ABSTRACT

Lithium-sulfur (Li-S) battery has attracted extensive attention because of its ultrahigh theoretical energy density and low cost. However, its commercialization is seriously hampered by its short cycling life, mainly due to the shuttle of soluble lithium polysulfides (LiPSs) and poor rate capability due to sluggish reaction kinetics. Although significant efforts have been devoted to solving the problems, it is still challenging to simultaneously address all the issues. Herein, titanium nitride hollow multishelled structure (TiN HoMS) sphere is designed as a multi-functional catalytic host for sulfur cathode. TiN, with good conductivity, can effectively catalyze the redox conversion of S and LiPSs, while its surficial oxidation passivation layer can strongly anchor LiPSs. Besides, HoMS enables TiN nanoparticle subunits to expose abundant active sites for anchoring and promoting conversion of LiPSs, while the multiple shells provide physical barriers to restrict the shuttle effect. In addition, HoMS can buffer the volume expansion of sulfur and shorten the charge transport pathway. As a result, the sulfur cathode based on triple-shelled TiN HoMS exhibits an initial specific capacity of 1016 mAh·g^{-1} at a high sulfur loading of 2.8 mg·cm^{-2} and maintains 823 mAh·g^{-1} after 100 cycles. Moreover, it shows a four times higher specific capacity than the one without TiN host at 2 C.

KEYWORDS

lithium-sulfur batteries, titanium nitride, hollow multishelled structure, shuttle effect, rate capability

1   Introduction

Lithium-sulfur (Li-S) battery, which possesses a high theoretical energy density of 2600 Wh·kg^{-1}, abundant sulfur storage, low cost, and environmentally friendliness, has drawn intensive interest [1–5]. However, Li-S battery suffers from a series of challenges, such as poor rate capability due to the low electrical conductivity of S and sluggish reaction kinetics. More severely, the large volume expansion of S and the shuttle of long-chain lithium polysulfide (LiPS) intermediates cause short cycling lifespan and low S utilization, which seriously hinders the commercialization of Li-S batteries [6–13]. Great efforts have been devoted to solving these problems, mainly including design of novel S cathode architecture, binder optimization, electrolyte component optimization, or the use of solid-state electrolyte [14, 15]. Typically, hollow structured materials have been extensively employed as S host in Li-S batteries [16–24]. The large internal cavity buffers the volume expansion of S during lithiation process, while the polar metal compounds are capable of adsorbing polysulfides. Wherein, hollow multishelled structures (HoMS) with multiple ordered shells have been proven promising for as S host as well as multiple other application fields [25–30]. For example, Wang's group developed a TiO$_{2-x}$ as S host [25], which provides more adsorption and redox active sites and restricts the shuttle of LiPSs effectively. Additionally, porous thin shells can shorten the electron and ion transport paths [31–41]. Nonetheless, most metal compound hollow materials possess poor electrical conductivity and limited active centers. Therefore, the performance of Li-S battery still remains to be improved.

Herein, we develop TiN HoMS for the first time as multi-functional catalytic host for S cathode. As shown in Scheme 1, such polar TiN HoMS host has abundant desirable advantages: (1) TiN has an excellent electrical conductivity of up to 55,000 S·cm^{-1}, and it enables catalytic conversion of LiPSs after their adsorption and capture, further promoting redox reactions [42–47]; (2) TiN can anchor LiPSs via forming N–S bonds, in addition, its naturally formed surficial oxide passivation layer could also anchor LiPSs via forming S–Ti–O bonds, thus effectively inhibiting the shuttle of LiPSs [48, 49]; (3) the large internal cavity of HoMS significantly buffers the volume expansion of S material during lithiation [50, 51]; and (4) the HoMS could increase the contact area between TiN and active substances, providing more adsorption and redox active sites [52, 53]. As a result, the Li-S battery, by adopting triple-shelled TiN HoMS as S host, exhibits an initial specific capacity of 1016 mAh·g^{-1} under a high sulfur loading of 2.8 mg·cm^{-2} and the specific capacity maintains at 823 mAh·g^{-1} after 100 cycles. More impressively, a much better rate capability than the one without S host is achieved.

2   Results and discussion

TiN HoMSs were fabricated through a sequential templating
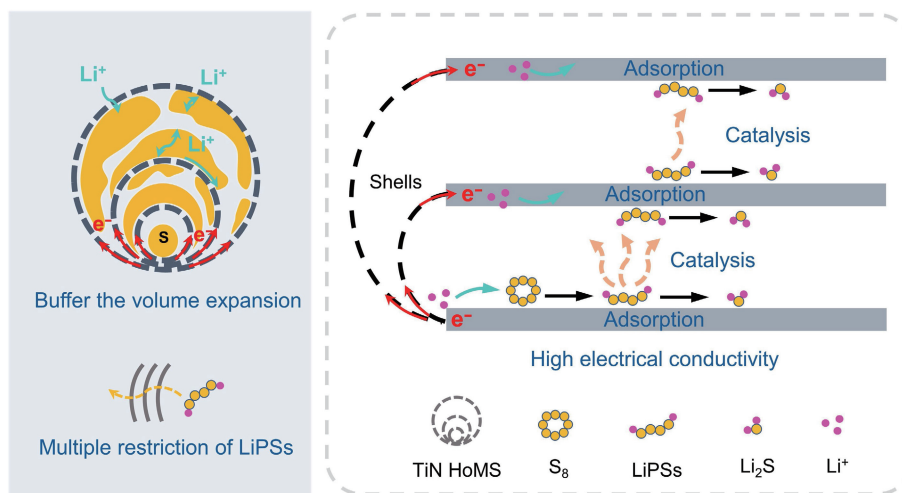

Scheme 1 Schematic illustration of the electrode process for the S@3s-TiN HoMS cathode.

approach (STA), which has been proven quite fruitful for HoMS synthesis [54–57], followed by a nitride treatment. Firstly, TiO$_2$ HoMSs were synthesized by the STA method, as reported in Refs. [30, 58, 59], which were then nitrided to become TiN using melamine as nitrogen source. Figures 1(a)–1(c) show transmission

electron microscopy (TEM) images of TiO$_2$ hollow sphere (HS) and double- and triple-shelled (2s- and 3s-) TiO$_2$ HoMS, respectively. The multishelled structure was well-maintained after being nitrided (Figs. 1(e)–1(g)) to obtain TiN HoMS. As characterized by scanning electron microscopy (SEM) (Figs. 1(d)

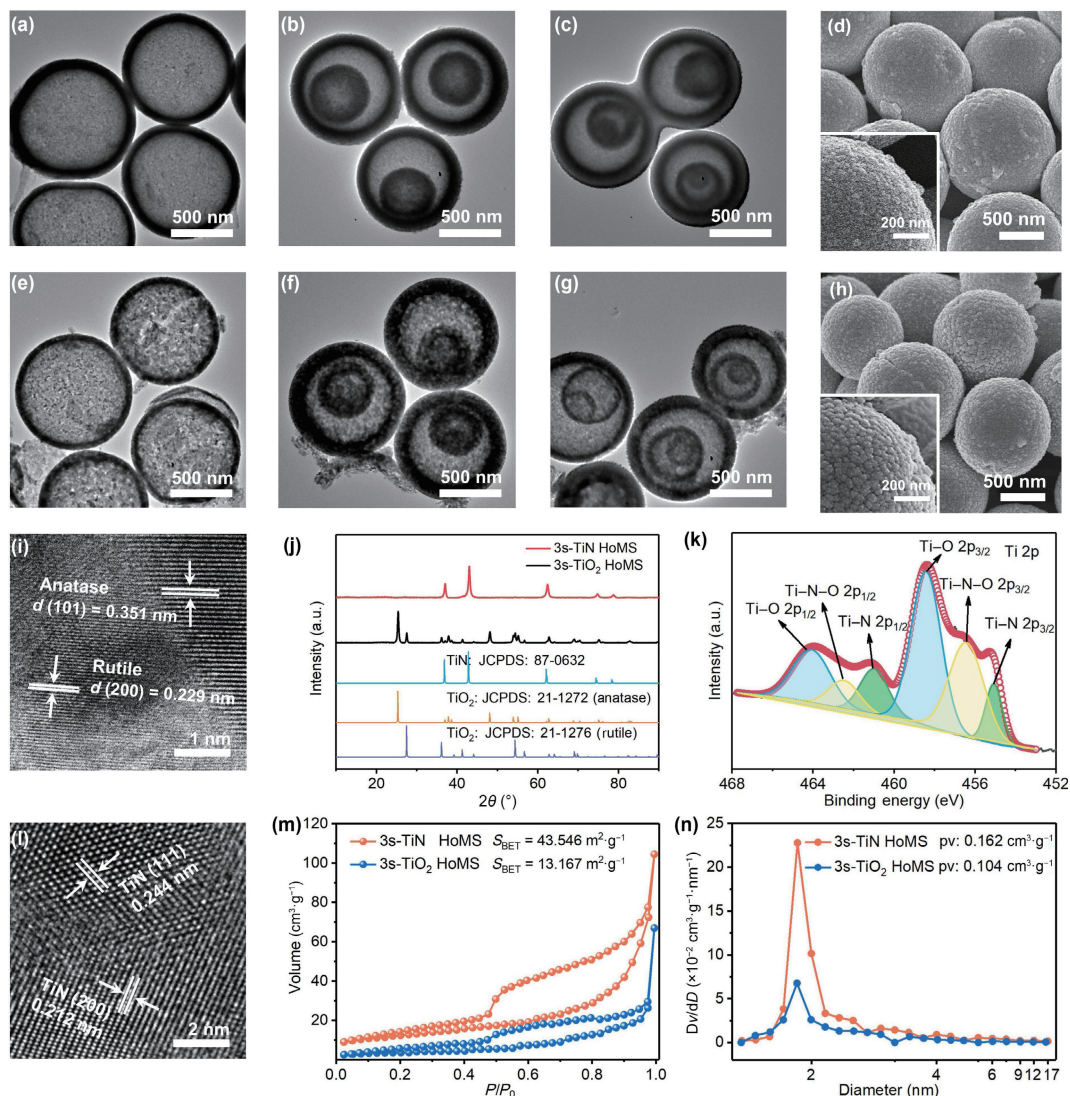

Figure 1 TEM images of (a) TiO$_2$ HS, (b) 2s-, and (c) 3s-TiO$_2$ HoMS. (d) SEM images of 3s-TiO$_2$ HoMS. TEM images of (e) TiN HS, (f) 2s-, and (g) 3s-TiN HoMS. (h) SEM images of 3s-TiN HoMS. The HRTEM images of (i) 3s-TiO$_2$ HoMS and (l) 3s-TiN HoMS. (j) Powder XRD patterns of 3s-TiO$_2$ HoMS and 3s-TiN HoMS. (k) Ti 2p XPS spectra of 3s-TiN HoMS. and 1(h)), both shells of TiO$_2$ HoMS and TiN HoMS are composed of nanosized grains. X-ray diffraction (XRD) patterns (Fig. 1(j)) and the high-resolution TEM (HRTEM) (Fig. 1(i)) indicate that 3s-TiO$_2$ HoMS is composed of anatase and rutile phase, while only the peaks of TiN without any impurity phases are detected in the TiN HoMS sample, which indicates the total transformation of TiO$_2$ HoMS to TiN HoMS after nitridation treatment. In addition, clear lattice fringes with an inter-planar spacing of 0.212 and 0.244 nm are observed in the HRTEM (Fig. 1(l)), which is assigned to the (200) and (111) planes, respectively, of TiN [42]. X-ray photoelectron spectroscopy (XPS) test was also performed on TiN HoMS (Fig. 1(k) and Fig. S4 in the Electronic Supplementary Material (ESM)). The signals at 460.98 and 455.08 eV are ascribed to the Ti–N configuration, and the peaks at 462.48 and 456.44 eV are attributed to the Ti–N–O species. In addition, there are two signals at 464.08 and 458.42 eV, corresponding to the Ti–O signals of TiO$_2$, which may be due to that oxide layer is formed on the surface of TiN when it is exposed to ambient air [42]. What is more interestingly, Brunauer–Emmett–Teller (BET) N$_2$ adsorption–desorption analysis (Fig. 1(m), and Fig. S3 and Table S1 in the ESM) shows that the specific surface area of TiN HoMS is three times that of TiO$_2$ HoMS. In addition, the pore size distribution indicates that TiN HoMS possesses more mesopores (Fig. 1(n)). The higher specific surface area and more mesopores of TiN HoMS are favorable for anchoring sulfur and LiPSs.

The S@TiN composite was synthesized by a melting-diffusion method, and details could be found in the ESM. TiN HoMS maintains its original spherical shape after S loading, and the contrast within the cavity between shells is obviously darkened compared to bare TiN samples (Figs. 2(a)–2(c)). Energy-dispersive X-ray (EDX) element mapping (Fig. 2(d)) proves that S has been successfully loaded into the internal space of TiN hollow sphere. The linear scan analysis of S@2s-TiN HoMS composite further proves the presence of high content of S distributed in the cavity of TiN HoMS (Figs. 2(e) and 2(f)). In addition, sharp XRD peaks of S were detected in the S@TiN composite, suggesting that crystalline S has been successfully encapsulated into TiN HoMS (Fig. 2(g)). Thermogravimetric analysis shows that the loading mass ratios of S in the S@TiN HS, S@2s-TiN HoMS, and S@3s-TiN HoMS are about 65.4%, 70.3%, and 80.1%, respectively. The higher S loading of the 3s-TiN HoMS may be that its multiple shells could better inhibit the S loss comparable to TiN HS during the washing process to remove the surface residual S.

To compare the LiPS adsorption ability of different samples, parallel adsorption measurements were performed by placing the same mass amount of samples into Li$_2$S$_6$ solution (5 mmol·L^{-1}). After 12 h of immersion, the color of the solution added with TiN-nanoparticle (NP) turned lighter (Fig. 3(a)) but remained yellowish. Comparatively, solutions containing TiN HS or HoMS turned colorless, which may be because that TiN HS or HoMS possesses a larger specific surface area and better adsorption of Li$_2$S$_6$. The ultraviolet–visible (UV–Vis) spectral characterization (Fig. 3(a)) further confirmed the above results. The chemical interaction mechanism between titanium nitride and LiPSs was

determined by XPS measurements. Figure 3(b) illustrates an overall shift of the peaks of TiN HoMS-Li_2S_6 toward lower binding energies compared to TiN HoMS, which indicates a stronger interaction between TiN and Li_2S_6. Likewise, a similar peak shift is observed in the N 1s spectrum (Fig. S5 in the ESM). TiN HoMS-Li_2S_6 exhibits a new peak at 456.42 eV, corresponding to the formed S–Ti–O bond [60]. The above results suggest that TiN HoMS provides strong anchoring ability to LiPSs, which is conducive to confining the diffusion shuttle of LiPSs.

In addition to chemical anchoring LiPSs, TiN HoMS is able to catalyze the conversion of LiPSs and promote Li_2S nucleation and growth [61, 62]. To verify the electrocatalytic activity of TiN HoMS, a symmetric cell was assembled. As shown in Fig. 3(c), cells based on TiN HoMS electrodes show higher currents than those based on TiN-NP electrodes. Additionally, the magnitude of the current was increased with an increase in shell number in the TiN sample. The electrocatalytic activity was further verified through cyclic voltammetry (CV) and potential polarization experiments. In Fig. 3(d), the reduction peak at R1 corresponds to the reduction of S_8 molecules to soluble long-chain polysulfides (Li_2S_n, n = 4–8) during discharge process, and the reduction peak at R2 corresponds to the reduction of soluble polysulfides (Li_2S_n, n = 4–8) to electrolyte-insoluble Li_2S_2 and Li_2S [63]. Two oxidation peaks O1 and O2 correspond to the oxidation of Li_2S_2/Li_2S to S_8 during the charge process. Figures 3(e) and 3(f) show the Tafel slopes during the oxidation and reduction processes, respectively. The Tafel slopes of S@TiN HS, S@2s-TiN HoMS, and S@3s-TiN HoMS are 93, 61, and 51 mV·dec^{-1} for the Li_2S to Li_2S_n conversion and 183, 141, and 115 mV·dec^{-1} for the S_8 to Li_2S_n conversion, which further proves the electrocatalytic activity of TiN HoMS.

Normally, the reaction kinetics of the conversion from soluble polysulfide to insulating solid Li_2S is poor in the late stage of discharge process, wherein the precipitation of Li_2S greatly affects the capacity of the battery. To evaluate the effect of TiN on the precipitation of Li_2S, cells were assembled by using equal mass of TiN-NP and 3s-TiN HoMS loaded carbon fiber cloth (CFC) as cathode and lithium metal as anode. Cells were discharged to 2.06 V at a current density of 0.112 mA and then held potential at 2.05 V until the current dropped below 10^{-5} A. According to Faraday's law, the Li_2S precipitates were evaluated according to the charge [47, 64]. As shown in Figs. 3(g)–3(i), the deposition capacity of Li_2S on the surface of CFC + 3s-TiN HoMS reaches 411 mAh·g^{-1}, which is the largest among the three cells, confirming that 3s-TiN HoMS can enhance the conversion of LiPLs to Li_2S and the nucleation and growth of Li_2S. The reasons are ascribed to that the excellent electrical conductivity of TiN facilitates electron diffusion and the HoMS can shorten the transport path of ions and electrons.

The electrochemical performance is evaluated by assembling CR2032 coin cells with lithium metal used as the counter and reference electrode. Figure 4(a) shows the first-cycle charge/discharge voltage profiles of the S@3s-TiN HoMS, S@2s-TiN HoMS, S@TiN HS, S/TiN-NP, and S/C electrodes at 0.2 C. S@3s-TiN HoMS exhibits the highest specific capacity and high initial Coulombic efficiency of 98.3%. It is worth mentioning that TiN hosts have no contribution to the overall capacity by themselves (Fig. S6 in the ESM). In addition, it is worth noting that the specific capacities of the five electrodes are relatively similar in the first discharge plateau but differ dramatically in the
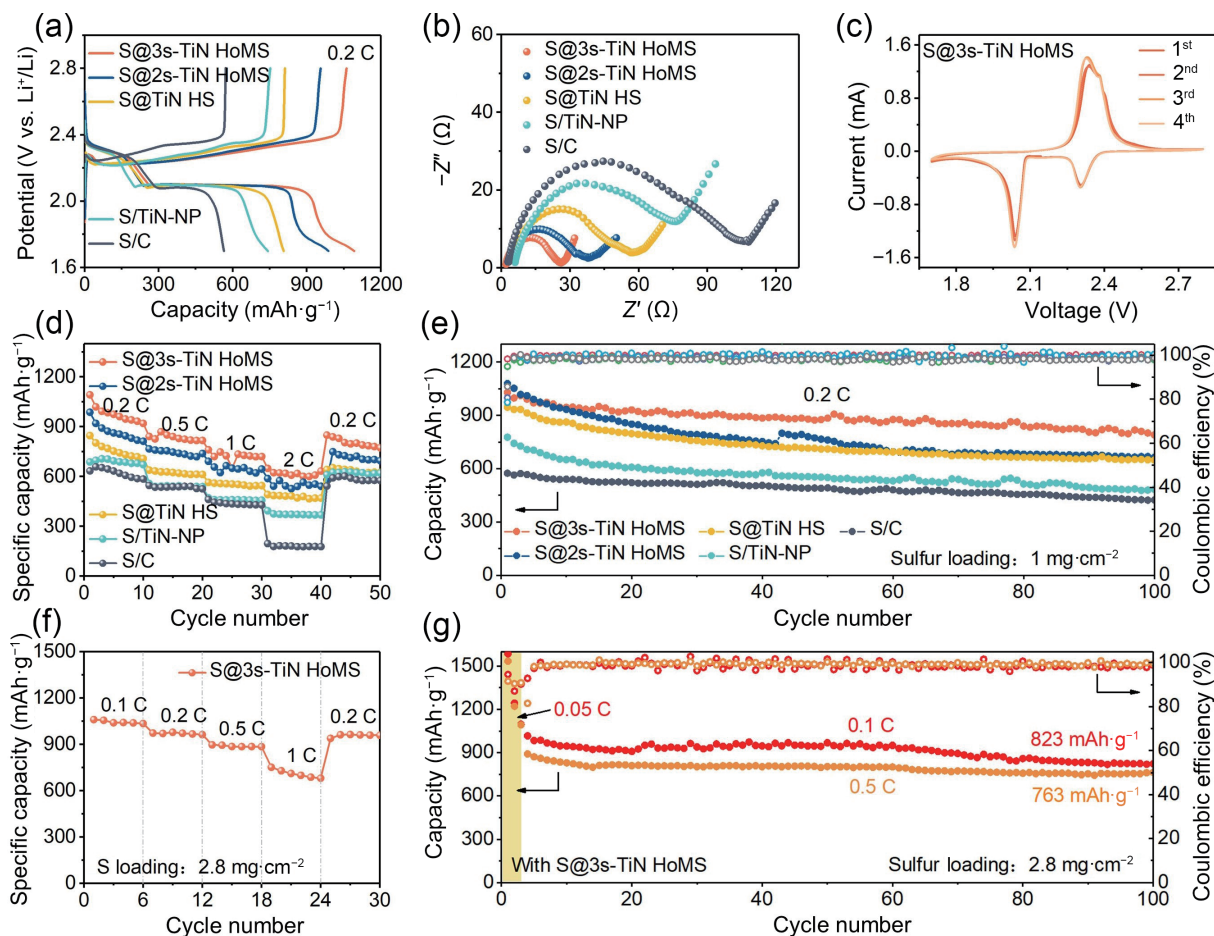

Figure 4 (a) Galvanostatic charge–discharge voltage profiles of S@TiN HoMS, S@TiN HS, S/TiN-NP, and S/C at a rate 0.2 C. (b) Nyquist plots of S@TiN HoMS, S@TiN HS, S/TiN-NP, and S/C from 0.1 to 100 MHz. (c) CV profiles of S@3s-TiN HoMS at a scan rate of 0.2 mV·s^{-1}. (d) Rate capabilities of S@TiN HoMS, S@TiN HS, S/TiN-NP, and S/C electrodes tested at 0.2, 0.5, 1, and 2 C, with a mass loading of 1.0 mg·cm^{-2}. (e) Cycling performance of S@TiN HoMS, S@TiN HS, S/TiN-NP, and S/C at 0.2 C (activated at 0.05 C was removed). (f) Rate capabilities of 2.8 mg·cm^{-2} sulfur-loaded S@3s-TiN HoMS cathode. (g) Cycle performance and Coulombic efficiency of 2.8 mg·cm^{-2} sulfur-loaded S@3s-TiN HoMS cathode at 0.1 and 0.5 C.

second discharge plateau (Fig. S8 in the ESM). The ratios of the capacity obtained in the second discharge plateau to those obtained in the first plateau for S@3s-TiN HoMS, S@2s-TiN HoMS, S@TiN HS, S/TiN-NP, and S/C are 3.1:1, 3.0:1, 2.2:, 2.0:1, and 0.9:1. It is demonstrated that 3s-TiN HoMS host enables the catalytic conversion of polysulfides more effectively.

The magnitude of the charge transfer resistance (R_{ct}) can be compared by the depressed semicircle of the Nyquist curve in the high frequency region. As shown in Fig. 4(b), the R_{ct} of S/TiN-NP is significantly lower than that of S/C due to the better conductivity of TiN (4000–55,000 S·cm^{-1}) than carbon (0.2–0.5 S·cm^{-1}) [57]. In particular, the R_{ct} of TiN HoMS decreases with the increase in the number of shells. It is due to that multiple shells are connected with each other and form a percolated conductive pathway, which is able to reduce the overall resistance of the circuit [65].

Figure 4(c) demonstrates the CV curves of the cell with the S@3s-TiN HoMS cathode in the first five cycles at 0.2 mV·s^{-1}. The CV cycle almost overlapped, demonstrating good reversibility and stability of the S@3s-TiN HoMS electrode. Moreover, the cycle performance of S@TiN HoMS composite is generally superior to the S@TiN HS, S/TiN-NP, and S/C composite (Fig. 4(e)). Specifically, S@3s-TiN HoMS achieves the highest capacity of 790 mAh·g^{-1} after 100 cycles at 0.2 C, followed by S@2s-TiN HoMS (663 mAh·g^{-1}), S@TiN HS (648 mAh·g^{-1}), S/TiN-NP (648 mAh·g^{-1}), and S/C (424 mAh·g^{-1}). Figure 4(d) shows the rate capability at 0.2, 0.5, 1, 2, and 0.2 C rate, respectively. Obviously, the S@TiN HoMS exhibited a better rate capability compared to

S@TiN HS, S/TiN-NP, and S/C, delivering a discharge capacity of 1019, 869, 747, and 618 mAh·g^{-1} at 0.2, 0.5, 1, and 2 C rate, respectively. Moreover, the discharge capacity can almost be recovered to the similar value when the current density decreases back to 0.2 C, indicating that S@3s-TiN HoMS has excellent multiplicative performance. This is mainly due to the shortened ion and electron transport path and the effective confinement of LiPSs by TiN HoMSs.

Considering the requirements of practical application, electrochemical performance with a high sulfur loading is explored. When the sulfur loading was increased to 2.8 mg·cm^{-2}, the cathodes of S@3s-TiN HoMS still performed a good rate capability, showing discharge capacities of 1060, 970, 896, and 751 mAh·g^{-1} at 0.1, 0.2, 0.5, and 1 C rate, respectively (Fig. 4(f)). When the rate was switched back from 1 to 0.2 C, the discharge capacity recovered to 964 mAh·g^{-1}. In addition, the cycle life of the S@3s-TiN HoMS electrode with areal sulfur loading of 2.8 mg·cm^{-2} was tested at 0.2 and 0.5 C for 100 cycles (Fig. 4(g)). Upon the initial activation cycle at 0.05 C, the discharge capacities of 1585 and 1534 mAh·g^{-1} are delivered, corresponding to an areal capacity of 4.4 and 4.3 mAh·cm^{-2}, respectively. The S@3s-TiN HoMS electrode delivers capacities of 1016 mAh·g^{-1} (2.8 mAh·cm^{-2}) at 0.1 C and 891 mAh·g^{-1} (2.5 mAh·cm^{-2}) at 0.5 C, respectively. The capacities are stabilized at above 823 mAh·g^{-1} (2.3 mAh·cm^{-2}) and 763 mAh·g^{-1} (2.1 mAh·cm^{-2}) over 100 cycles, respectively, which is attributed to the good conductivity of TiN and its effective catalytic effect promoting the conversion of LiPSs.

To further understand the reaction mechanism, *in situ* Raman
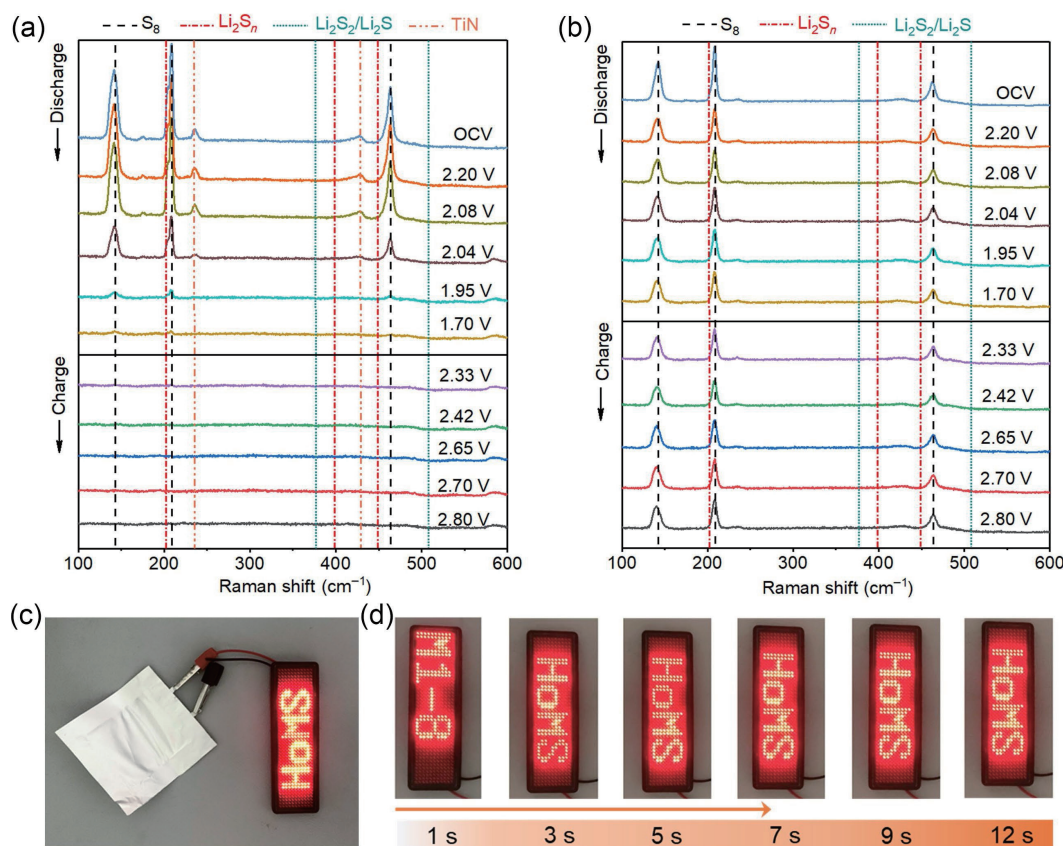

Figure 5 *In situ* Raman spectra of Li-S batteries based on (a) S@3s-TiN HoMS and (b) S/C cathodes during the discharge–charge processes. Pouch cells were assembled by pairing S@3s-TiN HoMS cathode with Li foil anode, (c) LED display light lighting test and (d) long-time bright screen test of LED display.

spectroscopy was carried out to monitor the real-time evolution of sulfur species. Figures 5(a) and 5(b) depict the *in situ* Raman spectra obtained for S@3s-TiN HoMS and S/C cathode surface, respectively, during the discharge–charge process. Characteristic peaks around 145, 211, and 463 cm^{-1} corresponding to S_8^{2-} can be observed at the beginning of the discharge process for these two cathodes [66, 67]. As for the S@3s-TiN HoMS cathode, characteristic peaks around 232 and 427 cm^{-1} corresponding to TiN can also be observed. With the continuous discharge, the peaks of S_8^{2-} became weaker and totally disappeared at the end of discharge process, indicating that S_8^{2-} has been totally converted and no S_8^{2-} species has been transported to the anode side. In addition, the signal of S_8^{2-} gradually re-appeared during the charge process, indicating the reversible and fast redox reaction. In contrast, as for the S/C cathode, the peaks of S_8^{2-} were slightly weakened and could be observed during the whole discharge process, indicating that the reduction reaction of S_8^{2-} was incomplete, which may be ascribed to the severe shuttle effect happened in the S/C cathode. To further investigate the practicability of 3s-TiN HoMS host, a pouch cell based on S@3s-TiN HoMS cathode and lithium foil anode was constructed. As shown in Figs. 5(c) and 5(d), this pouch cell could easily and continually power the light-emitting diode (LED) screen with a "HOMS" pattern.

3 Conclusions

In summary, TiN HoMS was synthesized and employed as a catalytic host for S cathode. TiN not only improves the conductivity of sulfur cathode but also promotes the redox reaction kinetics, and its strong adsorption ability of lithium polysulfide effectively inhibits the LiPSs shuttle effect. Meanwhile, HoMS not only effectively buffers the volume expansion of S but also shortens the ion and electron transport pathways, as well as

inhibits shuttle effect by providing abundant adsorption sites and multiple physical barriers. As a result, 3s-TiN HoMS simultaneously exhibits a high specific capacity, good cycling stability, and superior rate capability, reaching an initial specific capacity of 1016 mAh·g^{-1} and maintained at 823 mAh·g^{-1} after 100 cycles with a high sulfur loading of 2.8 mg·cm^{-2}, and showing a four times high specific capacity than the one without TiN host at 2 C. This work provides novel insight into the design of multifunctional hosts for Li-S batteries with better multiplicative performance, high capacity, and long cycle stability.
