, it can be seen that the proposed approach in this paper is slightly superior to the bilateral density filtering with parameters chosen in the 0-1 convergence, topology consistency and CPU time required.

#### *8.3 Freely vibrating thin-plate structures*

In the third example, freely vibrating thin-plate structures similar to Ref [43] are used to further verify the validity of the proposed method. As shown in Fig. 10, these thin-plate struc-

(c) one edge clamped and  $m = m_s$ . structures using the proposed approach with  $40\times40$  mesh: (a) four Fig. 11. The initial optimal topologies of freely vibrating thin-plate edges clamped and  $m = 0.3$   $m_s$ ; (b) four corners supported and  $m = m_s$ ;

| ( ) ( ) | 10 *a k a k* <sup>r</sup> <sup>r</sup> <sup>+</sup> - - < (where *<sup>ρ</sup>* the average density of non-empty elements) or max *k k* <sup>&</sup>gt; , is tures are with the same design domain of 40 mm $\times$ 40 mm $\times$ 40 mm, but three different cases of boundary conditions and attached concentrated, nonstructural masses. The material is **Fig. 11.** The initial optimal topologies of freely vibrating thin-plate structures using the proposed approach with 40×40 mesh: (a) four edges clamped and  $m = 0.3$   $m_s$ ; (b) four corners supported and  $m = m_s$ ; (c) one edg fraction and filter radius are respectively specified as 0.5 and 1.5. For hinge detection parameters,  $\delta_1$  takes the value of 0.1, 0.7, and 0.1 respectively, while  $\delta_2$  is specified as 1. Moreover,  $N_1$  is respectively given as 50, 60, 50, while  $N_2$  is specified as 20. The optimization objective is to maximize the fundamental eigenvalue.

The design domains are all discretized using 4-node 40×40 plate elements. Based on the typical OC, the initial optimal topologies corresponding to these three cases are firstly obtained, as shown in Fig. 11. From this figure, it can be seen that intermediate design variables render the associated elements as gray. Therefore, each solution is used as a starting point and then the follow-up optimization is implemented to cure these problems in the topology layouts. The hingeremoval strategy and updated optimality criterion are applied in the optimization process.

Fig. 12 and Table 4 depict the optimal topologies and numerical results corresponding to parameters chosen. By comparing Fig. 12 with Fig. 11, it can be seen that resultant topologies from the proposed approach with appropriate parameters are almost truly 0-1 optimal designs satisfying the volume constraint. Clearly, this is due to the function of the updated optimality criterion. And by tracking the optimization process, the one-point hinge connection problem is found only in the case of four corners supported and concentrated mass at the center of the structure and is cured effectively as shown in Figs. 12(c) and (d). Again, it can be seen that final topologies

and  $\Delta \alpha = 0.02$ ; (e) one edge clamped and  $m = m_s$ ,  $\alpha = 0.3$  and  $\Delta \alpha = 0.025$ ; (f) one edge clamped and  $m = m_s$ ,  $\alpha = 0.5$  and  $\Delta \alpha = 0.02$ . (f) and adapt alamnad and  $= 0.3 m_s$ ,  $\alpha = 0.5$  and  $\Delta \alpha = 0.02$ ; (c) four corners supported and  $m = m_s$ , and  $m = 0.3m_s$ ,  $\alpha = 0.3$  and  $\Delta\alpha = 0.025$ ; (b) four edges clamped and *m* using the proposed approach with  $40\times40$  mesh: (a) four edges clamped Fig. 12. Optimal topologies of freely vibrating thin-plate structures  $\alpha = 0.3$  and  $\Delta \alpha = 0.025$ ; (d) four corners supported and  $m = m_s$ ,  $\alpha = 0.5$ 

in Fig. 12 and objective function values in Table 4 are relatively consistent for the same boundary conditions and attached masses. At the same time, the optimized topologies are also preserving the volume constraint. These all indicate that the present approach is competent in producing expected black-and-white and hinge-removal designs for eigenvalue problems.

Moreover, one can still find that a large iteration number is required to achieve convergence due to the continuation on *α* for each boundary condition. The increase in the computational burden is however moderate, because only low computation cost is required by the proposed approach.

Further, for the purpose of comparison, the example of freely vibrating thin-plate structures is tested using the powerlaw OC-GSS algorithm proposed by Groenwold and Etman [19] again. The convergence criterion in Ref. [19], i.e.  $|\boldsymbol{\rho}^{k+1}$ - sa  $\rho^k$ || < 10<sup>-6</sup> or  $k > 100$ , is adopted. Optimal topologies and numerical results are respectively shown in Fig. 13 and Table 5, wherein notations  $p_1 > 1$  respectively  $q_1 > 1$  mean that continuation strategies described in Ref. [19] are employed. Comparing these results with Fig. 12 and Table 4, it can be seen that the power-law OC-GSS algorithm can also provide quasi 0-1 discrete solutions and is a bit more efficient in some

Table 5. The numerical solutions of freely vibrating thin-plate structures with 40×40 mesh from OC-GSS algorithm.

cases than the present approach. However, topologies with different parameter values embody weak consistency for the same boundary condition. And one-point hinge connections are encountered in the topology layouts. From the latter, the proposed approach is slightly superior to the power-law OC- GSS algorithm.

#### **9. Conclusions**

In this paper, an optimization approach for black-and-white

and hinge-removal topology designs is studied. To achieve this motive, an optimal topology allowing grey boundaries is found firstly. When a suitable design has been obtained, this solution is then used as a starting point for the follow-up optimization with the goal to free unfavorable intermediate elements. For this purpose, an updated optimality criterion in which a threshold factor is introduced to gradually suppress elements with low density is proposed. The typical optimality method and new technique proposed are applied to the design procedure sequentially. Besides, to circumvent the one-point hinge connection problem producing in the process of freeing intermediate elements, the hinge-removal strategy is also proposed. During the optimization, the binary constraints on design variables are relaxed based on the scheme of solid isotropic material with penalization. Meanwhile, the meshindependency filter is employed to ensure the existence of a solution and remove well-known checkerboards. In this way, a solution that has few intermediate elements and is free of one point hinge connections is obtained. Finally, different numerical examples including the compliance minimization, compliant mechanisms and vibration problems demonstrate the validity of the proposed approach.
