

ORIGINAL ARTICLE

Vitamin K-induced effects on body fat and weight: results from a 3-year vitamin K2 intervention study

MHJ Knapen, KM Jardon and C Vermeer

BACKGROUND/OBJECTIVES: Vitamin K status has been linked to fat and glucose metabolism by several authors, but whether high vitamin K intake influences body weight or composition has remained unclear. Here we tested the hypothesis that increased vitamin K intake decreases body fat or fat distribution.

SUBJECTS/METHODS: In a randomized placebo-controlled human intervention trial, 214 postmenopausal women, 55–65 years of age, received either 180 mcg/day of vitamin K2 (menaquinone-7, MK-7) or placebo for 3 years. Osteocalcin (OC) carboxylation was used as a marker for vitamin K status, and fat distribution was assessed by dual-energy X-ray absorptiometry total body scan.

RESULTS: In the total cohort, MK-7 supplementation increased circulating carboxylated OC (cOC) but had no effect on body composition. In those with an above-median response in OC carboxylation ('good responders'), MK-7 treatment resulted in a significant increase in total and human molecular weight adiponectin and a decrease in abdominal fat mass and in the estimated visceral adipose tissue area compared with the placebo group and the poor responders.

CONCLUSIONS: The fact that changes in body composition measures or markers for fat or glucose metabolism were not associated with changes in uncarboxylated OC (ucOC) does not support the assumption that ucOC stimulates fat metabolism in humans. Instead, high vitamin K2 intake may support reducing body weight, abdominal and visceral fat, notably in subjects showing a strong increase in cOC. A causal relation between the changes in cOC and body fat or distribution cannot be concluded from these data.

European Journal of Clinical Nutrition (2018) 72, 136–141; doi:10.1038/ejcn.2017.146; published online 27 September 2017

INTRODUCTION

The osteoblast-specific protein osteocalcin (OC) has received much attention in the past owing to its proposed function as a key component in the interplay between bone homeostasis and fat metabolism in humans.^{1–4} OC contains three residues of the amino-acid γ -carboxyglutamic acid (Gla) that are formed in a vitamin K-dependent way. Initially, it was suggested that uncarboxylated OC (ucOC) acts as a hormone-stimulating fat metabolism via the adiponectin pathway.^{1–4} This hypothesis implies that decreasing ucOC by vitamin K supplementation would decrease fat metabolism and lead to obesity. Arguments supporting this hypothesis were almost exclusively found in mice injected with ucOC, showing a reduction in fat mass and improvement in glucose metabolism.^{5,6} In contrast, long-term supplementation of phyloquinone (vitamin K1) and menaquinone-4 (MK-4, a short-chain vitamin K2) reduced total fat accumulation and serum triglycerides in rats.⁷ Although plasma OC status remained undetermined in this study, one could expect enhanced vitamin K-dependent OC carboxylation, contradicting the suggested beneficial effects of ucOC. In humans, the first outcomes were conflicting, and the role of OC carboxylation is not always clear because conformation-specific testing was not performed.⁸ During recent years, however, most human studies on the potential relation of vitamin K, vitamin K status and vitamin K-dependent OC conformations with body weight, obesity and type-2 diabetes mellitus suggest a beneficial effect of vitamin K on glucose and fat metabolism.^{9–24}

In conclusion, most cross-sectional studies in humans suggest a link between the bone protein OC and body composition, wherein carboxylated OC (cOC) and not ucOC exhibits hormonal activity. Consistently, in a 4-week intervention study MK-4 supplementation both improved OC carboxylation and increased insulin sensitivity index in healthy young men.²⁵ Furthermore, Shea *et al.*²⁶ did not find an association between vitamin K-induced reduction of ucOC and changes in fat mass and fat-free mass in a 3-year intervention period in older men and women.

Recently, additional evidence for a link between vitamin K and body mass was found during a 3-year intervention period among postmenopausal women aged between 55 and 65 years.¹¹ This group was selected because bone loss (the primary end point) is known to be high in the first decade after menopause. The present study is an exploratory analysis within the framework of the latter randomized clinical trial,²⁷ in which we tested the hypothesis that 3-year vitamin K2 (in the form of menaquinone-7 (MK-7)) supplementation in postmenopausal women will also affect waist circumference, body composition (fat mass/fat free mass) and visceral fat as assessed by dual-energy X-ray absorptiometry.

SUBJECTS AND METHODS

Study participants

The study was performed in a previously described cohort of 244 apparently healthy women aged between 55 and 65 years, at least 2 years

postmenopausal, body mass index $< 30 \text{ kg/m}^2$, not using medication known to affect calcium and bone metabolism and/or vitamin K-containing supplements.²⁷ All participants gave written informed consent for participation in this study. This study was conducted in agreement with the Declaration of Helsinki and approved by the local Medical Ethics Committee. Trial registration code: clinicaltrials.gov NCT00642551.

Study products and design

The study was double-blind, randomized, placebo controlled and had a two-armed parallel design in which participants received either placebo capsules ($n = 124$) or capsules containing $180 \mu\text{g}$ MK-7 (MenaQ7) ($n = 120$). The proprietary product MenaQ7 utilized in the study was provided by NattoPharma (Høvik, Norway). One capsule was taken daily either with breakfast or dinner during a period of 36 months. No side effects have been reported of long-term use of MK-7 in the study dose. There were no dietary restrictions and participants were asked to continue their regular diet and physical activities throughout the study. Participants exercising more than once weekly were considered to be physical active. From the 244 volunteers who entered the study, 21 discontinued their participation and were not available for the follow-up measurements (drop-out rate: 8.6%). Between 2008 and 2011, participants came to the research site annually for a general checkup to monitor changes in dietary pattern, physical activity, medication and/or general health. After admission and randomization, subjects entered the study between the months May and October, and care was taken that during follow-up they were monitored in the same month in subsequent years.

Waist-to-hip ratio

Waist-to-hip ratio was calculated by taking the ratio between the waist and hip circumference (both in cm), with a precision of 0.5 cm.

Whole-body composition

The distribution of fat and fat-free mass of the whole body and of the different regions was determined at baseline and after 3 years of treatment by performing a whole-body scan using dual-energy X-ray absorptiometry with the APEX software Version 4.0.2 (Hologic Discovery A, Waltham, MA, USA). The fat mass index (FMI) was calculated from the formula $\text{FMI} = \text{FM}/\text{height}^2$ (in kg/m^2) and the fat-free mass index (FFMI) from the formula: $\text{FFMI} = \text{FFM}/\text{height}^2$ (in kg/m^2). The android region of interest (ROI) is determined as 1/5 of the distance between the horizontal secants of the pelvis and neck. The lower boundary of the ROI is placed against the pelvic horizontal secant. The gynoid ROI is two times the height of the android ROI and its upper boundary is placed below the pelvic horizontal line by 1.5 times the height of the android ROI. To determine the visceral adipose tissue (VAT), the APEX software locates a region of 5 cm across the abdomen. The lower boundary of this region is located 1 cm above the iliac crest. The estimated VAT is calculated by subtracting the amount of subcutaneous fat on both sides of the region (between the skin line and outer abdominal wall) from the total amount of fat in this region. Inadequate or missing measurements of whole-body composition were excluded from subsequent statistical analyses, resulting in a total subject number of $n = 214$.

Laboratory analyses

Blood was taken to prepare plasma and serum, in which the following biomarkers were measured: ucOC and cOC (Takara Shuzo Co., Kyoto, Japan), leptin (DIAsource ImmunoAssays, Ottignies-Louvain-la-Neuve, Belgium), insulin (DRG Instruments, Marburg, Germany), glucose (Abcam, Cambridge, MA, USA), total adiponectin (AdipoGen, Epalinges, Switzerland), human molecular weight (HMW) adiponectin (R&D Systems, Abingdon, UK), interleukin-6 (ultra-sensitive; Invitrogen, Camarillo, CA, USA), high-sensitive C-reactive protein (hsCRP; DRG International, Springfield, NJ, USA), and tumour necrosis factor- α (R&D Systems Europe, Abingdon, UK). Within- and between-assay precisions for ucOC were 4.8% and 7.7%, for cOC 2.3% and 10.6%, for glucose 2.4% and 5.1%, for leptin 9.4% and 15.8%, for insulin 9.1% and 6.8%, for total adiponectin 5.3% and 9.1% and for HMW adiponectin 6.7% and 10.9%, for interleukin-6 6.4% and 7.8%, for hsCRP 7.7% and 8.3% and for tumour necrosis factor- α 5.4% and 8.3%, respectively. We also calculated the HMW/total adiponectin ratio as an additional measure of adiponectin status. Adiponectin and leptin were used as markers for fat metabolism.

The total of markers for fat and glucose metabolism will be designated here as markers for energy metabolism. We tested samples obtained at baseline and at the end of the study (year 3).

Statistics

The calculated sample size of this study ($n = 120$ per group) was based on bone strength in postmenopausal women, as described previously.²⁷ After discontinuation of 21 subjects and inadequate measurements of 11 subjects, data sets of $n = 214$ were available for analysis (placebo: $n = 107$, MK-7: $n = 107$). Normal distribution was tested by the one-sample Kolmogorov–Smirnov test. Log-transformation was performed if variables were not normally distributed (hsCRP, leptin, insulin, glucose, HMW adiponectin). One-way analysis of variance (for continuous variables) and Fisher's Exact test (for categorical variables) were used to test between-group differences at baseline. Associations at baseline between variables of interest were assessed by Pearson correlation analysis. The response of cOC and ucOC to placebo and MK-7 was measured by calculating the differences between baseline and 3 years. To define good and poor responders in cOC and ucOC in the MK-7 group, the 50th percentile was taken. One-way analysis of variance was used to analyze the differences between the good and poor responders to MK-7 compared with placebo (3 groups). Mean values are given with s.d. or with s.e. (Figures). $P < 0.05$ (two-sided significance level) was considered to be statistically significant. SPSS version 19.0 for Windows was used to perform statistical analyses (SPSS Inc., Chicago, IL, USA).

RESULTS

Baseline data

Baseline measurements are given in Table 1. No significant differences were found between the placebo and the MK-7 group. Poor vitamin K status as deduced from low cOC plasma concentrations was associated with a higher fat mass at different body sites, including the android region, and with waist circumference but not with FFMI. No associations were found between baseline ucOC and markers for adiposity. On the other hand, cOC showed inverse associations with hsCRP, leptin and insulin but not with total adiponectin and HMW adiponectin (Table 2).

Effect of MK-7 supplementation on body composition

After 3 years of treatment, the ratio between fat mass in the android region and that in the gynoid region had increased 1.4% (s.e. 0.6%) in the placebo group, whereas it had not changed in the MK-7 group (-0.5% (s.e. 0.6%), $P = 0.021$). MK-7 treatment also induced a significant increase of circulating cOC as compared with placebo (21.5% (s.e. 1.9%) and 2.6% (s.e. 1.5%), respectively; $P < 0.0001$). ucOC had decreased significantly in the MK-7 group by 50.1% (s.e. 2.0%), whereas it had hardly changed in the placebo group (+4.3% (s.e. 4.8%); $P < 0.0001$).

In a subsequent analysis, we have focused on the good responders in the MK-7 group, who were defined as those who had increased their circulating cOC concentration with a value above the 50th percentile (+0.92 ng/ml) of the 3-year change of this variable (Table 3). These subjects were compared with the poor responders (below the 50th percentile) in the same group and with the placebo group. Similarly, we have also subdivided the MK-7-treated group into good and poor responders based on the decrease of ucOC (-1.67 ng/ml). No significant differences were found between the baseline values of the variables of body composition in the good and poor responders in cOC and ucOC compared with the placebo (Table 3).

Outcomes based on response in cOC. The change in cOC in the poor responders was 0.38 ng/ml (s.e. 0.07 ng/ml) or 7.7% (s.e. 1.3%) and in the good responders it was 1.66 ng/ml (s.e. 0.087 ng/ml) or 34.9% (s.e. 2.3%) $P < 0.0001$. Compared with the poor responders, the good responders showed a significant increase in total and in HMW adiponectin ($0.71 \mu\text{g/ml}$ (s.e. $0.29 \mu\text{g/ml}$),

$P=0.044$ and $1.01 \mu\text{g/ml}$ (s.e. $0.29 \mu\text{g/ml}$), $P=0.002$) after 3 years of MK-7 treatment. No differences between both groups were found for the other markers for fat or glucose metabolism. With respect to the body fat distribution, significant decreases of the variables of the abdominal region (waist circumference, fat mass trunk, android fat mass, estimated VAT area), as well as the android/gynoid fat mass ratio were observed in the good responders group compared with the placebo as well as to the poor responders (Figure 1).

Outcomes based on response in ucOC. The change in ucOC in the poor responders was -0.83 ng/ml (s.e. 0.08 ng/ml) or -37.7%

Differences between the placebo and MK-7 group were not statistically significant.

(s.e. 2.8%) and in the good responders it was -3.04 ng/ml (s.e. 0.14 ng/ml) or -62.7% (s.e. 1.6%) $P < 0.0001$. No differences between good and poor responders were found except for fat mass of the trunk, which showed a small but non-significant decrease in the group of the good responders (data not shown).

DISCUSSION

In this paper, we report that poor vitamin K status at baseline (as deduced from low serum cOC concentrations) is associated with a higher waist circumference and a higher fat mass in the android region in healthy women between 55 and 65 years of age. It is now widely accepted that obesity is associated with a chronic state of inflammation and that a number of inflammatory factors are secreted by adipose tissue. Consistently, we have found that poor vitamin K status (low cOC) is associated with higher levels of the pro-inflammatory marker hsCRP. However, we could not confirm that vitamin K supplementation leads to a decrease in inflammation markers. This is probably due to the fact that the study group was selected to be healthy, so inflammation markers were low at baseline already and did not significantly decline further during the 3-year treatment period. Additionally, we found

Abbreviations: BMI, body mass index; cOC, carboxylated osteocalcin; EstVAT, estimated visceral adipose tissue; FFMI, fat-free mass index; FM, fat mass; FMI, fat mass index; MK-7, menaquinone-7; ratio A/G, ratio of FM android and gynoid region; ucOC, uncarboxylated osteocalcin; WHR, waist-to-hip ratio. One-way analysis of variance was performed between placebo, poor and good responders to MK-7 in cOC (absolute change < 0.92 ng/ml and ≥ 0.92 ng/ml, respectively) and in ucOC (absolute change > -1.67 ng/ml and ≤ -1.67 ng/ml, respectively). **P* < 0.05; ***P* < 0.0001: poor or good responders compared with placebo. †*P* < 0.05; ††*P* < 0.0001: poor responders compared with good responders in MK-7.

inverse associations between cOC and insulin, and leptin, which is suggestive for an endocrine function of cOC (but not of ucOC) in metabolic pathways leading to adiposity. As compared with baseline values, MK-7 supplementation increased OC carboxylation but did not lead to any changes in body composition in the total study group. Detailed analyses revealed, however, that good responders to MK-7 treatment (as deduced from the increase of serum cOC) showed a significant increase in HMW adiponectin and a reduction of body fat in the abdominal area (waist circumference, android fat mass and estimated VAT area) compared with poor responders.

Several authors have reported that OC acts as a hormone-regulating adiposity and energy metabolism in mice,^{1–6} whereas in wild-type rats the opposite was found.⁷ Most results found in human studies do not support this role for ucOC,^{7–11,13,19} but some papers have shown conflicting evidence.²⁰ In humans, about 30% of the circulating OC occurs in its uncarboxylated form, and this can be readily decreased to values below the detection limit by using vitamin K supplements. In two unrelated placebo-controlled human intervention trials in which 1 mg/day of vitamin K1 (ref. 28) and 45 mg/day of MK-4 (ref. 29) were given for 3 years to postmenopausal women, we had data on body weight, body mass index and waist circumference, but in both trials we observed a tendency toward lower rather than higher indices for fat mass in the vitamin K-treated groups.¹¹

In the present paper, we found at baseline that low serum cOC was associated with a higher fat mass at different sites. The inverse association between cOC and leptin and insulin is suggestive for a direct role of cOC in glucose homeostasis. These data are consistent with those reported by Rasekhi *et al.*,³⁰ who showed that phylloquinone supplementation improves glycemic status independent of the effects of adiponectin levels in premenopausal women with prediabetes. The fact that also a weak inverse association was found between cOC and hsCRP may result from a direct anti-inflammatory effect of vitamin K. It may also be the consequence of a decreased fat mass, as chronic low-grade inflammation is a common condition in obese patients. Consequently, CRP being a biomarker indicating chronic low-

grade inflammation is often increased in subjects with higher fat mass.³¹

Our 3-year follow-up data show that increasing cOC at the expense of ucOC by vitamin K supplements was paralleled by a decreased ratio between the android/gynoid fat mass ratio and a decreased estimated visceral fat area. In a further analysis, we have subdivided the MK-7-treated subjects in a group with a strong increase of OC carboxylation (above the median) and a group in which the response was relatively poor (below the median). As compared with the poor responders, the good responders showed a significant increase in total and HMW adiponectin and a more favorable fat mass and fat distribution, that is: significant decreases of the variables of the abdominal region (waist circumference, android fat mass, estimated VAT area), as well as the waist-to-hip circumference ratio and android/gynoid fat mass ratio. Although our data demonstrate a favorable effect of MK-7 on body fat mass and distribution, they do not prove that this is effectuated via cOC or ucOC. Alternatively, the increase of OC carboxylation and the changes in body fat composition may be epiphenomena that occur independently.

The current study must be interpreted within the context of its strengths and potential limitations. Strong points are the good compliance (95%) of participants and the long duration of the study (3 years). Our study also has a number of limitations. First, it was powered for bone strength and not for changes in body weight and fat mass. Second, no associations were found between the vitamin K-induced change in cOC and a number of biomarkers for fat and glucose metabolism, so that the mechanism underlying the observed effect of vitamin K on fat distribution remains unexplained. Finally, the data were obtained in healthy postmenopausal women aged between 55 and 65 years and may not be extrapolated to the general population (for example, men or children).

In conclusion, in this trial we demonstrate the beneficial effects of vitamin K supplementation on fat mass and body composition. Our data suggest that cOC rather than ucOC is a key component in the interplay between bone and energy metabolism, but the

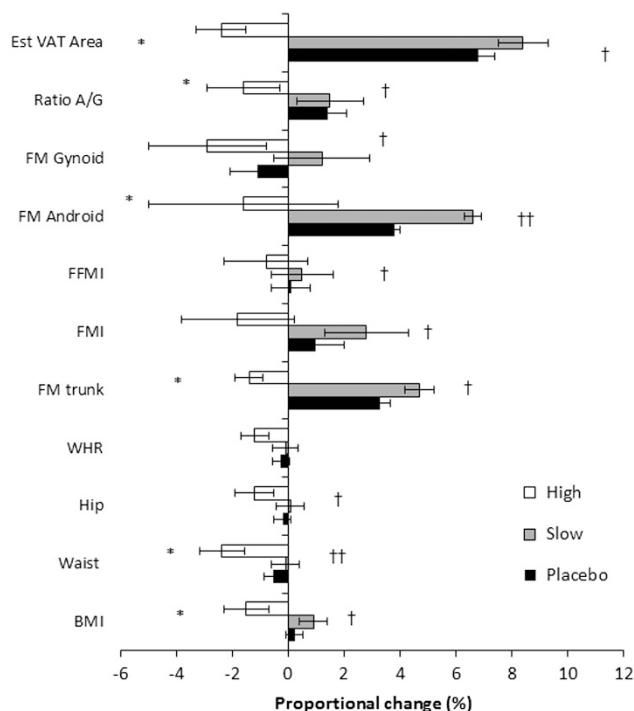

Figure 1. Proportional change of body composition variables in the placebo group and in the poor and good responders (as deduced from serum cOC increase). One-way analysis of variance was performed between placebo (black bars, $n = 107$), poor (gray bars, $n = 53$) and good (white bars, $n = 54$) responders to MK-7 treatment (increase of serum cOC < 0.92 ng/ml and ≥ 0.92 ng/ml, respectively). Bars represent mean proportional change with corresponding error bars (s.e.). * $P < 0.05$ relate to comparison between poor and good responders with placebo. † $P < 0.05$ and †† $P < 0.005$ relate to comparison between poor and good responders to MK-7 treatment. WHR, waist-to-hip ratio; Ratio A/G, ratio of FM android and gynoid region; Est VAT area, estimated visceral adipose tissue area.

precise mechanism underlying this effect remains to be determined in future studies.

CONFLICT OF INTEREST

The authors declare no conflict of interest.
