FeSe₂ clusters, superior rate capability, excellent cycling stability, sodium-ion batteries, pseudocapacitive behavior

ABSTRACT

Sodium-ion batteries (SIBs) have great promise for sustainable and economical energy-storage applications. Nevertheless, it is a major challenge to develop anode materials with high capacity, high rate capability, and excellent cycling stability for them. In this study, FeSe₂ clusters consisting of nanorods were synthesized by a facile hydrothermal method, and their sodium-storage properties were investigated with different electrolytes. The FeSe₂ clusters delivered high electrochemical performance with an ether-based electrolyte in a voltage range of 0.5–2.9 V. A high discharge capacity of 515 mAh·g⁻¹ was obtained after 400 cycles at 1 A·g⁻¹, with a high initial coulombic efficiency of 97.4%. Even at an ultrahigh rate of 35 A·g⁻¹, a specific capacity of 128 mAh·g⁻¹ was achieved. Using calculations, we revealed that the pseudocapacitance significantly contributed to the sodium-ion storage, especially at high current rates, leading to a high rate capability. The high comprehensive performance of the FeSe₂ clusters makes them a promising anode material for SIBs.

1 Introduction

Currently, electrical energy storage plays an important role in our daily lives. As efficient energy-storage devices, lithium-ion batteries (LIBs) are widely used in portable devices and are expected to power electric vehicles owing to their high energy density and long cycle life [1–3]. However, concerns regarding the limited resources and growing cost of lithium have prompted researchers to seek alternative solutions for

sustainable energy storage [4, 5]. Recently, sodium-ion batteries (SIBs) have attracted considerable attention as a substitute for LIBs because of their low cost and natural abundance [6–12]. Many cathode materials, such as Na₃V₂(PO₄)₃ [13], Na_{1.25}V₃O₈ [14], Na₂Fe₂(SO₄)₃ [15], and Prussian blue materials [16], have been investigated for SIBs. SIB cathode materials have exhibited remarkable performances [13–15]. Nevertheless, it is a major challenge to develop high-performance anode materials for SIBs.

To date, SIB anode materials based on intercalation [17–21], alloying [22–25], and conversion reactions [26–28] have been proposed. Materials with insertion–extraction mechanisms exhibit good cycling performance, but their specific capacity is not high [17, 18]. Thus, considerable attention has been paid to high-capacity anode materials with alloying and conversion mechanisms. Among these, transition metal sulfides and selenides have attracted significant attention owing to their low cost, high capacity, and environmental benignity [11, 29–34]. Previous studies have focused on the fabrication of carbon-assisted composites to improve the electrochemical performance [31, 32]. However, carbon materials exhibit a low tapping density, which leads to a low practical volumetric energy density. Therefore, it is necessary to explore novel strategies for developing high-performance transition metal sulfides and selenides without introducing conductive carbon materials. FeSe₂ has been extensively studied in a variety of fields, e.g., those concerning solar cells [35], absorption [36] and electromagnetics [37], owing to its environmental benignity, low cost, and good conductivity. Chen et al. synthesized FeSe₂ microspheres and used them for the first time as an SIB anode [38]. The FeSe₂ anode delivered a stable discharge capacity of 372 mAh·g⁻¹ at 1 A·g⁻¹. However, the specific capacity and rate performance of the FeSe₂ SIB anode needs to be further enhanced.

Three-dimensional (3D) structures composed of sub-nanostructures have attracted attention as efficient electrode configurations [39–41]. They can not only reduce the ion diffusion length but also mitigate the self-aggregation of low-dimensional nanostructures; thus, they are used to enhance the electrochemical performance of batteries [39]. In addition, pseudocapacitive charge storage is beneficial for achieving a high rate capability [42–44]. Huang et al. [43] demonstrated that the Na⁺ intercalation pseudocapacitance in graphene-coupled titanium oxide yielded a high rate capability and long cycle life in SIBs. Thus, it is desirable to obtain SIBs with a high rate capability and excellent cycling stability by constructing a 3D structure and enhancing the pseudocapacitive charge storage process in the electrodes.

In this study, we constructed FeSe₂ clusters assembled

by nanorods using a facile hydrothermal reaction. The unique 3D structures reduced the ion diffusion length, mitigating the sluggish electrochemical kinetics. Quantitative kinetics analysis revealed that the pseudocapacitive charge storage significantly contributed to the sodium-ion storage. As an SIB anode, the as-prepared FeSe₂ clusters exhibited high rate performance, high initial Coulombic efficiency, and stable cycling performance.

2 Experimental

2.1 Material synthesis

The FeSe₂ clusters (C-FeSe₂) were synthesized as follow. (NH₄)₂Fe(SO₄)₂ (1 mmol) were added to distilled water (30 mL) under stirring. Then, SeO₂ (2 mmol) and hydrazine hydrate (6 mL) were sequentially added to the resulting mixture. Finally, the obtained solution was transferred into a Teflon-lined stainless-steel autoclave and maintained at 180 °C for 12 h. The product was collected via centrifugation, washed with distilled water and ethanol, and dried at 70 °C for 12 h in vacuum. For comparison, FeSe₂ particles (P-FeSe₂) were synthesized using the same procedure with hydrazine hydrate (3 mL). Furthermore, time-dependent experiments were performed to investigate the growth process of the FeSe₂ clusters.

2.2 Characterization

X-ray diffraction (XRD) patterns were recorded using a D8 Advance X-ray diffractometer with a non-monochromated Cu K α X-ray source. Raman spectra were obtained using a micro-Raman spectroscopy system (inVia, Renishaw). Field-emission scanning electron microscopy (FESEM) images and energy-dispersive X-ray spectra (EDS) were obtained using a microscope (JEOL-7100F). Transmission electron microscopy (TEM) images and high-resolution TEM (HRTEM) images were obtained using another microscope (JEM-2100F).

2.3 Electrochemical measurements

The electrochemical properties were measured by assembling 2016 coin cells in a glove box filled with pure argon gas. Sodium chips were used as the counter

electrode. The working electrode was obtained by mixing the as-prepared materials, acetylene black, and carboxyl methyl cellulose at a weight ratio of 70:20:10. The slurry was cast on copper foil, dried at 70 °C for 12 h, and heated at 120 °C for 2 h in a vacuum oven. The active material loaded on the copper foil was 1.0–1.5 mg·cm⁻². Three different electrolytes were used: 1 M NaCF₃SO₃ dissolved in diethyleneglycol dimethylether (DIGLYME), 1 M NaClO₄ in ethylene carbonate and dimethyl carbonate (EC/DMC), and 1 M NaClO₄ in EC/DMC with 5% fluoroethylene carbonate (FEC) electrolytes. Galvanostatic charge/discharge measurements were performed in a potential range of 0.5–2.9 V vs. Na⁺/Na using a multichannel battery testing system (LAND CT2001A). Cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) were performed using electrochemical workstations (CHI600D and Autolab Potentiostat Galvanostat 302N). All of the measurements were performed at room temperature.

3 Results and discussion

3.1 Structural characterization

As shown in Fig. 1(a) and Fig. S1 in the Electronic Supplementary Material (ESM), the XRD peak for the obtained FeSe₂ clusters and particles is indexed to the orthorhombic phase of FeSe₂ (JCPDS card No. 01-079-1892). The Raman spectrum of as-prepared FeSe₂ clusters is shown in Fig. 1(b). Three characteristic peaks at 179.2, 216.3, and 254.4 cm⁻¹ are observed. The peaks at 179.2 and 254.4 cm⁻¹ correspond to the Se–Se librational and stretching vibrations or their

combination, and the peak at 216.3 cm⁻¹ is attributed to the Se–Se stretching vibrations [36]. The morphology of the as-prepared FeSe₂ clusters was characterized using scanning electron microscopy (SEM) and TEM. The low-magnification SEM image shown in Fig. S2 in the ESM indicates that the as-prepared 3D FeSe₂ clusters had a diameter of 500–800 nm. Elemental-mapping images were obtained to determine the chemical composition of the as-prepared FeSe₂ clusters (Fig. S3 in the ESM). The elements Se and Fe were uniformly distributed in the obtained product. The EDS results show that the atomic ratio of Fe/Se was approximately 1:2. The high-magnification SEM image shown in Fig. 2(a) indicates that the FeSe₂ clusters were composed of nanorods. The HRTEM image shown in Fig. 2(b) indicates that the nanorods had a diameter of 100–150 nm. A lattice fringe with a *d*-spacing of approximately 0.37 nm, which corresponds to the (110) plane of the FeSe₂ crystal, is observed in the HRTEM image of Fig. 2(c). The selected-area electron diffraction (SAED) pattern shown in Fig. 2(d) is indexed to the (110) and (121) crystal planes of the orthorhombic FeSe₂ phase. The morphology of the FeSe₂ particles was investigated using SEM (Fig. S4 in the ESM), revealing that some nanoparticles aggregated to form larger particles.

To investigate the formation process of the obtained FeSe₂ clusters, time-dependent experiments were performed. The morphologies of the prepared samples at different stages were characterized using SEM (Fig. S5 in the ESM). When the reaction time was 1 h, irregular nanoparticles and rods formed. When the reaction time was extended to 3 h, obvious rod clusters appeared. After 6 h of reaction, the rods were longer.

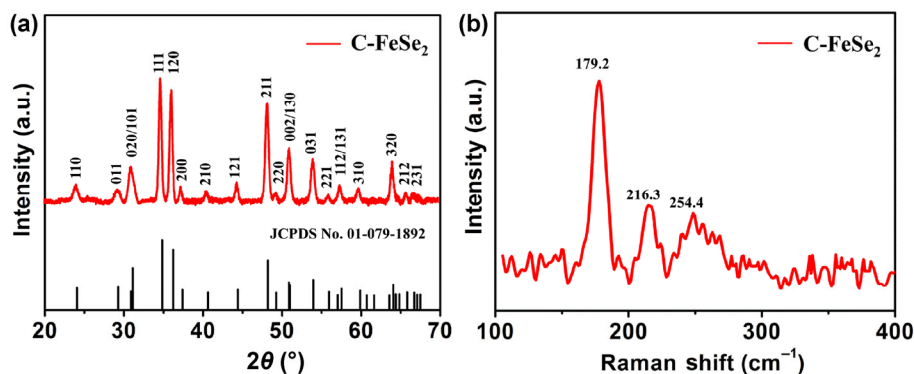

Figure 1 (a) XRD pattern and (b) Raman spectrum of the as-prepared FeSe₂ clusters.

Figure 2 (a) SEM image, (b) high-magnification TEM image, (c) HRTEM image, and (d) SAED pattern of the as-prepared FeSe₂ clusters.

As the reaction time increased to 8 h, the particles existing on the rods were consumed, and the rod clusters became larger.

According to the aforementioned experimental results, the growth process of the obtained FeSe₂ clusters was schematically illustrated, as shown in Fig. S6 in the ESM. In the initial stage, nanoparticles and rods formed. As the reaction continued, particles were consumed, and the clusters assembled by the rods became larger and more uniform through Ostwald ripening [37]. Consequently, 3D rod clusters were obtained.

3.2 Electrochemical performance in SIBs

The electrochemical performance of FeSe₂ electrodes was tested in 1.0 M NaCF₃SO₃ in DIGLYME. The charge–discharge profiles (1st, 30th, 100th, 200th, 300th, and 400th cycles) of the as-prepared FeSe₂ clusters at 1 A·g⁻¹ are shown in Fig. 3(a). During the first sodiation process, an obvious voltage plateau was observed around 1.35 V. This is attributed to the slow reaction kinetics and the intercalation and conversion reactions that simultaneously occurred during the first discharge

process, which have been previously reported [45–48]. Figure 3(b) shows the cycling performance of the FeSe₂ clusters and particles at a current density of 500 mA·g⁻¹. Notably, the initial Coulombic efficiency of the FeSe₂ clusters reached 97.2%. The high Coulombic efficiency is attributed to the high cutoff voltage, which allows the avoidance of the irreversible capacity in the voltage range of 0.5–0 V, according to published reports [49]. Moreover, the as-prepared FeSe₂ clusters exhibited high capacity retention of nearly 100% after a few cycles of activation. Clearly, the FeSe₂ clusters exhibited a higher capacity and better cycling stability than the FeSe₂ particles. After 100 cycles, the FeSe₂ clusters retained a capacity of 508 mAh·g⁻¹, which is significantly higher than that for the FeSe₂ particles (389 mAh·g⁻¹). The long-life cycling performance of the as-prepared FeSe₂ was investigated at 1 and 3 A·g⁻¹ (Fig. 3(c) and Fig. S7 in the ESM, respectively). The as-prepared FeSe₂ exhibited a high initial Coulombic efficiency of 97.4% and a discharge capacity of 515 mAh·g⁻¹ after 400 cycles at 1 A·g⁻¹. At a high current density of 3 A·g⁻¹, the FeSe₂-cluster electrode retained a capacity of >425 mAh·g⁻¹ with a Coulombic efficiency of ~100% for 200 cycles.

The rate performances of the as-prepared FeSe₂ clusters and particles were investigated by changing the current density from 1 to 35 A·g⁻¹, as shown in Fig. 3(d). Because the capacity remained stable after 50 cycles, the rate performance was tested after 50 cycles at 1 A·g⁻¹. The average discharge capacities of the as-prepared FeSe₂ clusters were 510, 436, 410, 368, 280, 235, 183, and 128 mAh·g⁻¹ at current densities of 1, 3, 5, 10, 20, 25, 30, and 35 A·g⁻¹, respectively. When the current density returned to 1 A·g⁻¹, the capacity increased to the original value. In contrast, the capacities of the FeSe₂ particles were only 420, 350, 318, 243, 100, 37, 42, and 40 mAh·g⁻¹ at the current densities of 1, 3, 5, 10, 20, 25, 30, and 35 A·g⁻¹, respectively. These results indicate that the FeSe₂ clusters composed of the nanorods had better cycling capacity and rate performance than the FeSe₂ particles.

EIS was performed to identify the reason for the enhanced electrochemical performance of the as-prepared FeSe₂ clusters. The results are shown in Fig. 3(e), revealing that the resistances of the electrolyte and cell components (R_s), the resistance of the solid electrolyte interface (R_{SEI}), and the charge-transfer resistance (R_{ct}) of the FeSe₂ clusters were smaller than those of the FeSe₂ particles, indicating the faster kinetics

of the FeSe₂ clusters (Table S1 in the ESM). Fast electron/ion transfer kinetics is beneficial for improving the electrochemical performance of electrodes [50–52].

To investigate the effect of the electrolyte parameters on the cycling capability of the electrodes, different electrolytes (1 M NaClO₄ in EC/DMC, EC/DMC-5%FEC) were used to study the cycling performance of the as-prepared FeSe₂ clusters (Fig. S8 in the ESM). The as-prepared FeSe₂ clusters with carbonate-based electrolytes (NaClO₄ in EC/DMC, EC/DMC-5%FEC) suffered from rapid capacity decay (8 and 128 mAh·g⁻¹ after 100 cycles at 500 mA·g⁻¹, respectively). The appropriate ether-based electrolyte effectively suppressed the side reactions between the electrolyte and the anionic groups, improving the cycling performance of the electrodes [38, 53]. Figure S9 in the ESM shows the EIS results for the as-prepared FeSe₂ clusters in carbonate-based electrolytes. The resistances of the FeSe₂ clusters in the carbonate-based electrolytes were larger than those for the ether-based electrolyte, indicating the slower kinetics.

To explain the high electrochemical performance of the FeSe₂ clusters, CV curves for the FeSe₂ clusters and particles were obtained at different scan rates ranging from 0.2 to 1 mV·s⁻¹ (Fig. 4(a) and Fig. S10

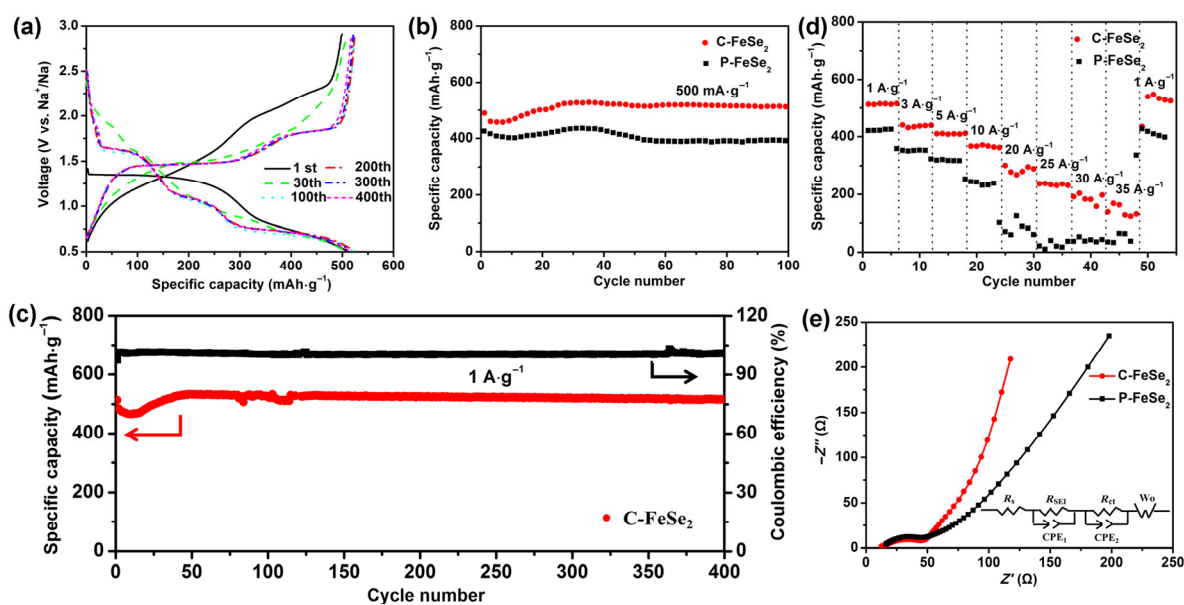

Figure 3 Electrochemical performance of the as-prepared FeSe₂ electrodes for SIBs. (a) Charge–discharge profiles of the FeSe₂ clusters at a current density of 1 A·g⁻¹. (b) Cycling performance of the FeSe₂ clusters and particles at 500 mA·g⁻¹. (c) Long-life cycling performance of the FeSe₂ clusters at 1 A·g⁻¹. (d) Rate performance of the FeSe₂ clusters and particles after 50 cycles at current densities ranging from 1 to 35 A·g⁻¹. (e) Nyquist plots for the FeSe₂ clusters and particles.

in the ESM). The CV curves for the FeSe₂ clusters overlapped to a greater degree than those of the FeSe₂ particles at different scan rates, indicating the better cycle reversibility of the FeSe₂ clusters. The sodium-diffusion coefficient was calculated using the Randles–Sevick equation [54, 55]

$$I_p = 0.4463nFAC(nFvD/RT)^{1/2} = [(269000)n^{3/2}AD^{1/2}C]v^{1/2} \quad (1)$$

where I_p is the peak current, n is the number of electrons transferred in the redox process, F is Faraday's constant, A is the surface area of the electrode, D is the diffusion coefficient, C is the concentration of sodium ions, and v is the scan rate. Using Eq. (1), the plot of the peak current I_p vs. the square root of the scan rate ($v^{1/2}$) was obtained for the peak oxidation current at a voltage of 1.52 V (Fig. 4(b)). The calculated diffusion coefficient D for the FeSe₂ clusters ($1.32 \times 10^{-8} \text{ cm}^2\cdot\text{s}^{-1}$) was significantly greater than that for the FeSe₂ particles ($6.1 \times 10^{-10} \text{ cm}^2\cdot\text{s}^{-1}$). Moreover, this value is greater than that commonly reported for anodes used in SIBs [56, 57], indicating the potential of the FeSe₂ clusters for high-rate applications.

To provide insights and quantify the total capacitive contribution in the material, the capacitive and diffusion contributions were separated at a fixed voltage according to the following equation

$$i(V) = k_1v + k_2v^{1/2} \quad (2)$$

where k_1v and $k_2v^{1/2}$ represent the capacitive and diffusion contributions, respectively. Figure 4(c) shows the separation of the capacitive and diffusion currents of the FeSe₂ clusters at a scan rate of $0.6 \text{ mV}\cdot\text{s}^{-1}$. The quantification results indicate that 72.6% of the total charge storage was capacitive. The ratios of the capacitive contribution to the diffusion contribution at different scan rates are presented in Fig. 4(d). The capacitive contribution gradually increased as the scan rate increased. At a scan rate of $0.8 \text{ mV}\cdot\text{s}^{-1}$, the capacitive-contribution ratio was 89.4%. A large capacitive contribution was beneficial for fast charge storage and yielded the high rate capability of the FeSe₂ clusters. This capacitive behavior is similar to that previously reported [11, 43].

To investigate the reaction kinetics of Na/FeSe₂ cells, EIS was performed on an electrode comprising

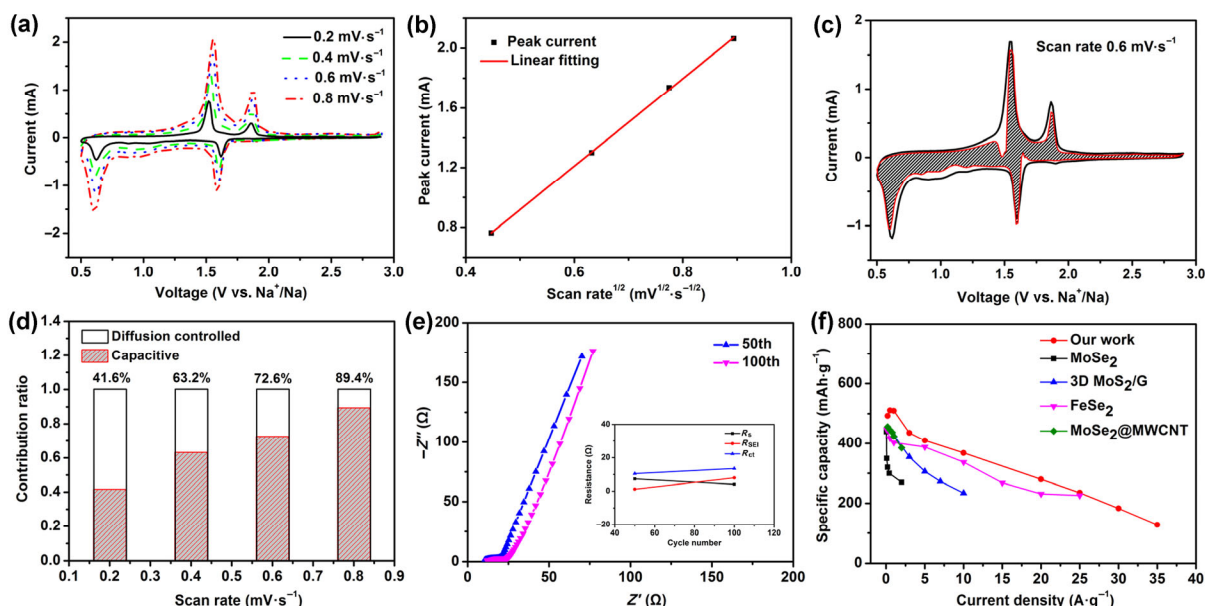

Figure 4 (a) CV curves of the as-prepared FeSe₂ clusters at different scan rates after 50 cycles. (b) Randles–Sevick plot for the as-prepared FeSe₂ clusters obtained from the CV data. (c) Separation of the capacitive and diffusion currents in the FeSe₂ clusters at a scan rate of $0.6 \text{ mV}\cdot\text{s}^{-1}$. (d) Contribution ratio of the capacitive and diffusion-controlled charge storage in the FeSe₂ clusters at 0.2, 0.4, 0.6, and $0.8 \text{ mV}\cdot\text{s}^{-1}$. (e) Nyquist plots for the as-prepared FeSe₂ electrode in the fully charged state after cycling from 1st to 100th. (d) Impedances R_s , R_{SEI} , and R_{ct} of the FeSe₂ electrode during cycling. (f) Comparison between other SIB anode materials and the material proposed herein.

as-prepared FeSe₂ clusters in the fully charged state after cycling (Fig. 4(e)). The as-prepared FeSe₂-cluster electrode exhibited stable values of R_s , R_{SEI} , and R_{ct} after 50 cycles (inset of Fig. 4(e)), indicating the highly stable electrochemical process. Figure 4(f) compares the rate performance of the as-prepared FeSe₂ clusters with those of other anode materials for SIBs [30–32, 38]. Clearly, the FeSe₂ clusters had a higher capacity and better rate performance than the other anode materials.

In situ XRD was performed to further investigate the intrinsic reaction mechanisms of the FeSe₂-cluster electrodes. An *in situ* cell was discharged to 0.5 V and then charged to 2.9 V under a constant current of 100 mA·g⁻¹ at room temperature (Fig. S11 in the ESM). During the first discharge process, there were three diffraction peaks (30.89°, 34.83°, and 36.23°), which correspond to the (020), (111), and (120) planes of FeSe₂, respectively. During the reaction, these peaks became weaker and then disappeared. No obvious diffraction peaks appeared in the subsequent charge and discharge process. These results indicate that the amorphization of the FeSe₂ electrode occurred after the electrochemical sodium-ion insertion.

According to the aforementioned results, the excellent electrochemical performance of the as-prepared FeSe₂ clusters was due to the unique 3D structure, the highly capacitive behavior, and the appropriate ether-based electrolyte. The unique 3D structure enhanced the electron/ion-transfer kinetics. The highly capacitive behavior was beneficial for fast charge storage. The appropriate ether-based electrolyte suppressed the side reactions between the electrolyte and the anionic group of the intermediate, enhancing the cycling performance of the as-prepared FeSe₂-clusters electrode.

4 Conclusions

We successfully synthesized 3D FeSe₂ clusters composed of nanorods using a facile hydrothermal method. As an anode material for SIBs, the as-prepared FeSe₂ clusters exhibited excellent cycling performance and a rate capability as high as 35 A·g⁻¹. They delivered a high initial Coulombic efficiency of 97.4% and a high discharge capacity of 515 mAh·g⁻¹ after 400 cycles at 1 A·g⁻¹. Furthermore, we demonstrated that the unique 3D structure, highly capacitive behavior, and

appropriate ether-based electrolyte contributed to the high electrochemical performance. The excellent overall performance of the FeSe₂ clusters makes them a promising anode material for SIBs.
