**ABSTRACT** Global warming has seriously threatened the industrial/agricultural productions and human life and has become one of the major challenges facing the world today. Carbon neutrality is an important measure for mitigating the greenhouse effect, and photocatalytic CO<sub>2</sub> reduction can effectively reduce carbon emissions and promote the carbon cycle. g-C<sub>3</sub>N<sub>4</sub> has attracted much attention due to its simple preparation process, high stability, suitable energy band position, and excellent photocatalytic performance; thus, improving its efficiency in photocatalytic CO<sub>2</sub> reduction has become the focus of current research. The importance of carbon neutrality for the global ecological balance and environmental sustainability and the important role and development prospects of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction in the context of carbon neutrality are the main focuses of this review. The current methods and technical means to solve the difficulty of the g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction are summarized. The possible problems in the field of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction are discussed, and future research directions are proposed. The aim of this work is to provide theoretical support for the practical applications of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction and to present potential design concepts for efficient g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts.

**Keywords:** carbon neutral, photocatalysis, CO<sub>2</sub> reduction, graphitic carbon nitride, modification strategy

## INTRODUCTION

Global warming has seriously threatened the productivity of humans and has become one of the major challenges facing the world today. Global warming is caused by the continuous emissions of carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>), ozone (O<sub>3</sub>) and other greenhouse gases that produce the greenhouse effect; thus, the temperature continues to rise. Global warming has catastrophic impacts on the earth and production life on which human depends and is a common concern of all countries and governments around the world. CO<sub>2</sub>, as the main greenhouse gas, is an important medium of the global carbon cycle and has the dual properties of transforming organic matter in the ecosystem and causing the greenhouse effect [1]. To address climate change caused by the greenhouse effect, the Paris Agreement

and the Intergovernmental Panel on Climate Change (IPCC) took the lead in proposing the goal and concept of carbon neutrality in 2015 [2]. In the context of the global climate change and carbon neutrality, CO<sub>2</sub> reduction and conversion have become inevitable trends and choices for green development. Carbon capture and CO<sub>2</sub> conversion and utilization have become key areas of research; additionally, technologies need to be developed urgently and include the development of low-carbon energy, low-carbon transformation of industrial enterprises, low-carbon transformation of domestic energy use, low-carbon transformation of transportation and travel, and the capture and transformation of unavoidable CO<sub>2</sub> emissions [3,4]. Among them, the catalytic reduction of CO<sub>2</sub> to methanol (CH<sub>3</sub>OH), CH<sub>4</sub> and other fuels for reuse under the action of catalysts is a key step in achieving carbon neutrality as well as mitigating the greenhouse effect and energy crisis; this reduction is one of the most direct and effective measures for promoting carbon neutrality.

After decades of research, the more mature CO<sub>2</sub> reduction technologies include electrocatalytic reduction, photocatalytic reduction, bioreduction, chemical reduction, reforming reduction and inorganic reduction [5,6]. The recent studies have focused mainly on the electrocatalytic reduction and photocatalytic reduction of CO<sub>2</sub> because of their great potentials in the reduction of CO<sub>2</sub> into other chemicals. Electrocatalytic CO<sub>2</sub> reduction is considered to be an effective strategy; here, electrical energy is stored during the electrocatalytic CO<sub>2</sub> reduction reaction by the reorganization of the molecular bonds between CO<sub>2</sub> and water to form oxygen and CO<sub>2</sub> reduction products [7]. Although the mechanism of the electrocatalytic CO<sub>2</sub> reduction reaction is relatively understood after years of exploration, some problems still remain in the electrocatalytic reduction of CO<sub>2</sub>, including the need for electrical energy consumption, unstable reaction kinetics, low energy efficiency, and poor selectivity. Due to these problems, its practical application has been limited [8]. The reduction of CO<sub>2</sub> to chemicals using solar photocatalysis is considered a green and sustainable process; for example, in artificial photosynthesis, CO<sub>2</sub> is converted to various hydrocarbon fuels, such as CH<sub>4</sub>, formaldehyde (HCHO), CH<sub>3</sub>OH, and formic acid (HCOOH), and this reaction is driven by the renewable solar energy in the presence of a catalyst at ambient temperature and pressure [9]. This is considered a promising

technology for CO<sub>2</sub> reduction and carbon cycling in the context of carbon neutrality because it is green and environmentally friendly and does not consume other energy sources. The efficiency of photocatalytic CO<sub>2</sub> reduction depends mainly on the photocatalysts, and several types of photocatalysts have been developed, including metal oxides (TiO<sub>2</sub> [9,10], CuO/Cu<sub>2</sub>O [11], CeO<sub>2</sub> [12,13], ZnO [14], WO<sub>3</sub> [15], In<sub>2</sub>O<sub>3</sub> [16], Bi<sub>2</sub>WO<sub>6</sub> [17], etc.), nonmetallic semiconductors (g-C<sub>3</sub>N<sub>4</sub> [18,19], graphene oxide (GO) [20,21], boron nitride (BN) [22], etc.), and metal organic frameworks (MOFs) [23–25].

Among these photocatalysts, g-C<sub>3</sub>N<sub>4</sub> has attracted much attention due to its low cost, simple preparation process, high stability, suitable energy band position and excellent photocatalytic performance. g-C<sub>3</sub>N<sub>4</sub> was first reported by Wang *et al.* [26] in 2009 for visible light photocatalytic cracking of water, and g-C<sub>3</sub>N<sub>4</sub> was formally applied to the field of catalysis. With an optical band gap of approximately 2.7 eV, g-C<sub>3</sub>N<sub>4</sub> is a good visible light responsive material, and its conduction band (CB) and valence band (VB) have energy positions of −1.1 and 1.6 eV relative to the normal hydrogen electrodes (NHEs), respectively. Because of its suitable CB and VB and good stability, g-C<sub>3</sub>N<sub>4</sub> is widely used for photocatalytic pollutant degradation, photocatalytic water splitting, photocatalytic CO<sub>2</sub> reduction and so on. For photocatalytic CO<sub>2</sub> reduction, the redox potential of the CO<sub>2</sub> reduction product is generally between −0.16 and −0.62 eV relative to the standard hydrogen electrode. The bottom of the CB of g-C<sub>3</sub>N<sub>4</sub> is more negative with respect to the redox potential of the CO<sub>2</sub> reduction products, which provides the necessary conditions for the catalytic reaction [27,28]. However, the low utilization efficiency of g-C<sub>3</sub>N<sub>4</sub> for sunlight limits its practical application in photocatalytic CO<sub>2</sub> reduction, mainly due to the fast electron and hole recombination rate (low electron utilization) of pure g-C<sub>3</sub>N<sub>4</sub> and the low absorption efficiency of visible light. To overcome the above disadvantages in enhancing the efficiency of photocatalytic CO<sub>2</sub> reduction, various modulation methods, such as heterostructure building, elemental doping, and noble metal deposition, have been studied and reported. These modulation methods provide more possibilities for the practical applications of g-C<sub>3</sub>N<sub>4</sub> in photocatalytic CO<sub>2</sub> reduction.

Herein, we focus on the importance of carbon neutrality for global ecological and environmental sustainability and the important role and development prospects of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction in the context of carbon neutrality. First, a basic understanding of carbon neutrality and the basic principles of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> are introduced. Second, the current methods and technical means to solve the difficulties limiting g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction are reviewed. Finally, the possible future problems of g-C<sub>3</sub>N<sub>4</sub> in the field of photocatalytic CO<sub>2</sub> reduction are discussed, and future research directions are presented. This review aims to provide theoretical support for the applications of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction in a carbon-neutral environment and provides suggestions for promoting the practical applications of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction and the design of efficient g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts.

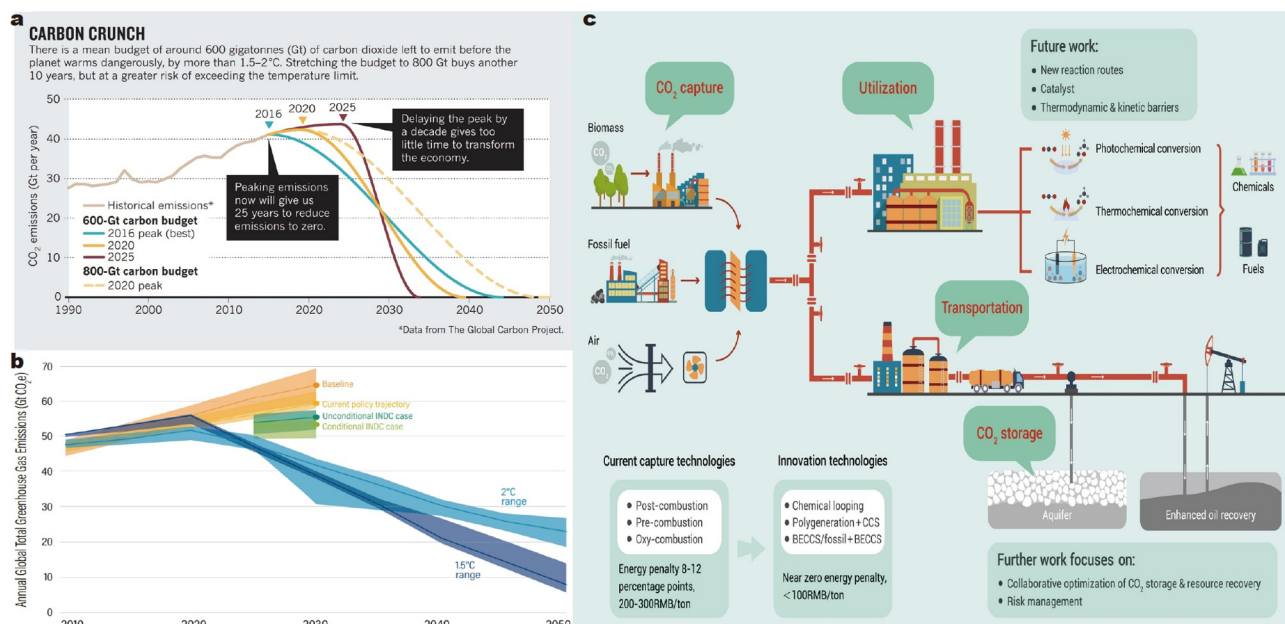

## SIGNIFICANCE AND NECESSITY OF CARBON NEUTRALITY

With the development of human civilization and the global economy, climate change has become the most important issue

facing humanity today. Due to global warming, we are experiencing a series of catastrophic weather and climate events, such as heat waves, floods, droughts, forest fires and sea level rise. Global warming is caused by the massive use of fossil fuel energy by humans since the industrial revolution, the massive amounts of manufacturing, housing infrastructure, and other activities; these activities have resulted in the emission of large amounts of greenhouse gases (mainly CO<sub>2</sub> but also CH<sub>4</sub>, nitrous oxide, and chlorofluorocarbons), which are commonly called carbon emissions. To limit the harm of global warming, global carbon emissions need to be rapidly reduced. Carbon neutrality, also known as carbon offset, is an inevitable option that can reduce global warming in response to climate change. The concept of carbon neutrality was first proposed by environmentalists in the late 1990s, and the global and national carbon neutrality targets originated from the 2015 Paris Agreement on climate change and the relevant reports of the IPCC [29]. Carbon neutrality means that the total amount of carbon dioxide or greenhouse gas emissions generated directly or indirectly by a country, enterprise, product, activity or individual over a certain period of time can be offset through afforestation, energy conservation and emission reduction to achieve a positive or negative offset and attain relative “zero emissions” [30]. An important point in the process of carbon neutrality is peak emissions, also known as carbon peaking, which refers to a point in time when CO<sub>2</sub> emissions stop increasing, reach a peak and then gradually decrease and is the turning point of CO<sub>2</sub> emissions from increasing to decreasing. The goals set out in the Paris Agreement require parties to the United Nations Framework Convention on Climate Change are as follows: to make immediate and explicit intended nationally determined contributions (INDCs) to climate change mitigation; to peak carbon emissions as early as possible; to achieve carbon neutrality in the second half of the 21st century; and to limit the increase in global surface temperature to 2°C relative to preindustrial levels by the end of the 21st century; this effort would move towards the control target temperature of 1.5°C [31,32].

In this dire situation, future greenhouse gas emission limits will be extremely stringent in the longer term. In a special report in 2018, the IPCC stated that countries must achieve “net zero” CO<sub>2</sub> emissions by 2050 to maintain global warming within 1.5°C of preindustrial levels [33]. However, to maintain temperatures within 2°C at minimal cost, scientific studies have found that global greenhouse gas emissions need to peak by 2020. Figueres *et al.* [34] argued that the emission pathway limits the average carbon balance to 600 Gt CO<sub>2</sub>; this is consistent with limiting warming to 1.5–2°C. They noted that increasing the emissions budget to 800 Gt CO<sub>2</sub> while still peaking in 2020 would reduce the need for high decarbonization rates after the peak but would increase the risk of temperature increases beyond the 1.5–2°C target (Fig. 1a). Fig. 1b shows the median values for various studies’ assessments of anticipated emissions levels in 2025 and 2030 based on the INDCs; these assessments are in contrast with what is needed for limiting warming to 1.5 or 2°C and indicate continuous growth, on average, in emissions between 2025 and 2030 [35].

To combat climate change and achieve the carbon neutrality goals envisioned in the Paris Agreement, governments should actively set carbon neutrality targets and pursue a range of related policies. Socioeconomic, energy and industrial systems as well as individual consumption behaviour will need to be sig-

nificantly rebuilt. The realization of the vision of carbon neutrality requires a combination of policies and the development of relevant emission reduction and sequestration technologies from two main aspects: energy efficiency and carbon capture (Fig. 1c) [2,3]. In terms of energy conservation and emission reduction, emerging technologies and technological innovation have become important tools for promoting energy conservation and emission reduction [36]. At present, the technologies used to achieve carbon neutrality mainly include renewable energy technology, low carbon utilization and energy efficiency improvement technology, carbon capture, and utilization and storage (CCUS) technology. Renewable energy is a complete technology system that needs not only solar energy, wind energy, geothermal energy, and ocean energy but also the cooperation of energy storage technology to form a new energy system. Nuclear energy and hydrogen energy have the advantages of being clean, low-carbon, green and environmentally friendly and are important technologies for achieving carbon neutrality. Low carbon use and energy efficiency technologies are mainly applied in industry, transportation and buildings. These include the following: clean and efficient utilization technology of coal, oil and natural gas; low carbon and zero carbon industrial process reengineering technology; electrification and intelligent transportation technology; and direct and flexible light storage to build photovoltaic integration technology systems. CCUS technology mainly includes carbon dioxide into chemicals, carbon dioxide into fuel, microalgae production, concrete carbon capture, carbon capture and storage of bioenergy, afforestation [2,37,38]. In addition, effective policies, such as launching low-carbon pilot projects, promoting “green markets”, need to be implemented, and carbon emission trading market mechanisms need to be established [39]. However, the total emissions from aviation, long-distance transport, shipping, structural materials, and highly reliable electricity that are difficult to eliminate are

approximately 920 million tons of CO<sub>2</sub>, accounting for 27% of the global CO<sub>2</sub> emissions from all fossil fuels at that time (2014) (Fig. 2a) [40,41]. Therefore, the development of carbon sequestration technologies capable of capturing and converting CO<sub>2</sub> is particularly important in the process of achieving carbon neutrality, and photocatalytic CO<sub>2</sub> reduction as artificial photosynthesis can effectively contribute to the carbon cycle and reduce CO<sub>2</sub> emissions (Fig. 2b–d) [42–44]. As shown in Fig. 2e, g-C<sub>3</sub>N<sub>4</sub> has the most suitable energy band position among many common photocatalysts and can meet the redox potential of most reactions. Therefore, it has broad prospects and research significance in the field of photocatalytic CO<sub>2</sub> reduction. The process of achieving carbon neutrality requires long-term effort, and technological innovation is the key to achieving carbon neutrality. In today’s rapid economic development, achieving carbon neutrality has become a development initiative, and the attainment of carbon neutrality has great and long-term value for human survival and development.

## BASIC PRINCIPLE OF g-C<sub>3</sub>N<sub>4</sub> PHOTOCATALYTIC REDUCTION OF CO<sub>2</sub>

### Basic principle and thermodynamic study of photocatalytic CO<sub>2</sub> reduction

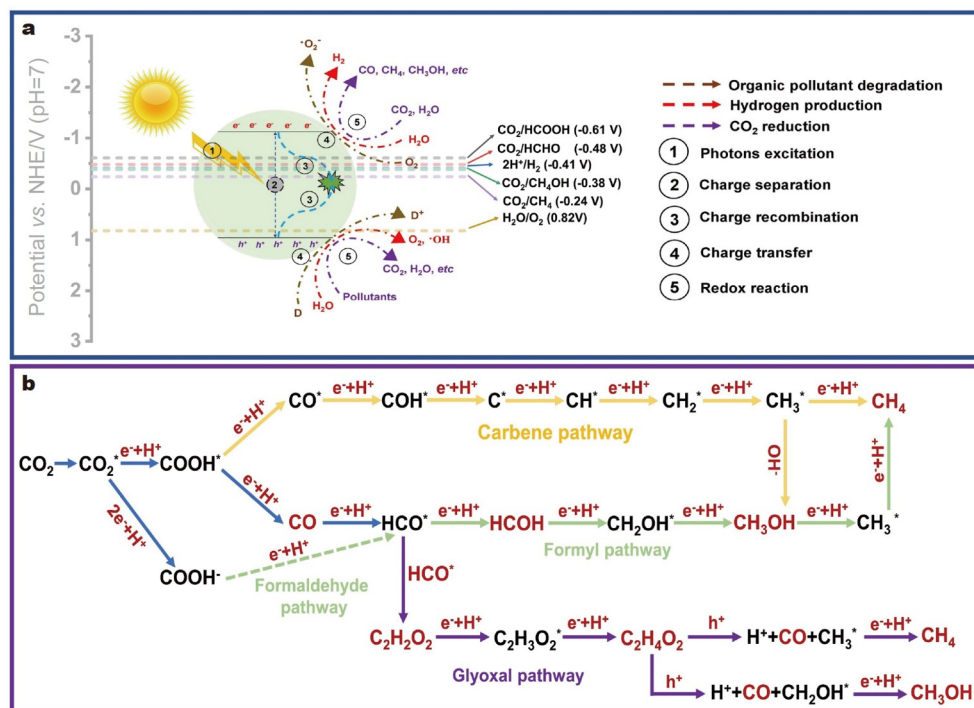

Photocatalytic technology uses renewable solar energy as the only energy source and semiconductors with suitable energy band locations as catalysts to transform light energy into chemical energy to cause the oxidation and reduction reactions of various substances; thus, environmental remediation and material circulation can be attained with the characteristics of high efficiency, environmental friendliness and economy [45]. In early 1979, Inoue and colleagues [46] first reported the photocatalytic reduction of CO<sub>2</sub> to form organic compounds such as HCHO, HCOOH, CH<sub>3</sub>OH, and CH<sub>4</sub> in the presence of a

(e) Comparison of band positions of common photocatalysts with redox potentials of different products generated by photocatalytic CO<sub>2</sub> reduction.

semiconductor powder suspended in water as a catalyst. Since then, researchers have been interested in the photocatalytic CO<sub>2</sub> reduction in semiconductors. The photocatalytic activity of semiconductor catalysts is produced by their special energy band structure. Semiconductor catalysts are usually composed of the following: a low-energy VB, which is occupied by electrons; a high-energy CB, which is not occupied by electrons; and a band gap. When the sun shines on the surface of the semiconductor, the semiconductor absorbs the energy of the photon, and when the energy of the photon is greater than or equal to the bandgap energy (bandgap width) of the semiconductor, the electrons in the VB will be excited to transition to the CB, leaving relatively

stable holes in the VB, thus forming an electron-hole pair. Subsequently, the electron-hole migration to the surface of the catalyst and the substances adsorbed on the surface of the catalyst cause reduction and oxidation reactions, thus achieving environmental remediation or material cycling (Fig. 3a) [47]. In a typical photocatalytic reaction, there are four key steps: (1) adsorption of reactants on the catalyst surface; (2) light excitation production of e-h<sup>+</sup> pairs; (3) separation and migration of e-h<sup>+</sup> pairs; and (4) oxidation and reduction reactions on the catalyst surface. Therefore, the number of adsorption sites (reaction sites) on the catalyst surface, the absorption efficiency of sunlight, the separation efficiency of e-h<sup>+</sup> pairs and the

appropriate energy band structure are crucial to the efficiency of the photocatalytic reaction [48,49].

Driven by sunlight, the use of photocatalytic materials to catalyse the conversion of CO<sub>2</sub> into renewable hydrocarbon fuel at room temperature and pressure to achieve CO<sub>2</sub> reduction and carbon recycling is considered to be the most environmentally friendly and effective way to mitigate the greenhouse effect and alleviate the energy crisis. CO<sub>2</sub>, the most common greenhouse gas, is linearly connected between carbon and oxygen atoms by two C=O bonds with a C=O bond energy of up to 750 kJ mol<sup>-1</sup> [27]; this energy is much greater than the energy required to split C–C, C–O, and C–H bonds, and the C=O bond is one of the most thermodynamically stable carbon compounds ( $\Delta G_f^\circ = -394.39 \text{ kJ mol}^{-1}$ ) [50]. If CO<sub>2</sub> reduction is achieved, sufficient energy is needed to break the C=O bond; thus, its conversion into valuable chemicals without a catalyst and sufficient energy is almost impossible to achieve. In addition, CO<sub>2</sub> has a high band gap of approximately 13.7 eV between its highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) with a large electron affinity ( $-0.6 \pm 0.2 \text{ eV}$ ); thus, it is considered to be an inactive molecule [51]. Due to its inactivity, the one-electron reaction produces a negative redox potential (Equation (1) vs. NHE at pH 7), which is thermodynamically unfavourable for the reaction [52]. In contrast, for the CO<sub>2</sub> reduction reaction to be carried out more easily, bypassing the formation of  $\cdot\text{CO}_2^-$  by using a proton-assisted multielectron reduction step with a lower redox potential might be more thermodynamically advantageous, and this depends on the number of protons involved and the number of electrons transferred. CO<sub>2</sub> can be reduced to different fuels and chemicals, such as HCOOH, CO, HCHO, CH<sub>3</sub>OH, and CH<sub>4</sub> (Equations (2)–(6) vs. NHE at pH 7) [43,52].

The formation path of photocatalytic CO<sub>2</sub> reduction products is shown in Fig. 3b, and its reaction pathways mainly include the carbene pathway, formyl pathway, and glyoxal pathway [53–56]. The smooth progress of the photocatalytic CO<sub>2</sub> reduction reaction must meet the basic thermodynamic requirements. In simple terms, the position at the bottom of the CB must be more negative than the redox potential of CO<sub>2</sub> to ensure that the CO<sub>2</sub> reduction reaction has sufficient driving force. The position of the top of the VB should be more corrected than the redox potential of H<sub>2</sub>O to produce protons and consume holes. Otherwise, the accumulated holes may be annihilated by the photogenerated electrons, or they can react with the reduction products of carbon dioxide [57]. The adsorption of CO<sub>2</sub> molecules on the surface of a photocatalyst changes its molecular structure from a linear structure to a curved structure. When the O–C–O bond angle of CO<sub>2</sub> molecules decreases from 180°, the LUMO energy of CO<sub>2</sub> decreases, thereby reducing its reaction barrier and promoting the CO<sub>2</sub> reduction reaction [58,59].

#### Principle of g-C<sub>3</sub>N<sub>4</sub> photocatalytic reduction of CO<sub>2</sub>

Among various photocatalysts, g-C<sub>3</sub>N<sub>4</sub> is a promising photocatalyst for CO<sub>2</sub> reduction. As early as 1922, Franklin [60] introduced the concept of “carbonic nitride” (C<sub>3</sub>N<sub>4</sub>) and suggested that C<sub>3</sub>N<sub>4</sub> might be obtained as the final deamination product of a series of ammono-carbonic acids by heating melon [61]. Later, Pauling and Sturdivant [62] clarified that the basic structural unit of carbon nitride and its derivatives was the coplanar tri-s-triazine ring. After years of research, C<sub>3</sub>N<sub>4</sub> was

found to mainly include five different structures:  $\alpha$ - $C_3N_4$ ,  $\beta$ - $C_3N_4$ , cubic  $C_3N_4$ , pseudo- $C_3N_4$  and graphitic  $C_3N_4$  (g- $C_3N_4$ ) [63]. Among them, g- $C_3N_4$  is a metal-free mid-bandgap P-type semiconductor with reliable chemical and thermal stability; thus, it is very popular in photocatalyst research. g- $C_3N_4$  can be synthesized by the thermal condensation of various nitrogen-rich precursors, such as melamine [64–66], dicyandiamide [67,68], cyanamide [69], urea [70,71], and thiourea [72]. The  $sp^2$  hybridization of carbon and nitrogen atoms in g- $C_3N_4$  results in the formation of a highly delocalized  $\pi$ -conjugated system, producing a suitable band gap for visible light photocatalytic reactions of approximately 2.7 eV [73]. Notably, the CB position of g- $C_3N_4$  at approximately  $-1.1$  eV and the VB position at approximately 1.6 eV (relative to NHE) are ideal band positions for most photocatalytic reactions, including  $CO_2$  reduction [50]. The basic structure, physical and chemical properties of g- $C_3N_4$  and the basic principle of photocatalysis have been reviewed by many scholars [74–82]; thus, here, we focus on the basic principle and application of g- $C_3N_4$  in the field of photocatalytic  $CO_2$  reduction.

The outstanding performance of g- $C_3N_4$  in the field of photocatalytic  $CO_2$  reduction has prompted researchers to explore and uncover its reduction mechanism. Furthermore, the photocatalytic reduction process of  $CO_2$  on g- $C_3N_4$  is a typical semiconductor catalyst-led photocatalytic  $CO_2$  reduction process, and its basic reaction process is consistent with the reaction mechanism mentioned above. The adsorption and activation of  $CO_2$  on a catalyst surface is a critical and challenging step in the  $CO_2$  photoreduction process and is used to determine the photocatalytic  $CO_2$  reduction rate and product selectivity [83]. Compared with normal  $CO_2$  molecules,  $CO_2$  in the chemisorbed state (mainly carbonate and/or  $CO_2^-$  anion) has a bent O–C–O bond angle, and its LUMO is reduced; this facilitates charge transfer from the photoexcited semiconductor to the surface-adsorbed  $CO_2$  molecules [43]. Generally, the adsorption of  $CO_2$  molecules by atoms on the surface of semiconductor catalysts

mainly includes three situations [84]: O of  $CO_2$  is separately adsorbed on the acidic surface atom of the catalyst (Fig. 4a), C of  $CO_2$  is separately adsorbed on the basic surface atom of the catalyst (Fig. 4b), and the C and O atoms of  $CO_2$  are mixed adsorbed on the surface of the catalyst (Fig. 4c). g- $C_3N_4$  is prone to interactions with the C atom of the acid  $CO_2$  gas (a Lewis acid) due to the presence of lone electron pairs on the Lewis base at the N atomic site on its surface [85]. There are two main adsorption modes of  $CO_2$  on the surface of g- $C_3N_4$  molecules: vertical adsorption and parallel adsorption. According to the density functional theory (DFT) calculations by Zhu *et al.* [86], the adsorption of  $CO_2$  on the surface of g- $C_3N_4$  was more prone to parallel adsorption, and the doubly coordinated N atom was the main adsorption site, with a maximum adsorption energy of  $-0.42$  eV. In addition, their study also showed that g- $C_3N_4$  showed a strong adsorption capacity for  $CO_2$  and  $H_2O$  ( $E_{Ads}$  greater than  $-0.30$  eV), while the adsorption strength for CO and  $CH_4$  was weak ( $E_{Ads}$  less than  $-0.163$  eV). Fortunately,  $CO_2$  and  $H_2O$  were the reactants of the  $CO_2$  photocatalytic reduction. In contrast, CO and  $CH_4$  were products of  $CO_2$  photocatalytic reduction. Therefore, the adsorption behaviour of g- $C_3N_4$  was characterized by high adsorption of reactants and weak adsorption of products; this behaviour is very favourable for the photocatalytic reaction process [86]. However, most studies believe that the adsorption of  $CO_2$  on the surface of g- $C_3N_4$  is mainly physical adsorption process [86–88]. To further improve the efficiency and application prospects of photocatalytic  $CO_2$  reduction, g- $C_3N_4$  needs to be modified to improve its ability to adsorb and activate  $CO_2$  molecules, and the specific surface area, surface basic groups, increased adsorption sites and edge defects should be considered. Fu *et al.* [66] used continuous thermal oxidation spalling and rolling methods to prepare layered porous g- $C_3N_4$  nanotubes doped with O. Their results showed that O doping enhanced the adsorption capacity of the catalyst for  $CO_2$ , resulting in excellent photocatalytic  $CO_2$  reduction performance under visible light, and the methanol precipitation rate

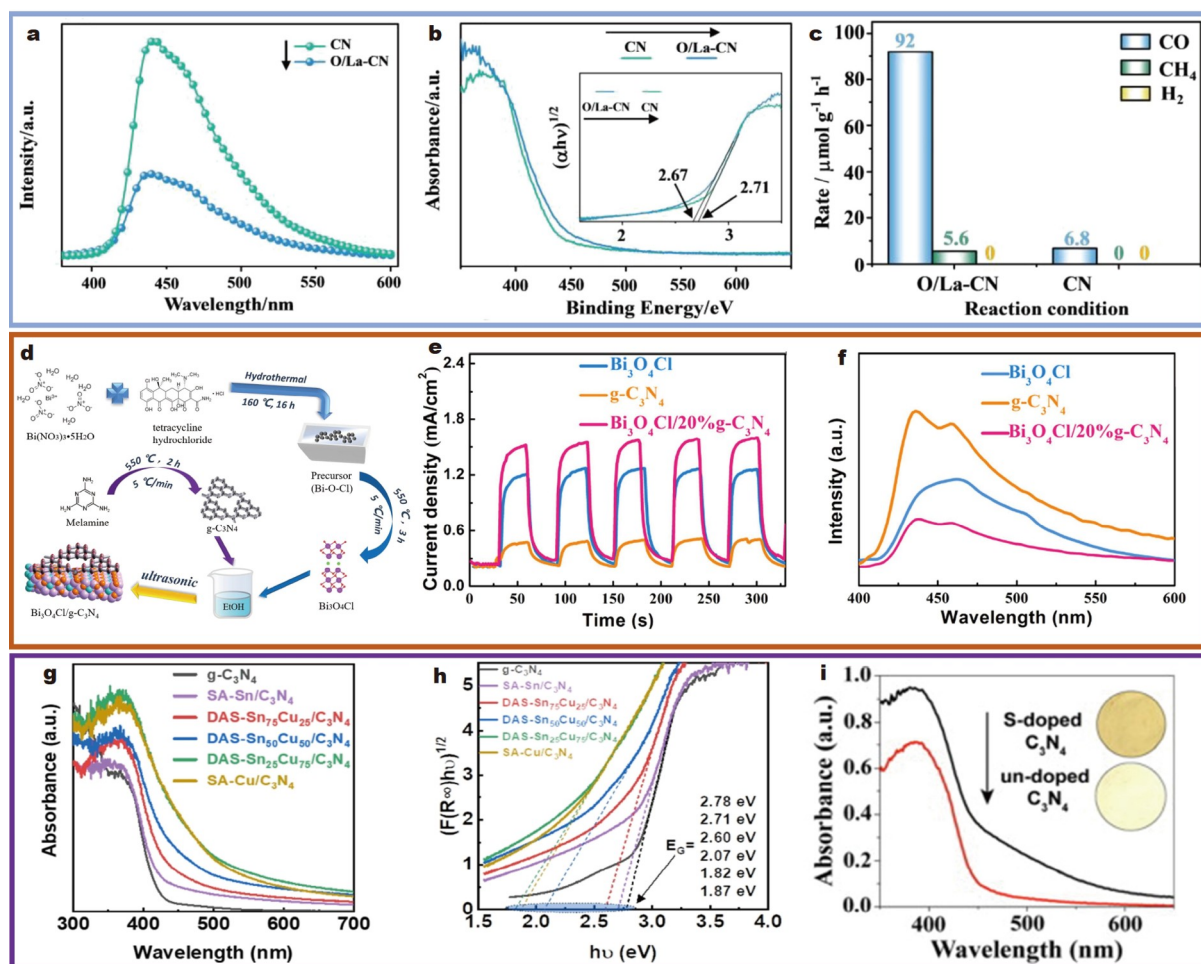

**Figure 4** Several configurations of surface atoms adsorbing  $CO_2$  molecules on semiconductor catalysts. Reprinted with permission from Ref. [84]. Copyright 2016, Royal Society of Chemistry.

was  $0.88 \mu\text{mol g}^{-1} \text{h}^{-1}$ . This value was five times greater than that of bulk  $\text{g-C}_3\text{N}_4$  ( $0.17 \mu\text{mol g}^{-1} \text{h}^{-1}$ ).

The photocatalytic activation of  $\text{CO}_2$  by  $\text{g-C}_3\text{N}_4$  depends on its optical and photoelectrochemical properties. Ultraviolet-visible diffuse reflection spectroscopy (UV-vis DRS) can be used to study the light absorption performance of a catalyst. Photoluminescence (PL) spectroscopy can show the separation and migration efficiency of photogenerated carriers after photo-excitation, and the photocurrent response can be used to explain the migration efficiency of photogenerated carriers to the catalyst surface [89]. Chen *et al.* [90] loaded a single La atom on  $\text{g-C}_3\text{N}_4$  to obtain O/La-CN, and the introduction of La-N bonds promoted the efficiency of the  $\text{CO}_2$  reduction reaction. After the single-atom loading of La, the PL intensity of O/La-CN significantly decreased (Fig. 5a), and its light absorption edge redshifted (Fig. 5b), resulting in a significant improvement in its photocatalytic  $\text{CO}_2$  reduction efficiency (Fig. 5c). Xu *et al.* [91] successfully constructed a van Der Waals (vdW) heterostructure between the layered  $\text{Bi}_3\text{O}_4\text{Cl}$  and two-dimensional (2D)  $\text{g-C}_3\text{N}_4$  for photocatalytic  $\text{CO}_2$  reduction (Fig. 5d). Compared with  $\text{Bi}_3\text{O}_4\text{Cl}$  and  $\text{g-C}_3\text{N}_4$ , the photocurrent response intensity of  $\text{Bi}_3\text{O}_4\text{Cl}/20\% \text{g-C}_3\text{N}_4$  was also greatly improved, which indicated

that the photoelectron-hole pair separation efficiency was greater after the construction of the vdW heterojunction (Fig. 5e). The PL test showed that  $\text{Bi}_3\text{O}_4\text{Cl}/20\% \text{g-C}_3\text{N}_4$  had the lowest electron and hole recombination efficiency (Fig. 5f). Owing to the good photoelectric performance of the catalyst, the photocatalytic reduction efficiency of  $\text{CO}_2$  was significantly improved.  $\text{g-C}_3\text{N}_4$  is a direct semiconductor with a band gap of 2.7 eV and a corresponding absorption edge of 460 nm. Appropriately reducing the band gap of  $\text{g-C}_3\text{N}_4$  through heteroatom doping can cause the redshift of the optical absorption edge of the catalyst, effectively improving the optical absorption efficiency and thus improving the efficiency of the  $\text{g-C}_3\text{N}_4$  photocatalytic reduction of  $\text{CO}_2$  [92]. Kim *et al.* [93] introduced Sn and Cu atoms into  $\text{g-C}_3\text{N}_4$ , which reduced the band gap and promoted light absorption (Fig. 5g, h), greatly improving the  $\text{CO}_2$  reduction efficiency. Similarly, the absorption edge of sulfur-doped  $\text{g-C}_3\text{N}_4$  (TCN) showed a redshift of 20 nm compared with that of undoped  $\text{g-C}_3\text{N}_4$ , reaching 475 nm (Fig. 5i). After doping, the band gap decreased from 2.70 to 2.63 eV, indicating that the TCN samples could absorb more solar energy and generate more photogenerated electrons and hole pairs. The yields of  $\text{CH}_3\text{OH}$  from TCN and undoped  $\text{g-C}_3\text{N}_4$  were 1.12 and

0.81  $\mu\text{mol g}^{-1}$ , respectively [94].

### Preliminary studies on photocatalytic CO<sub>2</sub> reduction by g-C<sub>3</sub>N<sub>4</sub>

g-C<sub>3</sub>N<sub>4</sub> is a promising photocatalyst for CO<sub>2</sub> reduction due to its abundant surface functions, highly specific electronic properties and suitable band structure. Goettmann *et al.* [69] showed that using mesoporous graphite carbon nitride (mpg-C<sub>3</sub>N<sub>4</sub>) as a heterogeneous metal-free catalyst could directly activate carbon dioxide to produce carbamate, which further oxidized benzene to phenol, and the formed CO could be used for subsequent *in situ* reactions (Fig. 6a). They also proposed that the activation of CO<sub>2</sub> adsorbed on the catalyst to form carbamate was considered to be the first step in artificial photosynthesis. Their study was the first attempt to apply g-C<sub>3</sub>N<sub>4</sub> in the field of photocatalytic CO<sub>2</sub> reduction, indicating its considerable research potential. Dong and Zhang [95] found that g-C<sub>3</sub>N<sub>4</sub> prepared with melamine hydrochloride as the precursor system could effectively photocatalyze the reduction of CO<sub>2</sub> to CO under visible light irradiation in the presence of water vapour and without other assistance. Xia *et al.* [96] showed that crystalline carbon nitride with a surface defect design could efficiently reduce gas-phase CO<sub>2</sub> to hydrocarbon fuel at a rate of 12.07  $\mu\text{mol h}^{-1} \text{g}^{-1}$  with a selectivity of 91.5% (Fig. 6b). Studies have shown that in the presence of water vapour, the band structure of the g-C<sub>3</sub>N<sub>4</sub>

photocatalyst can regulate the selectivity of the CO<sub>2</sub> photo-reduction reaction [97]. The main products of CO<sub>2</sub> photo-reduction of bulk g-C<sub>3</sub>N<sub>4</sub> with a 2.77 eV band gap and g-C<sub>3</sub>N<sub>4</sub> nanosheets with a 2.97 eV band gap are CH<sub>3</sub>CHO and CH<sub>4</sub>, respectively (Fig. 6c). The above study provides a reference for the design of efficient and highly selective photocatalysts for CO<sub>2</sub> reduction from the perspective of the energy band. These early studies demonstrate the potential of g-C<sub>3</sub>N<sub>4</sub> in the field of photocatalytic CO<sub>2</sub> reduction and provide theoretical support for further research.

Due to the following advantages, g-C<sub>3</sub>N<sub>4</sub> has potential for use in CO<sub>2</sub> reduction reactions. First, its band structure effectively aligns with the oxidation-reduction potentials of CO<sub>2</sub> reduction products. Second, the 2D or multidimensional layered or wrinkled structure of g-C<sub>3</sub>N<sub>4</sub> provides more adsorption sites for CO<sub>2</sub> and facilitates the rapid migration of photogenerated electrons to catalytic surface adsorption sites. Third, the band structure of g-C<sub>3</sub>N<sub>4</sub> is highly tuneable, enabling the synthesis of g-C<sub>3</sub>N<sub>4</sub> with different band structures by using different precursors and synthesis methods. Furthermore, its band structure and optoelectronic properties can be easily modified through elemental doping. However, pristine g-C<sub>3</sub>N<sub>4</sub> has several drawbacks that limit its photocatalytic CO<sub>2</sub> reduction efficiency and practical applications. These include a low specific surface area,

**Figure 6** (a) Possible mechanism for the formation of phenol from benzene and CO<sub>2</sub> catalyzed by mpg-C<sub>3</sub>N<sub>4</sub>. Reprinted with permission from Ref. [69]. which hinders CO<sub>2</sub> adsorption, and poor separation of the photogenerated electrons and holes, leading to low photocarrier separation efficiency. Moreover, it exhibits low utilization efficiency for visible light. To overcome these issues and improve photocatalytic efficiency, several strategies have been developed. These strategies aim to enhance CO<sub>2</sub> adsorption, improve the separation and transfer of photogenerated carriers, and extend the light absorption range. These methods include heterojunction construction, elemental doping, and deposition of noble metals, among other modification techniques. These modification strategies provide more possibilities for the practical application of g-C<sub>3</sub>N<sub>4</sub> in photocatalytic CO<sub>2</sub> reduction.

## SURFACE MODIFICATION IMPROVEMENT IN THE EFFICIENCY OF g-C<sub>3</sub>N<sub>4</sub> PHOTOCATALYTIC CO<sub>2</sub>

### Doping engineering

g-C<sub>3</sub>N<sub>4</sub> is a visible light-responsive photocatalyst, with its CB mainly composed of C 2p<sub>z</sub> orbitals and the N (2p<sub>x</sub>, 2p<sub>y</sub>) orbitals contributing to its VB. However, the 2.7 eV band gap of g-C<sub>3</sub>N<sub>4</sub> restricts its utilization of solar radiation at wavelengths below 460 nm. Generally, the ideal band gap for a semiconductor is approximately 2.0 eV. Therefore, reducing the band gap of g-C<sub>3</sub>N<sub>4</sub> can enhance its light absorption properties and provide more photogenerated electrons. Element doping is one of the most commonly used methods to modulate the optical properties and electronic structure of semiconductor photocatalytic materials, providing advantages such as simplicity and high efficiency. By introducing foreign elements into the semiconductor, the charge carrier separation and transfer in the photocatalyst can be facilitated, or the band structure of the semiconductor can be adjusted to improve the light absorption range or match the redox potential of the target reaction. Incorporating suitable elements into g-C<sub>3</sub>N<sub>4</sub> can effectively enhance its photocatalytic activity and improve the efficiency of photocatalytic CO<sub>2</sub> reduction. Extensive research has been conducted on enhancing the photocatalytic activity of g-C<sub>3</sub>N<sub>4</sub> through metal doping or nonmetal doping.

### Metal doping

Metal elements affect the activity and kinetics of photocatalytic reactions mainly by influencing the behaviour of photogenerated carriers in semiconductor photocatalysts. From the point of view

of chemical structure, the entry of doped metal atoms into a semiconductor will affect its electronic structure, which will affect the recombination of the photogenerated electrons and holes. For example, when a doped atom becomes a potential well for electrons or holes, it can extend the lifetime of the carrier [98]. In addition to affecting the separation of photogenerated carriers, metal element doping can also expand the optical absorption range of semiconductors because the doped atoms will form new impurity levels in the bandgap of the semiconductor [99]. In general, metal ions (M<sup>n+</sup>), especially transition metal ions, are doped into large caverns (triangular pores) between connected trinitrogen structures on the g-C<sub>3</sub>N<sub>4</sub> plane through strong coordination interactions with negatively charged nitrogen atoms (Fig. 7a); however, alkali metals are more inclined to be doped in the interlayer structure of g-C<sub>3</sub>N<sub>4</sub> (Fig. 7b). Fe [100], Cu [101,102], Mo [103], Mg [104], Eu [105], alkali metals (K [68,106], Ca [107], Rb [108]) and other metallic elements have been used to enhance the activity of the g-C<sub>3</sub>N<sub>4</sub> photocatalytic reduction of CO<sub>2</sub>.

Duan *et al.* [109] doped Cu into g-C<sub>3</sub>N<sub>4</sub> to introduce Cu single-atom sites (Fig. 8a, b). The results showed that the Cu single-atom centre promoted the chemisorption and activation of CO<sub>2</sub> through the accumulation of photogenerated electrons, and the N<sub>2C</sub>V site promoted the dissociation of H<sub>2</sub>O, thus promoting the conversion of COO\* to COOH\*. Cu<sub>1</sub>/N<sub>2C</sub>V-CN has a high selectivity (98.50%) and a good CO yield (11.12 μmol g<sup>-1</sup> h<sup>-1</sup>) (Fig. 8c). Li *et al.* [110] used different transition metals to modify g-C<sub>3</sub>N<sub>4</sub> to obtain MeCN (Me = Cu, Co, Ti, or Fe). The CO evolution rate of the optimized MeCN was significantly greater than that of the undoped g-C<sub>3</sub>N<sub>4</sub>, in which the Fe-doped g-C<sub>3</sub>N<sub>4</sub> showed the highest photocatalytic activity (490 μmol g<sup>-1</sup> h<sup>-1</sup>) (Fig. 8d). The increase in the photocatalytic CO<sub>2</sub> reduction activity was attributed to the increase in the catalyst surface area, CO<sub>2</sub> adsorption capacity, visible light absorption, and charge separation and transfer efficiency. Wang *et al.* [106] reported a novel study on potassium-doped g-C<sub>3</sub>N<sub>4</sub> (K-CN) for visible light-driven CO<sub>2</sub> reduction. DFT calculations and X-ray photoelectron spectroscopy (XPS) tests indicated that potassium doping occurred between the layers, altering the electronic structure of g-C<sub>3</sub>N<sub>4</sub> (Fig. 8e). Under visible light irradiation, K-CN-7 achieved efficient CO<sub>2</sub> reduction without any noble metal cocatalyst, yielding a CO production rate of 8.7 μmol g<sup>-1</sup> h<sup>-1</sup>; this value was 25 times greater than that of

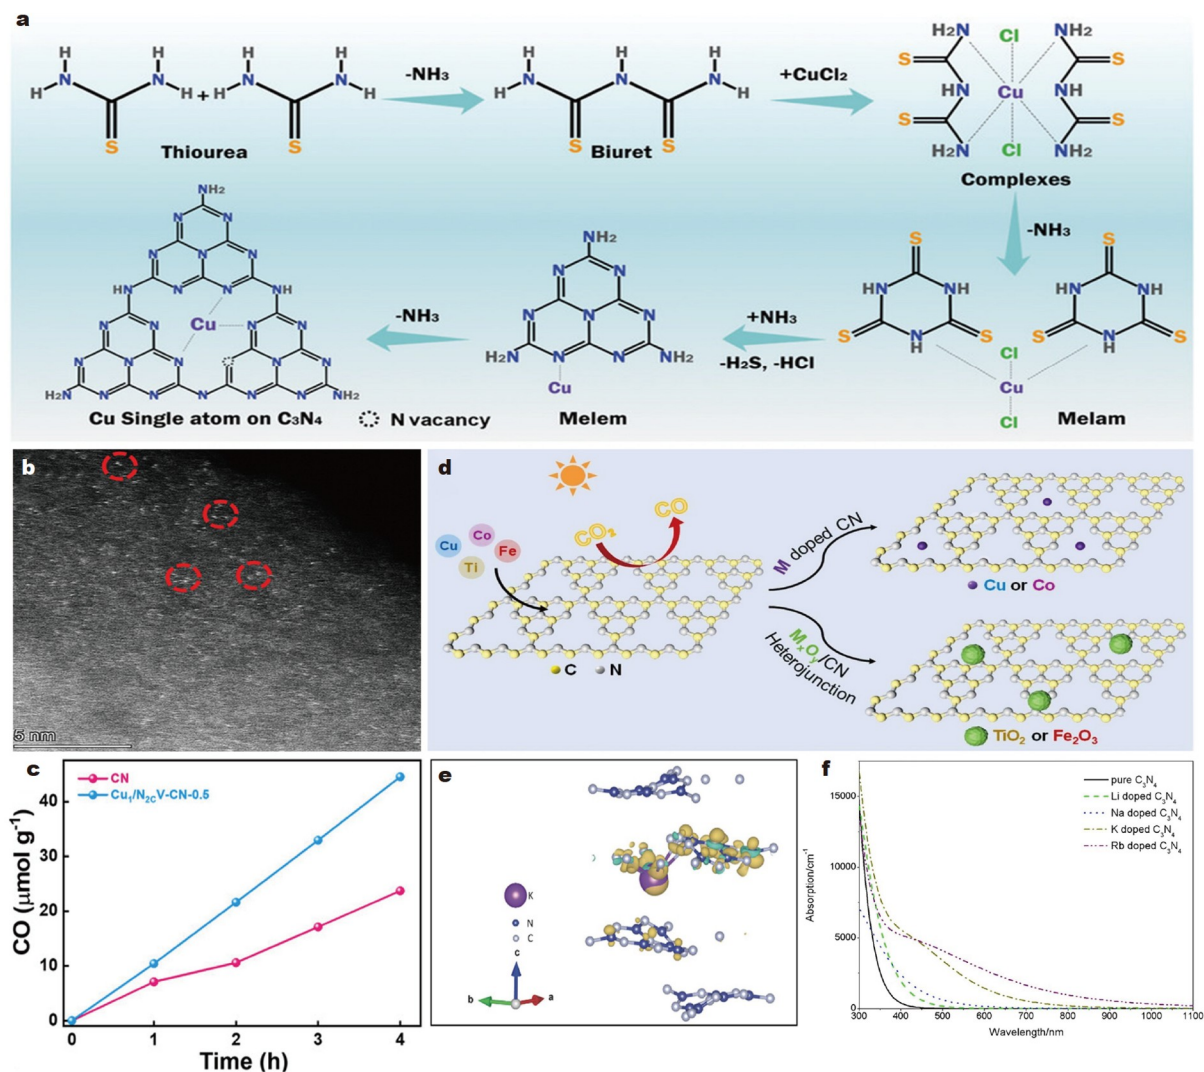

Figure 7 Common locations of metal doped g-C<sub>3</sub>N<sub>4</sub>.

pristine g- $\text{C}_3\text{N}_4$ . Zhang *et al.* [108] prepared alkali metal (Li, Na, K, Rb)-doped g- $\text{C}_3\text{N}_4$  using a hydrothermal and high-temperature calcination method. The calculated results showed a significant increase in the absorption spectrum of Rb-doped g- $\text{C}_3\text{N}_4$  within the range of 500 to 1100 nm, consistent with the UV-vis spectra (Fig. 8f). Compared with bulk g- $\text{C}_3\text{N}_4$ , Rb-doped g- $\text{C}_3\text{N}_4$  exhibited the best  $\text{CO}_2$  photoreduction performance, with a more than threefold increase in CO production. Experimental and theoretical evidence demonstrated that the enrichment of surface electrons and optimization of the electronic structure on the catalyst surface were crucial factors in enhancing the photocatalytic performance.

#### Nonmetallic doping

Nonmetal element doping can effectively reduce the bandgap of g- $\text{C}_3\text{N}_4$ , thereby enhancing its light harvesting capability. Unlike metal elements, nonmetal elements play a unique role in

enhancing light absorption and modulating the energy band positions for efficient redox reactions [111]. Furthermore, due to their high electronegativity and ionization potential, nonmetal elements can typically form covalent bonds by gaining electrons from other compounds. Several nonmetal elements have been studied for their ability to enhance the  $\text{CO}_2$  reduction efficiency in g- $\text{C}_3\text{N}_4$ , including B [68,112], P [113–115], O [66,116,117], S [18,118,119], Se [120], F [121,122], Cl [123], Br [124,125], I [126], and others.

Arumugam *et al.* [127] prepared nonmetal (B, O, P, and S)-doped g- $\text{C}_3\text{N}_4$  through solid-state condensation of urea. The highest  $\text{CH}_4$  yield of  $55.10 \text{ nmol (mL}_{\text{H}_2\text{O}} \text{ g}_{\text{cat}})^{-1}$  was achieved with S-doped g- $\text{C}_3\text{N}_4$  after 7 h of irradiation (UV) (Fig. 9a, b). The results demonstrated that nonmetal element doping improved the charge separation and served as an effective pathway to enhance photocatalyst performance. Yan *et al.* [124] prepared surface-brominated g- $\text{C}_3\text{N}_4$  (CNBr) for the stable and

(e) Photocatalytic H<sub>2</sub> evolution rates and (f) photocatalytic CH<sub>4</sub> evolution rates for (1) CN, (2) CN/CNI-20%, (3) CN/CNI-40%, (4) CN/CNI-40% (physical mixture), (5) CN/CNI-60%, (6) CNI, and (7) CNI-R catalysts under visible-light irradiation ( $\lambda > 420$  nm). Reprinted with permission from Ref. [126]. Copyright 2020, Elsevier.

efficient photocatalytic reduction of CO<sub>2</sub> to generate CH<sub>4</sub>, achieving a reaction rate of  $16.68 \mu\text{mol h}^{-1} \text{g}^{-1}$  (with a selectivity of 70.27%) (Fig. 9c, d). By utilizing Br as an active site, CO<sub>2</sub> could accumulate on the catalyst surface, and localized photo-excited electrons could activate the adsorbed CO<sub>2</sub>, leading to subsequent hydrogenation and the generation of CH<sub>4</sub>. Xia *et al.* [126] employed a combination of a water bath method and *in situ* sintering to prepare g-C<sub>3</sub>N<sub>4</sub>/iodine-doped g-C<sub>3</sub>N<sub>4</sub> (CN/CNI) homojunction powder catalysts. The CN/CNI-40% catalyst with a proper CN content had good visible light photocatalytic performance and stability. The rates of photocatalytic CH<sub>4</sub> generation were 4.9, 3.5, and 3.6 times greater than those of CN, CNI, and CNI-R, respectively (Fig. 9e, f). Generally, due to their smaller atomic radii, the F and Cl atoms are doped mainly by substituting C or N, while Br and I, with larger atomic radii, are difficult to substitute and are more likely to be doped into the

gaps between three tri-*s*-triazine units. Research has shown that the work function of g-C<sub>3</sub>N<sub>4</sub> decreases with increasing atomic number of halogen dopants. This occurs because the electro-negativity of halogen atoms gradually decreases with increasing atomic number, resulting in more electrons transferring from halogen atoms to g-C<sub>3</sub>N<sub>4</sub>; thus, the Fermi level of g-C<sub>3</sub>N<sub>4</sub> increases and the work function decreases, thereby enhancing its photocatalytic performance [79].

In summary, nonmetal doping adjusts the band structure of g-C<sub>3</sub>N<sub>4</sub>, resulting in a narrower band gap and an extended light absorption range to the visible region, thereby enhancing its photocatalytic performance in CO<sub>2</sub> reduction. Introducing impurity elements into g-C<sub>3</sub>N<sub>4</sub> also facilitates the alteration of the surface charge distribution, promoting the separation and transfer of photoinduced charge carriers. Additionally, the incorporation of nonmetal elements may favour CO<sub>2</sub> adsorption.

### Heterojunction engineering

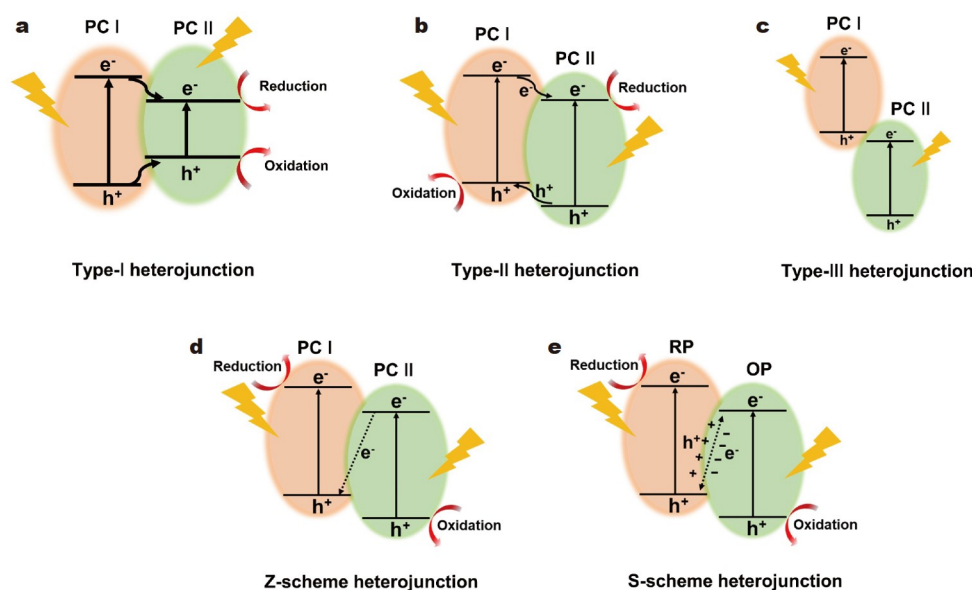

A heterojunction refers to the interface of two different semiconductor materials with different atomic and electronic band structures. Among the existing strategies for regulating g-C<sub>3</sub>N<sub>4</sub>, interface engineering to construct heterojunctions by coupling g-C<sub>3</sub>N<sub>4</sub> to different semiconductors has gained research interest. The construction of heterostructures can facilitate the photo-induced electron and hole separation. Under the action of a heterojunction electric field, electrons can migrate through the semiconductor, thereby improving the charge transfer efficiency and effectively inhibiting the recombination of photogenerated charges and holes. Traditional heterojunctions can be classified into three types based on the relationship between energy bands: straddling gaps (Type-I heterojunctions, Fig. 10a), staggered gaps (Type-II heterojunctions, Fig. 10b) and broken gaps (Type-III, heterojunctions, Fig. 10c). However, among the three heterojunctions, only Type-II heterojunctions can achieve effective interface transfer and spatial separation of the electron-holes under photoexcitation. This occurs because under light conditions, after the generation of electron-hole pairs, electrons can transfer from photonic crystal (PC) I to PC II, and the photo-generated holes move in the opposite direction to achieve the spatial separation of photogenerated electrons and holes. Type-I heterojunctions and type-III heterojunctions can only achieve effective interfacial transfer of electrons and holes under photoexcitation conditions but not spatial separation of electrons and holes. To further improve the catalytic effect of photocatalysts, in which the electrons accumulate at higher energy levels and the holes accumulate at lower energy levels, to enhance the redox ability of photocatalysts, researchers have developed heterojunctions such as Z-scheme heterojunctions and S-scheme heterojunctions. The construction of a suitable heterostructure based on g-C<sub>3</sub>N<sub>4</sub> not only solves the problem of low photogenerated carrier separation efficiency in the original g-C<sub>3</sub>N<sub>4</sub> but also improves the photocatalytic photoelectric performance in conjunction with other components of the heterostructure. Therefore, constructing heterostructures based on g-

C<sub>3</sub>N<sub>4</sub> has become a popular for improving the performance of photocatalytic CO<sub>2</sub> reduction. Currently, the main semiconductors consisting of heterostructures with g-C<sub>3</sub>N<sub>4</sub> include metal oxides (TiO<sub>2</sub>, ZnO, NiO, CeO<sub>2</sub>, etc.), metal sulfides (SnS<sub>2</sub>, CdIn<sub>2</sub>S<sub>4</sub>, Bi<sub>2</sub>S<sub>3</sub>, etc.), and other nonmetallic semiconductors [128]. According to the different mechanisms of the photo-induced carrier transfer between g-C<sub>3</sub>N<sub>4</sub> and the coupled component, the most studied g-C<sub>3</sub>N<sub>4</sub>-based heterostructure photocatalysts can be divided into the following types: g-C<sub>3</sub>N<sub>4</sub>-based type-II heterostructures, g-C<sub>3</sub>N<sub>4</sub>-based Z-scheme heterostructures, g-C<sub>3</sub>N<sub>4</sub>-based S-scheme heterostructures and other types of g-C<sub>3</sub>N<sub>4</sub>-based heterojunctions.

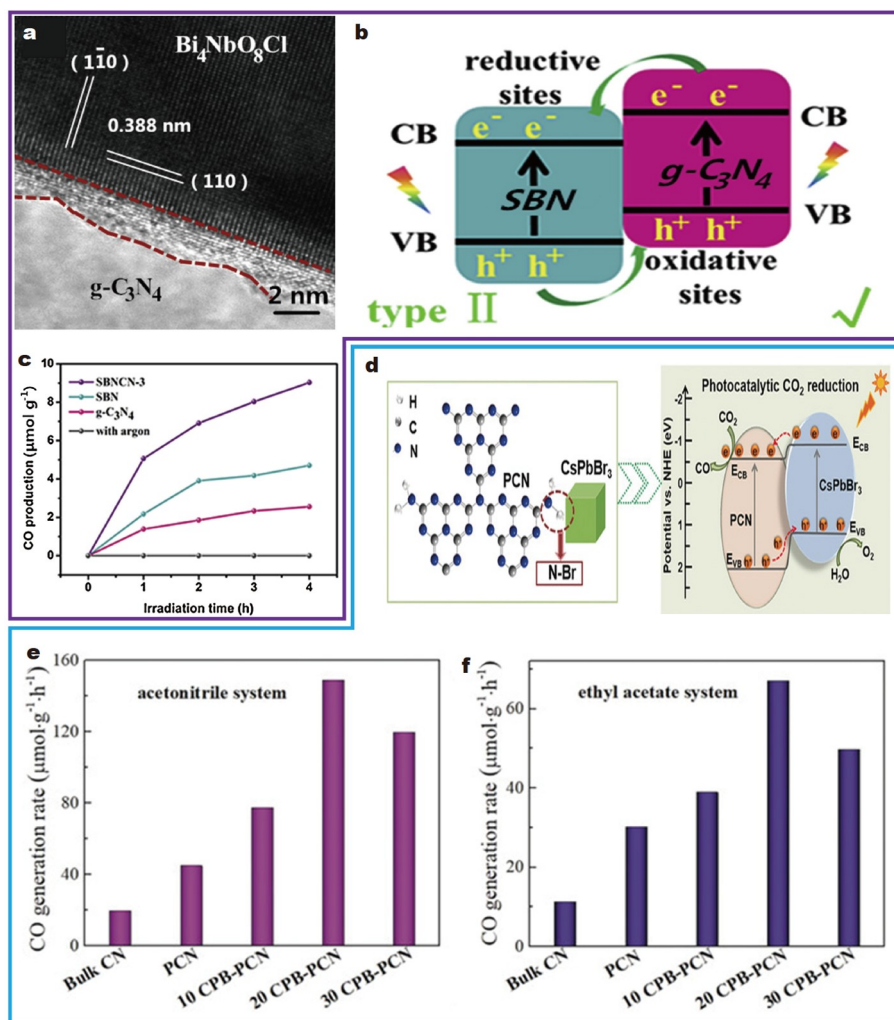

#### g-C<sub>3</sub>N<sub>4</sub>-based type-II heterostructures

Type II heterojunction nanocomposites possess staggered bandgaps and appropriate CB and VB. When the CB of PC I is more negative than that of PC II and the VB of PC II is more positive than that of PC I, under the driving force of the built-in electric field, the electrons in the CB of PC I transfer to the CB of PC II, and the holes in the VB of PC II transfer to the VB of PC I. CO<sub>2</sub> is reduced to hydrocarbon compounds on the CB of PC II. The effective charge transfer at the interface of the two semiconductors achieves efficient separation of photoinduced carriers, thereby preventing the recombination of photoinduced electrons and holes (Fig. 10b).

Xu *et al.* [129] first used a molten salt growth method to prepare exposed Bi<sub>4</sub>NbO<sub>8</sub>Cl nanosheets and then fabricated 2D/2D Bi<sub>4</sub>NbO<sub>8</sub>Cl/g-C<sub>3</sub>N<sub>4</sub> heterostructure photocatalysts through high-energy ball milling and subsequent sintering, achieving a closely interacting interface (Fig. 11a, b). All Bi<sub>4</sub>NbO<sub>8</sub>Cl/g-C<sub>3</sub>N<sub>4</sub> composite materials exhibited significantly improved photocatalytic activity compared with Bi<sub>4</sub>NbO<sub>8</sub>Cl nanosheets and g-C<sub>3</sub>N<sub>4</sub>, showing enhanced CO production activity for photocatalytic CO<sub>2</sub> reduction, with a yield of 2.26 μmol g<sup>-1</sup> h<sup>-1</sup>. The remarkable increase in the photocatalytic activity of the Bi<sub>4</sub>NbO<sub>8</sub>Cl/g-C<sub>3</sub>N<sub>4</sub> composite materials was attributed to the synergistic effect of the well-defined 2D/2D structure, the con-

**Figure 10** Schematic diagram of three common g-C<sub>3</sub>N<sub>4</sub> base heterojunctions. (a) g-C<sub>3</sub>N<sub>4</sub>-based Type-I heterostructure. (c) CO production curves of SBNCN-3, SBN and  $\text{g-C}_3\text{N}_4$ . Reprinted with permission from Ref. [129]. Copyright 2020, Elsevier. (d)  $\text{CsPbBr}_3$  quantum dots are fixed on polymer semiconductor  $\text{g-C}_3\text{N}_4$  porous nanosheets by strong N-Br bond to form type-II heterojunction. Generation of CO in (e) acetonitrile/water and (f) ethyl acetate/water systems over various photocatalysts. Reprinted with permission from Ref. [130]. Copyright 2018, Wiely.

struction of type II heterojunctions, and the close interaction interface, which promoted the charge separation (Fig. 11c). Ou *et al.* [130] anchored  $\text{CsPbBr}_3$  quantum dots (CPBs) onto porous  $\text{g-C}_3\text{N}_4$  nanosheets (PCNs) rich in  $-\text{NH}_x$  to construct a type-II heterojunction through N-Br chemical bonding (Fig. 11d). The unique N-Br bonding enhanced the charge separation between the two materials and prolonged the lifetime of the carriers. The CPB-PCN photocatalyst with 20 wt% quantum dots exhibited excellent stability and achieved a CO production rate of  $149 \mu\text{mol h}^{-1} \text{g}^{-1}$  for photocatalytic  $\text{CO}_2$  reduction in acetonitrile/water under visible light irradiation, which was approximately 15 times greater than that of  $\text{CsPbBr}_3$  quantum dots (Fig. 11e, f).

Wang *et al.* [131] prepared titanium dioxide ( $\text{TiO}_2$ )-modified  $\text{g-C}_3\text{N}_4$  composite photocatalysts through ball milling and calcination. The study showed that  $\text{TiO}_2$  successfully formed a type-II heterojunction with  $\text{g-C}_3\text{N}_4$ , effectively improving the separation of photoinduced electrons and holes. Compared with the pure  $\text{g-C}_3\text{N}_4$  photocatalysts, the heterojunction photocatalysts exhibited significantly enhanced photocatalytic  $\text{CO}_2$

reduction. Under 8 W UV light irradiation for 4 h, the production rates of  $\text{CH}_4$  and CO were  $72.2$  and  $56.2 \mu\text{mol g}^{-1}$ , respectively. Li *et al.* [132] designed and synthesized mesoporous  $\text{CeO}_2/\text{graphitic carbon}$  ( $\text{m-CeO}_2/\text{g-C}_3\text{N}_4$ ) type-II heterostructures using a hard template method. Their study demonstrated that the photocatalytic response of  $\text{m-CeO}_2/\text{g-C}_3\text{N}_4$  was significantly enhanced, enabling the efficient separation and transfer of photoinduced carriers at the interface of mesoporous  $\text{CeO}_2$  and  $\text{g-C}_3\text{N}_4$ . Therefore,  $\text{m-CeO}_2/\text{g-C}_3\text{N}_4$  markedly enhanced the photocatalytic reduction of  $\text{CO}_2$ . After 1 h of  $\text{CO}_2$  reduction using a 50 mg nanocomposite photocatalyst, the production rates of CO and  $\text{CH}_4$  were  $0.590$  and  $0.694 \mu\text{mol}$ , respectively.

Based on these studies, the formation of type-II heterostructures between semiconductors with suitable band structures and  $\text{g-C}_3\text{N}_4$  can effectively suppress the rapid recombination of photoinduced electron-hole pairs and promote the separation and transfer of photoinduced carriers to the catalyst surface for  $\text{CO}_2$  reduction. However, efficient charge separation in type-II heterostructures is achieved at the expense of sacrificing pho-

photoinduced carriers with strong redox capability, which limits the thermodynamic requirements of photocatalytic CO<sub>2</sub> reduction [133].

#### *g-C<sub>3</sub>N<sub>4</sub>-based Z-scheme heterojunctions*

Due to the increased coulombic repulsion between the electrons during the process of electron transfer from the CB of one semiconductor to the VB of another semiconductor, the application of type II photocatalysts is limited. Additionally, after electrons are transferred to a semiconductor with a lower potential, the photocatalytic reduction capability is relatively low, providing an opportunity for the research and development of Z-scheme heterostructures. In Z-scheme heterostructures, electrons in the CB of PC II can undergo interface transfer and recombine with the VB of PC I, and this process enables the participation of carriers from both CB of PC I and VB of PC II in the redox process and is unaffected by electron-hole recombination (Fig. 10d). Z-scheme heterostructures involve the close alignment of the Fermi energy levels of two semiconductors, resulting in inwards band bending at their band edges. This facilitates the movement of electrons from the CB of the oxidizing semiconductor to the VB of the reducing semiconductor, contributing to improved redox potentials and enhanced photocatalytic activity. Furthermore, due to the sufficiently negative CB position of g-C<sub>3</sub>N<sub>4</sub>, which exhibits strong reduction ability, g-C<sub>3</sub>N<sub>4</sub> tends to form Z-scheme heterostructures with photocatalysts possessing a sufficiently positive VB potential, thereby attaining enhanced oxidation capability [134].

Jiang *et al.* [134] employed a hierarchical direct Z-scheme system composed of sea urchin-like haematite and g-C<sub>3</sub>N<sub>4</sub> to enhance the photocatalytic activity for CO<sub>2</sub> reduction. They achieved a CO production rate of 27.2 μmol g<sup>-1</sup> h<sup>-1</sup> without the need for auxiliary catalysts or sacrificial agents; additionally, this rate was 2.2 times higher than that using g-C<sub>3</sub>N<sub>4</sub> alone (10.3 μmol g<sup>-1</sup> h<sup>-1</sup>). The introduction of 3D α-Fe<sub>2</sub>O<sub>3</sub> increased light absorption capacity (due to its narrow bandgap), enabling more light energy to participate in CO<sub>2</sub> reduction. Wang *et al.* [135] synthesized a novel MnO<sub>2</sub>/g-C<sub>3</sub>N<sub>4</sub> Z-scheme heterostructure composite material for the first time by *in situ* redox reaction of KMnO<sub>4</sub> with adsorbed MnSO<sub>4</sub>·H<sub>2</sub>O on the surface of g-C<sub>3</sub>N<sub>4</sub>. The formation of the Z-scheme heterostructure enhanced the photocatalyst's light absorption capacity, and the well-matched band structures facilitated effective separation of photoinduced electrons and holes, thereby enhancing the photocatalytic activity for CO<sub>2</sub> reduction. Bhosale *et al.* [136] prepared a g-C<sub>3</sub>N<sub>4</sub>/FeWO<sub>4</sub> Z-scheme heterostructure composite material capable of selectively reducing CO<sub>2</sub> to CO as a solar fuel under sunlight. The Z-scheme coupling of visible light-active FeWO<sub>4</sub> nanoparticles and g-C<sub>3</sub>N<sub>4</sub> nanosheets demonstrated excellent CO production rates, reaching 6 μmol g<sup>-1</sup> h<sup>-1</sup> at room temperature; this value was nearly six times higher than that of pristine g-C<sub>3</sub>N<sub>4</sub> and fifteen times higher than that of pristine FeWO<sub>4</sub>. Furthermore, the selectivity for CO was 100% higher than other carbon products from CO<sub>2</sub> reduction and more than 90% higher than hydrogen products from water splitting.

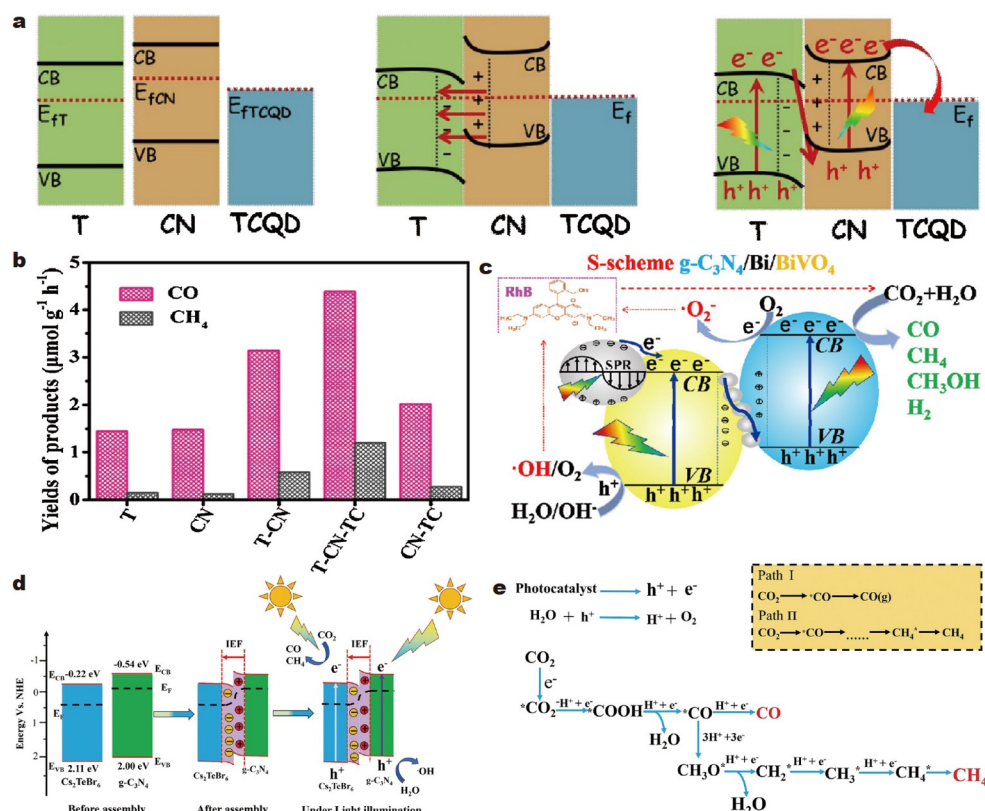

In summary, Z-scheme heterostructures composed of two different semiconductor materials can optimize the band structure by adjusting the bandgap sizes and energy level structures of different materials. This enables high efficiency in the separation of electrons and holes, effectively converting light energy into chemical energy for CO<sub>2</sub> reduction and enhancing photo-

catalytic activity. Z-scheme heterostructures achieve selective control over different reaction products by matching and adjusting the band positions, leading to highly selective CO<sub>2</sub> reduction. Moreover, the fabrication process of Z-scheme heterostructures is relatively simple, enabling the synthesis of different forms and structures through various methods; thus, superior photocatalytic performance and reaction outcomes with good scalability are attained.

#### *g-C<sub>3</sub>N<sub>4</sub>-based S-scheme heterojunctions*

The charge transfer process in S-scheme heterojunctions is illustrated in Fig. 10e. This type of heterojunction is primarily composed of a reducing semiconductor photocatalyst (RP) with a smaller work function and higher Fermi level and an oxidizing semiconductor photocatalyst (OP) with a larger work function and lower Fermi level. The S-scheme heterojunction facilitates the efficient spatial separation of the electron-hole pairs with strong redox capabilities. In the S-scheme heterojunction, the combination of the built-in electric field, band bending, and electrostatic interaction enables the spatial separation of photo-generated electrons and holes in a strong redox environment [137]. Under the driving force of the built-in electric field and band bending, the accumulated holes on the VB of OP are consumed by sacrificial agents, and the accumulated electrons on the CB of RP react with CO<sub>2</sub> to produce other products. Therefore, constructing S-scheme heterojunctions based on g-C<sub>3</sub>N<sub>4</sub> significantly enhances the photocatalytic performance of CO<sub>2</sub> reduction. Generally, g-C<sub>3</sub>N<sub>4</sub> is a typical RP and tends to form S-scheme heterojunctions with OPs such as TiO<sub>2</sub>, BiVO<sub>4</sub>, WO<sub>3</sub>, Ag<sub>3</sub>PO<sub>4</sub>, CeO<sub>2</sub>, ZnO, and SrTiO<sub>3</sub> [138].

He *et al.* [139] synthesized a TiO<sub>2</sub>/C<sub>3</sub>N<sub>4</sub> composite material with surface-loaded Ti<sub>3</sub>C<sub>2</sub> MXene quantum dots (TCQD) for the efficient photocatalytic reduction of CO<sub>2</sub> into hydrocarbon fuels (Fig. 12a). The presence of TCQDs accelerated the spatial migration of electrons on the CB of g-C<sub>3</sub>N<sub>4</sub>, serving as a channel and acceptor for electron transfer. The results demonstrated that the synergistic effect of the S-scheme heterojunction and TCQDs significantly enhanced the photocatalytic reduction activity of CO<sub>2</sub>, with a CO evolution rate of 4.39 μmol g<sup>-1</sup> h<sup>-1</sup>; this value was three times higher than that of individual C<sub>3</sub>N<sub>4</sub> and TiO<sub>2</sub> (Fig. 12b). Xie *et al.* [140] successfully constructed a bifunctional ternary g-C<sub>3</sub>N<sub>4</sub>/Bi/BiVO<sub>4</sub> hybrid photocatalyst, which exhibited excellent aerobic photocatalytic oxidation performance for organic pollutant degradation and impressive photocatalytic CO<sub>2</sub> reduction performance under anaerobic conditions. The exceptional dual-functional photocatalytic performance of the g-C<sub>3</sub>N<sub>4</sub>/Bi/BiVO<sub>4</sub> hybrid photocatalyst was attributed to the formation of efficient S-scheme hybrid junctions, which not only greatly promoted appropriate charge dynamics but also maintained good charge potentials. Moreover, the introduction of metallic Bi nanoparticles enhanced visible light absorption through the surface plasmon resonance (SPR) effect and promoted interfacial charge transfer through the S-scheme bridging effect (Fig. 12c). Zhou *et al.* [141] constructed a new lead-free double perovskite Cs<sub>2</sub>TeBr<sub>6</sub> that combined with metal-free semiconductor g-C<sub>3</sub>N<sub>4</sub> to form S-scheme heterojunction, and this heterojunction was first used for photocatalytic CO<sub>2</sub> reduction (Fig. 12d). The formation of S-scheme heterojunctions led to efficient space charge separation and preserved the strong electrons and holes, thus enhancing photocatalytic activity. The results showed that the 5%-CTB/CN heterojunction material

**Figure 12** (a) S-scheme heterojunction of TiO<sub>2</sub>/C<sub>3</sub>N<sub>4</sub>/Ti<sub>3</sub>C<sub>2</sub> quantum dots: before contact, after contact, and after contact upon irradiation and charge migration and separation. (b) Photocatalytic CO<sub>2</sub> reduction performance of the prepared samples after irradiation for 1 h. Reprinted with permission from Ref. [139]. Copyright 2020, Elsevier. (c) Bifunctional S-scheme g-C<sub>3</sub>N<sub>4</sub>/Bi/BiVO<sub>4</sub> hybrid photocatalysts demonstrate both superior aerobic photocatalytic organic pollutant oxidation performance and impressive anaerobic photocatalytic CO<sub>2</sub> reduction ability. Reprinted with permission from Ref. [140]. Copyright 2020, Elsevier. (d) Diagram of S-scheme charge transfer process in CTB/CN heterojunction. (e) Schematic diagram of reaction routes for CO<sub>2</sub> photoreduction. Reprinted with permission from Ref. [141]. Copyright 2023, Wiley.

exhibited the best photocatalytic reduction of CO<sub>2</sub> under visible light irradiation. After 3 h of light exposure, the yields of CO and CH<sub>4</sub> were 468.90 and 61.31 μmol g<sup>-1</sup>, respectively. The yield of CO was 1.5 and 32 times higher than those of pure Cs<sub>2</sub>TeBr<sub>6</sub> and g-C<sub>3</sub>N<sub>4</sub>, and the yield of CH<sub>4</sub> was 2 times higher than that of pure Cs<sub>2</sub>TeBr<sub>6</sub>. Furthermore, based on the *in situ* Fourier transform infrared (FT-IR) test results, the reaction route of CO<sub>2</sub> photoreduction was proposed (Fig. 12e).

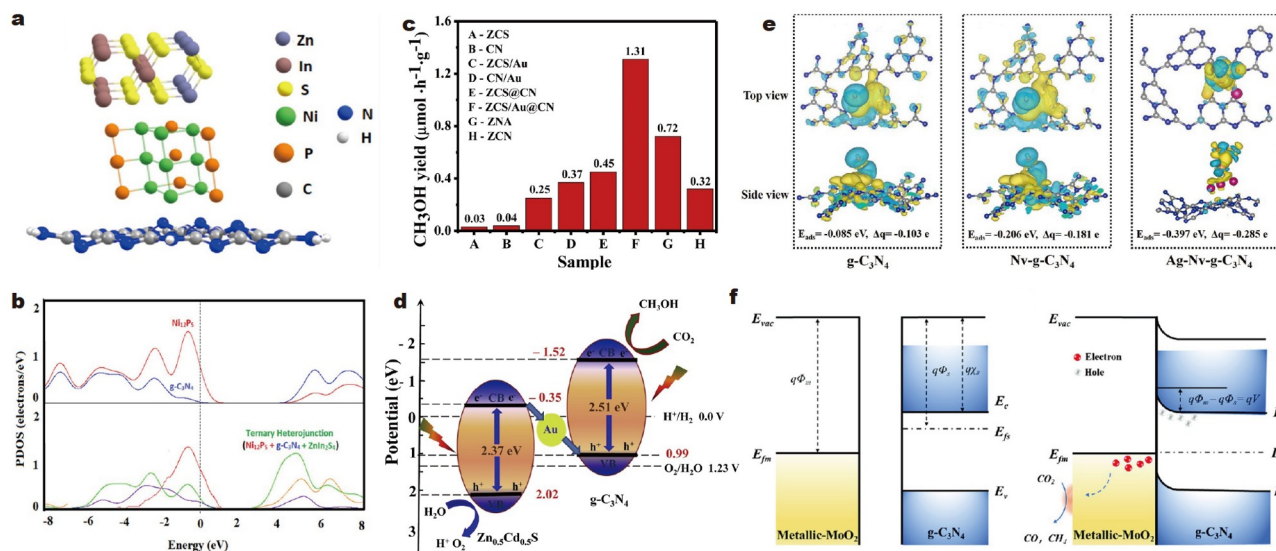

The bandgap of the S-scheme heterojunction could match the visible and even UV regions, providing the heterojunction with high catalytic activity in the photocatalytic CO<sub>2</sub> reduction reaction and significantly improving the reaction rates and product selectivity. The excellent charge transfer performance of the S-scheme heterojunction can effectively promote the separation and transfer of photoinduced charge carriers, thereby improving the photoelectrochemical conversion efficiency and enhancing the catalytic performance of photocatalytic CO<sub>2</sub> reduction.

#### *g-C<sub>3</sub>N<sub>4</sub>-based heterojunctions of other types*

In addition to the aforementioned heterojunction types, other g-C<sub>3</sub>N<sub>4</sub>-based heterojunctions for CO<sub>2</sub> reduction mainly include multivariate heterojunctions and Schottky heterojunctions. They have also been shown to have excellent photocatalytic CO<sub>2</sub> reduction properties.

The unique geometry and photocatalytic system composition

of ternary heterojunction catalysts have many advantages, such as short diffusion length and high conductivity for efficient charge separation and transport and high specific surface area and effective active site for enhanced photoredox catalytic activity. Saikia's group [142] used a ternary heterojunction photocatalyst consisting of g-C<sub>3</sub>N<sub>4</sub>/Ni<sub>12</sub>P<sub>5</sub>/ZnIn<sub>2</sub>S<sub>4</sub> to convert CO<sub>2</sub> to methanol. When the ratio of ZnIn<sub>2</sub>S<sub>4</sub> to NPCN was 0.1, the heterojunction could provide the maximum methanol yield of 164 μmol g<sup>-1</sup>; this value was 1.5 and 3.1 times higher than those of binary Ni<sub>12</sub>P<sub>5</sub>/g-C<sub>3</sub>N<sub>4</sub> (NPCN) and ZnIn<sub>2</sub>S<sub>4</sub>/g-C<sub>3</sub>N<sub>4</sub> (CNZ), respectively. The optimized model (Fig. 13a) showed that the doping of Ni<sub>12</sub>P<sub>5</sub> and ZnIn<sub>2</sub>S<sub>4</sub> led to a certain distortion of g-C<sub>3</sub>N<sub>4</sub>, and the calculated adhesion energy of -1.3 eV confirmed the stability of the heterojunction structure. As indicated by the surface projected density of states (PDOS) (Fig. 13b), in the ternary NCZ heterojunction, the valence band maximum (VBM) was contributed by Ni<sub>12</sub>P<sub>5</sub>, while the conduction band maximum (CBM) was mainly composed of ZnIn<sub>2</sub>S<sub>4</sub>, which could provide stability to the heterojunction. Furthermore, the reduced band gap in the ternary heterojunction produced a more effective photocatalyst than the binary composite. This study elucidated the important role of transition metal phosphides as an electronic bridge between two components forming a ternary heterojunction to improve photocarrier separation efficiency and provided a new perspective for the design of highly reactive photoactive materials for CO<sub>2</sub> photoreduction. In

**Figure 13** (a) Optimised structural model of  $g\text{-C}_3\text{N}_4\text{-Ni}_{12}\text{P}_5\text{-ZnIn}_2\text{S}_4$ . addition, Cheng's group [143] used a simple photodeposition hydrothermal method to prepare  $\text{Zn}_x\text{Cd}_{1-x}\text{S}/\text{Au}@g\text{-C}_3\text{N}_4$  heterojunction composite photocatalyst, and good contact was achieved among ZCS, AuNPs, and CN. The catalyst showed a high  $\text{CH}_3\text{OH}$  formation rate ( $1.31 \mu\text{mol h}^{-1} \text{g}^{-1}$ ), which was approximately 43.6 and 32.7 times higher than those of the pure ZCS and CN samples, respectively (Fig. 13c). As shown in Fig. 13d, a mechanism for the enhanced  $\text{CO}_2$  reduction performance was proposed and included the formation of Fermi level equilibrium at the ZCS, Au, and CN interfaces before illumination and the rapid migration of electrons on ZCS CB to AuNPs after illumination. Thus, the electrons accumulated in the high potential CB of CN could reduce  $\text{CO}_2$  to  $\text{CH}_3\text{OH}$ , while the holes left in the VB of ZCS promoted the photooxidation process to generate  $\text{H}^+$  and reactive oxygen species. The results from this study showed that the development and application of ternary heterojunctions facilitated the further development of the photocatalytic reduction of  $\text{CO}_2$ , and this research strategy could also be extended to other solar-related applications.

The  $g\text{-C}_3\text{N}_4$  can also form Schottky heterojunctions with metal nanoparticles to enhance carrier migration.  $g\text{-C}_3\text{N}_4$ -based Schottky heterojunctions with metals can provide effective catalytically active centres to further enhance the photocatalytic performance of  $g\text{-C}_3\text{N}_4$ . Plasmonic Ag NPs were successfully constructed by *in situ* self-assembly on nitrogen vacancy-modified  $g\text{-C}_3\text{N}_4$  nanotubes (ACNNTs); this process produced highly efficient visible-light photocatalytic  $\text{CO}_2$  conversion ( $88.2 \mu\text{mol g}^{-1} \text{h}^{-1}$ ), which was more than 10.9 times that of BCN [144]. As shown in Fig. 13e, the DFT calculations indicated that the introduction of nitrogen vacancies could change the Schottky potential barrier at the interface while lowering the energy barrier for  $\text{CO}_2$  activation. Therefore, the optimized Schottky barrier height not only accelerated the charge dynamics through the driving force of the Schottky junction but also

prevented the photoelectrons captured by Ag from flowing back to  $g\text{-C}_3\text{N}_4$  in the visible light; this effectively inhibited photo-generated carrier complexation, leading to a more efficient  $\text{CO}_2$  photoreduction. This study revealed the significance of carbon nitride-based Schottky heterojunctions in the field of photocatalytic  $\text{CO}_2$  reduction. In addition to metal nanoparticles, the formation of Schottky heterojunctions with metal oxides and  $g\text{-C}_3\text{N}_4$  could solve the problems of low carrier separation rate and low surface activity of  $g\text{-C}_3\text{N}_4$ . Qiu's group [145] constructed Schottky heterojunctions by loading and optimizing  $\text{MoO}_2$  with metallic properties on  $g\text{-C}_3\text{N}_4$  to improve the photocatalytic  $\text{CO}_2$  reduction activity. As shown in Fig. 13f, due to the built-in electric field,  $\text{MoO}_2$  was able to rapidly abstract photogenerated electron-hole pairs, accelerate the separation of photogenerated electron-hole pairs, and enhance the  $\text{CO}_2$  activity of  $g\text{-C}_3\text{N}_4$ . This study provided a new concept in improving the  $\text{CO}_2$  reduction performance of  $g\text{-C}_3\text{N}_4$  photocatalytic materials.

### Noble metal deposition

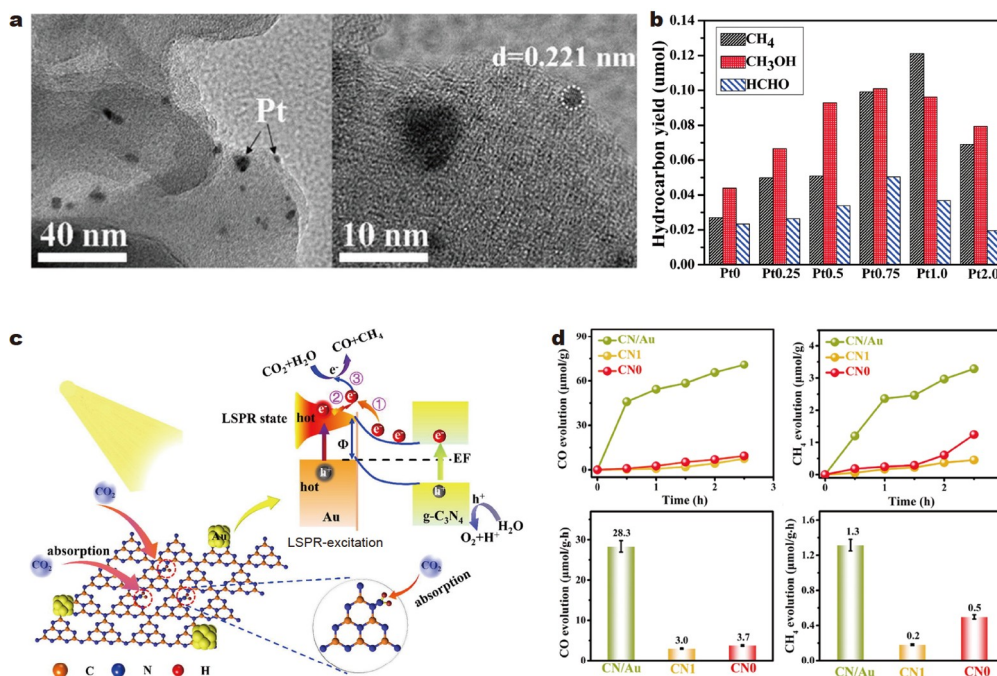

Noble metal deposition can enhance the number of catalytic active sites and the surface area of photocatalytic materials, adjust the surface electronic structure of the photocatalytic material, promote charge transfer, and suppress photocorrosion. Deposition of noble metals can introduce localized SPR effects, enhancing light absorption capacity and improving the efficiency of photocatalytic reactions. Additionally, the localized surface electric field of noble metals can accelerate the separation and transfer of photoinduced charge carriers, thereby enhancing the effectiveness of photocatalytic  $\text{CO}_2$  reduction reactions. Using noble metals as catalysts can significantly improve the photocatalytic performance of  $g\text{-C}_3\text{N}_4$  semiconductors and the selectivity of  $\text{CO}_2$  reduction products. Noble metal nanoparticles can effectively activate  $\text{CO}_2$  adsorbed on the surface of  $g\text{-C}_3\text{N}_4$  since they have higher work functions and lower Fermi levels

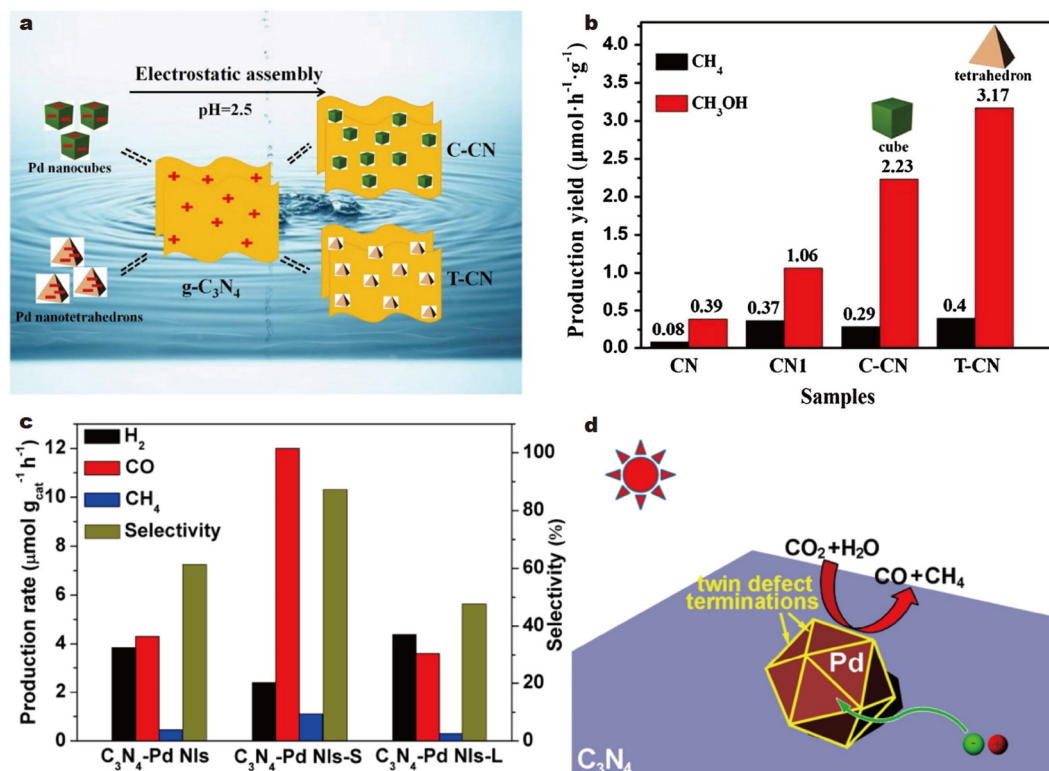

when deposited on the surface. The combination of noble metals with semiconductors forms composite materials, leading to an upwards bending of the energy band of g-C<sub>3</sub>N<sub>4</sub> and improving the charge separation efficiency [146]. Due to its bending, the total Fermi level of the composite material shifts to a more negative potential, and the bending ultimately balances with the Fermi level of the semiconductor. Noble metals become reservoirs for photoinduced electrons on the semiconductor surface, forming Schottky junctions that prevent electrons from flowing back into the semiconductor. Consequently, electron accumulation occurs in the metal, while hole accumulation occurs in the semiconductor, thereby enhancing photocatalytic performance [147]. Currently, the noble metals used for modifying g-C<sub>3</sub>N<sub>4</sub> catalytic activity mainly include Pt [148,149], Au [150,151], Ag [152,153], Pd [154,155], and others. The deposition of these noble metals can significantly improve the catalytic efficiency of g-C<sub>3</sub>N<sub>4</sub> in photocatalytic CO<sub>2</sub> reduction.

Yu *et al.* [148] deposited a certain amount of Pt on the surface of g-C<sub>3</sub>N<sub>4</sub> to prepare g-C<sub>3</sub>N<sub>4</sub>-Pt nanocomposites (Fig. 14a). With an increase in Pt content from 0 to 0.75 wt%, the yields of CH<sub>3</sub>OH and HCHO also increased and reached their maximum value at a Pt content of 0.75 wt% (Fig. 14b). Their study demonstrated that Pt nanoparticles could effectively promote the transfer and enrichment of photoinduced electrons from g-C<sub>3</sub>N<sub>4</sub> to its surface, thereby enhancing the photocatalytic CO<sub>2</sub> reduction capability of g-C<sub>3</sub>N<sub>4</sub>-Pt nanocomposites. Li *et al.* [150] employed a method involving HAuCl<sub>4</sub>·3H<sub>2</sub>O impregnation of g-C<sub>3</sub>N<sub>4</sub> powder and N<sub>2</sub> plasma treatment to prepare gold nanoparticle (CN/Au)-modified amino-functionalized g-C<sub>3</sub>N<sub>4</sub>. CN/Au exhibited strong photocatalytic activity for CO<sub>2</sub> reduction under visible light irradiation without the addition of auxiliary catalysts or sacrificial agents (Fig. 14c). The CO and CH<sub>4</sub> evolu-

tion rates for CN/Au were 28.3 and 1.3 μmol h<sup>-1</sup> g<sup>-1</sup>, respectively, which were 7.6 and 2.6 times higher than those of pristine g-C<sub>3</sub>N<sub>4</sub> (CN-0) (Fig. 14d). Cao *et al.* [154] showed the significant effects of Pd cocatalysts on CO<sub>2</sub> photoreduction on g-C<sub>3</sub>N<sub>4</sub>. By adjusting the quantities of (1 1 1) and (1 0 0) facets, the surface atomic structure of Pd cocatalysts could be precisely controlled, thereby regulating the interface charge carrier transfer, CO<sub>2</sub> adsorption, and CH<sub>3</sub>OH desorption. Their results showed that tetrahedral Pd nanocrystals on the exposed (1 1 1) facets were more favourable for enhancing the photocatalytic performance of g-C<sub>3</sub>N<sub>4</sub> in CO<sub>2</sub> reduction compared with cubic Pd nanocrystals on the exposed (1 0 0) facets (Fig. 15a, b). Notably, the CH<sub>3</sub>OH production rate for T-CN (3.17 μmol h<sup>-1</sup> g<sup>-1</sup>) was 1.42 times higher than that of the C-CN hybrid photocatalyst. Lang *et al.* [155] demonstrated that defect-engineered Pd catalysts greatly enhanced the photocatalytic performance of CO<sub>2</sub> reduction. Their results indicated that the twin-boundary (TB) sites on the surface of Pd cocatalysts were highly active for CO<sub>2</sub> reduction. Based on the proposed mechanism, the photocatalytic activity and selectivity of CO<sub>2</sub> reduction were further enhanced by increasing the surface density of the TB sites and reducing the size of the Pd nanopolyhedra cocatalysts (Fig. 15c, d). Heng *et al.* [152] synthesized mesoporous g-C<sub>3</sub>N<sub>4</sub> (MCN) with a high specific surface area and investigated the relationship between CO<sub>2</sub> adsorption capacity and photocatalytic CO<sub>2</sub> reduction activity. Additionally, Ag particles served as active sites, effectively enhancing charge separation efficiency and promoting photocatalytic activity (Fig. 16a). Importantly, the synergistic effect between the mesoporous structure (providing strong CO<sub>2</sub> adsorption capacity) and Ag particles (facilitating efficient charge separation) significantly improved the photocatalytic activity. The CO evolution rate of 3.0% Ag/mesoporous g-C<sub>3</sub>N<sub>4</sub>

[155]. Copyright 2017, IOP Publishing.

(Ag/MCN) reached 1.66 μmol g<sup>-1</sup> h<sup>-1</sup>, which was 2.81, 2.41, and 4.37 times higher than that of pristine MCN, 1.0% Ag/bulk g-C<sub>3</sub>N<sub>4</sub> (Ag/BCN), and pristine bulk g-C<sub>3</sub>N<sub>4</sub> (BCN), respectively (Fig. 16b–e). In addition to single noble metal deposition, the synergistic enhancement of CO<sub>2</sub> photocatalytic activity by multi-noble metal deposition has great research potential. Currently, research on multi-noble metal deposition is relatively scarce. For example, Wang *et al.* [156] demonstrated that Pt-Ag bimetallic nanoparticles deposited on g-C<sub>3</sub>N<sub>4</sub> effectively regulated the selectivity and increased the yield of CO<sub>2</sub> reduction products, highlighting the effectiveness of bimetallic structures in enhancing the photocatalytic efficiency of g-C<sub>3</sub>N<sub>4</sub> for CO<sub>2</sub> reduction. This research direction may serve as an effective strategy for enhancing the photocatalytic activity of CO<sub>2</sub> reduction.

#### Other surface modulation methods

In addition to the aforementioned g-C<sub>3</sub>N<sub>4</sub> modulation methods, which can effectively enhance the photocatalytic activity of g-C<sub>3</sub>N<sub>4</sub> for CO<sub>2</sub> reduction, other modulation strategies can also enhance the photocatalytic activity of g-C<sub>3</sub>N<sub>4</sub>; these strategies include morphology adjustment, defect engineering, and surface functional group modification. Different morphologies have different specific surface areas and void ratios, and by adjusting the morphology of g-C<sub>3</sub>N<sub>4</sub> to increase its specific surface area, more reactive sites can be exposed, thus enhancing the adsorption and reduction reaction of CO<sub>2</sub>. In addition, different morphologies of g-C<sub>3</sub>N<sub>4</sub> also affect its light absorption properties

and thus the CO<sub>2</sub> reduction efficiency. For g-C<sub>3</sub>N<sub>4</sub>, a variety of different morphologies have been investigated and include 1D rods, tubes, 2D nanosheets, 3D hollow spheres, honeycomb structures, anti-opal structures, and many others [147]. Tian *et al.* [157] prepared porous tubular yolk-shell g-C<sub>3</sub>N<sub>4</sub> (PTYS CN-2) by precursor recrystallization (Fig. 17a). The tubular structure increased the light scattering and thus enhanced the light absorption. Due to the enhanced light absorption and abundant reaction sites, the CO yield of PTYS CN-2 was 40.3 μmol g<sup>-1</sup> at 4 h; this value was 5.6 times higher than that of g-C<sub>3</sub>N<sub>4</sub> (Fig. 17b). Ultrathin porous g-C<sub>3</sub>N<sub>4</sub> has excellent photocatalytic CO<sub>2</sub> reduction performance. Yang *et al.* [158] prepared ultrathin porous g-C<sub>3</sub>N<sub>4</sub> (THCN) with high specific surface area and high CB position using a stepwise synergistic exfoliation method. Their results showed that THCN had the highest efficiency of CO<sub>2</sub> conversion to CH<sub>4</sub> and CO fuel compared with g-C<sub>3</sub>N<sub>4</sub> (HCN) prepared by hydrochloric acid-assisted hydrothermal vapour extraction and g-C<sub>3</sub>N<sub>4</sub> (TCN) prepared by aerothermal vapour extraction/etching (Fig. 17c, d). Moreover, the excellent photocatalytic CO<sub>2</sub> reduction performance is mainly attributed to its high specific surface area and abundant pores, the good separation and utilization efficiency of the photogenerated carriers, and the more negative position of the CB. Designing defect engineering in the perfect g-C<sub>3</sub>N<sub>4</sub> structure to enhance light absorption and drive electron transfer may have a positive effect on CO<sub>2</sub> photocatalytic reduction. Li *et al.* [159] introduced nanodiamond (ND) and nitrogen defects (ND/g-C<sub>3</sub>N<sub>4</sub>(NH)) on

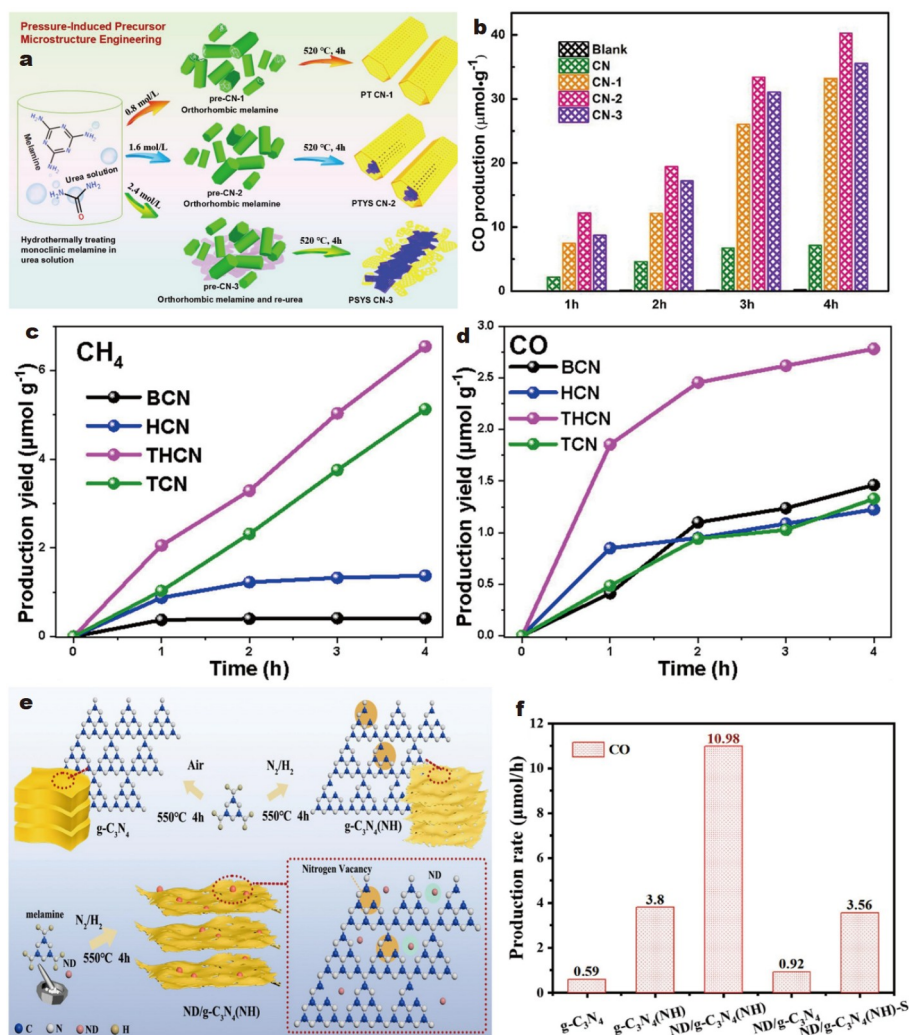

**Figure 16** (a) Schematic diagram of the mechanism of enhancing CO<sub>2</sub> photoreduction activity by promoting charge separation and CO<sub>2</sub> adsorption with Ag mesoporous g-C<sub>3</sub>N<sub>4</sub>. CO evolution rates of Ag/BCN (b, c) and Ag/MCN (d, e) with different loading amounts. Reprinted with permission from Ref. [152]. Copyright 2022, Elsevier.

the g-C<sub>3</sub>N<sub>4</sub> surface using an *in situ* thermal polymerization method (Fig. 17e). Under visible light irradiation, ND/g-C<sub>3</sub>N<sub>4</sub> (NH) exhibited excellent CO<sub>2</sub> photocatalytic performance with a CO yield of 10.98 μmol h<sup>-1</sup> (18.6 times higher than that of pristine g-C<sub>3</sub>N<sub>4</sub>) (Fig. 17f). The synergistic effect of nitrogen vacancy engineering and ND modification improved CO<sub>2</sub> photoreduction, significantly enhanced visible light absorption, promoted electron transfer pathway, and effectively facilitated carrier separation and transfer. Functional group modifications are generally used to change the energy band structure of g-C<sub>3</sub>N<sub>4</sub> and the adsorption of CO<sub>2</sub>, and some common functional groups, such as carboxylation (carboxylation), amination, sulfonation, hydroxylation, and cyanation, have been used to modify g-C<sub>3</sub>N<sub>4</sub> to enhance its photocatalytic activity [146]. Wang *et al.* [160] prepared g-C<sub>3</sub>N<sub>4</sub> amine-rich mesoporous nanosheets by a thermal stripping method. Due to their large surface areas, abundant mesoporous and high concentration of -NH<sub>2</sub> groups, these nanosheets showed higher CO<sub>2</sub> adsorption

and selectivity than pure g-C<sub>3</sub>N<sub>4</sub> materials.

## CHALLENGES AND PROSPECTS

As global climate change continues to intensify, reducing greenhouse gas emissions has become an important task facing the global community. Carbon neutrality refers to the reduction of greenhouse gas emissions through various measures and, if necessary, the use of carbon sink technologies to reduce the net CO<sub>2</sub> emissions in the atmosphere to zero. In this context, the research and application of photocatalytic CO<sub>2</sub> reduction technology is highly important. Photocatalytic CO<sub>2</sub> reduction converts CO<sub>2</sub> into useful compounds such as CH<sub>4</sub>, HCOOH, and CH<sub>3</sub>OH. These compounds can be used as fuels or chemicals, thus enabling the resourceful use of CO<sub>2</sub>. Compared with conventional fossil fuels, the use of these CO<sub>2</sub> reduction products does not increase CO<sub>2</sub> emissions and thus can significantly reduce the greenhouse gas emissions. Compared with other CO<sub>2</sub> reduction technologies, photocatalytic CO<sub>2</sub> reduction has the

**Figure 17** (a) Schematic illustration of the formation of CN- $x$  ( $x = 1-3$ ). (b) CO production rates over pure CN and CN- $x$  samples. Reprinted with permission from Ref. [157]. Copyright 2021, Elsevier. (e) Preparation processes for ND/g-C<sub>3</sub>N<sub>4</sub>(NH), g-C<sub>3</sub>N<sub>4</sub>(NH) and g-C<sub>3</sub>N<sub>4</sub>. (f) Comparison of CO production rates for g-C<sub>3</sub>N<sub>4</sub>, g-C<sub>3</sub>N<sub>4</sub>(NH), ND/g-C<sub>3</sub>N<sub>4</sub>(NH), ND/g-C<sub>3</sub>N<sub>4</sub>, and ND/g-C<sub>3</sub>N<sub>4</sub>(NH)-S. Reprinted with permission from Ref. [159]. Copyright 2022, Elsevier.

advantages of direct solar energy utilization and relatively simple and low-cost operation. Therefore, photocatalytic CO<sub>2</sub> reduction technology has received much attention. g-C<sub>3</sub>N<sub>4</sub> has been studied and applied as an efficient and economical photocatalyst for CO<sub>2</sub> photocatalytic reduction; however, the photocatalytic reduction activity of pristine g-C<sub>3</sub>N<sub>4</sub> for CO<sub>2</sub> is not high, and various modulation tools have been applied to enhance the catalytic performance of g-C<sub>3</sub>N<sub>4</sub> for CO<sub>2</sub> photocatalytic reduction and achieved good results in the laboratory. Although researchers have made many efforts to enhance the efficiency of g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts for photocatalytic CO<sub>2</sub> reduction, much research is still needed before they can be applied in practice. Unfortunately, due to the current climate issues and policy regulations, the low efficiency of g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts for CO<sub>2</sub> reduction needs to be addressed to meet practical needs. To meet these challenges, several suggestions and perspectives for future research are presented below.

(1) Improvement of the adsorption of CO<sub>2</sub>: CO<sub>2</sub> adsorption is the first step of the photocatalytic CO<sub>2</sub> reduction reaction, and enhancing the adsorption of CO<sub>2</sub> by a catalyst is beneficial for

improving the efficiency of CO<sub>2</sub> reduction. The adsorption of CO<sub>2</sub> can be effectively enhanced by introducing functional groups or ligands that act as Lewis base sites. However, too strong of an adsorption can cause difficulty for the reduction products to desorb and occupy the active sites; thus, the proper adsorption of CO<sub>2</sub> by the catalyst is beneficial for enhancing its photocatalytic reduction efficiency.

(2) Optimization of the use of sacrificial agents: H<sub>2</sub>O can be used as a sacrificial agent for the g-C<sub>3</sub>N<sub>4</sub> photocatalytic reduction of CO<sub>2</sub> by providing additional electrons and protons and thus promoting the reduction of CO<sub>2</sub>. Compared with other sacrificial agents, such as methanol and ethanol, the use of water as a sacrificial agent is more environmentally friendly. In the photocatalytic reduction of CO<sub>2</sub> with H<sub>2</sub>O as a sacrificial agent, a competing reaction of hydrogen precipitation and decomposition of H<sub>2</sub>O produces oxygen molecules; these processes may cause oxidation reactions with the CO<sub>2</sub> reduction products, leading to a decrease in the selectivity of the reaction. Therefore, more efficient g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts need to be researched and designed in the future to reduce the dependence on

sacrificial agents.

(3) In-depth investigation of the mechanism of the CO<sub>2</sub> reduction process: the basic principle of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction has been initially studied, but the specific reaction process and especially the mechanism of reduction product generation have not been studied in depth; additionally, there is no systematic understanding of the physicochemical process of photocatalytic CO<sub>2</sub> reduction, which hinders the design of more efficient g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts. Therefore, to develop g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts that meet practical needs, a deeper study of the reaction mechanism should be carried out to design synthetic catalysts to ensure the optimal level of catalyst performance in each reaction process.

(4) Improvement of the selectivity of the reduced products: in general, the position of the CB can determine the type of reduced products, and the energy band modulation of g-C<sub>3</sub>N<sub>4</sub> by different modulation strategies can be used to select the reduced products. In addition, increasing the mobility of photogenerated carriers is beneficial for enhancing the selectivity of the reduced products. The photogenerated electrons avoid complex migration with holes to the catalyst surface, and a large number of photogenerated electrons accumulate on the catalyst surface, which can effectively improve the reaction rate and increase the selectivity for the reduced products in highly reduced states.

(5) Design of catalysts and processes under practical conditions: the g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts studied at this stage not only have low photoconversion efficiency to meet the needs of practical applications but also have not yet been tested for stability and reusability in practical applications. In addition, most research has been performed in the laboratory without designing reaction devices to meet actual needs, and the catalytic efficiency of the synthesized catalysts under actual working conditions is not able to be determined. Therefore, the design and optimization of catalytic reaction systems will be the focus of future research.

The aim of this review is to provide theoretical support for the applications of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction in a carbon-neutral context and to promote the practical applications of g-C<sub>3</sub>N<sub>4</sub> photocatalytic CO<sub>2</sub> reduction and the design of efficient g-C<sub>3</sub>N<sub>4</sub>-based photocatalysts. In the future, with the joint efforts of scientific researchers worldwide, g-C<sub>3</sub>N<sub>4</sub>-based high-efficiency photocatalysts will likely be able to meet the practical needs of industrial CO<sub>2</sub> reduction, achieve large-scale CO<sub>2</sub> conversion, reduce CO<sub>2</sub> emissions, and contribute to the global carbon neutrality goal and sustainable development of global energy.

**Author contributions** Zhou Q supervised the project and conceived the idea. Zhan H wrote the draft. Zhou R, Liu K, Ma Z, Wang P, and Zhan S revised the manuscript and provided constructive suggestions. All authors discussed and commented on the manuscript.

**Conflict of interest** The authors declare that they have no conflict of interest.

**Haiyin Zhan** is a PhD candidate at the College of Environmental Science and Engineering, Nankai University (China) under the supervision of professor Qixing Zhou. His current research area is the construction of highly-efficient atomic catalysts for Fenton-like reactions.

**Qixing Zhou** is a distinguished professor of Nankai University (China) and serves at the College of Environmental Science and Engineering. He received his PhD degree in ecology from the Chinese Academy of Sciences and Karlsruhe University (Germany) in 1992. His research interests focus on ecological geochemistry, green advanced materials, and environmental remediation.

## 碳中和背景下基于g-C<sub>3</sub>N<sub>4</sub>光催化CO<sub>2</sub>还原的研究进展与挑战

展海银<sup>1</sup>, 周睿人<sup>2</sup>, 刘可望<sup>1</sup>, 马志辉<sup>1</sup>, 王鹏飞<sup>1</sup>, 展思辉<sup>1</sup>, 周启星<sup>1\*</sup>

**摘要** 全球变暖对人类的生产生活造成了严重的威胁, 已成为当今世界面临的重大挑战之一。碳中和这一重要举措能够有效缓解全球变暖的进程, 在这一背景下光催化CO<sub>2</sub>还原可有效减少碳排放且促进碳循环。g-C<sub>3</sub>N<sub>4</sub>因其制备工艺简单、稳定性高、能带位置适宜以及优异的光催化性能而备受关注。因此, 提高g-C<sub>3</sub>N<sub>4</sub>光催化CO<sub>2</sub>还原效率是当前研究的热点问题。本文重点探究了碳中和对于全球生态平衡和环境可持续发展的重要性以及在碳中和背景下g-C<sub>3</sub>N<sub>4</sub>光催化CO<sub>2</sub>还原的重要作用和发展前景; 综述了目前解决限制g-C<sub>3</sub>N<sub>4</sub>光催化CO<sub>2</sub>还原瓶颈问题的方法和技术手段。对g-C<sub>3</sub>N<sub>4</sub>在光催化CO<sub>2</sub>还原领域存在的问题进行讨论, 提出了未来的研究方向, 并进行展望。本综述旨在为碳中和背景下基于g-C<sub>3</sub>N<sub>4</sub>催化剂光催化CO<sub>2</sub>还原的应用提供理论支持, 为基于g-C<sub>3</sub>N<sub>4</sub>高效CO<sub>2</sub>还原光催化剂的设计提供思路。
