In this study, an anatase/rutile mixed-phase titanium dioxide (TiO₂) hierarchical network deposited with Au nanoparticles (Au/TiO₂ ARHN) was synthesized using a facile hydrothermal method followed by a simple calcination step. Such a unique structure was designed for improving the light harvest, charge transportation/separation, and the performance of photo-electro-chemical (PEC) cells. The properties of the as-synthesized Au/TiO₂ ARHN in PEC cells were investigated by electrochemical measurements using a three-electrode system in a 1 M NaOH electrolyte. Remarkably, a 4.5-folds enhancement of the photocurrent for Au/TiO₂ ARHN was observed as compared to that for TiO₂ nanowire (NW), under AM1.5G solar illumination, suggesting its potential application in PEC cells. A mechanism has been proposed to explain the high photocurrent of Au/TiO₂ ARHN in PEC water splitting.

Honda and Fujishima elucidated the possibility of water splitting using TiO₂ as electrode¹. Since then, various TiO₂ nano-architectonic topographies have been greatly desired for enhancing the performance of PEC cells^{2–8}. In general, a predominant PEC cell relies on two factors: the efficient usage of solar energy and the instant transportation/separation of charges⁹. Hence, the development of nano-sized photo-active semiconductors to satisfy the requirements has been a long-standing objective in the research of PEC cells, especially for one-dimensional TiO₂ due to its superior charge transport property¹⁰. To date, many hierarchical TiO₂ nanostructures based on nanowires (NWs) and nanotubes (NTs) have been synthesized for enhanced photo-electric efficiency in solar energy harvesting, conversion, and pollutant purification^{11–13}. Such a heterojunction nanostructure would stagger energy levels and scatter incident light to enlarge light absorption in the UV region¹⁴. However, the strategies for fabricating hierarchical TiO₂ nanostructures have the disadvantages of an extremely time-consuming process, specific/highly expensive fabricating apparatus and back-side illumination, thus making it economically non-competitive^{15–25}.

Recently, to expand the TiO₂ optical adsorption spectrum from the UV into the visible region, plasmonic electrodes composed of Au/TiO₂ nano-architectonic topographies have been developed with localized surface plasmon resonance (LSPR) property^{26–35}. However, most of these reports focus on the discussion of the relationship between particle size/shape/distance/concentration and the photo-electrochemical performance^{28–30,32–35}. Especially, one novel example of demonstrating the influence of TiO₂ nanostructure on the LSPR property was reported by Wang *et al.*³⁶. An Au/TiO₂/Au nanostructure with a 5-nm-thick TiO₂ middle layer was synthesized which resulted in a maximum 38-fold enhancement of the electric field density of LSPR and about 3-fold improvement of the photocurrent in a wavelength range of 400–650 nm. The enhanced performance is mainly arising from the thickness of TiO₂, satisfying the requirement for generating the coupling effect between the oppositely aligned and nearly touching Au NPs on TiO₂ nanosheet. However, the longer time (4 days) required to synthesize the TiO₂ nanostructures and the non-transparency of the Au/TiO₂/Au film limit their application. Furthermore, there is limited knowledge on how to design and synthesize a TiO₂ nanostructured film on a transparent substrate by a simple yet effective method. Therefore, the aim of this study is to provide a novel strategy for building a new TiO₂ nanostructure to intensify the coupling effect between Au NPs that significantly enhances the photoelectric conversion.

Herein, a three-dimensional (3D) web constructed by Au plasmonic NPs on TiO₂ anatase/rutile hierarchical network (Au/TiO₂ ARHN) is proposed, which is schematically shown in Fig. 1. In order to strengthen the

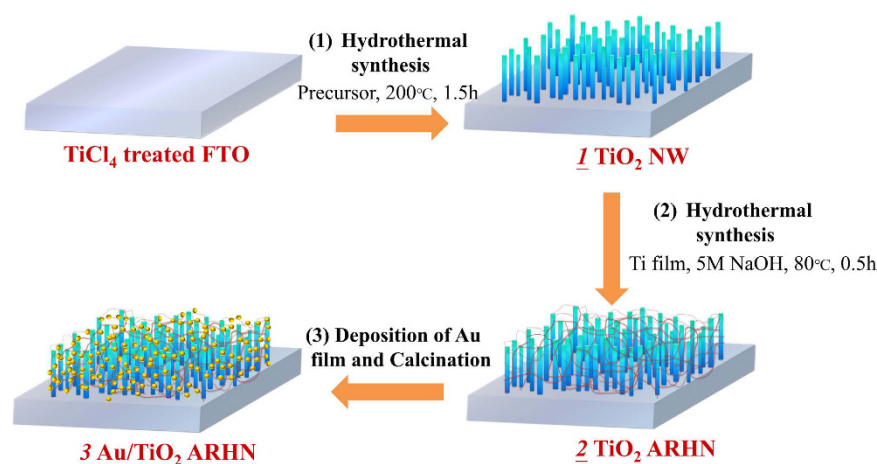

Figure 2. Schematic description of the synthesis process of TiO₂ NWs, ARHN and Au/TiO₂ ARHN on FTO substrates.

electromagnetic coupling of the Au NPs, the solid support—TiO₂ NWs connected with TiO₂ threads—was synthesized by a two-step hydrothermal process. When tested in the PEC experiment, the TiO₂ ARHN and Au/TiO₂ ARHN exhibited 1.5 times and 4.5 times higher photocurrent than TiO₂ NWs.

Results and Discussion

Figure 2 schematically depicts the three-step fabrication process of reproducible Au/TiO₂ ARHN. Figure 3a represents a top-view SEM image of the TiO₂ NWs. The light-gray needle-like regions in the SEM image represent the TiO₂ NWs and the dark regions are the underlying FTO substrate. A cross-sectional SEM image of the NWs (Fig. 3b) shows that the thickness of TiO₂ layer is ~1 μm and the NWs have an average diameter of 40 nm. XRD patterns of the TiO₂ NWs show predominantly rutile phase with preferential orientation of (110) (Supplementary Fig. 1). The top-view and cross-sectional SEM image of the TiO₂ ARHN (Fig. 3c,d) shows that the TiO₂ threads are bridged with the TiO₂ NWs to form a 3D hierarchical network. Nest-like porous cavities with diameters of a few hundred nanometers are clearly observed and the diameters of the threads are ~10 nm. The XRD patterns and Raman spectra show that the threads belong to the anatase phase (Supplementary Figs 2 and 3). The top-view SEM image of the Au/TiO₂ ARHN is shown in Fig. 3e. The white dot regions in the SEM represent the Au NPs. The size distribution histograms of Au NPs show an average particle size of 15 nm (Fig. 3f).

To investigate the formation mechanism of TiO₂ ARHN, a series of experiments were performed. Firstly, we failed to obtain TiO₂ ARHN without TiCl₄ treatment. We found that TiO₂ threads cannot grow on TiO₂ NWs with a smooth surface. Secondly, in the absence of the Ti film in step 2 (in Fig. 2), only TiO₂ NWs were observed. These findings suggest that both TiCl₄ treatment and the formation of the Ti layer for the formation of TiO₂ ARHN are indispensable. Therefore, we propose that small TiO₂ seed crystals grow on the surface of TiO₂ NWs after TiCl₄ treatment, which leads to a rough surface for the growth of TiO₂ threads. Moreover, during alkali

Figure 3. FESEM images. (a,c,e) top images of top TiO₂ NW, TiO₂ ARHN and Au/TiO₂ ARHN, respectively; (b,d) cross-sectional images of TiO₂ NW and TiO₂ ARHN; (f) the size distribution of Au NPs.

hydrothermal process, the Ti layers can generate large amounts of Ti-containing species^{37,38} as precursors that can deposit on the TiO₂ seeds and produce a network structure.

To evaluate the enhanced PEC performance of the designed Au/TiO₂ ARHN, the linear sweep voltammograms and the photocurrent-versus-time (I-t curve) of TiO₂ NW and TiO₂ ARHN with/without Au NPs were conducted under AM 1.5 G simulated solar illumination, as shown in Fig. 4. The measured photocurrent was normalized to the sample area to obtain the photocurrent density for comparison. As presented in Fig. 4a, the TiO₂ NW electrode produced a photocurrent density of $4 \times 10^{-5} \text{ A cm}^{-2}$ at 0.23 V vs. Ag/AgCl, which is the potential often chosen as a metric to evaluate the performance of photoanodes as it corresponds to the water oxidation potential⁴. The low photocurrent density is attributed to the limit of wide band-gap characteristics of TiO₂ (3.2 eV for anatase³⁹ and 3.0 eV for rutile⁴⁰), due to which only UV light can be used in the PEC water splitting system. The photocurrent was enhanced for the TiO₂ ARHN ($6 \times 10^{-5} \text{ A cm}^{-2}$) when compared with TiO₂ NW, with an enhancement factor of 1.5. As expected, a significant photocurrent density enhancement was clearly observed on the Au/TiO₂ ARHN, having a photocurrent density of $1.8 \times 10^{-4} \text{ A cm}^{-2}$. As compared to TiO₂ NW, a photocurrent enhancement higher than 4.5 times was achieved. From Fig. 4b, all electrode represent a good reproducibility and stability as the illumination was turned on and off. Furthermore, the sharp spike in the photocurrent during the on/off illumination cycles demonstrates the predominant transport of photogenerated electrons in the designed TiO₂ structure⁴¹.

Figure 5. UV-Vis spectra of desorbed N719 solution.

We suggest the enhanced photocurrent of TiO₂ ARHN electrode could be attributed to better photocatalytic activity, due to increased surface area, or better light harvest efficiency, due to the hierarchical network structure. Therefore, the dye absorption/desorption experiment and UV-visible spectrum measurement were performed to verify it. Here, dye N719 was chosen as an adsorbate to execute dye absorption/desorption experiment due to its monolayer adsorption on the surface of TiO₂. Therefore, we can evaluate the related surface area via measuring the absorption of N719 dye which detaches from the TiO₂ structure. As shown in Fig. 5, there are three absorption peaks of N719 located at 310 nm, 370 nm and 505 nm, respectively⁴². It is observed that the absorption of detached N719 solution based on TiO₂ ARHN is obviously larger than TiO₂ NW on the entire spectrum. This represents that the surface area of TiO₂ ARHN is larger than TiO₂ NW due to the larger amount of dye adsorbed on TiO₂ ARHN. Based on the result, we are confident that the high surface area of TiO₂ ARHN is a reasonable reason which brings about high photoactivity in PEC measurement.

Furthermore, the UV-visible absorption spectra of TiO₂ NW and TiO₂ ARHN with/without Au NPs are shown in Fig. 6. TiO₂ NW exhibits a stronger absorption at wavelengths below 400 nm due to electron transitions of TiO₂ from the valence band to the conduction band. In addition, the absorption spectra of TiO₂ ARHN showed enhanced absorption in the entire spectral range compared with TiO₂ NW, which is attributed to the scattering effect in the ARHN structure; this also explains the increased photocurrent in the TiO₂ ARHN. With deposited Au NPs, the absorption shows a significant enhancement in the visible range, which is driven by the LSPR absorption. From incident photon-to-electron conversion efficiency (IPCE) measurement (Supplementary Fig. 4), it demonstrates that such an absorption successfully boosts the PEC performance in the region from 400 nm to 700 nm.

In this work, a LSPR peak for the Au NPs with an average size of 15 nm centered at around 540 nm. For Au NPs of size 10–20 nm, the absorption peak of plasmon resonance is usually located at 520–525 nm^{43,44}. A redshift of 15–20 nm of the plasmon resonance peak was observed as compared to previous reports. This may be attributed to the TiO₂ changing the surrounding dielectric property of Au NPs (Au NPs well deposited and in contact with TiO₂ surface) and the enhancement of the electromagnetic field of LSPR^{30,45,46}. It has been reported that the high electromagnetic field of LSPR and strong coupling between Au NPs and TiO₂ will benefit the plasmon-induced charge transportation and separation, enabling SPR-enhanced photocatalysis. Typically, the LSPR-induced charge separation at the interface between the Au NPs and TiO₂ can occur by transferring the energy contained in the oscillating electrons or local plasmonic field from Au NPs to TiO₂ through direct electron transfer, also known

as hot electron injection^{47,48}. Higher electromagnetic field generates more hot electron^{49,50}. In order to verify our assumption, the design of TiO₂ ARHN is helpful to improve electromagnetic field as compared to NWs, the PEC measurement was performed to check the hot electron effect. Figure 7 shows the I-t curve measured under visible-light illumination. From Fig. 7, it is obvious that the photocurrent of Au/TiO₂ ARHN is two times higher than Au/TiO₂ NW. It means that the high plasmon electromagnetic field of Au/TiO₂ ARHN results in a high hot-electron current. Therefore, we confirm that the design of TiO₂ ARHN successfully provides a model for strengthening LSPR ability and demonstrates a remarkable enhancement on PEC performance.

In this study, we are further interested in the effectiveness of density effect and size effect on the performance of photo electrochemical property. The related data and discussion were shown in Supplementary Information. In addition, the stability test and Faradaic efficiency were obtained. Under continuously illumination for 10800 seconds (equal to 3 hr), the photocurrent density was decrease from 1.8×10^{-4} A/cm² to 1.5×10^{-4} A/cm² in the case of Au/TiO₂ ARHN, as shown in Fig. 8a. This photocurrent decay is similar to previous report⁵¹. We suggest it could be attributed to photo induced corrosion which competes with water oxidation reaction⁵¹. However, such a corrosion could be suppress by surface treatment of TiO₂ nanostructure or use of sacrificial reagent/catalyst for longstanding application⁵¹. From Fig. 8b, the calculated Faradaic efficiency exceed 90% and 85% for TiO₂ ARHN and Au/TiO₂ ARHN, respectively. The high value of Faradaic efficiency of oxygen gas during 10 hr demonstrated that the photo generated current indeed utilized for water oxidation. Also, we could observe hydrogen gas from real picture as shown inset diagram in Fig. 8c. Therefore, we propose the electron transfer mechanism in Au/TiO₂ ARHN system as shown in Fig. 8c. Under illumination, Au NPs absorb visible light, generating the energetic hot electrons from the process of SP excitation, and injecting them into the conduction band of the adjacent TiO₂ (green arrow). Simultaneously, the UV light is absorbed by TiO₂, producing a photo-excited electron and a hole (black arrow). The plasmon-induced electromagnetic field promotes the separation of photogenerated electrons and holes. Furthermore, as illustrated, the energy bands of anatase and rutile are different which provides a driving force to promote electron transfer from anatase to rutile (blue arrow). Finally, the electrons transferred to the cathode (Pt) react with H⁺ ions and produce H₂ (pink arrow) whereas the holes present in the anode oxidize H₂O and generate O₂.

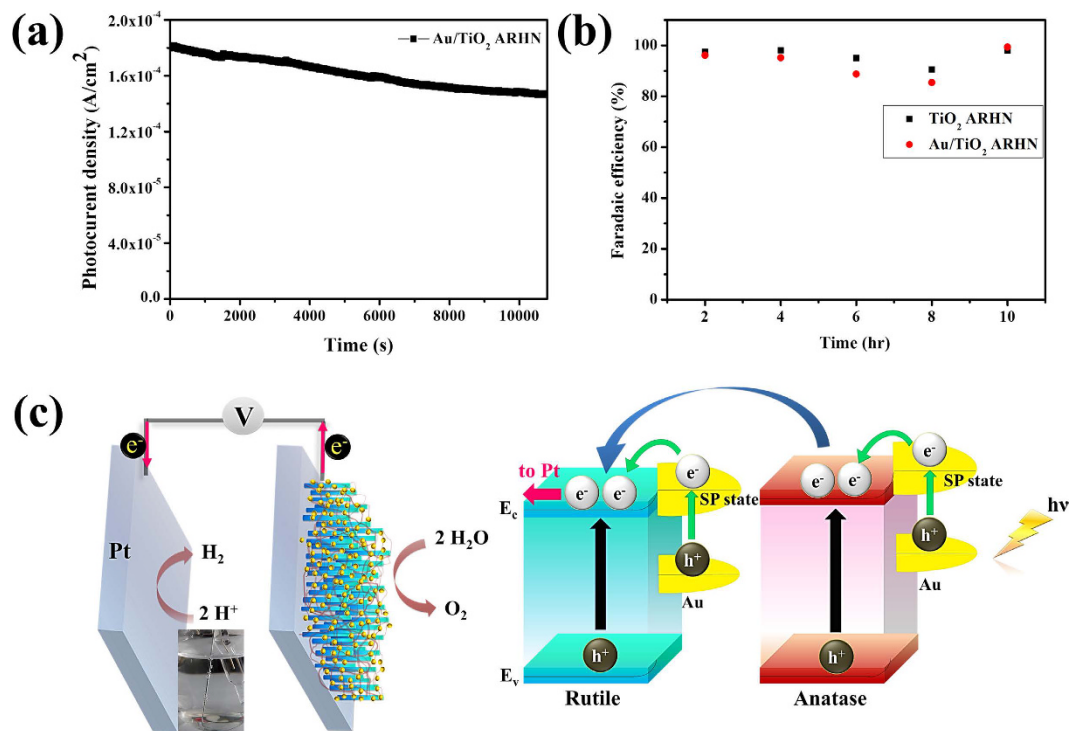

Figure 8. (a) Current—time curves of Au/TiO₂ ARHN collected in 1 M NaOH at 0.23 V vs Ag/AgCl under 100 mW/cm² for 3 h. (b) The calculated Faradaic efficiency for O₂ gas evolution. (c) Charge transfer mechanism of Au/TiO₂ ARHN under solar illumination.

In conclusion, this work demonstrates a plasmon-induced effect on a designed 3D web architecture constructed from rutile TiO₂ NWs, anatase TiO₂ threads and Au NPs. Such a nanostructure was achieved for the first time through a simple and inexpensive hydrothermal procedure followed by calcination. The PEC performance tests, reveal that the photocurrent of Au/TiO₂ ARHN was 4.5 times greater than that of the TiO₂ NW photoelectrode. The observed optical properties and dark current measurements confirm that the excellent PEC performance of Au/TiO₂ ARHN was due to three reasons: (1) the high surface area of TiO₂ ARHN that increase the photoactive center, (2) the scattering effect in the TiO₂ ARHN and the LSPR properties of Au NPs that enhanced the light harvest, (3) the strength coupling effect between Au NPs and TiO₂ nanostructure that accelerated the charge transportation and separation. The mechanism of charge transportation in the Au/TiO₂ ARHN was proposed based on our findings. Practical use of the Au/TiO₂ ARHN was demonstrated to indicate their significant potential for use in photoelectric conversion system.

Methods

Materials. F:SnO₂ (FTO) (1.5 cm × 3 cm, TEC-7, 7 ohm/sq., 2.2 mm thick) was used as the substrate for growth of the TiO₂ film. All chemicals were used without further purification. Sodium hydroxide (NaOH, 99%), titanium tetrachloride (TiCl₄, 99%), 2-butanone (C₄H₈O, >99%), hydrochloric acid (HCl, 12 M) and nitric acid (HNO₃, 65%) were purchased from Merck. Tetrabutyl titanate (C₁₆H₃₆O₄Ti, >97%) and ruthenium 535 bis-TBA (N719 dye) were obtained from Aldrich and Solaronix, respectively.

Hydrothermal synthesis of TiO₂ NWs on FTO substrates. First, FTO was cleaned by ultrasonic agitation in a mixture of ethanol, acetone and deionized water (volume ratio of 1:1:1) for 15 min. The FTO substrates were immersed in an aqueous of 0.5 M TiCl₄ at 80 °C for 30 min, followed by heat treatment at 500 °C for 30 min to yield a thin TiO₂ layer. The TiCl₄-treated substrates were then suspended in a reagent solution containing 6 mL HCl, 6 mL 2-butanone and 0.6 mL tetrabutyl titanate in a Teflon vessel. The Teflon vessel was sealed in an autoclave and heated at 200 °C for 1.5 h. Further annealing at 500 °C for 30 min resulted in the growth of crystalline TiO₂ NWs on FTO substrates⁵².

Hydrothermal synthesis of TiO₂ ARHN on FTO substrates. The TiO₂ NW substrate (without calcination) was first treated with TiCl₄ solution as mentioned above. A 200-nm-thick Ti layer was sputtered on the TiCl₄-treated TiO₂ NW using a magnetic sputter (K575X, Quorum Technologies). The substrates were then transferred to a Teflon vessel with the addition of a 5 M aqueous NaOH solution and were encapsulated in a stainless-steel autoclave. Then, the autoclave was heated at 80 °C for 30 min. After the low-temperature hydrothermal process, the substrate was rinsed with 0.1 M HNO₃ followed by deionized water, and was finally calcined at 500 °C for 30 min to obtain hierarchical nanostructures.

Synthesis of Au/TiO₂ ARHN. A 5-nm Au layer was sputtered on the TiO₂ NW and ARHN using a magnetic sputter. The Au deposited TiO₂ were subsequently calcined at 500 °C for 1 h to obtain Au/TiO₂ ARHN.

Characterizations and measurements. The surface and cross-section morphologies of samples were examined by field-emission scanning electron microscopy (FE-SEM, Zeiss Ultraplus). The SigmaScan Pro 5 software was used to calculate particle size (300 particles were counted). The crystal structure was characterized by X-ray diffraction (XRD, PANalytical X'Pert Pro MRD) and Raman spectroscopy (Tokyo Instruments, INC). A UV/Vis spectrometer (Perkin Elmer/Lambda 900) was used to obtain the absorption spectra. The dye absorption/desorption experiment was performed by desorbing a dye-sensitized TiO₂ electrode in a 0.1 M NaOH solution in 1:1 H₂O/EtOH⁵³. Subsequently, a UV-vis spectrometer was introduced to measure the absorbance of the desorbing solution. The electrochemical measurement was carried out using three-electrode system. TiO₂ electrode with or without Au NPs was the working electrode; an Ag/AgCl (3 M KCl) electrode in saturated KCl was the reference electrode; the Pt plate was used as the counter electrode. All PEC cells were examined in 1 M NaOH solution with a PARSTAT 2263 Advanced Electrochemical System under illumination by Newport solar simulator with AM 1.5 G (100 mW/cm²). The incident photon-to-current conversion efficiency (IPCE) was measured with an action spectrum measurement setup (Pecell, PEC-S20).

Acknowledgements

We greatly acknowledge financial support from the Ministry of Science and Technology of Taiwan (104-2113-M-005 -011 -MY3; 105-2811-M-005-020). We would like to thank Prof. Hao-Ming Chen from National Taiwan University for his cooperation in the measurement and calculation of Faradaic efficiency and Prof. Chen-Yu Yeh from National Chung Hsing University for his kindly help in the IPCE measurement.

Author Contributions

Y.C.Y. and K.J.L. conceived and design the project. J.A.C., S.O. and Y.S.C. conducted experimental work. Y.C.Y. and J.A.C. analyzed the data. Y.C.Y. wrote the main manuscript text. All authors discussed the results and reviewed the manuscript.
