Abstract Geoelectrical resistivity techniques are increasingly being applied in addressing a wide range of hydrological, environmental, and geotechnical problems. This is due to their effectiveness in near-surface characterization. In the present study, a suite of vertical electrical soundings (VESs) was integrated with 2D geoelectrical resistivity and time-domain induced polarization (IP) imaging to characterize the near-surface and delineate the underlying aquifer in a sedimentary terrain. The geophysical survey was conducted as part of preliminary studies to evaluate the potential of groundwater resource in Iyana-Iyesi and Canaan Land area of Ota, southwestern Nigeria. A high-yield confined sandy aquifer overlain by a low-yield aquitard was delineated; overlying the aquitard is a very resistive and thick layer that is predominantly composed of kaolinitic swelling clay intercalated with phosphate mineral.

Keywords Groundwater investigation · Resistivity and IP imaging · Near-surface geophysics · Subsurface characterization

Introduction

Geophysical methods have been used for groundwater exploration and aquifer delineation; they are increasingly becoming more relevant in a wide variety of hydrological

and hydrogeological investigations (e.g., Chandra et al. 2008; Massoud et al. 2010; Niwas and Celik 2012; Hubbard et al. 1999, 2001; Rubin and Hubbard 2005; Vereecken et al. 2006). Geophysical methods are generally non-invasive or minimally invasive, fast, and cost effective, and provide information on the spatial distribution of the physical properties of subsurface features. Thus, the spatial distribution and temporal variability of the subsurface hydrological state can be inferred from the resulting geophysical models. Also, estimates of the hydrological and petro-physical parameters that influence flow and transport processes within the subsurface porous media can be made.

Geoelectrical resistivity technique is one of the most commonly used geophysical methods for hydrological investigations. The technique has been widely used in groundwater exploration to determine depth-to-water table, delineate aquifer geometry, assess groundwater quality, and delineate freshwater-saline water interface (e.g., Wilson et al. 2006). Usually, numerical inversion techniques are used to obtain inverse models of the subsurface electrical resistivity distribution from the measured apparent resistivity data set. This is achieved by solving the non-linear and mixed-determined inverse problem whose solution is inherently non-unique and sometimes unstable. Typically, the resolution of the inverse model differs spatially; some regions of the inverse model may be well resolved while others may exhibit artifacts or anomalies that are not representatives of the physical properties of the subsurface features and, therefore, constitute interpretation errors (Day-Lewis et al. 2005; Loke et al. 2013). In particular, the resolution of the inverse models for subsurface electrical resistivity decreases with depth.

Conventional vertical electrical sounding (VES) has been widely used in geoelectrical electrical resistivity applications for hydrologic, engineering, and environmental

investigations. However, in areas where the subsurface geology is relatively complex and subtle such that the spatial distribution of the resistivity varies rapidly over short lateral distances, the conventional resistivity sounding is relatively inaccurate and unable to adequately account for the rapid lateral changes in the subsurface resistivity distribution. Despite this inherent limitation of resistivity sounding technique, VES has been very useful in delineating depth-to-bedrocks and water-table/aquifer, aquifer geometry, interface between freshwater, and saline water, as well as in regional geological studies where the one dimensional model of interpretation is approximately true. Two-dimensional (2D) and/or three-dimensional (3D) resistivity models, which provide more accurate models of the subsurface resistivity distribution (Aizebeokhai et al. 2010b; Loke et al. 2013), are alternatives interpretation models. The 2D and/or 3D geoelectrical resistivity surveys are used to construct reliable 2D and/or 3D models of subsurface resistivity distribution; they are particularly useful in hydrological, environmental, and engineering investigations where the geology is usually more complex and subtle (e.g., Aizebeokhai et al. 2010b; Aizebeokhai and Oyeyemi 2014; Amidu and Olayinka 2006; Chambers et al. 2006, 2011; Dahlin et al. 2002; Dahlin and Loke 1998; Rucker et al. 2010).

Often, geoelectrical resistivity technique is unable to discriminate between saturated sandy and clayey formations as both are characterized with low resistivity anomaly. The resistivity technique is often combined with other geophysical methods such as induced polarization (IP) that is capable of distinguishing clay mineralization from sandy formations. In this study, geoelectrical resistivity soundings were integrated with 2D geoelectrical resistivity and time-domain IP imaging to characterize the subsurface and delineate the aquifer layer. The survey was conducted as part of preliminary investigations for assessing the potential of groundwater resource in Iyana-Iyesi and Canaan Land area of Ota, southwestern Nigeria (Figs. 1 and 2). This assessment is required for groundwater resource development planning as well as monitoring.

Description and geological setting

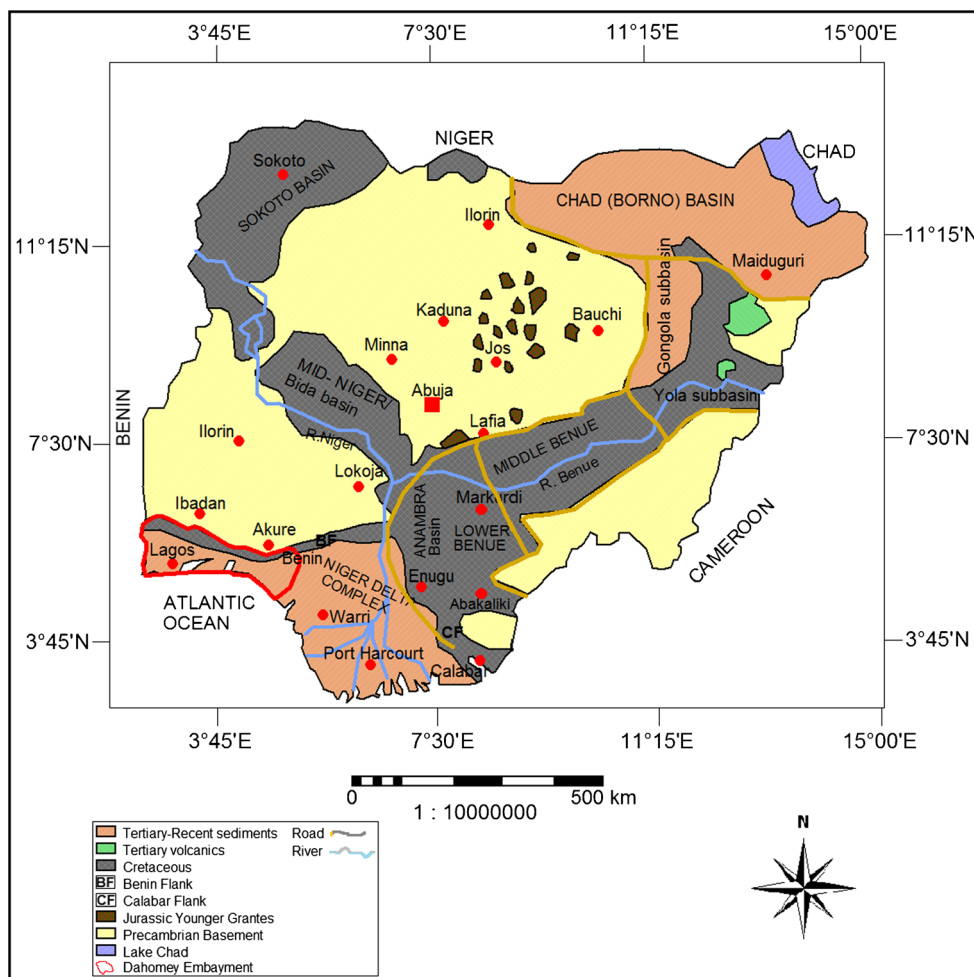

The study area (Figs. 1 and 2) is located in Ado-Odo/Ota Local Government Area of Ogun State, southwestern Nigeria. The topography is gentle sloping with elevation averaging about 75 m above mean sea level; the regional climate is tropical humid characterized by two major climatic seasons—dry and rainy seasons. Usually, the dry season spans from November to early March while the rainy season is between late March and October and is dominated by heavy

rainfall. Occasional rainfall is often witnessed in the area during the dry season because of its proximity to the Atlantic Ocean. Rainfall forms the major source of groundwater recharge in the area as in most tropical humid regions; mean annual rainfall exceeds 2000 mm. The average monthly temperature ranges from a minimum of 23° C in July to a maximum of 32° C in February; mean annual temperature is 27° C.

Geologically, the study area is within the eastern part of Dahomey Basin (Fig. 1); Dahomey Basin is an extensive basin that stretches along the continental margin of the Gulf of Guinea from southern Ghana through Togo and Benin Republic on the west side. The basin is separated from the Niger Delta in the eastern section by the Benin Hinge Line and Okitipupa Ridge; it marks the continental extension of the chain fractured zone (Onuoha 1999; Wilson and Williams 1979). The sedimentary formations of the basin outcrop in an arcuate belt are roughly parallel to the ancient coastline. Sedimentation in the basin was largely controlled by basement fracturing and subsidence associated with the rifting of the South American and African plates. The rocks in the basin are generally Late Cretaceous to Early Tertiary in age (Billman 1992; Ogbé 1970; Okosun 1990; Olabode 2006; Omatsola and Adegoké 1981). The stratigraphy of the basin (Fig. 3) has been grouped into six lithostratigraphic formations. These formations, from the oldest to the youngest, include Abeokuta, Ewekoro, Akinbo, Oshosun, Ilaro, and Benin Formations. However, some of the early researchers described the Cretaceous Abeokuta Formation as Abeokuta Group consisting of Ise, Afowo, and Araromi Formations.

The Cretaceous Abeokuta Formation, which overlies the basement, is predominantly composed of poorly sorted sequence of continental grits and pebbly sands over the entire basin. Occasional siltstones, mudstones, and shale-clay with thin limestone beds due to marine transgression are often observed in the formation. The Abeokuta Formation is overlain by the Ewekoro Formation which is mainly composed of shallow marine limestone due to the contamination of the marine transgression. The limestone-dominated Ewekoro Formation is Palaeocene in age. Overlying the Ewekoro Formation is the shale-dominated Akinbo Formation of Late Palaeocene to Early Eocene (Ogbé 1970; Okosun 1990). The shale and clayey sequence of the Akinbo Formation is concretionary, predominantly kaolinitic and passes gradationally into massive mud/mudstone. The Akinbo Formation is overlain by the Oshosun Formation composed of thickly laminated, glauconitic, and phosphate-bearing Eocene shale with sandstone inter-beds. The Oshosun Formation is overlain by the Ilaro Formation, a predominant sequence of coarse sandy estuarine, deltaic and continental beds with occasional thin bands of phosphate. The Ilaro Formation displays rapid lateral facies changes and is Eocene in age. The Ilaro Formation is overlain by the Benin Formation which is predominantly Coastal Plain Sands and Tertiary alluvium deposits.

Fig. 1 Geological sketch map of Nigeria showing the major geological components: Basement, Younger Granites, and Sedimentary Basins (modified after Obaje 2009; Aizebeokhai and Oyeyemi 2014)

The local geology of the study area, generally consistent with the regional geology of eastern part of the Dahomey Basin, is predominantly Coastal Plain Sands and Recent sediments. The Coastal Plain Sands consist of poorly sorted clayey sands, reddish mud/mudstone, clay and sand lenses, and sandy clay with lignite of Miocene to Recent. These sediments are underlain by a sequence of coarse sandy estuarine, deltaic, and continental beds of the Ilaro Formation which are largely characterized by rapid changes in facies.

Geophysical survey

Data measurements and field procedure

The geophysical survey consists of VES and 2D geoelectrical resistivity and time-domain IP imaging. Manual data measurement was adopted; an ABEM Terrameter (SAS 1000 series) was used for the data measurements for both the resistivity soundings and the 2D geoelectrical resistivity and time-domain IP measurements. The survey was designed such that the VESs and traverses cover the entire area of interest;

however, it was largely controlled by accessibility and road network (Fig. 2). The survey was conducted during the months of January and February (dry season), although occasional rainfall was witnessed mainly during the nights. A total of 32 VESs were conducted within the area with the aim of delineating the subsurface layering, depth-to-aquifer, and aquifer geometry. Schlumberger array with maximum half-current electrode separation (AB/2) ranging between 240 and 420 m (but mostly 320 m) was used for data measurements of the resistivity soundings. The number of soundings conducted in the area and electrode spread for each sounding were largely determined by availability of space and accessibility. The electrode spread used for the soundings was considered sufficient for the effective depth of investigation anticipated.

The 2D geoelectrical resistivity and time-domain IP survey was conducted along seven traverses (Fig. 2); Wenner array was used for the data measurements. Each of the traverses was 500 m in length; however, traverse 6 was 450 m long due to space limitation. The electrode separation used for the measurements ranges from 10.0 to 160.0 m in an interval of 10.0 m (10.0 m to 120.0 m electrode spacing was used for

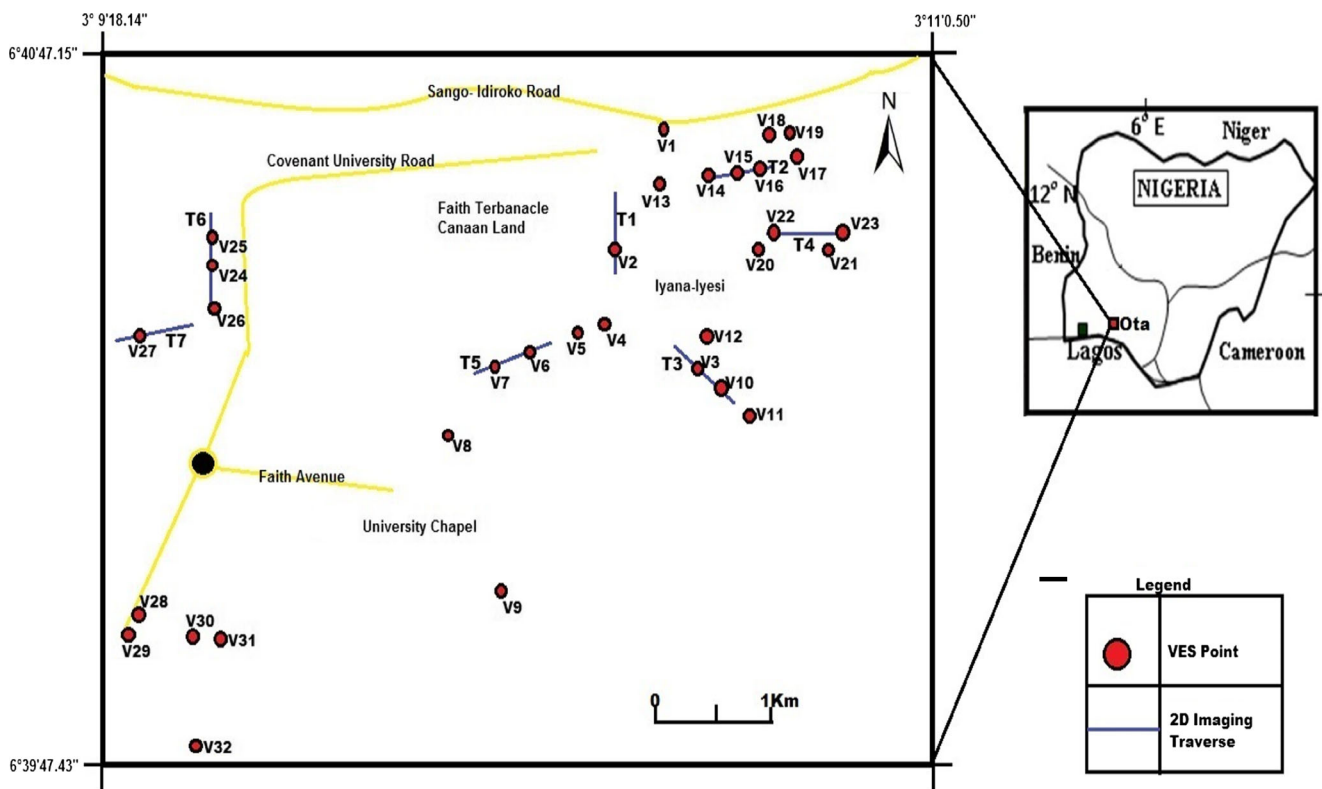

Fig. 2 Map of the study area showing the Traverses and VES location points

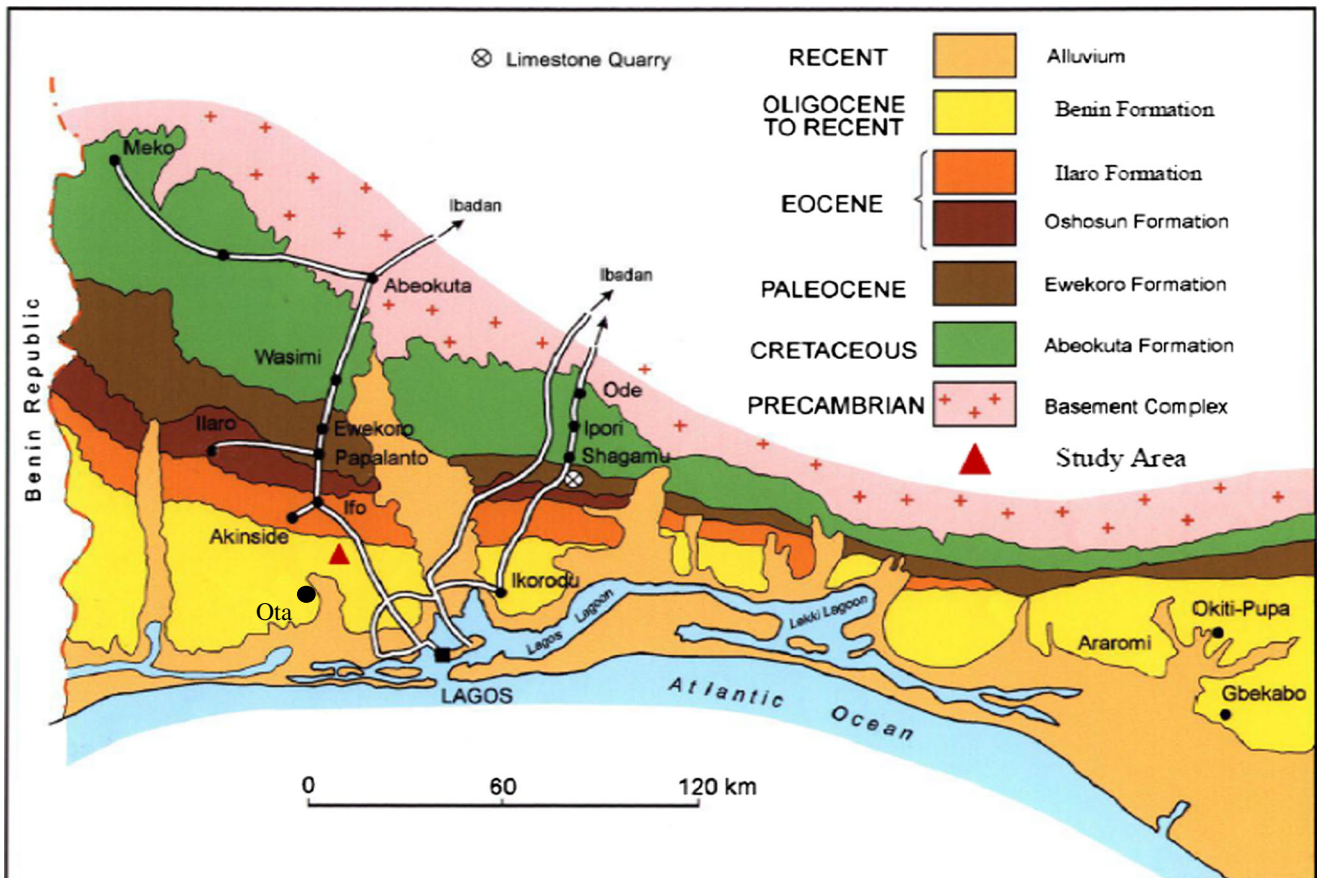

Fig. 3 Geological map of the Nigerian section of Dahomey basin (modified after Gebhardt et al. 2010)

the data measurements in traverses 1, 2, and 6). The 2D apparent resistivity and chargeability (time-domain IP effect) were measured concurrently in all the traverses except for traverses 4 and 5 where only apparent resistivity was measured. The chargeability of the IP effect was measured by integrating the area under the IP decay curve according to the relation

$$M = \frac{1}{V_0} \int_{t_1}^{t_2} V(t) dt, \quad (1)$$

where V_0 is the voltage measured while the current is turned on, t_1 and t_2 is the start and stop time interval, respectively, and $V(t)$ is the decaying voltage.

To ensure data quality, the electrode positions were clearly marked and pegged before the commencement of the data measurements for each traverse as well as the resistivity soundings. This ensured that electrode positioning error commonly associated with manual multi-electrode data measurements was minimized. The earth resistivity meter was set for repeat measurements with minimum data stacking of 3 and maximum of 6. Good connectivity between the electrodes and the connecting cables was ensured, while maintaining effective contact between the ground and the electrodes. The root-mean-squares error in the measurements was generally less than 0.3 %; however, isolated cases in which the root-mean-squares error was up to 0.5 % were repeated after ensuring the electrodes were maintaining good contact with the ground. The injected current was automatically selected from a minimum of 1.0 mA to a maximum of 200.0 mA by the resistivity meter based on the subsurface conductivity.

Data processing and inversion

The observed apparent resistivity dataset for the resistivity soundings was plotted against half-current electrode spacing (AB/2) on bi-logarithmic graph sheets. The field curves obtained were then curve-matched with Schlumberger master curves to delineate the number of layers and estimate of the corresponding resistivity and thickness of the delineated layers. The estimated geoelectric parameters were then used as initial models for computer iteration on a Win-Resist program to obtain model geoelectric parameters for the delineated layers.

Similarly, the observed 2D apparent resistivity and chargeability dataset for each traverse were processed and inverted concurrently using RES2DINV inversion code (Loke and Barker 1996). The RES2DINV program uses a non-linear optimization technique that automatically determines the inverse model of the 2D resistivity and chargeability distribution of the subsurface for the measured apparent resistivity and chargeability data set (Griffiths and Barker 1993; Loke and Barker 1996). The RES2DINV program subdivides

the subsurface into a number of rectangular blocks according to the spread and density of the observed data. The size and number of the blocks is determined by the survey parameters (electrode configuration, electrode separations and positions, and data level) used for the data measurements. Least-squares inversion technique with standard least-squares constraint (L_2 -norm or smoothness), which minimizes the square of the difference between the observed and the computed apparent resistivity and chargeability values, was used for the data inversion. The least-squares equation for the inversion was solved using the standard Gauss-Newton optimization technique. Smoothness constraint was applied to both data and model perturbation vectors; appropriate damping factor for the inversion was selected based on the estimated noise level on the measured data.

Results and discussions

Representative inverse model curves for the geoelectric parameters obtained from the computer iteration of the resistivity soundings are shown in Figs. 4 and 5. The summary of the geoelectric parameters obtained from the inverse model curves are presented in Table 1. In general, nine geoelectric layers were delineated from the sounding curves. The geoelectric parameters of the delineated layers show consistency among the sounding curves, particularly in the deeper sections where the model resistivities and thicknesses are relatively uniform (Table 1). The lithology of the delineated geoelectric layers was established by integrating available information from lithologic samples collected from boreholes and hand-dug wells, known local geology and previous studies (Aizebeokhai et al. 2010a; Aizebeokhai and Oyebanjo 2013; Aizebeokhai and Oyeyemi 2014). The delineated geoelectric layers (from top to bottom) are characterized as top soil, sandy mud/mud stone, sandy/silty clay lens, consolidated lateritic clay, sand lens, lateritic/kaolinitic clay, clayey sand, unconsolidated sand and clay/shale. The geoelectric parameters of some resistivity soundings (selected based on proximity and linearity) were used to construct representative geoelectric cross-sections of the area (Fig. 6).

The top soil is mainly composed of unconsolidated sandy clay and is characterized with low resistivity ranging from 39.7–313.2 Ω m. The thickness of the top soil varies between 0.5 and 2.3 m. The top soil is underlain by a relatively high resistive layer that is laterally continuous across the study area; this layer is described as sandy mud/sandy mudstone. The inverse model resistivity and thickness of this layer vary largely and ranges from 202.9–1167.6 Ω m and 0.9–16.6 m, respectively. The large variation observed in the model resistivity of this layer is attributed to differences in the degree of compaction of the unit coupled with lateral changes in

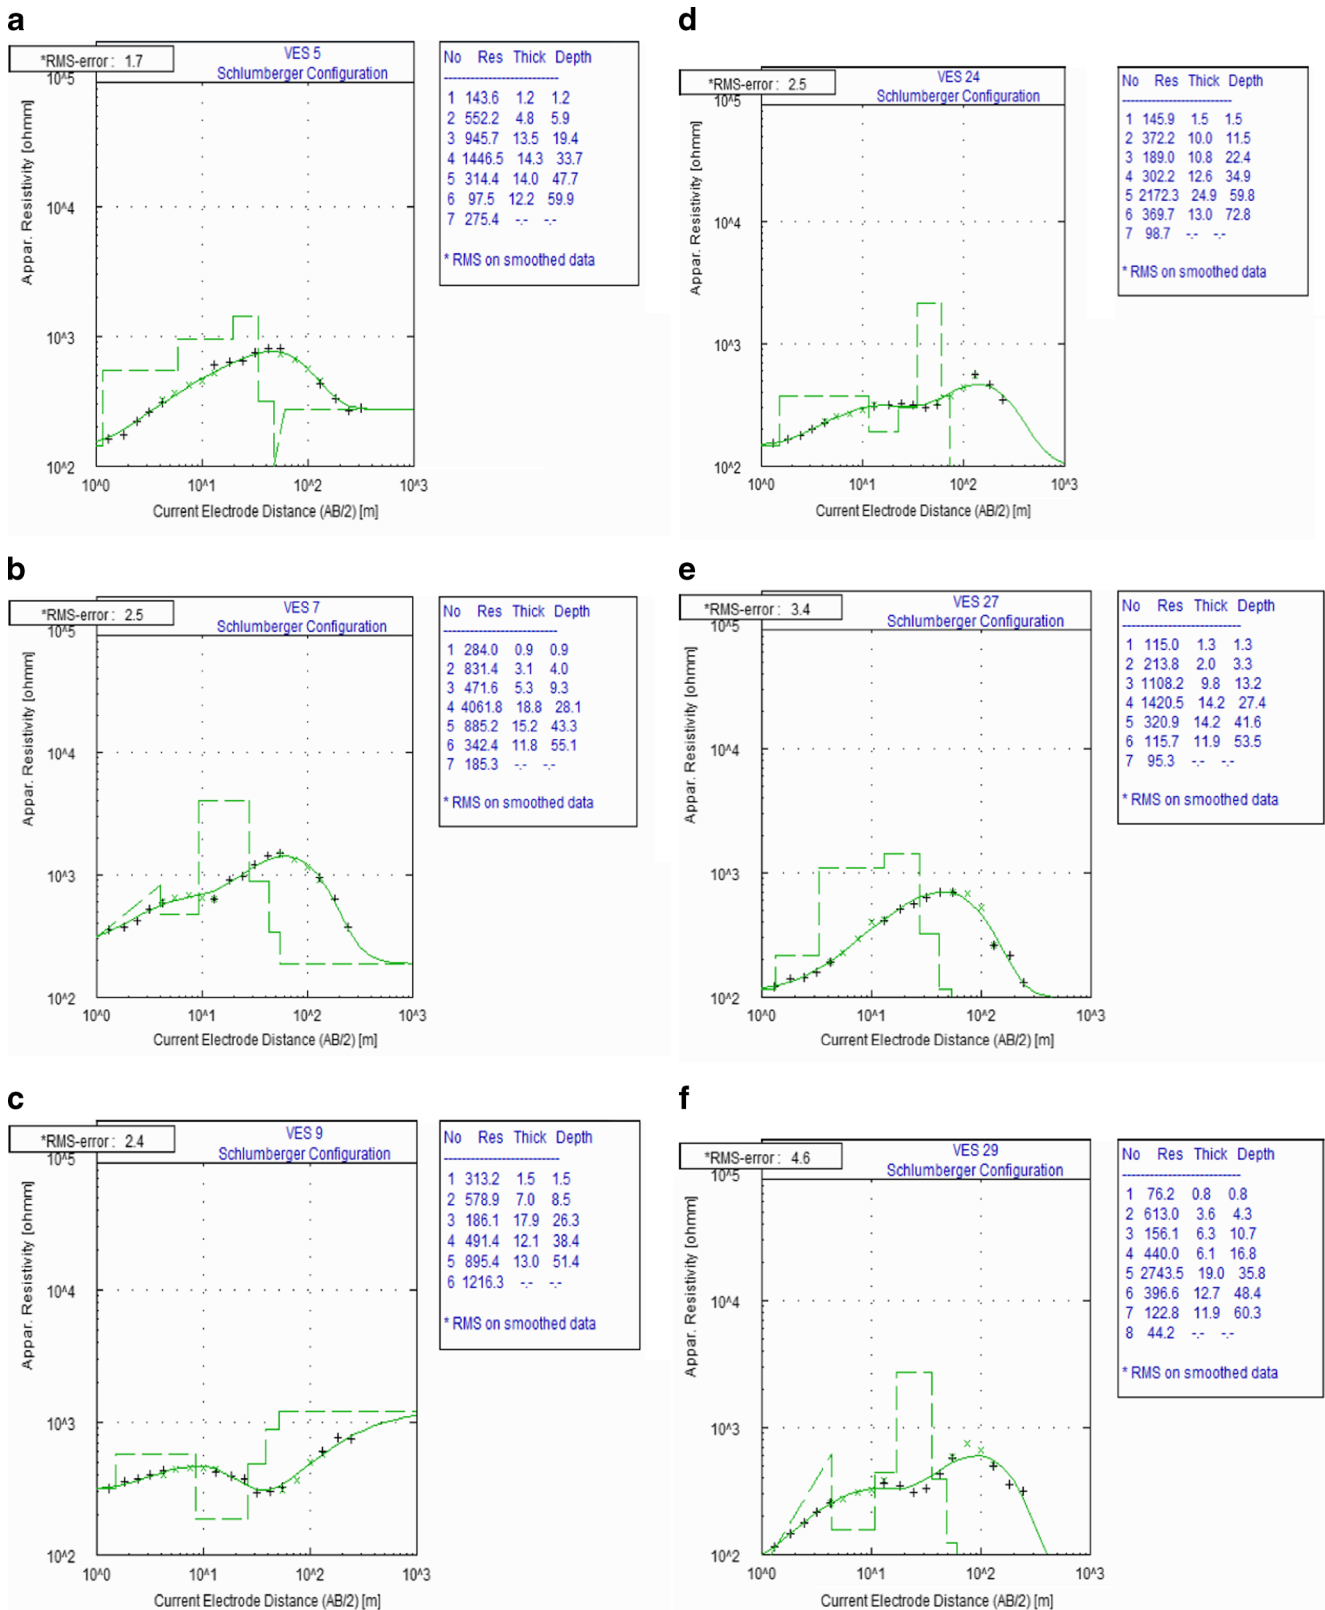

Fig. 4 Representative vertical electrical sounding curves: **a** VES 5, **b** VES 7, **c** VES 9, **d** VES 24, **e** VES 27, and **f** VES 29

mineralogy. Underlying the second geoelectric layer is a low resistivity sandy/silty clay unit observed to be

laterally discontinuous in the study area; it appears as a lens with varying model resistivity ranging from 56.4

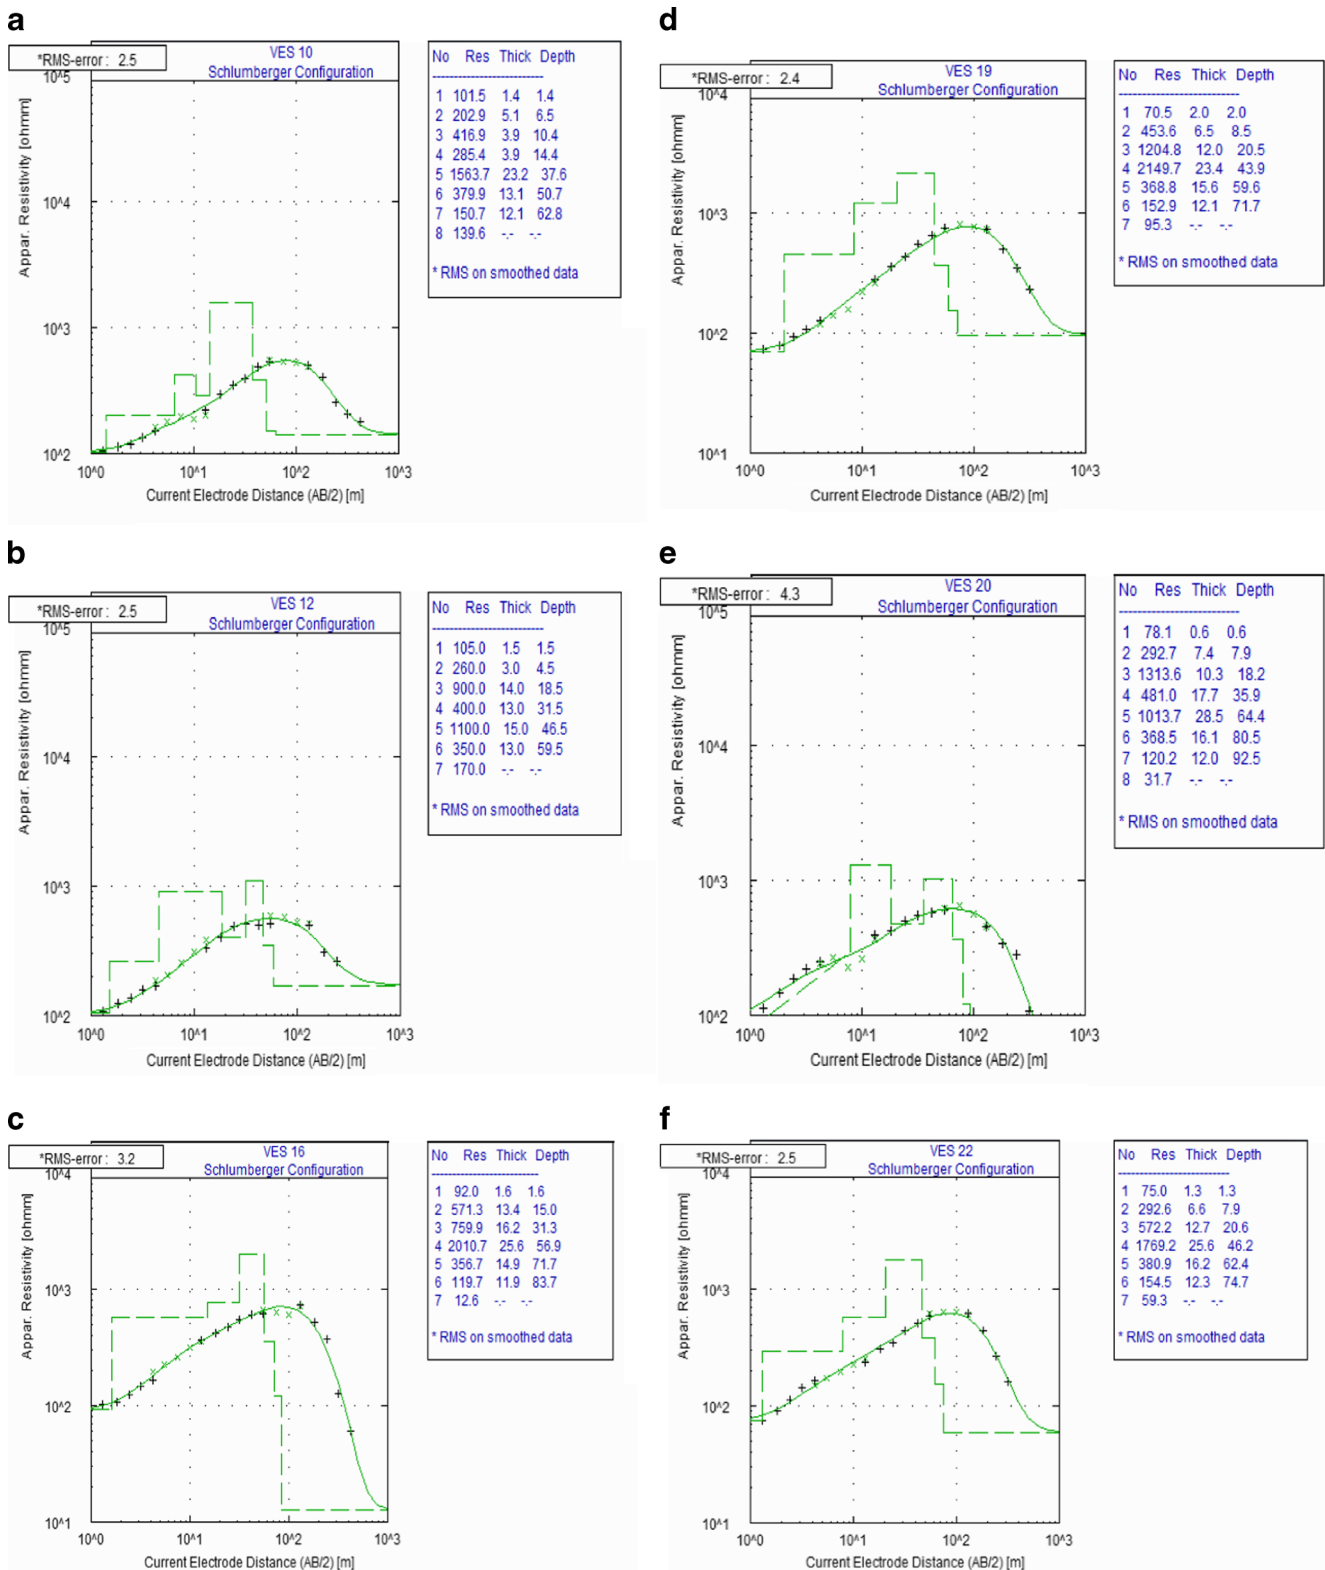

Fig. 5 Representative vertical electrical sounding curves: **a** VES 10, **b** VES 12, **c** VES 16, **d** VES 19, **e** VES 20, and **f** VES 22

–618.8Ωm and thickness ranging between 2.4 and 22.9 m. The fourth layer delineated is a high resistive unit that is laterally continuous across the study area; it

is underlain by a sand lens in some parts of the study area and merges with the sixth layer in areas where the sand lens is absent.

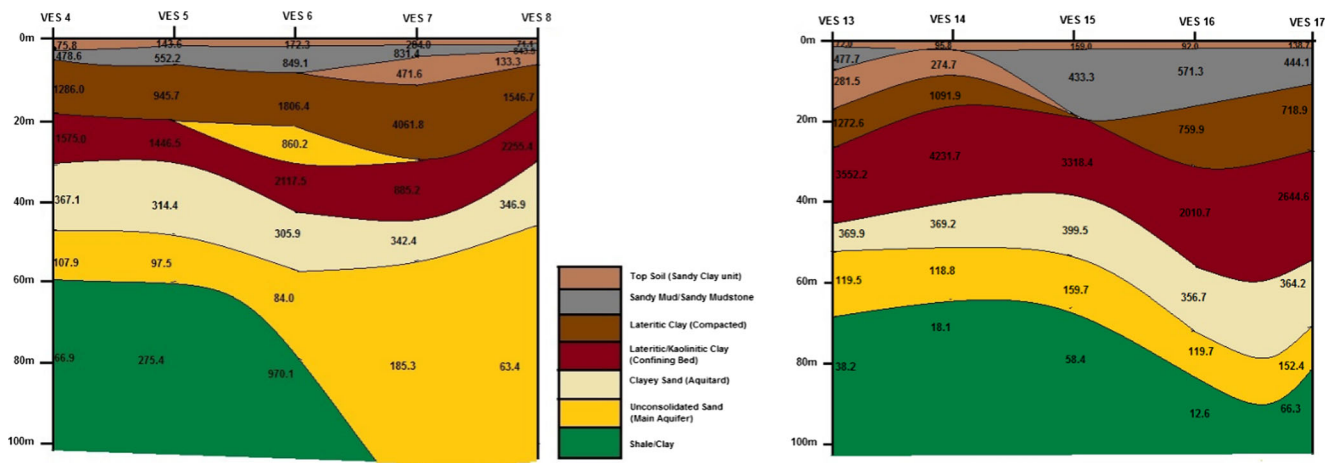

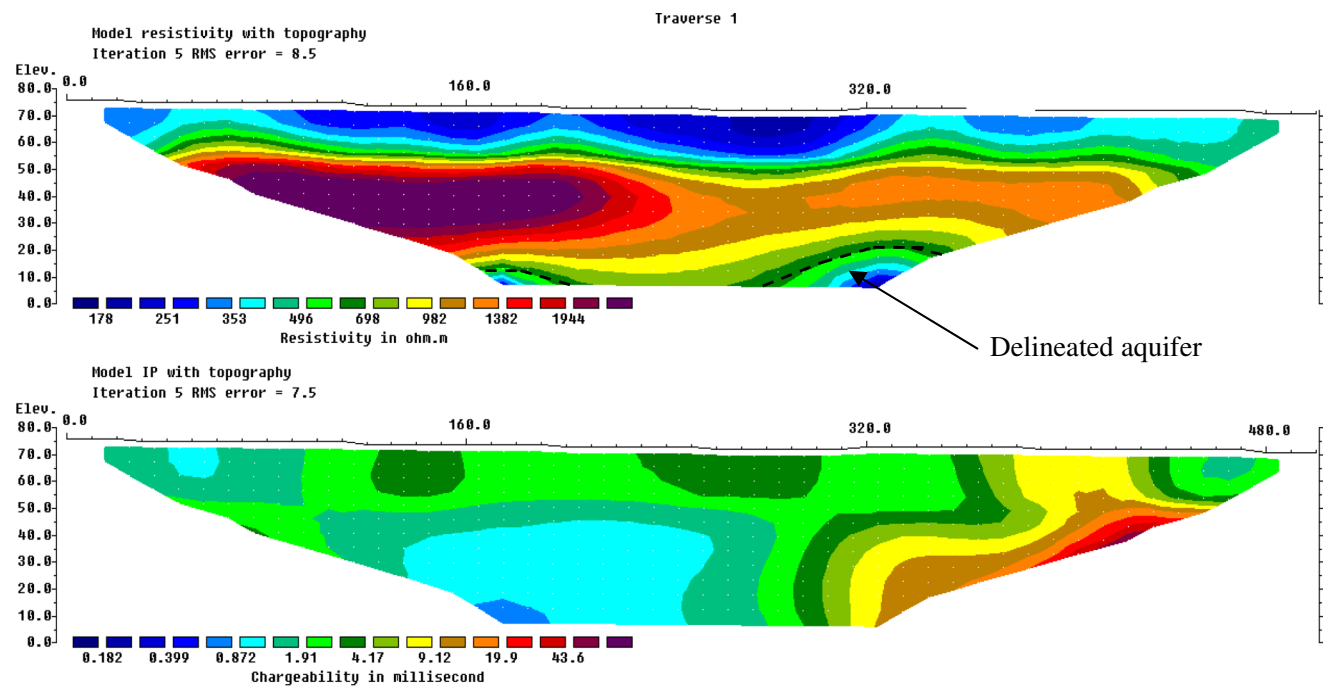

Fig. 6 Representative geoelectric cross-sections constructed from the geoelectric parameters of the delineated layers for selected resistivity soundings

The sixth layer is equally a very resistive unit; it is relatively thick and laterally continuous across the study area. The model resistivity and thickness of this layer is largely uniform across the sounding curves. The high resistive unit is underlain by a relatively low resistive clayey sand unit with largely uniform model resistivity ranging from 278.7–415.3 Ωm and an appreciable thickness ranging from 10.1–16.2 m, respectively. Underlying the clayey sand is an unconsolidated sand unit characterized with low resistivity that ranges from 58.8–228.3 Ωm and a thickness that is largely uniform ranging between 11.8 and 13.3 m, except in VES 6 where the thickness delineated is 19.2 m; it is thought that the underlying unit

at this VES point could not be distinguished (no resistivity contrast) from this sand unit and this possibly accounts for the large thickness delineated. The last layer delineated is thought to be a clayey/shale unit due to its very low resistivity; however, this layer was not penetrated or distinguished from the overlying unit in some of the VES locations.

In general, the geoelectric layers delineated from the resistivity soundings (Table 1 and Fig. 6) are laterally continuous across the entire study area and correlate well in terms of geoelectric-lithology as expected in a sedimentary terrain. In particular, the thicknesses and resistivities of the layers in the deeper section are largely uniform across the study area.

Horizontal scale is 23.98 pixels per unit spacing
 Vertical exaggeration in model section display = 0.99
 First electrode is located at 0.0 m.
 Last electrode is located at 500.0 m. Unit Electrode Spacing = 10.0 m.

Fig. 7 2D inverse model resistivity and chargeability for traverse 1

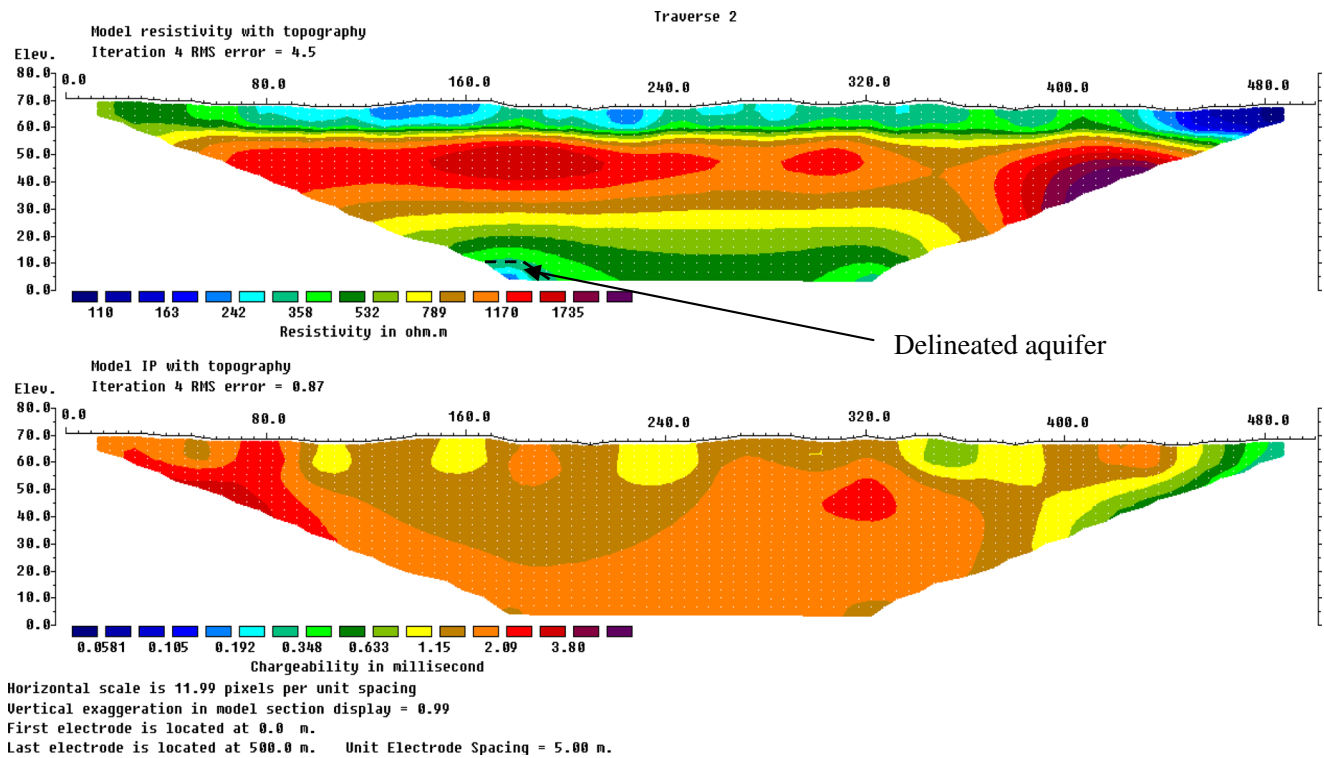

Fig. 8 2D inverse model resistivity and chargeability for traverse 2

Layers 3 and 5 are not observed in some of the VESs points and are thought to be sandy/silty clay and sand lenses, respectively. In particular, layer 5 may have been masked in some of the VESs locations due to the high resistivity values of layers

4 and 6; also, it may have thin-out completely in some cases as observed in VESs 1, 6, 11, 18, 22, and 23 locations. The observed clay and sand lenses together with large variations in the model resistivity of the upper section depict rapid lateral

Fig. 10 2D inverse model resistivity for: **a** traverse 4 and **b** traverse 5

facies changes and near-surface heterogeneities that commonly characterized the Ilaro Formation (Ogbe 1970; Okosun 1990). Samples from drilled and hand-dug wells indicate that the high resistive unit (layer 6 in Table 1 and Fig. 6) is highly consolidated and predominantly composed of swelling clay rich in kaolin and intercalated with phosphate minerals. The kaolin and phosphate minerals are thought to account for the high resistivity values observed for this relatively thick clayey unit.

The 2D model resistivity and chargeability images of the subsurface obtained from the inversion of the observed apparent resistivity and chargeability data are presented in Figs. 7, 8, 9, 10, 11 and 12). The inverse models of the 2D resistivity and chargeability images of the subsurface show a general geoelectric-lithology trend very similar to that observed in the resistivity soundings. Reasonable correlation exists between the 2D inverse models and the geoelectric layered parameters obtained from the soundings. The lateral continuities of geoelectric layers (geoelectric-lithology) and near-surface heterogeneity observed in the resistivity soundings are clearly depicted in the inverted 2D resistivity images. The top soil

delineated in the resistivity soundings is not distinctly observed in the 2D images due to its small thickness (0.5–2.3 m averaging 1.18 m) relative to the minimum electrode spacing of 10.0 m used for the 2D survey. Evidence of the clay and sand lenses delineated in the resistivity soundings is observed traverse 6 (Fig. 11), where a sand lens overlies a clay lens. The sand lenses often form shallow perched aquifers in the area which may not yield appreciable groundwater to drilled wells.

The unconsolidated sand unit in the geoelectric sounding parameters (layer 8 in Table 1 and Fig. 6), which is observed to be laterally continuous with relatively uniform model resistivity and thickness in the entire areal extent, is thought to be the main (regional) aquifer body in the area. The 2D inverse model resistivity of the delineated aquifer unit ranges from about 75–150 Ω m; this corresponds to the model resistivity observed in the resistivity soundings for the same geoelectric unit (layer 8 in Table 1 and Fig. 6). The main aquifer unit delineated in the 2D resistivity and chargeability images is well penetrated in traverses 3, 4, 5, and 7 (Figs. 9, 10, and 12) but partially penetrated in traverses 1, 2, and 6 (Figs. 7, 8,

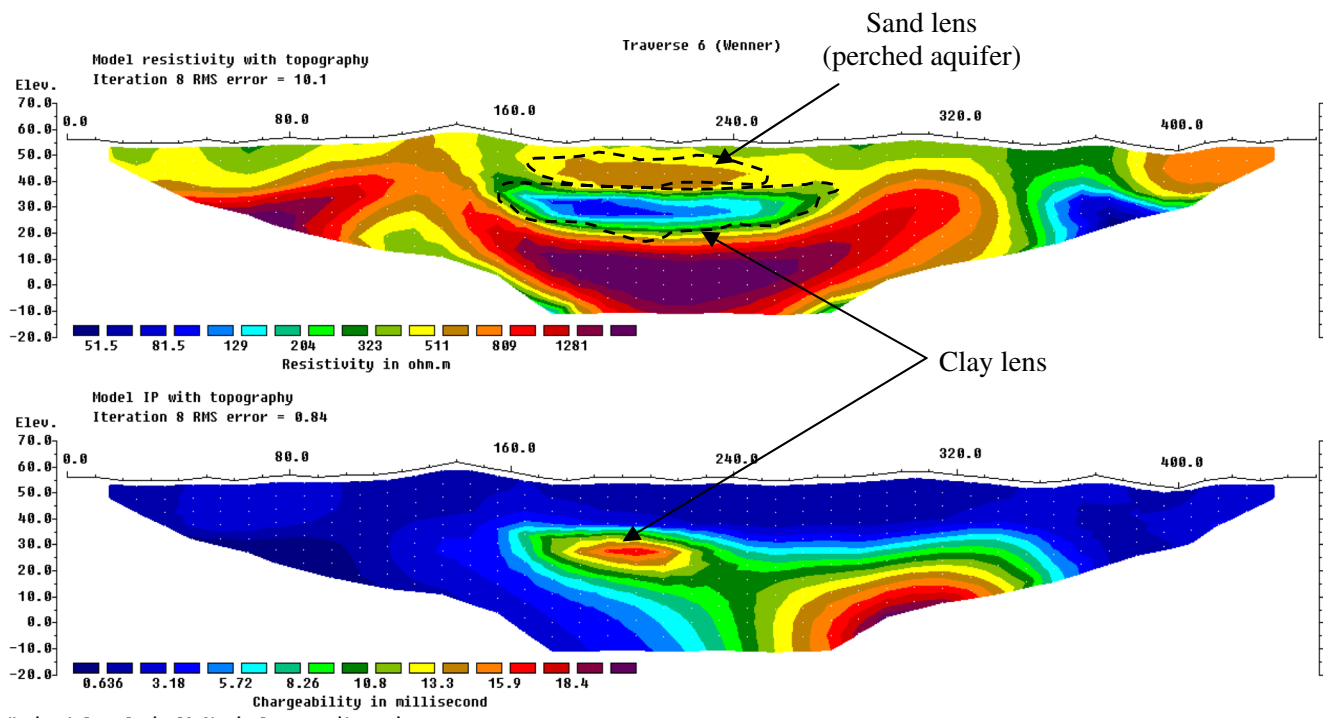

Fig. 11 2D inverse model resistivity and chargeability for traverse 6

and 11). This is due to the fact that data level of 12 (minimum electrode spacing of 10–120 m) was used for the data measurements in traverses 1, 2, and 6 as against data level of 16 (minimum electrode spacing of 10–160 m) used for the data

measurements of other traverses. The 2D resistivity images show that the delineated aquifer occurs at an elevation of about 5 m to about 20 m below mean sea level corresponding to an average depth-to-aquifer of about 80 to 100 m and

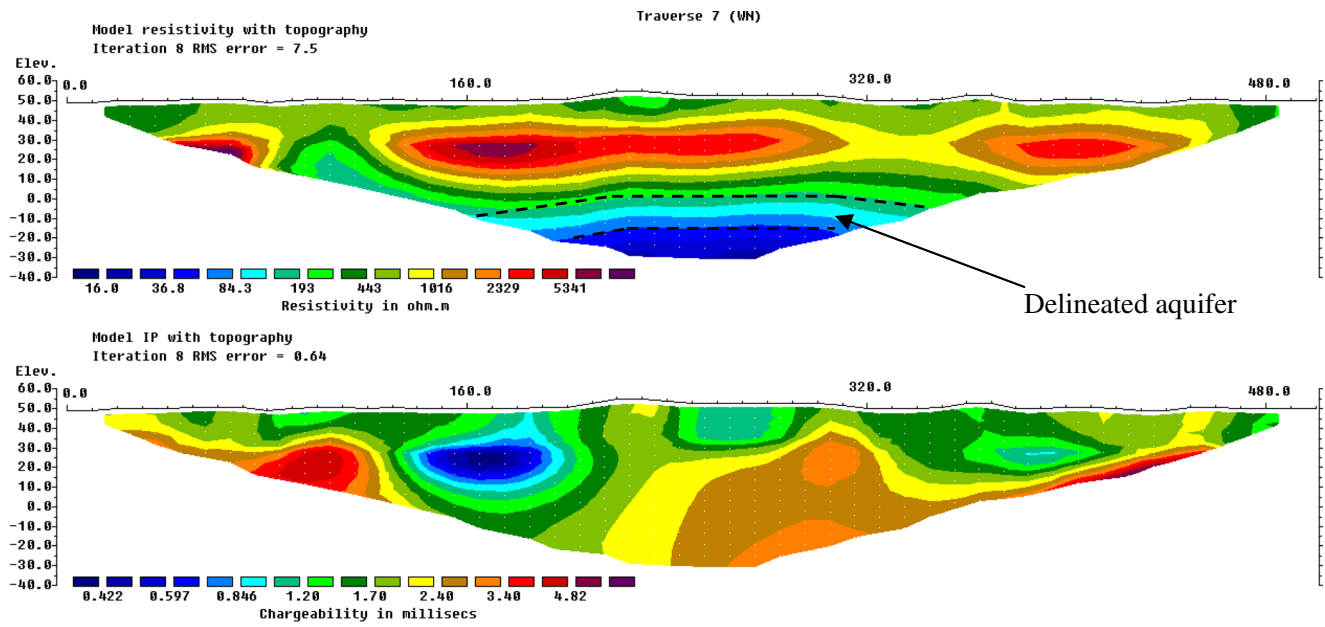

Fig. 12 2D inverse model resistivity and chargeability for traverse 7

average aquifer thickness of about 15 m. This model thickness agrees reasonably well with that observed in the geoelectric parameters of the resistivity soundings.

The main aquifer unit delineated is overlain by a relatively more resistive layer that is also observed to be laterally continuous in the entire area in both the 2D images and the resistivity soundings. The layer is characterized with relatively uniform inverse model resistivity value that range from about 280–400 Ωm and an average thickness of about 12.3 m. This unit is saturated but relatively impermeable; consequently, it serves both as a confining bed and aquitard to the main aquifer body. Most hand-dug wells in the area are tapping groundwater from this aquitard unit because of the large diameters with which the wells are dug.

The aquitard unit is overlain with a relatively thick and very resistive layer that is conspicuously observed in the 2D resistivity images of all the traverses as well as the resistivity soundings. This layer is laterally continuous across the entire area but the resistivity varies spatially due to changes in the degree of compaction and mineralogy. The chargeability anomaly (IP effect) observed for this high resistive layer is not very distinct, but a careful observation of the chargeability images show that the high resistive layer is characterized with a moderately high chargeability anomaly indicating massive or compacted clayey lithology for the layer. This is consistent with the results of previous studies conducted within the same geologic environment (Aizebeokhai and Oyeyemi 2014).

The aquifer unit is underlain by a very low resistivity unit as shown in both the 2D inverse models and the geoelectric parameters of the resistivity soundings (layer 9 in Table 1 and Fig. 6). This low resistivity unit is characterized with a distinct high chargeability anomaly as observed in traverses 3 and 7 (Figs. 10 and 12). The observed high chargeability anomaly for this low resistivity unit indicates that the delineated aquifer is underlain with clayey/shaley formation. This is also consistent with similar studies conducted around the area (Aizebeokhai and Oyebanjo 2013; Aizebeokhai and Oyeyemi 2014).

Conclusion

Geophysical survey involving resistivity sounding and 2D resistivity and time-domain IP imaging was carried out in Iyana-Iyesi and Canaan Land area, southwestern Nigeria. The survey is part of a preliminary assessment of the groundwater resource potential in the area. The knowledge of groundwater resource potential is essential for groundwater resource development planning as well as groundwater resource management and monitoring. The near-surface was characterized by integrating the geoelectric layered parameters obtained from the resistivity soundings with the 2D resistivity and chargeability inversion models. This integration is

found to be effective in characterizing near-surface heterogeneities. The aquifer unit delineated is thought to be high-yield regional aquifer and is confined by a low yield aquitard. The thickness of the aquifer delineated is largely uniform and average of about 12.5 m; depth to the aquifer progressively increases northward in the basin.

Acknowledgments The authors wish to thank Covenant University Management for providing the resources to conduct this study. Our profound appreciation goes to following undergraduate students who helped with the field data collection: Nelson-Atuonwu Cherish, Liadi Esther, Shotuyo Yewade, Lesinwa Fortune, Ijioma Nanna, Utor Joy, Tucker Miata, Uye Perpetual, and Ukabam Chukwuemeka.
