# **Abstract**

**Background** Interventions utilising the Nordic hamstring exercise (NHE) have resulted in reductions in the incidence of hamstring strain injury (HSI). Subsequently, quantifying eccentric knee fexor strength during performance of the NHE to identify an association with the occurrence of future HSI has become increasingly common; however, the data to date are equivocal.

**Objective** To systematically review the association between pre-season eccentric knee flexor strength quantified during performance of the NHE and the occurrence of future HSI.

**Design** Systematic review and meta-analysis.

**Data sources** CINAHL, Cochrane Library, Medline Complete, Embase, Web of Science and SPORTDiscus databases were searched from January 2013 to January 10, 2020.

**Eligibility criteria for selecting studies** Prospective cohort studies which assessed the association between pre-season eccentric knee fexor strength quantifed during performance of the NHE and the occurrence of future HSI.

**Methods** Following database search, article retrieval and title and abstract screening, articles were assessed for eligibility against pre-defned criteria then assessed for risk of bias. Meta-analysis was used to pool data across studies, with metaregression utilised where possible.

**Results** A total of six articles were included in the meta-analysis, encompassing 1100 participants. Comparison of eccentric knee fexor strength during performance of the NHE in 156 injured participants and the 944 uninjured participants revealed no significant differences, regardless of whether strength was expressed as absolute (N), relative to body mass (N kg<sup>-1</sup>) or between-limb asymmetry (%). Meta-regression analysis revealed that the observed efect sizes were generally not moderated by age, mass, height, strength, or sport played.

**Conclusion** Eccentric knee fexor strength quantifed during performance of the NHE during pre-season provides limited information about the occurrence of a future HSI.

# **1 Introduction**

Hamstring strain injury (HSI) is the most common injury in a number of running-based sports  $[1-3]$  $[1-3]$  $[1-3]$  and has a high recurrence rate compared to other lower limb muscles [[2,](#page-9-2) [4](#page-9-3)]. Previous injury (which leads to subsequent unavailability for training and/or matches) infuences subsequent injury risk [[5\]](#page-9-4) and impacts team's success [[6\]](#page-9-5). Furthermore prior HSI adversely efects individual performance [[7](#page-9-6)] and physical output [[8\]](#page-9-7) upon return from injury. As a result, strategies to mitigate the risk of HSI occurrence have received signifcant attention in the literature.

A central component of injury prevention models [[9](#page-9-8), [10\]](#page-9-9) is the identifcation of factors that can provide an indication

### **Key Points**

Meta-analysis of six studies (156 prospective HSIs and 944 uninjured participants) found no diference in preseason eccentric knee fexor strength quantifed during performance of the Nordic hamstring exercise (NHE) between prospectively injured and uninjured participants

Irrespective of whether pre-season eccentric knee fexor strength quantifed during performance of the NHE was expressed in absolute (N) or relative (N kg<sup>-1</sup>) terms or as a between-limb asymmetry (%) there was no diference between prospectively injured and uninjured participants

Accounting for potential effect modifiers (sport played, age, height, mass, average cohort NHE strength) did not alter the fndings

of an individual's risk of future injury and research on risk factors for HSI has increased in recent times [[11\]](#page-9-15). Whilst these risk factors can be extrinsic or intrinsic variables [[12\]](#page-9-16) those which are modifable are of most interest as they can be altered via intervention. Of the modifable factors examined, the magnitude of hamstring strength, and various associated ratios (e.g. hamstring to quadriceps strength ratio, between-limb asymmetry) are commonly reported in the literature [[11\]](#page-9-15); however, the fndings are often conficting across studies. Factors contributing to inconsistent fndings include diferent strength testing methodologies, the range of variables reported (e.g. peak force, limb symmetry, hamstring to quadriceps ratio) and the diferent cohorts examined. Subsequently, drawing inferences from the existing literature is difficult.

The Nordic hamstring exercise (NHE), a common partner-assisted eccentric strength training exercise for the knee fexors, has been shown to reduce the likelihood of sustaining a HSI across a number of cohorts [[13](#page-9-17), [14](#page-9-18)]. Recently, a device which quantifes eccentric knee fexor strength during the performance of the NHE in the feld [\[15\]](#page-9-14) has become prominent. It has been hypothesised that quantifying eccentric knee fexor strength during the NHE may provide information about an individual's risk of HSI as high force lengthening contractions of the hamstrings during high speed running are presumed to be implicated in the aetiology of HSI. An initial prospective cohort study to test this hypothesis, conducted in elite Australian Football, identifed a greater risk of future HSI in those who had lower levels of eccentric knee fexor strength during the NHE, compared to stronger athletes [[16\]](#page-9-11). Whilst this initial fnding was subsequently confrmed in a cohort of Australian soccer players [\[17](#page-9-19)], further studies in Qatari soccer [\[18](#page-9-12)], Australian rugby union [[19\]](#page-9-10), Australian Football [[20\]](#page-9-13), and Gaelic Football [\[21](#page-10-0)] have been conficting. Similarly, whilst greater between-limb asymmetry in eccentric strength during NHE has been reported to increase HSI risk previously [[19\]](#page-9-10), this is not a consistent finding  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$  $[16–18, 20, 21]$ .

Therefore, the aim of this study was to systematically review the association between pre-season eccentric knee fexor strength quantifed during the performance of the NHE and the occurrence of future HSI. A secondary aim is to determine whether larger between-limb asymmetry in eccentric knee fexor strength is associated with future HSI.

# **2 Methods**

## **2.1 Trial Registration**

This review was submitted for registration with the International Prospective Register of Systematic Reviews on December 12, 2019 and was registered on April 28, 2020 (PROSPERO ID registration number: CRD42020158618).

## **2.2 Literature Search Strategy**

The literature search and study selection process were conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) guidelines. A comprehensive search of CINAHL, Cochrane Library, Medline Complete, Embase, Web of Science and SPORTDiscus databases was conducted from January 2013 to January 10, 2020. The search was restricted to articles published from 2013 onwards as the frst report of the device used to measure eccentric knee fexor strength during the NHE was published in 2013 [[15](#page-9-14)]. The search strategy, including key terms and controlled vocabulary (i.e. Medical Subject Headings [MeSH] terms) can be found in Supplementary Table S1. The search terms were determined to align with the research question and aims of the review. Following retrieval all citations were imported into EndNote X9 (Thomson Reuters, New York City, NY, USA) where duplicated removal was performed.

## **2.3 Study Selection**

The title and abstract of retrieved articles were screened for inclusion by two authors (RGT, JTH) using Rayyan [[22](#page-10-1)]. Following the title and abstract screening, a full-text review was completed to determine eligibility by two authors (FPB, JTH). Included in the current review were prospective cohort studies that quantifed eccentric knee fexor strength during performance of the NHE and reported appropriate summary statistics (i.e. measures of central tendency and variation). The population investigated was those participating in sport of any level. Studies were included if they reported data separately for participants who did and did not sustain a subsequent HSI during a defned follow-up period. Only peer-reviewed publications in English were considered. Hand-searching of the reference list was performed on all included studies to identify any other potential articles for inclusion (only articles published form 2013 onwards were considered for inclusion in line with the search strategy).

#### **2.4 Risk of Bias Assessment**

The Quality in Prognosis Studies (QUIPS) tools [[23](#page-10-2)] was used to assess risk of bias of all included studies, per previous similar systematic reviews [[11\]](#page-9-15). Two authors (RGT, NvD) applied the QUIPS to each individual study, with any discrepancy between scoring discussed between these authors to reach a consensus. If a consensus could not be reached in this manner, a third author (FPB) was used to resolve the dispute.

An individual study was considered to have a low risk of bias if fve of the six domains defned in the QUIPS tool (study participation, study attrition, prognostic factor measurement, outcome measurement, study confounding, statistical analysis and reporting) were assessed as having a low risk of bias (defned as a score of≥75% for individual criteria under each domain). Any study that was determined to have a high risk of bias in the outcome measurement domain was automatically assigned a high risk of bias.

## <span id="page-2-0"></span>**2.5 Data Extraction**

Data pertaining to participant characteristics, including age, height, mass, sport, history of HSI and level of competition were extracted. Additional methodological details were also extracted, including the defnition used to determine the occurrence of a HSI, the NHE strength testing protocol, time of testing, and the length of participant follow-up. Measures of sample size, central tendency (typically a mean value) and variance (typically standard deviation) related to NHE strength in groups of individuals who did and did not sustain a HSI were also extracted. Specifcally, the following knee fexor strength data, quantifed during performance of the NHE were obtained: absolute knee fexor strength (N), knee flexor strength normalised to body mass  $(N \text{ kg}^{-1})$ , and between-limb asymmetry in knee fexor strength (%). Since between-limb asymmetry was computed diferently between studies, we sought data from the corresponding authors to compute between-limb asymmetry (%) according to the following equation:

Asymmetry<sub>i</sub> =  $100 \times \frac{\text{Limb}_{\text{max}} - \text{Limb}_{\text{min}}}{\text{Limb}_{\text{min}}}$  $\mathrm{Limb}_{\mathrm{max}}$ 

where Asymmetry*<sup>i</sup>* was the *i*th participant's between-limb asymmetry  $(\%)$ , Limb<sub>max</sub> was maximum force value generated by either limb, and  $\text{Limb}_{\text{min}}$  was the maximum force value generated by the weaker limb. Due to the positively skewed nature of asymmetry data, a log transformation was applied to the raw data to create a normally distributed variable:

 $\text{Transformed}_i = \ln \left( \text{Asymmetry}_i + 1 \right)$ 

where Transformed<sub>*i*</sub> is the *i*th participant's log-transformed asymmetry score and ln is the natural logarithm. Note that these log-transformed data were used for all subsequent analysis involving between-limb asymmetry.

## **2.6 Data Analysis**

Meta-analysis and meta-regression were conducted using the "meta"  $[24]$  $[24]$  and "metafor"  $[25]$  $[25]$  packages in R  $[26]$  $[26]$  $[26]$ . Data pertaining to the primary outcome (i.e. eccentric knee fexor strength or limb-asymmetry data) were converted to standardised mean diferences (SMD) and 95% confdence intervals (CI). These data were pooled across studies using a random efects model, with a restricted maximum likelihood method used to estimate variance. Each pooled efect size was interpreted as trivial  $( $0.20$ ), small  $(0.20-0.49)$ ,$ moderate (0.50–0.79) or large ( $\geq$  0.80) [\[27](#page-10-6)]. For each metaanalysis, visual inspection of funnel plots was used to assess publication bias and heterogeneity was evaluated using the  $I<sup>2</sup>$  statistic. Meta-analyses were conducted for prospectively injured limbs compared to the uninjured control group limbs for all outcomes (i.e. absolute knee fexor strength, body mass normalised knee fexor strength and between-limb asymmetry).

In addition, contact with corresponding authors enabled the determination of which injured participants had sufered a HSI in the 12 months prior to testing, which was subsequently used to perform subgroup analysis on "recurrent" and "non-recurrent" injuries for each of the aforementioned outcome variables. Athletes were classifed as "recurrent" if they had sufered a HSI (in the 12 months prior to testing) in the same leg that was injured within the study follow-up period.

Where possible, a meta-regression was performed to assess the impact of other potential efect modifers, including the sport played, mean age, height and mass of each cohort as reported within each study. Meta-regression was also performed for the average strength of each cohort, which was determined by computing the mean (weighted by sample size) of the injured limbs, contralateral uninjured limb and control group absolute knee fexor strength.

# **3 Results**

# **3.1 Search Strategy**

The search results are presented in Fig. [1.](#page-3-0) The initial search yielded 3585 items from all databases. After duplicate removal and title and abstract screening, 12 articles underwent independent application of the selection criteria, resulting in 6 articles in the systematic review and meta-analysis.

# **3.2 Risk of Bias Assessment**

Only one [[21](#page-10-0)] of the six included studies presented with a high risk of bias, with all others presenting a low risk. Full details of the scoring for the QUIPS tool for all included studies are provided in Supplementary Table S2.

## **3.3 Description of Studies**

## **3.3.1 Participants**

Across the 6 included studies, a total of 1100 male participants were included in the meta-analysis (weighted mean  $\pm$  pooled SD; age = 25  $\pm$  4 years; height =  $1.83 \pm 0.07$  m; mass =  $84 \pm 9$  kg). Of the included participants, 156 participants sufered a prospective unilateral HSI, and 944 participants remained uninjured during the follow-up periods. Two studies [[17](#page-9-19), [18\]](#page-9-12) investigated elite soccer players ( $n=376$  participants,  $n=55$  injured) and another two studies [\[16,](#page-9-11) [20](#page-9-13)] investigated elite Australian Football players ( $n=362$  participants,  $n=53$  injured). The two remaining studies investigated elite Gaelic Football players [[21\]](#page-10-0) (*n*=184 participants, *n*=28 injured) or elite and sub-elite Rugby Union players [\[19\]](#page-9-10) (*n*=178 participants,  $n=20$  injured). Participant characteristics are summarised in Supplementary Table S3.

<span id="page-3-0"></span>

## **3.3.2 Testing Protocol**

All studies conducted testing during the pre-season period, with three studies conducting knee fexor strength testing at the start of pre-season  $[16, 17, 20]$  $[16, 17, 20]$  $[16, 17, 20]$  $[16, 17, 20]$  $[16, 17, 20]$  $[16, 17, 20]$  and the remaining three studies conducting testing within pre-season [\[18](#page-9-12), [19,](#page-9-10) [21](#page-10-0)]. All studies used the same protocol, involving one set of three maximal effort repetitions of the NHE on a Nordic testing device.

#### **3.3.3 Injury Monitoring**

Athletes were monitored for HSI occurrences after pre-season testing for periods of  $\sim$  3 months [[21](#page-10-0)],  $\sim$  6 months [\[19](#page-9-10)] or 10 months [[16](#page-9-11)[–18](#page-9-12), [20](#page-9-13)]. Two studies included only magnetic resonance imaging (MRI) confrmed HSIs [\[16,](#page-9-11) [20](#page-9-13)], two studies included a mix of HSIs diagnosed via either imaging (MRI or ultrasound) confrmation or physical/clinical examination [\[18,](#page-9-12) [19](#page-9-10)], one study included injuries confrmed by clinical examination [[17\]](#page-9-19), whilst the remaining study [\[21](#page-10-0)] reported only that injuries were diagnosed by the club physiotherapists or medical doctor. For all included studies, the occurrence of HSIs in the 12 months prior to testing was also recorded. Note that details of the testing protocol and injury surveillance of each study are provided in Supplementary Table S4.

#### **3.3.4 Outcome Variables**

Five [[16](#page-9-11)[–18](#page-9-12), [20,](#page-9-13) [21](#page-10-0)] of the included studies calculated the average peak force (across the three repetitions), whilst one study [\[19\]](#page-9-10) only reported the peak force (i.e. the highest force value recorded across the entire set of three repetitions). All studies reported absolute knee fexor strength (N) and knee flexor strength normalised to body mass ( $N kg^{-1}$ ). Betweenlimb asymmetry was reported by all studies albeit computed via diferent equations. Two studies [\[18,](#page-9-12) [20\]](#page-9-13) reported between-limb imbalance in N, whilst the remaining studies expressed asymmetry as a percentage [[16](#page-9-11), [17,](#page-9-19) [19,](#page-9-10) [21](#page-10-0)]. As described in Sect. [2.5,](#page-2-0) original data were obtained from authors to recompute limb-asymmetry (in accordance with Eq. 1 for subsequent meta-analysis). One study [[17\]](#page-9-19) also reported knee fexor strength as torque (Nm) by accounting for the shank length. Since none of the other included studies had such data available, torque was not included in further analysis.

# **3.4 Strength Outcomes Quantifed During the Performance of the NHE**

#### **3.4.1 Absolute Knee Flexor Strength**

No signifcant diferences in absolute knee fexor strength were observed between the prospectively injured limbs

and the uninjured control group (SMD =  $-$  0.22, 95%  $CI = -0.50$  to 0.05; Fig. [2a](#page-5-0)) or the recurrent injured limbs compared to the uninjured control group ( $SMD = -0.32$ , 95% CI = − 0.77 to 0.13; Fig. [2b](#page-5-0)).

#### **3.4.2 Normalised Knee Flexor Strength**

Normalising knee flexor strength to body mass had no effect on any outcome, and the pooled effect sizes were almost identical to the absolute knee fexor strength. Specifcally, efect size remained small for all injured limbs  $(SMD=-0.23, 95\%CI=-0.55$  to 0.10; Fig. [3a](#page-6-0)) or recurrently injured limbs (SMD =  $- 0.32$ , 95%CI =  $- 0.90$  to 0.26; Fig. [3b](#page-6-0)) when compared to the uninjured group.

#### **3.4.3 Limb Asymmetry in NHE Strength**

No significant differences in between-limb knee flexor strength asymmetry were found between all injured participants (SMD = 0.01,  $95\%$ CI = - 0.24 to 0.25; Fig. [4a](#page-7-0)) or recurrently injured participants  $(SMD = 0.28,$  $95\%CI = -0.14$  to 0.70; Fig. [4](#page-7-0)b) compared to the uninjured group.

#### **3.4.4 Meta‑regression**

No signifcant relationships between absolute knee fexor strength and any covariate investigated (sport played, athlete age, height and mass or average absolute NHE strength of cohort) were found ( $p \ge 0.26$ ). For between-limb asymmetry, a significant effect was found for average age  $(p=0.007)$ , but not any other variable ( $p \ge 0.24$ ). Visualisation of regression relationships for continuous variables is provided in Fig. [5,](#page-8-0) whilst a full summary of meta-regression statistical results is provided in Supplementary Table S5.

# **4 Discussion**

This systematic review and meta-analysis are the frst to comprehensively synthesise the available data pertaining to eccentric knee fexor strength quantifed during performance of the NHE and the occurrence of future HSI. Overall, our analysis of 1100 participants revealed that pre-season knee fexor strength quantifed during performance of the NHE was not associated with HSI. This fnding was consistent regardless of whether strength was expressed as absolute, body mass normalised, or as a limb-asymmetry percentage. Additionally, our meta-regression analysis found that these fndings were generally not moderated by the sports played, or the average height, mass or strength of each cohort.

The importance of eccentric knee flexor strength in HSI has been investigated extensively in the literature.

<span id="page-5-0"></span>**Fig. 2** Standardised mean diferences (SMD) of absolute eccentric knee fexor strength (N) quantifed during performance of the Nordic hamstring exercise for hamstring strain injured limbs compared to the uninjured control group. Data are sub-grouped for **a** all injuries, **b** recurrent injuries, **c** non-recurrent injuries. Recurrent injury classifcation was achieved through author contact and was defned as athletes that suffered a hamstring strain injury (HSI) in the 12 months

Specifcally, the NHE has received signifcant attention recently, as its implementation as a training intervention has been consistently shown to reduce the incidence of HSI, relative to groups that do not perform the exercise [\[13,](#page-9-17) [14\]](#page-9-18). It is therefore conceivable that the measurement of knee flexor strength during the NHE may offer insight into the risk of subsequent HSI. The frst study in this area of research found that lower eccentric knee fexor strength during the NHE at the start of pre-season was associated with increased HSI risk in the subsequent season in a cohort of Australian Football players [\[16](#page-9-11)]. Further work across a number of diferent football codes [\[17–](#page-9-19)[21](#page-10-0)], however, has been conficting. Our meta-analysis combined these data and revealed, overall, no signifcant diferences in eccentric knee fexor strength quantifed during performance of the NHE between the prospectively injured limbs and either the

prior to test, and then suffered a subsequent HSI in the same leg during the follow-up period. Note that for one study  $[18]$  $[18]$ , the recurrent and non-recurrent injured-group limbs could only be identifed on a player-season level, not an individual participant level (due to participant de-identifcation). Due to 3 players in this study sufering injuries across both assessed seasons, the sum of recurrent and non-recurrent injuries exceeds the total amount of injuries reported in panel **a**

contralateral uninjured limbs or the uninjured control group. Whilst this suggests there is no relationship between eccentric knee fexor strength quantifed during performance of the NHE and future HSI, it is important to put these fndings into context.

Our a-priori power analysis suggested the six studies would achieve adequate power (>90%) to detect a moderate effect size  $(0.50)$ , even with a conservative within-study sample size estimate, and assuming the presence of high between-study heterogeneity (Supplementary Figure S1). The results from the current meta-analysis therefore indicate that if there is any efect of eccentric knee fexor strength, quantifed during performance of the NHE, on future HSI risk, the efect is at most small. The current meta-analysis, however, was not sufficiently powered to detect small effect sizes (i.e. 0.20). Since the pooled efect sizes observed in

<span id="page-6-0"></span>**Fig. 3** Standardised mean diferences (SMD) of body mass normalised eccentric knee flexor strength (N kg<sup>-1</sup>) quantified during performance of the Nordic hamstring exercise for hamstring strain injured limbs compared to the uninjured control group. Data are sub-grouped for **a** all injuries, **b** recurrent injuries, **c** non-recurrent injuries. Recurrent injury classifcation was achieved through author contact and was defined as athletes that suffered a hamstring strain injury (HSI) in the 12 months prior to test, and then sufered a subsequent HSI in the

 $\overline{1}$ 

ŀ

same leg during the follow-up period. Note that for one study [[18](#page-9-12)], the recurrent and non-recurrent injured-group limbs could only be identifed on a player-season level, not an individual participant level (due to participant de-identifcation). Due to 3 players in this study suffering injuries across both assessed seasons, the sum of recurrent and non-recurrent injuries exceeds the total amount of injuries reported in panel **a**

this analysis were small for all comparisons, we cannot defnitively conclude that there are no diferences in NHE strength between injured and uninjured legs, but rather that any diferences (if they do exist) are likely to be small, at most. Studies with larger sample sizes would be required to detect such small effects; however, the clinical utility of such data is limited. For context, the small effect sizes observed in the meta-analysis correspond to pooled mean differences of  $-18$  N (95%CI= $-40$  to 4 N) or  $-0.22$  N kg<sup>-1</sup>  $(95\%CI = -0.54$  to  $0.10 \text{ N kg}^{-1})$  between the injured limbs and the uninjured control groups. Importantly, the minimal detectable change of the Nordic hamstring device has been reported to be  $>60$  N [\[15](#page-9-14)].

Despite the well-documented benefit of performing eccentric knee fexor exercises for reducing HSI risk [\[28,](#page-10-7) [29](#page-10-8)], it is clear that measurement of eccentric knee fexor strength alone cannot predict HSI occurrence [\[20\]](#page-9-13), and likely interacts with other factors such as age and previous history of HSI [\[16](#page-9-11), [17,](#page-9-19) [19\]](#page-9-10). We attempted to account for these factors via meta-regression or subgroup analysis, respectively; however, due to the multi-factorial nature of HSI, there are many other potentially infuential factors that were unaccounted for in our analysis. For example, shorter biceps femoris long head fascicle lengths have been shown to be associated with greater risk of HSI [[17\]](#page-9-19). Isokinetic eccentric hamstring training  $[30]$ , as well as the NHE  $[31-36]$  $[31-36]$  $[31-36]$ , have been shown to not only increase eccentric knee fexor strength, but also increase biceps femoris long head fascicle lengths. However, there are numerous other methods by which eccentric knee fexor strength can be improved, some of which are associated with shortening of biceps femoris long head fascicle lengths (thus conceivably increasing HSI

<span id="page-7-0"></span>**Fig. 4** Standardised mean diferences (SMD) of log-transformed between-limb asymmetry (%) of eccentric knee fexor strength quantifed during performance of the Nordic hamstring exercise for hamstring strain injured limbs compared to the uninjured control group. Data are sub-grouped for **a** all injuries, **b** recurrent injuries, **c** non-recurrent injuries. Recurrent injury classifcation was achieved through author contact and was defned as athletes that sufered a hamstring strain injury (HSI) in the 12 months prior to test, and

then sufered a subsequent HSI in the same leg during the follow-up period. Note that for one study [\[18\]](#page-9-12), the recurrent and non-recurrent injured-group limbs could only be identifed on a player-season level, not an individual participant level (due to participant de-identifcation). Due to 3 players in this study sufering injuries across both assessed seasons, the sum of recurrent and non-recurrent injuries exceeds the total amount of injuries reported in panel **a**

risk), such as concentric isokinetic exercise [[30\]](#page-10-9). Additionally, muscle fascicle lengths are rapidly adaptable to both training and de-training [[30–](#page-10-9)[32\]](#page-10-12), and changes across a playing season, particularly in those with a prior HSI [[37\]](#page-10-13). Subsequently, future work investigating HSI risk factors should aim to comprehensively assess as many prospective factors as possible (in addition to eccentric knee fexor strength), including muscle architecture and accounting for exposure [\[38,](#page-10-14) [39\]](#page-10-15).

One important result of our analysis is the consistency of our fndings across various methods of expressing eccentric knee fexor strength quantifed during performance of the NHE. Debate around the normalisation of NHE knee fexor strength data has been presented in the literature, with some authors arguing that the most commonly expressed metric

of absolute strength is fundamentally fawed due to failure to account for difering body mass and/or lever arms between individuals [\[40](#page-10-16)]. However, all studies included in our analysis also reported body mass normalised knee fexor strength, and our meta-analysis showed a very similar relationship to HSI between absolute and normalised strength (Figs. [2,](#page-5-0) [3](#page-6-0), [5](#page-8-0), Supplementary Figure S5). Additionally, our metaregression showed that body mass and height had no moderating efect on the results of our analysis. However, it is important to acknowledge that our meta-regression assessed the relationship between the average characteristics of each cohort (i.e. age, height, mass and strength) and the efect size between the injured and uninjured groups. Subsequently, a more detailed analysis incorporating individual data points may be needed to more comprehensively determine the

<span id="page-8-0"></span>**Fig. 5** Meta-regression of eccentric knee fexor strength quantifed during performance of the Nordic hamstring exercise (NHE) standardised mean diference (SMD), between prospectively hamstring strain injured and uninjured limbs and continuous covariates. Regression analysis was conducted for eccentric knee fexor strength presented in absolute terms (top row, positive SMD indicates greater

strength in injured limbs) or between-limb asymmetry (bottom row, positive SMD indicates greater asymmetry in the injured group). Bubbles, data points representing each study (size of each bubble is inversely proportional to the standard error of the study); black line, regression line of best ft; grey shaded area, 95% confdence interval of regression line

value of normalisation of NHE knee fexor strength data to mass, height, lever length or an allometric scaling approach.

Despite the key insights provided by this study, our metaanalysis is not without limitations. First, the comprehensiveness of our search strategy cannot be guaranteed; thus, it is possible that some relevant literature was not obtained. However, given that only six articles were obtained from our search, it is unlikely there is additional literature that would have not been identifed via citation tracking and reference list searching. In these six included articles, the risk of bias cannot be completely avoided. However, our quality assessment revealed a high risk of bias for only one study [\[21\]](#page-10-0) which received this classification due to a lack of clear defnition of the outcome (HSI) and a lack of consideration of potential important confounders within the analysis. A meta-analysis and meta-regression of only six studies presents some additional limitations which must be acknowledged, including sparse-data bias [[41,](#page-10-17) [42](#page-10-18)] and publication bias. Evaluation of publication bias was done via visual inspection of funnel plots, yet such an approach can offer only limited insight with a low number of studies. However, our power analysis suggested that five studies were sufficient to detect a moderate ( $\geq$  0.50) effect size with > 80% power for our control group comparisons (Figs. [2](#page-5-0), [3,](#page-6-0) [4\)](#page-7-0) and contralateral limb comparisons (Supplementary Figure S2), even in the presence of high between-study heterogeneity (Supplementary Figure S1). Further to this, our analysis suggests that an estimated 19 studies would be needed to obtain adequate statistical power to detect small (0.20) efect sizes for control group comparisons (Supplementary Figure S3). It should also be noted that the analysis pertaining to recurrent injuries is particularly impacted by the small number of recurrent injuries  $(n=37)$ , and thus an even greater number of studies would be needed to substantiate these fndings. Furthermore, additional studies would also increase the veracity of the fndings from our meta-regression, which is commonly recommended to include at least 10 studies [[43\]](#page-10-19). Subsequently, our meta-analysis and meta-regression provides a much-needed synthesis of the presently available data for clinicians, until such a time that these additional studies would be completed. Based on our fndings, clinicians should be aware that such future studies, if they are conducted, are expected to demonstrate substantial heterogeneity (Supplementary Figure S4). Finally, it is important to recognise that our meta-analysis pertains specifcally to pre-season knee fexor strength measures with follow-up periods of between ~ 3 and 10 months. It is possible that more frequent strength tests (e.g. in-season) over longer periods may yield diferent fndings. Additionally, other methods of eccentric knee fexor strength assessment [[44,](#page-10-20) [45](#page-10-21)] may provide alternative conclusions if prospective data were available.

# **5 Conclusions**

Based on the available evidence, this systematic review and meta-analysis showed that pre-season eccentric knee fexor strength quantifed during performance of the NHE is not associated with future HSI. This fnding was consistent regardless of whether knee fexor strength was expressed in absolute terms, normalised to body mass, or expressed as a between-limb asymmetry. Despite the promising early work in the area, our pooled analysis of 1100 participants suggests that knee fexor strength quantifed during performance of the NHE alone provides limited insight about future HSI.

## **Declarations**

**Funding** No sources of funding were used to assist in the preparation of this article.

**Conflict of interest** Dr David Opar is listed as a co-inventor on a patent fled for a feld-testing device of eccentric hamstring strength (PCT/ AU2012/001041.2012) and is a minority shareholder in Vald Performance Pty Ltd, the company responsible for commercialising the device. The association between measures derived from the device and future hamstring strain injury is directly examined in this manuscript. Dr Opar is also the Chair of the Vald Performance Research Committee, a role that is unpaid. Dr Opar has received funding from Vald Performance for research unrelated to the current manuscript. Dr Opar's brother and brother-in-law are employees of Vald Performance. Dr Opar's brother is a minority shareholder in Vald Performance Pty Ltd. Ryan Timmins, Fearghal Behan, Jack Hickey, Nicol van Dyk, Kara Price and Nirav Maniar declare that they have no conficts of interest relevant to the content of this review.

**Availability of data and material** Access to data and/or material can be sought via contacting the corresponding author.

**Code availability** Not applicable.

**Authorship contributions** DAO, RGT, FPB, JTH, NM conceived the study. DAO, FPB and KP completed study protocol and registration. DAO and RGT completed database searches and extraction. RGT and JTH completed title and abstract screening. FPB and JTH completed full text review. RGT, NvD and FPB completed risk of bias assessment. NM, JTH and NvD completed data extraction. NM and JTH completed data analysis. DAO drafted the Introduction and Methods. NM drafted the Results and Discussion. All authors reviewed, revised and approved the fnal manuscript.
