Abstract Identifying critical hydrologic parameters that structuring biological communities is crucial for the conservation and restoration of wetland ecosystems. The present study determined the key parameters of water level fluctuations (WLFs) influencing the distribution of a typical wetland plant, *Carex*, in shallow lakes along the middle and lower reaches of the Yangtze River. The plant community and environmental variables in 13 shallow lakes with different WLFs were investigated during 2011–2015. A total of 14 parameters included in three components of WLFs were identified, and their effects on the distribution of *Carex* were analyzed. The results showed that distribution of *Carex* in the studied lakes differed obviously in time and space. WLFs were the critical factors influencing the taxa distribution, whereas soil organic matter, human disturbance, substrate type, and soil moisture were of little importance. Rate of water level change and elevation above water were the main parameters determining the coverage and biomass of *Carex* during the spring growing season. In the autumn growing season, rate of water level change, elevation above water, and emergence timing were important. These results provide important insights into the conservation and restoration of *Carex* and other hygrophytes in shallow lakes in this region.

Keywords Hygrophytes · *Carex* · Water level fluctuations · Yangtze River · Redundancy analysis

Introduction

Wetlands are diverse and productive ecosystems that harbor a variety of plants and animals and provide valuable goods and services to human society (Richardson 1994; Sellheim et al. 2016). In the past few decades, most wetlands worldwide have been degraded to various degrees due to hydrological alteration, pollution, habitat loss, and species invasion (Tharme 2003; Van Geest et al. 2005a; Wang et al. 2016a). Among these threats, hydrological alteration is the most important because periodic hydrological processes are widely regarded as the main driving forces in riverine ecosystems (Carter 1986; Poff et al. 1997).

In wetlands and lakes, water level fluctuations (WLFs) are very important factors (Coops et al. 2003; Leira and Cantonati 2008), and water level regulation is considered as a useful tool for vegetation restoration (Coops and Houser 2002; Van Geest et al. 2005a; Zhang et al. 2014). WLFs can be broken down into five components, i.e. magnitude, frequency, duration, timing, and rate of change (Poff et al. 1997; Webb et al. 2012). Previous studies have shown that plant assemblage is strongly structured by WLFs (Casanova and Brock 2000; Van Geest et al. 2005a; Raulings et al. 2010; Bornette and Puijalón 2011). Plants develop a range of morphological characteristics and life history strategies to adapt to the periodic water regime over a long period of time (Visser et al. 2000; Lytle and Poff 2004). For wetland plants, germination, seedling growth, flowering, and seed dispersal depend on WLFs to varying degrees (Rood et al. 1995; Smith and Brock 2007; Edwards et al. 2011; Yang et al. 2015). Most studies on the effects of WLFs have been conducted on riparian and macrophyte

species (Rood et al. 2005; Smith and Brock 2007; Zhang et al. 2013), whereas only very limited evidences are available for hygrophytes (Xu et al. 2015; Yang et al. 2015). Moreover, most studies tended to explore the effects of a single WLF component (e.g. magnitude or rate of change) on the germination and seedling growth of plants, mainly by manipulation experiments (Deegan et al. 2007; Smith and Brock 2007; Edwards et al. 2011; Wang et al. 2016b). Evidence regarding the combined effects of different WLF components remains scarce, especially from field investigations (Casanova and Brock 2000; Riis and Hawes 2002; Zhang et al. 2015).

The Yangtze River floodplain is among the most important ecoregions of the world, and there are thousands of shallow lakes located in this region (Wang et al. 2016a). Aquatic plants are abundant (approximately 400 hygrophytes have been recorded), and they play an important role in maintaining the regional biodiversity and functioning of the ecosystem. However, water regime in this region has been dramatically altered due to river-lake disconnection, hydropower projects, and embankment engineering etc. (Wang and Wang 2009), resulting in serious degradation of hygrophyte communities (Hu et al. 2015). Therefore, understanding the effect of WLFs on the hygrophytes is essential for the conservation and restoration of wetlands in this region.

In the present study, we investigated the effects of WLFs on a typical hygrophyte *Carex* through large-scale

field investigations. *Carex* is widely distributed in the Yangtze shallow lakes (Hu et al. 2013), and it is closely associated with water birds such as goose, providing food and habitats for these migratory species and other aquatic animals (Guan et al. 2014). Our objective is to determine the key parameters of WLFs structuring the *Carex* community in shallow lakes. We expect that our results can provide valuable information to aid in the conservation and restoration of *Carex* and other hygrophytes in shallow lakes in this region.

Materials and Methods

Studied Lakes

The shallow lakes along the middle and lower reaches of the Yangtze River (108–122°E, 24–34°N) cover an area of ca. 1.6×10^5 km², accounting for 1/5 of the total lake area in China. Climate in this region is subtropical monsoon. The annual average temperature is 13–20 °C, and the annual precipitation is 800–1600 mm (Wang et al. 2016a; Wang and Wang 2009). Field investigations were carried out in 13 lakes (Fig. 1), including six sub-lakes of Poyanghu Lake with different WLFs. The environmental characteristics of the studied lakes are shown in Appendix Table 4. According to their WLFs characteristics, the studied lakes can be divided into

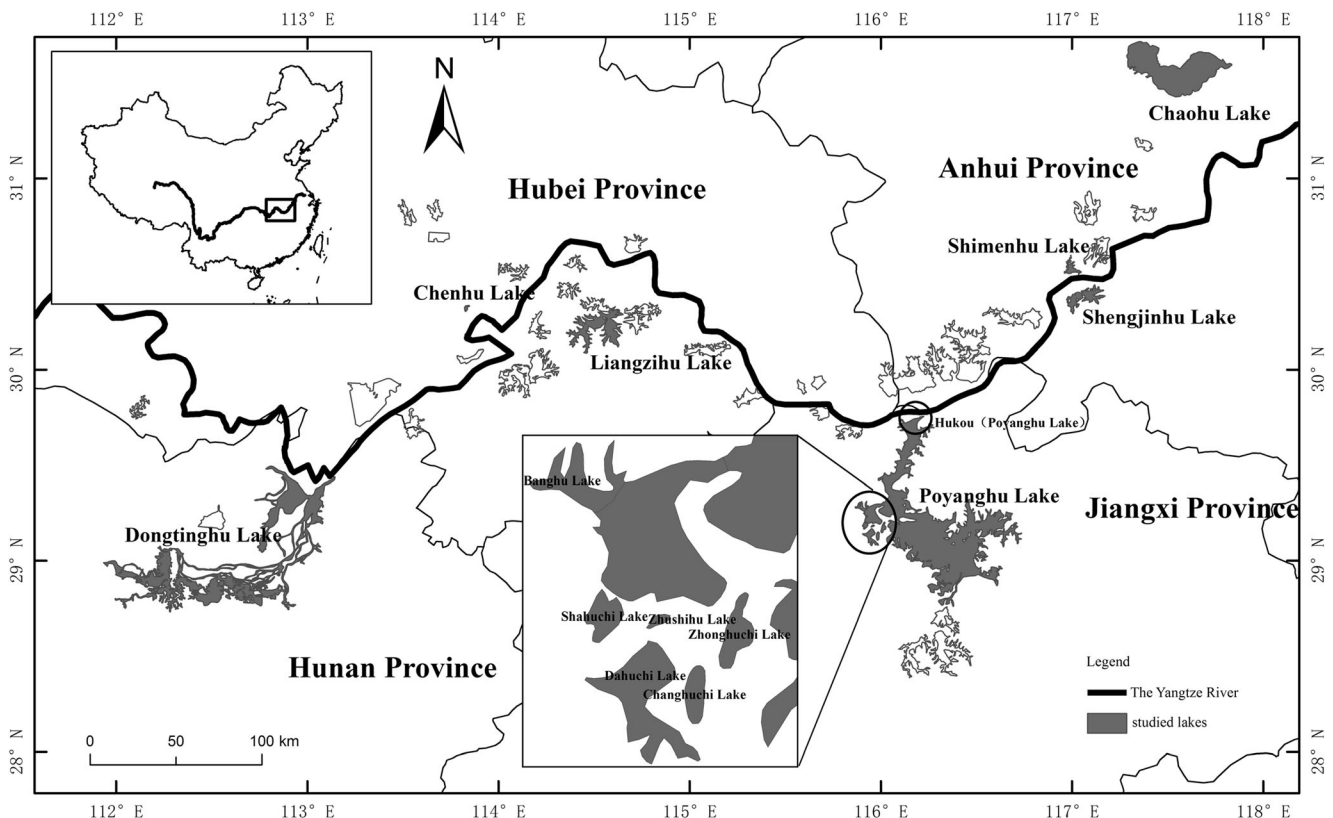

Fig. 1 Locations of the studied lakes along the middle and lower reaches of the Yangtze River

three types, i.e. quasi-natural, intermittent and reservoir-like (Fig. 2) (Zhang 2013). The WLFs of the quasi-natural and intermittent lakes are similar to the water regime of the Yangtze main stem, with the former being larger in amplitude than the latter. The water levels of the reservoir-like lakes are regulated and maintained in a reverse condition.

Field Investigations

Carex has two growing seasons each year: the first is from spring to summer (before the flood season), and the second starts after flood recession in autumn (Bernard 1990). Field investigations were therefore carried out in late spring (April–March) and autumn (October–November) during 2011–2015. A total of 88 sampling transects were randomly set, and 417 plots (0.5 m × 0.5 m) were sampled including 124 in spring and 293 in autumn. For each lake, one–three sampling transects were randomly selected. The lower limit of each transect began at the water edge and ended when terrestrial species were encountered (Zhang et al. 2014). In each transect, five–eight plots were set along an elevation gradient of the lake-shore. All species in each plot were recorded and identified according to taxonomic monographs (Zhao and Liu 2009, “*Flora Republicae Popularis Sinicae*” <http://frps.eflora.cn/>). The coverage of each species was estimated as the ratio of the projected area of its aboveground parts to the plot area (Li 2000). The total coverage of each plot was calculated as the sum of all species found in the plot. The aboveground parts in the plot were destructively harvested, and the fresh mass was measured with an electronic balance. The occurrence data were further organized as shown in Appendix Table 5.

Five classes of environmental variables were considered including lake morphometric parameters (shoreline development index), nutrition (soil organic matter), substrate (substrate types and soil moisture), human disturbance, and components of WLFs. The shoreline development index was calculated according to the following equation (Aronow 1982):

Fig. 2 Diagram of the three types of WLFs with standardized water level data

$D_L = L/2\sqrt{\pi A}$, where L is the shoreline length, and A is the lake area. The values for L and A were extracted from the literatures (Wang and Dou 1998; Zhang 2013; Wang et al. 2016a). Soil organic matter was measured by the $K_2Cr_2O_7$ titration method after digestion according to standard protocols (Lu 2000; Ding 2013). Substrate types were classified as silt, clay, loam, silt and sand, clay and sand, loam and sand, or sand. Soil moisture were measured with a portable soil moisture meter. Human disturbance was divided into three levels: small (with rare human activities), middle (near to roads or wharfs), and large (with embankment, grazing or cutting).

Calculations of Parameters of WLFs

The WLFs of each lake were quantified using the daily water level data collected from the Hydrology and Water Resource Bureau of Hubei Province (<http://www.hbswj.com>), Anhui Hydrological Telemetry Information System (<http://61.191.22.157/TYFW/InfoQuery/HeDao.aspx>), and records of local gauge stations (Dahuchi Lake and Shahuchi Lake). The data for Dahuchi Lake and Shahuchi Lake in 2011 were used to replace the missing data during field investigation in 2012. A total of 14 parameters were quantified belonging to three components of WLFs: magnitude, timing, and rate of change. The elevation above water (E) of each plot was estimated as the perpendicular distance from the center of the plot to the water surface (Zhang et al. 2014) and was treated as a measure of magnitude of WLFs. Monthly E values in February–April and August–October (E-Feb, E-Mar, E-Apr, E-Aug, E-Sep, E-Oct) were calculated to reflect the two growing seasons of *Carex*. Annual amplitude was also considered as a measure of magnitude, and was calculated as the difference between the minimum and maximum water level for each year (Smith and Brock 2007). Emergence timing (ET) occurred in autumn when water receded and was defined as the first day that the plot emerged. Rate of water level change (R) referred to the daily water level change and was calculated as the absolute difference in water levels between one day and the subsequent day. The R values in February–April (rising) and August–October (declining) (R-Feb, R-Mar, R-Apr, R-Aug, R-Sep, R-Oct) were calculated regarding the two growing seasons. Because of the lack of daily water level data, the amplitude and ET for five lakes (Zhonghuchi Lake, Changhuchi Lake, Zhushihu Lake, Banghu Lake, and Chenhu Lake) were estimated using monthly data, and the E and R values of these lakes could not be calculated.

Data Analyses

The relationships between *Carex* community and environmental variables were assessed using Spearman correlation analyses and curve estimation regression analyses based on

transect data. A redundancy analysis (RDA) was carried out to assess the influence of WLFs, soil moisture, and substrate types on *Carex* community using the plot data. Three species, i.e. *C. cinerascens*, *C. argyi*, and *C. laticeps*, were dominant in terms of frequency of occurrence, and the critical parameters of WLFs for them were further identified. The choice of the linear ordination method was based on the short gradient lengths determined from a preliminary detrended correspondence analysis (DCA). Data analyses were performed with SPSS 19.0 and Canoco 5.0.

Results

Community Characteristics

A total of 9 *Carex* species were identified, with the dominant species being *C. cinerascens* and *C. argyi* (Appendix Table 5). Besides *Carex*, there were 112 species belonging to 34 families. *Carex* grew better in spring than in autumn. The coverage and biomass values were $38.8 \pm 5.5\%$ (mean \pm SE) and $395.0 \pm 60.1 \text{ g/m}^2$ in spring, and $27.5 \pm 3.4\%$ and $364.1 \pm 34.6 \text{ g/m}^2$ in autumn, respectively. The biomass varied significantly among the studied lakes (Fig. 3). It was the highest in Banghu Lake in spring and Dongtinghu Lake in autumn, with average values of $891.5 \pm 292.3 \text{ g/m}^2$ and $651.2 \pm 147.1 \text{ g/m}^2$, respectively. The lowest biomass was found in Chaohu Lake both in spring and in autumn, with average values of $18.2 \pm 14.2 \text{ g/m}^2$ and $0.6 \pm 0.6 \text{ g/m}^2$, respectively.

Environmental Analyses

The occurrence, coverage, and biomass of *Carex* were significantly related with WLFs (Table 1). A significant negative correlation was found between occurrence and type of WLFs

($P < 0.01$), indicating that *Carex* rarely occurred in reservoir-like lakes such as Chaohu Lake and Liangzihu Lake. By contrast, occurrences in spring and in autumn, coverage and biomass in autumn had positive correlations with the amplitude of WLFs ($P < 0.05$), suggesting that higher amplitude of WLFs favored the growth of *Carex*. Shoreline development index was also important, since it significantly related to coverage and biomass in spring, and biomass in autumn ($P < 0.05$). However, no significant relationship was detected between the plant community and soil organic matter or human disturbance (Tables 1 and 2).

Key Parameters of WLFs

RDA analysis showed that the cumulative percentage variation of axes 1 and axes 2 was beyond 80% (Table 3), suggesting that environmental variables related to WLFs, soil moisture, and substrate types explained most of the variations in the distribution of *Carex*. The ordination diagrams of the species and environmental variables are shown in Fig. 4. Among the parameters of WLFs, R-Feb, R-Mar, and R-Apr played a pivotal role in determining the germination and growth of *Carex* during the spring growing season. E-Feb, E-Mar and E-Apr were of certain importance (Fig. 4a, b). In the autumn growing season, R-Aug, R-Sep, R-Oct, E-Aug, E-Sep, E-Oct and ET were the predominant parameters of WLFs (Fig. 4c, d), whereas soil moisture and substrate types were of little importance.

Discussion

Effects of WLFs

WLFs not only directly affect the growth and reproduction of plants, but also indirectly affect the moisture, oxygen, and

substrate that the plants depend on (Keddy and Reznicek 1986; Rood et al. 1995; Coops et al. 2003; Van Geest et al. 2005a; Yu and Yu 2009; Wei et al. 2010). The present study showed that WLFs were the critical factors that determined the distribution of *Carex* in Yangtze shallow lakes. The magnitude, timing, and rate of change were found to be significantly correlated with the taxa in their different life history stages. The shoreline development index was negatively correlated with *Carex*, indicating that the shoreline morphology was of certain importance. In

this study, lakes with a small shoreline development index usually held a large area of flat inshore region (e.g. Dahuchi Lake, Zhonghuchi Lake etc.), which was beneficial to *Carex* development. Previous studies have shown that substrate types and nutrients affected plant growth and vegetation succession to some extent (Barko and Smart 1983; Hu et al. 2011). However, they were of little importance in this study mainly because both the substrates and nutrients were quite homogeneous among the studied lakes.

Our results showed that *Carex* biomass differed markedly among the three types of lakes, with the highest values occurring in intermittent lakes and the lowest in reservoir-like lakes. These results suggested that the type of WLFs is very important in shaping the *Carex* communities in the shallow lakes. The type of WLFs describes the water regime and seasonality of water levels. A reverse condition of the water regime such as that in the reservoir-like lakes is detrimental to *Carex* as well as other wetland plants. The water levels of intermittent lakes are low and stable before the flood season (Zhang 2013; Wang et al. 2016a), which is beneficial to the germination and growth of these species. By contrast, the reservoir-like lakes usually maintain a higher water level during germination (Zhang et al. 2014; Wang et al. 2016a), exerting detrimental effects on plant development.

Key Parameters of WLFs

Like other wetland plants, *Carex* adopts life history strategies that are closely correlated with the natural water regime. In different life history stages, the plants are affected by specific components of WLFs. Regarding the magnitude of WLFs, amplitude is an important factor shaping the habitat and plant community (Keddy and Reznicek 1986; Riis and Hawes 2002; Leyer 2005; Van Geest et al. 2005b). Our study revealed that *Carex* grew better in lakes with a large amplitude (> 3 m). Similar results were also found in other studies in this region (Zhang et al. 2015). Due to the monsoon climate, the highest water level in the Yangtze shallow lakes usually occurs during July–August, when *Carex* species have already completed their life history in the first growing season. Under these conditions, the taxa could gain competition advantages because a large amplitude would eliminate competing species that cannot tolerate prolonged inundation. In addition, *Carex* reproduce mainly by belowground rhizomes, and can germinate again when the water recedes (Bernard 1990).

Rate of change in water level was found to be important in both growing seasons of *Carex*, especially during the germination and fast growing periods. Plants tend to develop a series of morphological adaptations with water level changes (Strand and Weisner 2001; Wu et al. 2012; Zhang et al. 2013), but time is needed for morphological adaptation to

occur. In the spring growing season, if the water level rises too fast for *Carex* to complete any morphological adaptations, the aboveground parts are exposed to inundation stress and even die because of light shortage (Wu et al. 2012) or rapid oxygen depletion (Brock et al. 1987). Also, the rapid decline of the water level in autumn might have detrimental effects on germination and seedling growth due to lack of water. Similar results were also documented in cottonwoods (*Populus* sp.) and willows (*Salix* sp.) (Mahoney and Rood 1998; Rood et al. 2005; Amlin and Rood 2002).

Regarding the timing of WLFs, we found that emergence timing in autumn was crucial to *Carex* development in the autumn growing season. Because *Carex* cannot germinate underwater, successful germination after water receded depends on the emergence timing and the temperature. If emergence occurs earlier, germination might be prohibited due to water shortage attributed by rapid decrease of water level (Zhang 2013). By contrast, if emergence occurs much later in the autumn growing season, *Carex* development might be limited by the decreased temperature and inundation stress. The delayed emergence timing in autumn could reduce the growth rate and biomass of *Carex*, and further result in food shortages of wintering geese in this region (Guan et al. 2014).

Many studies have reported that hygrophytes establish themselves at different elevations in response to WLFs in seasonally flooded wetlands (Lenssen and De Kroon 2005; Leyer 2005). Our results also indicated that elevation above water had significant correlations with the distribution of *Carex*. In the shallow lakes, elevation per se might have little

effects on the germination and growth of hygrophytes, but it is closely related to soil moisture, timing of submergence and emergence, which are crucial for hygrophyte development (Chen et al. 2015; Xu et al. 2015). Soil moisture is proved to be an important factor influencing the germination and growth of wetland plants (Booth and Loheide 2010; Xu et al. 2015; Yang et al. 2015). In the present study, however, no significant relationship was detected between soil moisture and *Carex* community, probably due to the reason that soil moisture in lakeshore of these shallow lakes was generally high (10%–50%).

Implications for Further Studies and Conservation

Regarding to the effects of WLFs, previous studies have usually conducted by simulation experiments. Water depth and soil moisture are the most concerned because the manipulation of other parameters such as timing and magnitude are difficult and even impossible. In the present study, we revealed the effects of each component of WLFs on the distribution of *Carex* through filed investigations. Our results provided some new insights compared to previous simulation experiments. For example, we revealed the importance of different parameters of WLFs during the different life history stages of *Carex*. In addition, several experimental manipulations indicated that a moderate amplitude was beneficial to aquatic plants. However, we found that *Carex* preferred a large amplitude under natural conditions. Moreover, simulation experiments have shown that inundation can inhibit the germination and growth of *Carex* (Wang et al. 2007; Yang et al. 2015), whereas

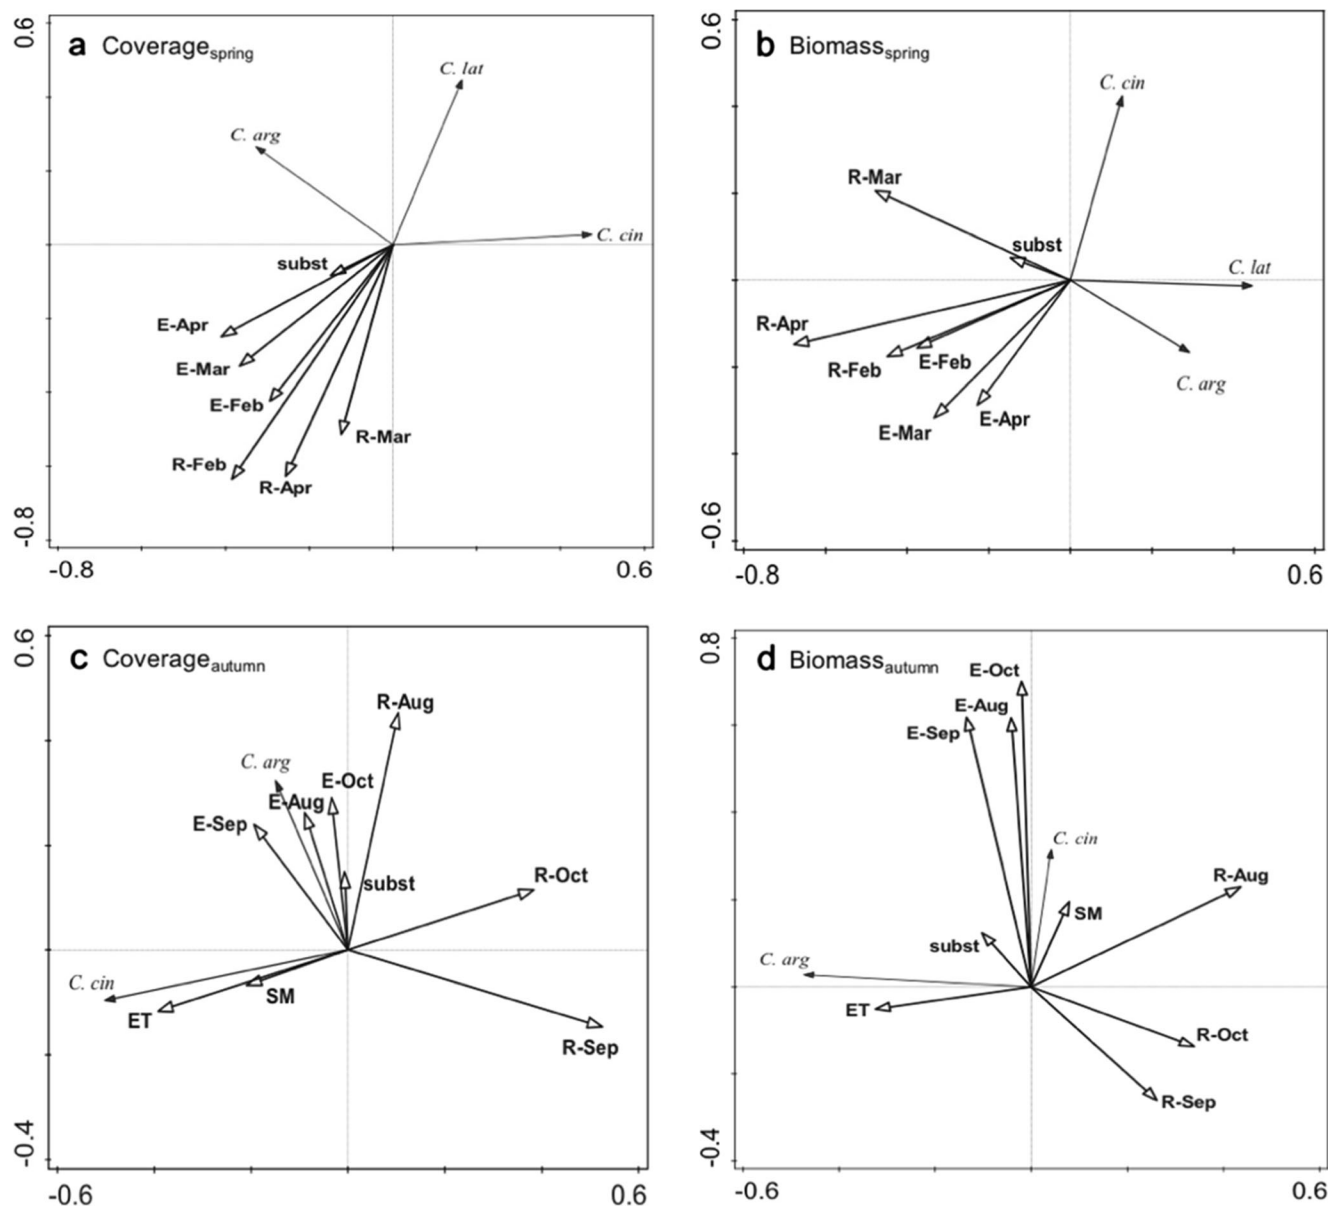

Fig. 4 RDA ordination diagram of species and environmental variables in spring (a, b) and autumn (c, d). Subst: substrate, E: average elevation above water in a month, e.g. E-Feb represents average elevation above

water in February, R: rate of change in a month, e.g. R-Feb represents rate of change in February, ET: emergence timing, SM: soil moisture, *C. arg*: *Carex argyi*, *C. Lat*: *Carex laticeps*, *C. Cin*: *Carex cinerascens*

we observed that prolonged inundation after the first growing season was necessary for the taxa to reduce interspecific competitions in shallow lakes. Since both simulation experiments and field investigations have pros and cons, a better approach would be to combine them together in the further studies.

In the present study, we determined the effects of different parameters of WLFs on the distribution of *Carex* by large scale field investigations. Our results can provide important implications considering the conservation and restoration of *Carex* and other hygrophytes in shallow lakes. Because a reservoir-like type of WLFs is harmful to vegetation development, it is important to keep the water regime in a natural or quasi-natural condition. The present study also revealed that

rate of change and emergence timing were key hydrologic parameters determining the distribution of *Carex*. Water level regulation in this region should take into consideration of these two factors regarding the restoration of *Carex* and other hygrophytes.
