doi:10.1007/s12350-014-9918-0

**Background.** The prognostic value of normal stress myocardial perfusion single-photon emission computed tomography (MPS) in patients with diabetes has only been evaluated in single-center studies of relatively limited sample size. We performed a meta-analysis of published studies, including diabetic patients with known or suspected coronary artery disease (CAD), to assess the predictive value for adverse cardiac ischemic events of normal stress MPS.

**Methods and Results.** Studies published between January 1990 and December 2013 were identified by database search. We included studies using stress MPS to evaluate diabetic patients with known or suspected CAD and providing data on clinical outcomes of non-fatal myocardial infarction or cardiac death with a follow-up time  $\geq 12$  months. A total of 14 studies were finally included, recruiting 13,493 patients. The negative predictive value (NPV) for non-fatal myocardial infarction and cardiac death of normal MPS was 94.92% (95% confidence interval 93.67-96.05), during a weighted mean follow-up of 36.24 months, resulting in estimated event rate after a negative test equal to 5.08% (95% confidence interval 3.95-6.33). The corresponding annualized event rate after a negative test was 1.60% (95% confidence interval 1.21-2.04).

**Conclusions.** Stress MPS has a high NPV for adverse cardiac events in diabetic patients with known or suspected CAD leading to define a “relatively low-risk” patients category. (J Nucl Cardiol 2014;21:893–902.)

**Key Words:** Myocardial perfusion imaging • diabetes mellitus • prognosis

### INTRODUCTION

Stress myocardial perfusion single-photon emission computed tomography (MPS) has taken a central role in risk stratify patients with suspected or known coronary artery disease (CAD). Accurate risk stratification has become increasingly important to optimize patient

outcomes and contains rapidly escalating medical care costs.<sup>1</sup> In particular, the prognostic value of negative stress MPS gives the possibility to identify low-risk patients, decreasing additional tests and interventions. However, after a normal stress MPS, diabetic patients are at higher risk for cardiac events than non-diabetic subjects also after balancing clinical characteristics and stress type by propensity score analysis.<sup>2</sup> Despite cardiac risk assessment in diabetic patients is challenging, based on current data, routine screening is not generally recommended. Higher knowledge of prognostic value of

normal MPS results in diabetic patients can be important considering that the reliance of temporal changes in risk during a long-term follow-up provides also a basis for identifying the timing of repeat testing.<sup>2,3</sup>

However, the prognostic value of a negative stress MPS in diabetic patients has only been evaluated in single-center studies of relatively limited sample size. Thus, we performed a meta-analysis of published studies, including diabetic patients with known or suspected CAD, to assess the predictive value for adverse cardiac ischemic events of normal stress MPS, defined as the absence of inducible perfusion defects.

## MATERIALS AND METHODS

### Data Sources and Study Selection

An English literature search was performed using the PubMed, Cochrane, Web of Science, and Scopus database to identify articles published between January 1990 and December 2013. Studies search was restricted to data obtained in humans and adults and was conducted using the following keywords (alone and in different combinations): prognosis, outcome, follow-up, diabetes, diabetic patients, and myocardial perfusion imaging. The title and abstract of potentially relevant studies were screened for appropriateness before retrieval of the full article when relevant by two reviewers (V.C., R.G.) and disagreements were resolved by consensus. The full-published reports of the all abstracts selected by the reviewers were retrieved and the same reviewers independently performed a second-step selection based on the inclusion criteria; disagreements were resolved by consensus. In addition, one reviewer manually reviewed the bibliographies of retrieved articles for additional citations. A study was included if all of the following criteria were met: (1) the study had prospective or retrospective analysis of diabetic subjects referred for suspected or known CAD who underwent pharmacological or exercise stress MPS for searching inducible ischemia; (2) the study included a negative test defined in the absence of inducible perfusion defects during stress MPS; (3) the study provided the absolute number of diabetic patients with a negative test and data on clinical outcomes of non-fatal myocardial infarction and cardiac death; and (4) the follow-up time of the study was at least 12 months. In case of multiple studies reported from the same research group, potential cohort duplication was avoided by including the largest study only. Overall study quality was not used as a pre-specified inclusion criterion.<sup>4</sup>

### Data Extraction and Quality Assessment

To evaluate eligibility for the meta-analysis, as previously described,<sup>5,6</sup> each study was initially identified by considering journal, author, and year of publication. Additional extracted variables included study design (retrospective or prospective), imaging system, criterion used to classify a test as negative, type of stressor used, type of radiotracer used, the number of patients with and without disease, and modality of data assessment

(qualitative, semiquantitative, or quantitative). Data were also collected on age and on prevalence of female sex, traditional cardiovascular risk factors besides diabetes (hypertension, dyslipidemia, family history of CAD, smoking), angina-like symptoms, and history of CAD (including previous myocardial infarction and previous myocardial revascularization). Mean or median follow-up time, number of events, or event rate based on negative tests, occurrence of non-fatal myocardial infarction, or cardiac death were recorded.

Quality assessment was performed using a previously described methodology<sup>7</sup> and was on the basis of the presence of the following parameters: (1) complete follow-up in the majority of subjects ( $\geq 90\%$  of the baseline cohort); (2) outcome data collected by investigators blinded to the test results; and (3) outcomes corroborated by hospital records and death certificates. Studies were defined as good quality if they fulfilled criterion 1 and  $\geq 1$  of the other 2 criteria, as fair quality if they fulfilled only the criterion 1, and as poor quality if they fulfilled none of the criteria.

### Statistical Analysis

Demographical and clinical characteristics of all patients included in this meta-analysis were obtained as weighted averages of those reported in the single studies, the weights being the total sample size for each study. Statistical heterogeneity between studies was assessed using the Cochrane Q statistic (with a value of  $P < .1$  reflecting significant heterogeneity) and  $I^2$  statistic,<sup>8,9</sup> which measures the percentage of total variability across studies not due to sampling error. Because of the large heterogeneity experienced, the pooled estimates of negative predictive value (NPV) for cardiac events and the pooled estimates of the event rate after negative tests (event rate after negative test =  $1 - \text{NPV}$ ) were computed with the 95% confidence interval (CI) using the random-effects model of DerSimonian and Laird.<sup>10</sup>

While fixed effects model assumes that the true effect size is the same in all study and that all of the variability between effect sizes is due to sampling error, the random-effects model assumes that the variability between effect sizes is due to sampling error (within study variance) plus variability in the effect size among the studies (between study variance). Accordingly, in a random-effects meta-analysis, the standard errors of the study-specific estimates are adjusted to incorporate a measure of the extent of between study variance.<sup>10</sup> The influence of each study on the overall results of the meta-analysis is expressed as weight. The higher the percentage weight (and the bigger the box in the forest-plot depicting the meta-analysis results), the more influence the study has on the overall results. In the present meta-analysis, the weight of each study was calculated with the inverse variance method, as a function of the variance of that study ( $V_i$ ) and of the variance of the true effects of the compound between the different studies ( $T^2$ ), using the formula:  $1/(V_i + T^2)$ .<sup>11</sup>

To correct for over dispersion, the raw proportions (NPV and event rate after negative test) were initially converted using the Freeman-Tukey transformation and back transformed after quantitative data synthesis.<sup>12,13</sup> For each study, the annualized event rate after negative test was obtained as average during the lengths of follow-up. In addition to the

overall random-effects model, univariate meta-regression analyses were performed to assess the evidence of prevalence modifiers. To formally evaluate potential publication bias, we performed a test proposed by Egger et al.<sup>14</sup> All analyses were performed with R statistics (version 2.15.0), using the additional packages META and METAFOR.

## RESULTS

The initial database search identified 165 potentially eligible citations. The reviewers, after the evaluation of the titles and abstracts of these studies, discharged 131 citations because they were judged to be non-relevant or non-pertinent. To determine eligibility, each investigator reviewed the full text of the remaining 34 independently, and disagreements were resolved by consensus. After revision, 20 articles were excluded and the final analysis considered 14 studies<sup>2,15-27</sup> including 13,493 patients. The complete literature search is presented in flow-chart form in Figure 1.

Demographical and clinical characteristics of patients included in the studies in the meta-analysis are detailed in Table 1. Data were obtained using exercise or pharmacologic stress test in ten studies and pharmacologic stress test in four studies (adenosine in

three and dobutamine in one). The imaging agent was a Tc-99m-based tracer in 12 studies and thallium-201 in 2 studies. Of the 14 studies, 9 used as cut-off of normal myocardial perfusion a summed stress score (SSS)  $\leq 3$  (17-segment score model in 7 studies and 20-segment score model in 2 studies) and 2 a SSS  $\leq 4$  (17-segment score model in one study and 20-segment score model in another study). In the last three studies, myocardial perfusion was defined as normal when a perfusion defect involved  $< 2$  myocardial segments. Study sample sizes ranged from 87 to 4,628 patients enrolled, including a proportion of patients with known CAD ranging from 20% to 40%. The mean age ranged from 57 to 65 years, with the proportion of women ranging from 13% to 50%. The duration of follow-up ranged from 2.2 to 4.8 years. After negative test, the event rate for non-fatal myocardial infarction or cardiac death varied between 0.90% and 9.62% and the annualized event rate between 0.41% and 3.24%. After quality assessment, 11 studies were graded as good quality and 3 studies as fair quality.

### Predictive Value of Stress MPS for Cardiac Death and Non-fatal Myocardial Infarction

Figure 2 shows the forest plot of NPV for non-fatal myocardial infarction and cardiac death for each study, as well as the pooled estimate yielded by the random-effect model. In the individual studies, NPV ranged from 90.38% to 99.10%. During a weighted mean follow-up of 36.24 months, the summary NPV was 94.92% (95% CI 93.67-96.05). The estimate of NPV was not significantly different ( $P = .14$ ) between studies including both asymptomatic and symptomatic patients (94.19%, 95% CI 92.91-95.35) and studies including only asymptomatic patients (95.83%, 95% CI 92.80-98.09). The pooled event rate after negative test was 5.08% (95% CI 3.95-6.33) in the overall studies, without differences ( $P = .14$ ) between studies including asymptomatic and symptomatic patients and those including only asymptomatic patients (Figure 3).

The corresponding pooled estimate of annualized event rate after negative test was 1.60% (95% CI 1.21-2.04). The estimate of annualized event rate was slightly lower ( $P = .06$ ) for the subgroup of studies including only asymptomatic patients (1.20%, 95% CI 0.54-2.09) as compared to those including both asymptomatic and symptomatic patients (1.93%, 95% CI 1.48-2.45) (Figure 4). Noteworthy, the pooled estimate of annualized event rate was not significantly different ( $P = .41$ ) between the four studies published before 2007 (1.95%, 95% CI 0.96-3.26) and those published after 2007 (1.48%, 95% CI 1.01-2.02).

A high level of heterogeneity was observed between studies for both NPV and event rate after negative test

**Figure 3.** Event rate after negative test (ERNT) for cardiac death and non-fatal myocardial infarction. *CI*, Confidence interval.

( $I^2 = 78.4\%$ ,  $P < .0001$ ) and for annualized event rate after negative test ( $I^2 = 84.6\%$ ,  $P < .0001$ ). At meta-regression analysis, no significant association was detectable between NPV and the considered variables: age, sex, dyslipidemia, smoking, hypertension, family history of CAD, and prior myocardial infarction.

**Publication Bias**

For studies enrolled in this meta-analysis, no evidence of significant publication bias was found for NPV (bias 0.12, standard error 1.2, slope 2.66,  $P = .92$ )

as well as for event rate after negative test (bias  $-0.12$ , standard error 1.2, slope 0.47,  $P = .92$ ), and annualized event rate after negative test (bias  $-0.25$ , standard error 1.47, slope 0.27,  $P = .8$ ).

**DISCUSSION**

This systematic review and meta-analysis is the first addressing the prognostic value of negative stress MPS result in diabetic subjects with known or suspected CAD. Our results demonstrate that in this patient population a negative stress MPS predicts a relatively

**Figure 4.** Annualized event rate after negative test (AERNT) for cardiac death and non-fatal myocardial infarction. *CI*, Confidence interval.

low risk of cardiovascular events over a mid-term follow up. One of the major strengths of stress MPS is the low subsequent cardiac event rate in patients with normal findings.<sup>3</sup> Several studies reported that patients with negative stress MPS have an excellent outcome, as less than 1% of patients with a normal study will experience hard cardiac events, such as cardiac death or non-fatal myocardial infarction.<sup>2,3</sup> However, the risk of hard event after a normal MPS is a function of the clinical and historical factors of the patients tested. In particular, diabetes is an important clinical variable in determining the risk of events after stress MPS. It has been demonstrated that after a normal stress MPS, diabetic patients are at higher risk (>1%) for cardiac events than non-diabetic subjects (<1%) also after balancing clinical characteristics and stress type by a propensity score analysis.<sup>2</sup> Summary data according to diabetes status after a normal stress MPS might be very useful considering that the low risk associated with normal MPS is an important component of a testing strategy that can lower the overall cost and enhance the effectiveness of test.<sup>3</sup>

Data already published evaluating the stratification power of a normal MPS finding in diabetic patients have been performed in heterogeneous studies. Therefore, the prognostic value of a normal stress MPS in patients with diabetes has been extrapolated by an overall population with suspected or known CAD, and several potential confounding may have affect the results reported. Often, the prognostic power of a normal stress MPS has not been specifically evaluated in diabetic patients, but has

been tested using diabetes as covariate in an overall patient population with suspected or known CAD.

From the present meta-analysis using restrict researching criteria (diabetic patients and normal MPS), it emerged that MPS has a high NPV leading to define a low-risk patients category. From published data it emerged that additional interventions can be avoided identifying a low-risk group of patients, defined by an annual event rate of <1%.<sup>28</sup> However, in our meta-analysis the pooled annualized event rate with normal test is 1.60%, higher that in the general population (<1%), leading to define diabetic patients with negative stress MPS results as a “relatively low-risk” patients category. It should be considered that a significant heterogeneity in the studies selected in this meta-analysis was observed. In particular, the range of annualized event rate has been reassuring (<1%) only in four studies<sup>23,25-27</sup> while in all the others studies it ranged from 1.47 to 3.24.<sup>2,15-22,24</sup>

It is still uncertain if all diabetic patients should be treated as CAD risk equivalents although many do not achieve that risk status<sup>29</sup> or if they should be further stratify to better align intensity of therapy with levels of cardiovascular risk.<sup>30</sup> The detection of occult CAD in order to initiate appropriate therapy at a time point when the disease process is more easily modifiable is the objective of non-invasively testing asymptomatic diabetic patients for risk stratification purposes. This strategy is expected to lead to declines in cardiac morbidity and mortality. Major society guidelines and position statements have made recommendations about

testing for asymptomatic CAD in diabetic patients. The American College of Cardiology considers appropriate the use of radionuclide imaging for asymptomatic diabetic patients >40 years old and other coronary risk equivalents.<sup>31</sup> The American College of Cardiology Foundation/American Heart Association guidelines give a weak class IIb (level of evidence C) recommendation to consider stress MPS for cardiovascular risk assessment in asymptomatic adults with diabetes.<sup>32</sup> A position statement of the European Society of Cardiology states that asymptomatic diabetic patients without known CAD should be considered for coronary calcium imaging followed by MPS for those with significant coronary calcium, in order to identify subjects with a moderate to severe extent of ischemia which are likely to benefit from invasive evaluation and revascularization (class of recommendation IIa).<sup>33</sup> The American Diabetes Association does not recommend screening for CAD in asymptomatic patients because it does not improve outcomes as long as cardiovascular risk factors are treated (level of evidence A).<sup>34</sup> Important questions are still to be addressed, such as the potential of coronary revascularization to reduce cardiac events in asymptomatic diabetic patients; the yield of non-invasive testing in identifying reliably a considerable proportion of those patients likely to benefit from this type of intervention in a cost-effective manner; and who, when, and how to test.<sup>35,36</sup> In the present meta-analysis, we found that the annualized event rate was not significantly different for studies including only asymptomatic patients compared to those including both asymptomatic and symptomatic patients.

Stress tests are most useful for patients with suspected CAD at intermediate pre-test probability of disease or in patients with known CAD at intermediate pre-test probability of ischemia, by moving them into a higher- or lower-risk group, thereby informing the choice of additional diagnostic tests, interventions, and medical management, which are costly and carry significant risks. Our study indicates that stress MPS in diabetic patients is useful in identifying such lower-risk subjects over a spectrum of pre-test probabilities. Even in study cohorts or subsets of patients with relatively high pre-test probability, such as those with a higher percentage of prior myocardial infarction, the event rate with normal stress MPS is relatively low. However, only identifying a low-risk group of patients, defined by an annual event rate of <1%, additional interventions can be avoided in most cases.<sup>37</sup> In diabetic patients a normal MPS assumes an important significance also considering that helps to identify a warranty period in establishing the time at which repeat testing might be appropriate.<sup>20</sup> Repeating testing remains a significant part in the evaluation of cost-effectiveness in the long-term follow-up of patients with suspected and known CAD.

## Limitations

Variation in test performance among subjects at very high or very low risk of disease (spectrum bias) may affect the results of prognostic studies, also in assessment of NPV.<sup>37</sup> Our systematic review includes studies of cohorts with supposedly varying pre-test risk of disease, as manifested by a broad range of percentage of subjects with major cardiovascular risk factor, history of CAD, prior myocardial infarction, history of previous coronary revascularization procedures or with symptoms (Table 1). The assessment of pre-test risk is relevant for evaluating the clinical impact of cardiovascular imaging,<sup>38</sup> but the availability of incomplete clinical data in many of the included studies prevents the possibility to perform subgroups analyses and, consequently, to evaluate more carefully the NPV in relation to pre-test risk. In fact, meta-regression analysis was performed only considering the variables available in the majority of the studies. We could not address the effect of some confounding factors such as cardiac medications, glycemic control, microvascular dysfunction, and differences between exercise and vasodilator testing. Also the impact of ejection fraction could not be considered because it was not reported in the subset of patients with normal myocardial perfusion in most the studies included in the meta-analysis.

## NEW KNOWLEDGE GAINED

The current study underscores the high NPV of a normal stress MPS in diabetic patients with known or suspected CAD. However, the pooled annualized event rate in subjects with normal test is higher (1.60%) than in the general population (<1%). Thus, our findings suggest that diabetic patients with negative stress MPS results are in an intermediate-risk category.
