Padoa-Schioppa, Tommaso (1940–2010)

Lorenzo Bini Smaghi

Abstract

Tommaso Padoa-Schioppa was a distinguished central banker and economist, a key player in the creation of Europe's single currency, a well-respected figure in international monetary policy-making and a former economy and finance minister of Italy.

Tommaso Padoa-Schioppa

Introduction

Born in Belluno (Italy) on 23 July 1940, Tommaso Padoa-Schioppa was an economist, a policy-maker and a citizen of Europe. A deep and complex personality, he pursued a Kantian quest for European unity, a mission to which he dedicated his professional and private life. He died in Rome on 18 December 2010.

The Economist and Policy-Maker

Padoa-Schioppa joined the Banca d'Italia in 1968. Italy's central bank, with its tradition of technical expertise and high standards of public service, was the obvious place to go for an economist wishing to serve his country. As a young economist working in the bank's research department, Padoa-Schioppa was keen to combine doing and understanding.

In the late 1960s the Bretton Woods system, which had given Italy a solid monetary framework, was showing signs of wear; the growth 'miracle' of the Italian economy was starting to lose momentum. The country had problems shaping an economic policy appropriate for those changing times: budgetary policy was slipping out of control and was set to turn into a burden for decades afterwards. Monetary policy, which was about to lose its exchange rate anchor to the dollar, was casting around for an alternative. Padoa-Schioppa saw the efforts to establish a

Macmillan Publishers Ltd (ed.), *The New Palgrave Dictionary of Economics*,

European monetary order not only as a chance to make decisive progress towards a unified Europe but also as an opportunity to help Italy overcome its economic problems in a sound and stability-oriented manner.

Padoa-Schioppa was influenced by some of the greatest post-war economists. Among them was Mundell, who, together with Hayek, discussed the ‘denationalisation’ of currencies. In his *Lectio Doctoralis* when he was awarded a *Laurea Honoris Causa* in International Economics of Trade and Currency Markets, in Trieste on 19 November 1999, Padoa-Schioppa argued that Mundell had sown the seeds which would complete the Treaty of Rome and established the theoretical foundations of the Maastricht Treaty. Triffin, with his book *Gold and the Dollar Crisis* (1960), also strongly influenced Padoa-Schioppa, as argued below.

Against this theoretical background, Padoa-Schioppa supported Italy’s membership of the European Monetary System (EMS), in spite of those who argued (with some reason) that Italy would have difficulty in complying with the exchange rate constraints of the EMS. He was, of course, aware of this, yet he did not want such an endeavour to start without Italian participation. Moreover, he believed that the so-called ‘monetarist’ view – whereby decisions taken on the exchange rate have effects on the conduct of monetary policy and on the economy – reflected the reality better than the so-called ‘economist’ view, according to which exchange rate constraints and a common currency could only be the climax of a perfect convergence of monetary policy and economic conditions.

These same ideas informed his action when he served at the European Commission from 1979 to 1983, the early years of the European Monetary System. There again, he faced an apparent trade-off between national and European forces and between monetary stability and a European monetary project. All his efforts as an economist and policy-maker were devoted to resolving these tensions and taking them in one direction – towards a European monetary endeavour that would bring monetary stability.

He took inspiration from the impossible trinity proposition, a corollary of the Mundell–Fleming model, which stated that a group of countries cannot simultaneously keep a fixed exchange rate, pursue autonomous monetary policies and maintain full capital mobility. In pursuing any two of these goals, the third one must be necessarily given up. The accomplishment of the central goal set down in the Treaty of Rome – a European common market, implying free trade and free capital movement – would inevitably call for enhanced, and eventually fixed, exchange rate stability across member countries. This is because exchange rate volatility, coupled with the systematic devaluation of a group of currencies against other currencies, would eventually impair the very functioning of the common market. Indeed, the whole history of European monetary cooperation between the collapse of Bretton Woods and the early 1990s is marked by attempts to maintain fixed exchange rates. These attempts were periodically punctuated by major tensions between national currencies (and consequently between Member States) each time a country was forced (or tempted) to devalue or even abandon the common fixed exchange rate arrangement. In this context, the economically most coherent way to reconcile intra-regional free trade and free capital movement with fixed exchange rates would be for European countries to adopt a single monetary policy and therefore a single currency floating against the rest of the world. In fact, Padoa-Schioppa preferred to talk about an ‘inconsistent quartet’ (*quartetto inconciliabile*), which included a fourth element, free trade, in order to take full account of the European context. In the early 1980s these ideas were still pioneering and visionary, but we all know how influential they have become in shaping the history of Europe, to the extent that they have transformed themselves from vision into reality. These ideas are contained in *Efficiency, Stability and Equity*, edited by Padoa-Schioppa and published in 1987.

Padoa-Schioppa followed the same course when he returned to the Banca d'Italia in 1984 and became Deputy Director-General, even if he had then to deal more directly with the continuing difficulties of Italian governance in respect of sound and stability-oriented macro policies.

While actively aiming to bring monetary stability to Italy and to move towards monetary unification in Europe, Padoa-Schioppa started working in payment systems – a relatively low-profile area. Before he took on responsibilities in this field at the Banca d'Italia, payment systems were not considered an independent (let alone a core) function of central banks. The activities carried out nowadays by payment system departments were largely non-existent at that time and performed mainly by IT departments and back offices.

Padoa-Schioppa provided the conceptual and economic rationale for a greater involvement by central banks in this area. A smooth functioning of payment systems is essential to ensure that money serves as a 'means of exchange', one of its key functions. Central banks came into being partly to ensure that this means of exchange remains adequate (i.e. confidence in the currency and its effective circulation). Central bank money is indeed universally recognised as the safest means of exchange and therefore as the ultimate way of discharging financial obligations. The smooth functioning of payment systems is also crucial for the effective conduct of monetary policy and financial stability.

Between 1985 and 1991, Padoa-Schioppa promoted and developed in Italy all the elements of an efficient and sound payment system. Under his guidance, the Banca d'Italia played a central role as an operator of settlement facilities, regulator and catalyst.

Padoa-Schioppa was the first person to use the word 'oversight' to describe the function to be conducted for payment systems, as opposed to '(banking) supervision'. He launched these activities before the Banca d'Italia was assigned formal specific statutory competence in this field. 'The function begets the organ and leads to the establishment of the legal basis', as he used to say, thereby acting as a catalyst. With hindsight, what Padoa-Schioppa did in Italy laid the foundations for the development of an analogous process at European level. His views on the role of central banks in payments systems can be found in particular in *The Euro and Its Central Bank*, published in 2004.

Padoa-Schioppa once again had a chance to be involved more actively in policy-making at European level when serving as secretary for the Delors Committee, which prepared the blueprint for the single currency in 1987–89. Although he was not a member of the Committee and, as such, was not supposed to intervene during the meetings, his personal relations with Jacques Delors and with Carlo Azeglio Ciampi, then Governor of the Banca d'Italia and a member of the Committee, as well as his role as 'rapporteur' allowed him to greatly influence the deliberations. It was an excellent opportunity to pursue his aspiration: a currency which was stable and which would significantly contribute to building the European Union.

In the 1989–91 negotiations that led to the Maastricht Treaty, Padoa-Schioppa fought to maintain the momentum towards monetary union which had been established by the Delors Committee. He feared that the decision to establish a temporary institution, the European Monetary Institute, instead of the European Central Bank, would be a critical mistake, also considering that a number of countries, including Italy, had ceased to conduct policies which were sufficiently stability-oriented.

The historic project of monetary unification came close to failure with the repeated exchange rate crises in the first half of the 1990s. But Europe's efforts eventually succeeded. In the 1993–97 preparatory work for the launch of the euro, Padoa-Schioppa had yet another chance to show his unique ability to build a strong conceptual, analytical and policy framework (the 'vision') on the one hand, and to implement a concrete set of measures and actions to turn the vision into reality on the other hand. His thoughts on the issue are summarized in *The Road to Monetary Union in Europe*, published in 1994, with the stimulating sub-title 'The Emperor, the Kings, and the Genies'.

In the field of financial stability, Padoa-Schioppa was convinced that in a single market, and even more so within a single currency area, the supervisory framework had to be as convergent as possible, entailing a transfer of supervisory responsibilities from national to EU level. He regarded the convergence of supervisory rules and of supervisory practices through enhanced cross-border cooperation as intermediate steps towards the final objective. It was he who coined the term 'EU supervisory rulebook' and, moreover, he was the founder of the Forum of European Securities Commissions, which promoted cooperation in the securities field. In his view, cross-border supervisory cooperation should be so strong and effective that the collective behaviour of supervisors would appear as a single effort. All these ideas started to take shape with the establishment of the Lamfalussy Committee, whose main purpose was to enhance supervisory convergence and cooperation. But his ideas have only been fully realised recently, with the setting-up in of three new European Supervisory Authorities (ESAs) as part of the European System of Financial Supervision, in January 2011.

Padoa-Schioppa was also convinced that central banks should play a key role in ensuring financial stability, as suggested in his 2004 book "Regulating Finance". Such a role should go beyond managing the risks incurred by individual financial institutions, a task performed by supervisors, and entail monitoring, controlling and managing the risks to the financial system as a whole (what is now commonly referred to as systemic risk). He essentially anticipated the issues which eventually came to the fore in the wide policy debate stemming from the financial crisis under the heading of macro-prudential supervision. This debate eventually led to the establishment of the European Systemic Risk Board.

He promoted these ideas in particular when he became Minister of Economy in the Italian government led by Romano Prodi (2006–08). As a Minister, Padoa-Schioppa found his country in a difficult situation. For a decade, its growth performance had been very disappointing, well below that of its main partners; Italy had also failed to maintain the progress in controlling public finances that it had achieved in the mid-1990s, in the run-up to the euro: the primary surplus, which had reached over five per cent of GDP, had been wiped out; public debt was on the rise again.

Padoa-Schioppa's three-pronged strategy – to pursue simultaneously the complementary objectives of stability, growth and social equity – soon became the manifesto of the government's economic policy. A programme of rigorous fiscal consolidation was in his view essential to revitalise the economy. He tried to instil a sense of urgency, in an often hostile political environment. In this field too he proved to be a reformer: he launched an ambitious spending review to overcome the purely incremental, history-dependent approach that dominated the political decisions on Italy's public budget. The objective was to reduce the quantity, and increase the quality, of public expenditure ("spend less, spend better"), by modifying the organisation of public administrations and their local branches, revising their structure according to the new needs, eliminating obsolete programmes and reconsidering the priorities, costs and ways of providing public services. The way forward was, in his words, "to promote excellence, by showing that there are already good practices in the country" so that it would become manifest that "we do not demand the impossible".

He largely succeeded in reversing the trend in public finances, attaining a significant reduction of the public deficit (from above four per cent of GDP in 2005 to below two per cent in 2007) and bringing the public debt-to-GDP ratio back on a downward path. This policy was unavoidable to get Italy out of its emergency situation; it was, for a country as indebted and under-capitalised as Italy, the only way forward to free up resources to invest in the future, in human and physical capital (infrastructures, education, research, environment) and to kick-start the Italian economy on a growth path again. His efforts concentrated primarily on the refinancing of infrastructural investments, an area where resources had completely dried up, and on reducing tax on labour and corporate income.

His brief spell as a Minister, coupled with the difficulties of a coalition government with a tiny majority in Parliament, prevented Padoa-Schioppa from exerting the more profound influence he would have been capable of. But his sense of direction and, especially, his determination to confront the problems of the Italian economy from a collective viewpoint and with a longer-run perspective than the country was used to, are still crucial points of reference for today's policy-makers.

In international relations, Padoa-Schioppa was convinced that the euro should gradually develop its role and policy at the global level: it owed this to its 'domestic constituency' as well as to the international community, as monetary unification in Europe could play an important role by enhancing global policy cooperation. In this area too, Padoa-Schioppa was a fervent advocate of the national central banks of the euro pooling their forces, acting as a system and playing a role consistent with the institutional mission and interests of the Eurosystem. His belief in international cooperation was founded on the conviction that there are, on the global agenda, many economic issues – including trade, finance, global imbalances, energy and the emergence of new global and regional players – whose scale and complexity call for policy efforts that go beyond national borders and make cooperation at global level desirable and feasible.

In the same spirit, Padoa-Schioppa considered it erroneous to believe that the euro and full national sovereignty were compatible. Indeed, he was critical of the notion of 'euro without a state'. In an increasingly globalised world political power cannot be concentrated in a single entity. This lesson is extraordinarily concrete and modern: Padoa-Schioppa was of the opinion that more integration is needed in domains ranging from fiscal policy to financial supervision.

Padoa-Schioppa belonged to that group of personalities who played a decisive role in shaping international cooperation. He contributed to formal and informal group discussions at global level, but also worked on a bilateral basis with countries, institutions, and people from Africa, Asia, Latin America and from the Mediterranean countries.

While Minister, he chaired the International Monetary and Financial Committee of the IMF, and played a key role in the process that eventually led to the reform of the quota and voting system of the IMF (finally adopted in April 2008). This brought the distribution of voting power more closely into line with the changing size of the member economies and resulted in better representation of the poorest countries.

In the performance of his international functions, Padoa-Schioppa was greatly influenced by J.M. Keynes and Robert Triffin. He argued that the 'Triffin dilemma' is still unresolved: if the main international standard and reserve currency is a national one there is an unresolvable incompatibility between domestic needs (in the short term) and global policy needs (in the long term). This incompatibility led, over time, to the collapse of the Bretton Woods system in the late 1960s and early 1970s. It was not resolved either under the US dollar-based non-system that took its place: a market-led system without a clear anchor. Over the last 10–15 years this has been referred to as Bretton Woods II. However, Padoa-Schioppa noted that 'exchange rates were determined by a bizarre combination of market behaviour and of policy actions vis-à-vis the dollar. Floating European currencies, including the euro, were at the mercy of a market prone to prolonged misalignments. Asian currencies were largely sheltered from the vagaries of the market and subjected to intense management by the national authorities'.

During his last years, Padoa-Schioppa became actively involved in an initiative of the Triffin International Foundation, which is based in Louvain-la-Neuve (Belgium). In his speech 'The Ghost of Bancor: the Economic Crisis and Global Monetary Disorder', given in Louvain in February 2010, he revisits the arguments proposed by Keynes in 1943 for a new international monetary system and eventually a world currency called Bancor.

The Legacy

Padoa-Schioppa's legacy as an economist, policymaker and citizen consists of at least six distinctive elements.

The first and most obvious is his faith in Europe. He saw Europe as a continent of peace, a 'gentle' force searching for its shared roots and a way to overcome problems that, if approached nationally, might retrigger the divisions and horrors of the past. Europe was always the focus, even when its representatives or actions did not deserve it. Padoa-Schioppa's Europe was an aspiration and an ideal, much bigger and longer lasting than the individuals that may at any given time symbolise it. His views can be found in particular in *Europe, a Civil Power*, published in 2004.

Padoa-Schioppa's approach to Europe was shaped by his views on federalism. He saw federalism as a constitutional system that owes a lot to the idea of *minimum government*, in the tradition of Locke and Tocqueville. According to his *Weltanschauung*, federalism would complement what he calls the 'horizontal division' of government functions – legislative, executive, judicial – with a 'vertical division', whereby government powers are distributed along all relevant levels. Such levels range from the village to the nation-state, from a regional arrangement to the whole world based on the principle of subsidiarity. This is the rule that 'the functions of higher levels of government should be as limited as possible and be subsidiary to those of lower levels' ('Economic Federalism and the European Union').

The second element of his legacy is that the future development of the Union can and will probably be built on the 'solidarité de fait' created by economic interdependence. Padoa-Schioppa was fond of reminding people that it was a single article in the US constitution – the one regulating inter-state commerce – that was used to lay the foundations for the federal government to have a significant role in US economic policies. But solidarity must go hand-in-hand with responsibility, and Europe's common destiny requires a reinforcement and a clarification of the rules of the game.

The third element in his approach to European and other issues was his faith in institutions. Only institutions (whether simple gatherings or forums, or formal debating and decision-making groups, up to structured organisations with physical premises) give continuity and strength to human efforts and aspirations that are, by nature, transient and mortal. 'Nothing is possible without humans, nothing is lasting without institutions', Jean Monnet wrote. The role of institutions in framing the operation of financial markets is well described in his BIS Per Jacobsson lecture given in June 2010, with the title 'Markets and government before, during and after the 2007–20xx crisis'.

The fourth key element is his approach to economics. There is no doubt that Padoa-Schioppa was an economist of the highest order: his early studies at MIT with Franco Modigliani, his outstanding scholarly publications, and his constant use of sophisticated economic thinking bear witness to this. But there is likewise no doubt that Padoa-Schioppa was a particular economist, unique in his own way. Economics was not for him an intellectual exercise in which implications are drawn from axioms through deductive logic. It was a method to analyse problems and to devise solutions that should constantly be tested in real life and discarded, if necessary, in a Popperian sequence. Economics should adapt to circumstances – not the other way round.

Padoa-Schioppa displayed his brilliant economic intuition on many occasions. In his article in *International Finance* entitled 'The crisis in perspective: the cost of being quiet' he described, already in 2008, the salient features of the crisis that surfaced only a year earlier. He placed the bursting of the housing bubble in the USA in an international context, linking it with domestic and foreign imbalances.

His clashes with doctrinaire economists (often classical, but not always) are proverbial. His view on the role of exchange rates as an instrument for adjusting economic imbalances turned out to be central to his career. The doctrine, for which several Nobel Prizes have been awarded, is that exchange rates are, in a wide variety of circumstances, an easier and less painful way to correct accumulated disequilibria among countries than changes (notably, reductions) in nominal wages and prices at national level. Not for Padoa-Schioppa. He viewed exchange rate variability, with the possibility of competitive devaluations and currency wars that it entails, as a fundamentally uncooperative and undesirable way to settle economic divergences, hence his preference for monetary cooperation and ultimately monetary union, in Europe and elsewhere. To be durable, cooperation was to be supported by institutions, notably central banks.

The fifth element of Padoa-Schioppa's thinking and practice consists of his conceptions of central banking and his actions as a central banker. This is the area to which he devoted most of his professional life. He did not start his career as a central banker – he often joked, particularly with those he considered not concrete enough, about his early job as a clothes seller – but in the end he personified the quintessential and all-round central banker as nobody else did, though always in an original way. He viewed central banks as complex and multi-faceted financial institutions pursuing the public good along several interconnected paths. It is the polar opposite of the notion of a single-minded and ring-fenced authority regulating interest rates just to achieve stable prices. Price stability is key, but should be filtered through a broader notion of monetary, financial and economic performance. And it should never be attained – typical of modern macroeconomic models – by simplistic decision rules, by some kind of autopilot. The strategy and transmission of monetary policy cannot abstract itself from the interconnections between the financial system as a whole, from the money markets where short-term assets are bought and sold, or from the payment system, through which money is exchanged for goods and services.

The last, but not least, component of his legacy concerns his profound trust in human beings: Padoa-Schioppa invested heavily in younger collaborators because he firmly believed that only by bringing the people of Europe closer together would there be a better world. At the end of his term as Executive Board member of the European Central Bank in 2005 he gave his colleagues and collaborators a paperweight made of Murano glass, on which he had had engraved the caption of a drawing by Goya which he found in the Prado showing a doddery old man, but one who is eager to keep on learning. The engraving reads, in Spanish, 'Aun aprendo', which means 'I am still learning' – reflecting his approach to life.

Palander became an engineer at the Royal College of Technology in Stockholm, before studying economics at Stockholm University. He published his dissertation *Beiträge zur Standortstheorie* (Contributions to Location Theory) in 1935. He was appointed Professor of Economics at the Business School of Gothenburg in 1941 and at Uppsala University in 1947. The dissertation is a standard reference in location theory; it was never published in English, though a Japanese edition was published in 1984.

Chapters III–X of the *Beiträge* contain a very detailed discussion of spatial economics from the classics to recent developments up to the date of Palander's own contribution. The Ricardian and von Thünen land rent theories, the Launhardt-Weber theories of location and market area formation are penetrated, and the spatial facets of Hotelling's and Chamberlin-Robinson's then fresh monopolistic competition theories are for the first time given due regard. Palander aims at an integration of classical location and land use theories with modern developments in general economics. Bringing in profit maximization under price-dependent demand and the possibility of spatial monopoly is one step in this direction. Another is the stress on the importance of factor substitution. Palander is extremely critical of Andreas Predöhl's attempts in this direction. His own planned contribution was withdrawn from the manuscript just before its publication, and the problem first got a satisfactory solution with the contribution by Leon Moses in 1958.

Palander's most original contributions are contained in Chapters XII–XIV. The central theme is to extend the classical models, where transportation is assumed to be along straight lines, to more realistic situations where transport rates are distance dependent, or traffic crosses different media, like land and sea. In the last context, the neat refraction law of traffic was discovered. These contributions set the stage for Martin Beckmann's (1952) continuous model of transportation.

One of the most attractive features of Palander's work is the artwork, which must be considered unsurpassed until the advent of computer graphics. Palander brings graphical analysis combined with simple algebra and analysis to perfection.

Palander remained in the USA as a Rockefeller Fellow during 1936, studying Chamberlin's monopolistic competition theory. His own contributions are a brief abstract in English of a presentation at the Cowles Commission conference at Colorado College 1936 (‘Instability in Competition between Two Sellers’) and an article in Swedish, ‘Konkurrens och marknadsjämvikt vid duopol och oligopol’ (‘Competition and Market Equilibrium in Duopoly and Oligopoly’), published in *Ekonomisk Tidskrift* (later *Scandinavian Journal of Economics*) in 1939. Palander’s particular interest was the stability of adjustment processes in classical Cournot and similar types of duopoly.

Palander belonged to the informal group of economists called the ‘Stockholm School’ and wrote an extensive critical review of their methods, ‘Stockholmsskolans begrepp och metoder’ (1941). Palander’s remarks concern in particular the lack of rigorous dynamic analysis.

Palander took a great interest in Keynesian macroeconomics. He edited a translation of the *General Theory* into Swedish in 1945 (*sysselsättningsproblemet*), with commentary, and wrote an extensive mathematical and graphical analysis of the work in 1942. This article, in comparison to the similar works by Hicks and Klein, contains a thorough analysis of all the different variants with the relations expressed in monetary, real and wage units.

Palander’s later work was mainly pedagogical, and his last research interest concerned monetary theory in connection with choice under uncertainty. He wrote a monograph (in Swedish) on the effects of index bonds upon an inflationary economy in 1957. Among his consultancies the most important was to the Swedish Railway Board on fare tariff policy.

Paley, William (1743–1805)

A. M. C. Waterman

Abstract

The whole of Paley’s contribution to economics is contained in a single chapter of *Moral and Political Philosophy* (1785). The object of ‘rational politics’ is to maximize ‘happiness’, and Paley argued that this is achieved by maximizing population. Population is determined by the total supply of ‘provisions’ produced by the agricultural sector. The demand (and hence supply) for ‘provisions’ and for ‘luxuries’ are reciprocally determined. As in Mandeville, the taste for ‘ luxuries’ stimulates production. But it also acts in the opposite direction because it deters population. Paley explicitly recognised the optimization problem and was the first economist to do so.

William Paley was one of the most powerful influences upon intellectual life in Britain and America from 1785 until the late 1850s. J. M. Keynes (1972, p. 79 n. 2) judged that 'Perhaps, in a sense, he [Paley] was the first of the Cambridge economists.' Paley's demand-led analysis of the determination of total output was in some respects even more 'Keynesian' than Malthus's heterodox macroeconomics of 1820; and it may have been this that earned Keynes's approval in 1933 when he was beginning to excogitate his *General Theory of Employment, Interest and Money* (Keynes 1936).

Paley's Life and Work

William Paley was a Yorkshire man, and was mildly derided at Cambridge for speaking Latin with a Yorkshire accent. He was born in Peterborough in July 1743. His father, the Revd William Paley, was then a Minor Canon of Peterborough, but was appointed Master of Giggleswick School in 1745, whereupon the family returned to Yorkshire. Like his father, the younger William went up to Christ's College, Cambridge, matriculating in 1759 and graduating BA in 1763 as senior wrangler [= highest performance among all Tripos candidates, who by that time were required to attempt a written examination in mathematics in addition to the five Latin disputations]. He was elected fellow of Christ's in 1766 and ordered deacon. In 1767 he was ordained priest and graduated MA. He was awarded the degree of Doctor of Divinity in 1795.

For ten years after election as fellow Paley occupied various college offices and played a large part in teaching undergraduates. At that time this was almost entirely conducted in colleges by college lecturers and tutors. Attendance at college classes was compulsory. All undergraduates faced a common curriculum designed to prepare the next generation of clergymen, magistrates and legislators for their public duties in a Christian society: biblical languages and literature, the Latin and Greek classics, and some reading in 'moral and political philosophy'. The small minority of ambitious students who sought an honours degree supplemented these studies with Newtonian 'natural philosophy' and mathematics. Paley was soon known throughout Cambridge as a superb teacher, and many students came from other colleges to attend his lectures. A later commentator wrote of Paley's 'utter inability to be obscure' (Annan 1984, p. 244). In all probability he taught the entire curriculum, with the possible exception of the classics, in addition to mathematics and natural philosophy for honours candidates.

In 1776 Paley was preferred to the rectory of Great Musgrave, Westmorland, and thus was at last able to marry, resigning his fellowship as was then required. His wife, Jane Hewitt of Carlisle, bore him 10 children, two of whom died in infancy. He remained in the diocese of Carlisle for the rest of his career, where his energy and efficiency soon led to promotion as Archdeacon (1782) and Chancellor (1785). But he also held benefices later in the dioceses of Lincoln and Durham, and in 1796 moved to Bishop Wearmouth in Durham whilst remaining Archdeacon of Carlisle. He was exemplary in parochial and diocesan duties, a leader in the campaign to abolish the slave trade, and active in promoting education of the poor. His first wife having died in 1791, he married Catherine Dobson of Carlisle in 1795. Paley died on 15 May 1805 after a lingering and painful illness, during which he completed his last book. He is buried in Carlisle cathedral.

Soon after leaving Cambridge his friends urged him to write up his college lectures. He began with *Moral and Political Philosophy* (1785) which brought instant fame and fortune. It was almost immediately adopted as a required text for all undergraduates at Cambridge, going through 20 English editions by 1814 (15 in Paley's own lifetime) and 10 American editions by 1821. In the USA it remained ‘the most popular text on moral philosophy from the 1790s to the Civil War’ (Haddow 1939, p. 67). Paley followed this success with two books on the New Testament: *Horce Paulina* (1790) and *Evidences of Christianity* (1794), the second of which led both to his doctorate and to valuable preferment amounting to nearly £2,000 a year. His last book, *Natural Theology* (1802), was a characteristically 18th century attempt to demonstrate the existence and attributes of God from the evidence of His work in nature: in this particular case, biological nature. Sidestepping David Hume’s sceptical critique of teleology (McLean 2003), Paley filled his book with detailed and well-informed examples of biological adaptation as evidence of ‘design’.

Paley said that his books had been written in the reverse order of that in which they should be read. *Natural Theology* established the scientific grounds for belief in God. *Evidences* and *Horce Paulina* showed that Christianity was definitive. *Moral and Political Philosophy* expounded the social and political norms of a Christian society. Thanks to Paley, the Anglophone intelligentsia – unlike their counterparts on the Continent – largely took Christianity for granted down to the 1850s. But the appearance of Charles Darwin’s work on evolution suddenly changed all this. Adaptation was no longer evidence of design, hence Paley’s entire structure fell to the ground. Sales of his books dried up. During the decade of the 1860s ‘Christian dogma fell away from the serious philosophical world of England, or at any rate of Cambridge’ (Keynes 1972, p. 168).

Intellectual Context of Paley’s Economic Analysis

Since there can be no obligation to do that which is unfeasible, moral and political philosophy must entail some positive investigation of the economic and social circumstances to which normative principles apply. Therefore an element of what we now call ‘economic analysis’ is often to be found, implicit or explicit, in all expositions of political philosophy, at least since Plato’s *Republic*.

By the 18th century a great deal of what became ‘political economy’ in the 19th century and ‘economics’ in the 20th had begun to circulate in informed circles in France and Britain, and the outlines of a common body of knowledge can be identified. (1) Agriculture normally affords more food than is necessary to feed those who produce it. (2) The cost of production – of food as of all other commodities – will not normally be incurred unless there is an expectation of an adequate return: ‘effectual demand’ is thus a necessary condition of production. (3) Since manufactured goods need inputs from agriculture (food to sustain manufacturers), an urban manufacturing sector can provide a demand for the agricultural surplus. (4) In the same way, a rural agricultural sector can provide demand for a manufacturing surplus, hence the two sectors are mutually sustaining. (5) Labour needed in production is produced by human beings supplied with food (and manufactured necessities). A certain average per capita income of food and other necessities will keep population and workforce constant. At a higher income these will grow and vice versa.

Though it is evident that Paley was familiar with these ideas, and indeed made them the focus of his own analysis, he gave us no help in discovering his sources: ‘I have scarcely ever referred to any other book, or mentioned the name of the author whose thoughts, and sometimes, possibly, whose very expressions I have adopted’ (Paley 1825, p. xiv). In addition to the common core associated in particular with Mandeville, Cantillon, Quesnay and Adam Smith, Paley is seemingly aware of many other elements of 18th century economic thought to be found in Locke, Hume, Berkeley, Steuart and Josiah Tucker. Yet only Berkeley’s ‘walls of brass, fifty cubits high’ appear with attribution (as they do in Malthus). What Paley seems not to know about, or at any rate not to think important enough to teach his under graduates, are (a) price theory as found in Adam Smith, (b) general equilibrium in competitive markets as pioneered by Boisguilbert, and (c) the virtues of *laissez-faire* as taught by the Physiocrats. The last is in marked contrast to his clerical predecessor, the Revd Josiah Tucker (1713–99), whose praise of the self-regulating market economy was later echoed by Smith.

Although Paley's lectures were prepared before the appearance of *Wealth of Nations* in 1776 (the year he left Cambridge), the occurrence of certain passages in *Principles* which read like summaries of Smith's work suggest the possibility that Paley did read it sometime between 1776 and 1785. Paley's remark that population may double in twenty years is found in Smith (1976, p. 479). His account of money, property and power (1785, p. 604) could be a digest of a similar argument in Smith. Adam Smith's famous trio, 'the butcher, baker, brewer' crops up in Paley, as does the assumption that 'the only spring which keeps human labour in motion' is 'the exclusive right to the produce' (Paley 1825, pp. 493, 489). However, any conclusion on the basis of such evidence can only be conjectural.

Paley's Economics

A single chapter of *Principles,* 'Of Population and Provision; and of Agriculture and Commerce as subservient thereto' (Paley 1825 part VI, chap. XI) contains the whole of Paley's economic writing. The most original features are its explicitly utilitarian basis and its careful analysis of optimality.

Paley's *Principles* was virtually simultaneous with Bentham's *Morals and Legislation* (1789). The two were the first to popularise utilitarian arguments in Britain and the latter is sometimes characterized as 'Paley with God left out'.

Paley's 'economics' chapter begins: 'The final view of all rational politics is the greatest quantity of happiness in a given tract of country' (Paley 1825, p. 477). Since 'communities' etc. are mere abstractions 'nothing really exists or feels but individuals'. In any society some will be happier than others, but Paley assumed that the happiness of individuals is additive and may be aggregated, and that the range and distribution of happiness is independent of scale. Hence 'twice the number of inhabitants will produce double the quantity of happiness' (Paley 1825, p. 478). It follows that the happiness of a community or district is proportional to its population, hence *that the object of 'rational politics' is to maximize population.*

Paley assumed that the human food requirement is biologically given and that human populations expand to the limit set by food supply. Hence the policy goal becomes that of maximizing 'provisions'. The production of 'provisions' is determined by aggregate demand: the sum of demand for food by food-producers themselves, by personal servants employed by their landlords, and by the producers of other goods which Paley labelled 'luxuries'. Similarly, the production of 'luxuries' is determined by the sum of the demand for luxury goods by luxury goods producers and by the producers of food. Social arrangements exist for the 'exchange' of food and luxuries. In a sophisticated version of Mandeville's doctrine, Paley explained that luxury stimulates employment and industry: 'The watchmaker, while he polishes the case, or files the wheels of his machine, is contributing to the production of corn as effectually, though not so directly, as if he handled the spade or held the plough' (Paley 1825, p. 496).

Outputs of 'provisions' and 'luxuries' are determined at equilibrium by the reciprocal demands of each sector for the other's product. Population (and therefore happiness) is determined at equilibrium by food production. The policy problem is therefore to identify the factors which determine equilibrium, and to operate where possible on those which increase production of 'provisions'. Paley abstracts completely from all supply constraints: his is a purely demand-driven model, which may explain why Keynes found it so congenial (Waterman 1996, pp. 681–3).

Given production techniques and the biological food requirement, the determinants of equilibrium are the size of landlords' rents and the taste of the whole population for 'luxuries'.

Since Paley is unaware of, or abstracts from, diminishing returns, he has no theory of rent. But he argued strongly for private property in land and for social arrangements that would give landlords an incentive to maximise rent (Paley 1825, pp. 489–90, 516–19). Landlords are assumed to spend all their rents on personal services, thus supporting an unproductive population and contributing to the demand for ‘provisions’.

The taste for luxuries is an important determinant of aggregate demand, but here Paley takes a large step beyond Mandeville. For it is also the case that a taste for luxuries may operate in the opposite direction to *reduce* population. In a passage that is almost certainly the chief source of Malthus’s concept of the ‘preventive check’, Paley remarks that ‘men will not marry, to *sink* their place or condition in society’ (Paley 1825, p. 485). An increase in luxury makes ‘the usual accommodations of life more expensive’ and raises the cost of ‘the established mode of living’ (Paley 1825, pp. 485–6). Marriage and family formation are deterred, so tending to reduce the population and workforce. For Malthus and his successors, luxury works against population. For Mandeville, luxury stimulates population. Paley is unique in recognizing both these effects.

As befitted a senior wrangler well trained in Newtonian ‘fluxions’ [= differential calculus], Paley also recognized what Malthus (1986, p. 102), himself a wrangler, later identified as ‘the problem of *de maximis* and *de minimis* in fluxions, in which there is always a point where a certain effect is the greatest, while on either side of this point it gradually diminishes’. Thus Paley (1825, p. 486) observed that ‘*luxury*, considered with a view to population, acts by two opposite effects; and it seems probable that there exists a point on the scale, to which luxury may ascend ... beyond which the prejudicial consequences begin to preponderate. Though this ‘arithmetical problem depends on circumstances too numerous . . . to admit of a precise solution’, a formal mathematical reconstruction of Paley’s implicit model can be made and conditions specified for maximization of population (Waterman 1996, pp. 677–80, 685). Paley seems to have been the first analyst in the history of political economy to have recognized clearly that optimization lies at the heart of scientific economic thinking.

Paley’s analysis of the reciprocal demand of ‘provisions’ and ‘luxuries’ was supplemented by consideration of technical progress (‘the abridgment of labour’ by ‘mechanical contrivances’), and of the effect of a ‘continual increase’ in the money supply that seems obviously derived from Hume. The immediate effect of technical progress appears from the reciprocal-demand model to be to diminish ‘provisions’ and population. But Paley argued that ‘some more general and remoter consequences’ may ‘increase the demand for work’ (Paley 1825, p. 514) and hence that employment and output will rise on balance.

Palgrave was born in London, the third of four male children of Francis Palgrave and Elizabeth Turner. He was named after Robert Harry Inglis – an Old Tory, Member of Parliament, and a friend of Palgrave's father. Quite incidentally, this R.H. Inglis edited some works by the economist Henry Thornton. Palgrave was denied the formal education provided for his two elder brothers, instead entering the banking business of Gurney & Co. (in which his maternal grandfather had been a partner) in Great Yarmouth at the age of 16. Palgrave himself subsequently became a partner in the bank, and married in 1859 a daughter of Mr George Brightwen, who was related to the Gurney family.

Family

Palgrave's father was born Francis Cohen in 1788, the son of Meyer Cohen, member of the London Stock Exchange during most of the years that the Ricardo's were members. Francis Cohen altered his name to Palgrave in 1823 upon marriage to Elizabeth Turner – Palgrave being Elizabeth Turner's mother's maiden name. She, in turn, was the daughter of Dawson Turner, a partner in the English country bank Gurney & Co. in Great Yarmouth. Sometime during the second decade of the 19th century, Francis Cohen renounced the Jewish faith and embraced the Christian religion in the form of the teachings of the Church of England. He was a medievalist of some repute, publishing *The Rise and Progress of the English Commonwealth* in 1832, and *The History of the Anglo-Saxons* in 1837. He was Deputy Keeper of H.M. Public Records, was knighted in 1832, and his literary friends included Macaulay and Henry Hallan (who Palgrave was to quote to moving effect in his editorial preface to the final volume of his *Dictionary*).

His first son, Francis Turner Palgrave (1824–1897), is still widely known today for his famous *Golden Treasury of English Lyrics and Verse*, the first edition of which appeared in 1861. He was educated at Charterhouse and Balliol College, Oxford, going up in 1843, and in 1846 acted as assistant private secretary to Gladstone. Between 1850 and 1855 he directed a government teacher training college near Twickenham. Thereafter he was engaged in the Department of Education in London until his retirement in 1884. In 1885 he was elected into the Professorship of Poetry at Oxford (with the support of Alfred Tennyson, whom he had met in his days near Twickenham).

The second son has William Gifford Palgrave (1826–1888), the least 'typical' of the family. After Charterhouse and Trinity College, Oxford, he moved to India, becoming a lieutenant in the 8th Bombay Regiment. He soon converted to Roman Catholicism, entered a Jesuit mission in Madras, and was ordained a priest of the Order. He remained as a missionary in India until 1853 when he was recalled to Rome. Later in that same year he went as a missionary to Syria. The *Dictionary of National Biography* reports that 'he could and did pass without difficulty for a native of the East', adding that 'the often repeated story that he had officiated as Imaum in mosques is without foundation'. When hostilities between the Druse and the Maronite Christians broke out, the Maronites invited him to become their leader – an invitation which it seems he declined. A massacre of Christians in Damascus in June 1881 precipitated his return to Europe. There he reported to Napoleon III on the Syrian situation. This contact led him into an expedition in 1862–1863 across the Middle East. This was financed by the French government, to whom he was to 'report on the state of the Arab attitude' towards France. Subsequent to this venture he returned to England.

At ‘home’ again, he published his *Narrative of a Year’s Journey Through Central and Eastern Asia* in 1865. This was the most widely read narrative on that region until the accounts of T.E. Lawrence appeared on the scene. He broke with the Jesuits, and became a diplomat in the service of the British government. He was dispatched to Abyssinia, and then went as consul to St. Thomas in the West Indies in 1873. There followed postings in Manila (1876), Bangkok (1879), and Uruguay (1884). He died in Montevideo on 30 September 1888.

The youngest son, Reginald Francis Douce Palgrave (1829–1904), was Clerk of the House of Commons. He was the only sibling to survive to see the publication of the *Dictionary* and Palgrave consistently requested Macmillan to forward to him complimentary copies of the work as it appeared.

Works

It is said that ‘as quite a young boy’ Palgrave received from his father a copy of the *Wealth of Nations*, which he treasured throughout his life. That book seems to exert a power so mysterious that few who take it up and study it seriously have been able to avoid the fate of a career in economics. However, his activities at Gurney & Co. in Great Yarmouth, while immersing him in the daily business of economics, delayed the entry of his name into its literature until 1870, when he received the Statistical Society’s Taylor Prize for an essay on local taxation in Britain and Ireland.

The work by which Palgrave’s name will be perpetuated is, of course, his *Dictionary of Political Economy*, one of the finest achievements of Victorian scholarship. Shortly after the publication of its last appendix he was knighted (1909).

Here, we shall consider only his other writings, all of which dealt with some aspect of banking practice or theory. His publications of 1873, 1874 (a and b) and 1877 typify a kind of statistical analysis of central banking, and their results are largely collated and summed up in *Bank Rate and the Money Market* of 1903. Of this book, Schumpeter commented:

> [It] is a masterpiece of the art of making figures speak . . . it is very difficult to formulate particular results but he who peruses this book page by page suddenly discovers that he understands its subject. (1954, p. 1080)

On matters of policy, he opposed bimetallism, opposed the monetary policy of the government in India, pushed for stability in Bank Rate, and was a supporter of the kind of regulations embodied in Peel’s Act of 1844. However, in a review of Bagehot’s *Lombard Street* (1874b) he formulated clearly the idea that the central bank was effectively an arm of government and thus a vehicle through which governments could effectuate monetary policy. The idea of the Bank of England as an autonomous agency governed only by the legislative provisions of its act of establishment was thereby altered. The new conception which was to take root was of a central bank more familiar nowadays than it was at that time.

In 1877, Palgrave became financial editor at the *Economist,* and on Bagehot’s death took over its editorship. He remained there until 1883. He also edited the *Banking Almanac* until his death, and was briefly editor of the *Banker’s Magazine* to which he contributed regularly after 1880.

Palgrave was also closely involved in the public affairs of the nation. In 1875 he gave evidence before the House of Commons Select Committee on Banks of Issue (George Goschen being the Committee’s economic expert) on behalf of the Country Bankers’ Association, and in 1885 he was a member of the Royal Commission on Depression of Trade and Industry. In the memorandum of evidence submitted to that Commission, Alfred Marshall remarked that he would not cover matters already dealt with in Mr. Palgrave’s memorandum since he was in broad agreement with that document.

It is said that as a boy Palgrave dreamed of becoming a Fellow of the Royal Society – a dream which became reality in 1882, thanks in part to the support he received from Jevons. The latter’s correspondence with Palgrave from that period (held in the archives of King’s College, Cambridge) speaks both to the modesty of Palgrave and the genuine friendship of which Jevons was capable. There is a postcard from Jevons, dated on the day the names of elected Fellows were published in the *Times*, containing no other communication than the name of its adressee: 'R.H. Inglis Palgrave, F.R.S.'

Inglis Palgrave's *Dictionary of Political Economy* appeared in volume form sequentially in 1894, 1896 and 1899. However, 1894 was not the year in which the *Dictionary* began publication. Under an earlier publishing plan, subsequently abandoned, a first part of the *Dictionary* (covering the entries Abatement to Bede) appeared in 1891, followed by two more in the next year (extending the project well into the letter C). Furthermore, 1899 does not accurately represent the completion date of the work. It was not until 1908, when the appendix to the third volume was published, that its publication could be said to have been complete. It took 17 years to effect the publication of the *Dictionary* – better than 20 years of work if one takes into account the fact that the contractual agreement between Palgrave and Macmillan is dated 1888.

Though the original contract called for a work in two volumes, it seems that this plan was subsequently revised to entail publication in parts, each of 120–130 pages in length, and to appear at quarterly intervals. It was envisaged that the entire work would run to between 12 and 14 parts.

The rationale behind the adoption of this plan seems to have derived from a number of considerations. In the first place, the French *Dictionnaire d'èconomie politique* and the German *Handswortsbuch der Staatswissenschaften* had already been appearing in parts, and Palgrave specifically cited these instances in support to the plan. Closer to home, the *Dictionary of National Biography* was also appearing in parts at the time, and successfully at that. Commercial considerations exerted due influence. Palgrave argued that 'each *part* of the Dictionary, as it comes out, may be expected to be noticed . . ., each *volume* would only receive a similar notice', so that '*parts* will be more frequently [brought] before public notice'. He was also concerned that any delay in commencing publication might allow competitors to beat him to the market.

The fact of sequential publication, whether in parts or in volumes, went hand in hand with sequential writing and sequential planning. In 1892, after this process had actually begun, Palgrave argued that it brought two substantial externalities – he might receive 'a good many valuable suggestions and hints', and he could easily refer contributors to the later parts back to earlier published parts in order to avoid overlap. But there were diseconomies as well. With the prospect of publication extending over four or five years, even if it was kept to a strict schedule, there was a real danger of contributor exhaustion. Perhaps more importantly, there was no way of making adjustments for recent advances, or for correcting oversights, or for taking advantage of the valuable advice an editor receives, if the relevant material had already gone to press.

The *original Dictionary* does seem to have suffered some of these disadvantages. Soon after 1899 it was in need of revisions substantial enough to require the printing of separate appendices (published separately at first, and bound in with subsequent reprints). Some of the reasons for this will be touched upon later. What is more, just how exhausted its contributors became during the process can be witnessed in the record of one of the most loyal among their number – F.Y. Edgeworth. In the first volume there were 77 entries from his pen. In the second, the tally had fallen to 38. In the third volume it was down to 17 (in the Higgs edition there are 10 more, mostly addenda to existing entries). Not only did Edgeworth's entries shrink in total number, they shrank in average length as well.

While little concrete detail is readily to hand concerning the editorial practices that Palgrave adopted, there is sufficient evidence available from which to make some fairly confident conjectures. To begin with, it is clear that the list of entries was planned well ahead, despite the more immediate horizons imposed by the choice of sequential publication. In November 1889, for example, before anything had been published, Palgrave reported to Macmillan that he had planned the list of entries down to the letter K. In a letter of 16 March 1892, he reported that he had 'forwarded a considerable number of articles . . . in the S' to the printer. Yet it is equally clear that there was no attempt to generate a list of entries that was in any significant sense 'complete' prior to the commissioning of contributors.

Just how Palgrave arrived at the actual entries to be included is not so easily established. It seems to have been a combination of his own ideas, and those of specialist contributors in particular fields. The list of entries classified by contributor to the original *Dictionary* (compiled by K. Newman and appearing as an appendix of the present work) reveals a pattern whereby certain contributors wrote nearly every entry in a given field. It seems likely that Palgrave simply gave them a free hand to generate the key entries in that field. This probably explains some of the singularities of the pattern of contributions in the original work. How else, for example, might one explain the fact that Mr F.E. Allum of the Royal Mint at Perth, Western Australia, contributed over 100 entries on various media of exchange – from the English Angel to the Japanese Yen. Or that A. Courtois *fils* contributed a similar number of biographical entries on (mainly) French writers – from the marquis d'Audiffret to Louis François Michel Raymond Wolowski. How free were the contributors' hands in determining the length of entries is indicated, perhaps, by the fact that M. Courtois *fils* produced two-and-a-half columns on the obscure Wolowski, and just two on Quesnay.

If the practice of deferring to 'specialists' seems to have introduced certain idiosyncrasies, in other cases it bore fruit, that of Edgeworth being exemplary. It is hardly necessary to add that even with his specialists, Palgrave experienced the usual problems of tardiness in the delivery of sacredly promised entries, and of restraining contributors to limits, even if flexible, as to length. On the whole, however, he seems to have handled these with admirable tolerance and forbearance – though at one point he did suggest that Macmillan might consider sending a man round to Robert Giffen's residence to await on the delivery of his promised essay on Bagehot (which, as it transpired, he did not obtain) – and with not a little creativity in the re-titling of entries so that they would appear further down the alphabet.

The reaction to the *Dictionary* can be considered from two rather different perspectives, that of the economics profession itself and that of the market. As to the latter, there were two phases, the first covering the three parts which appeared before the first 'recognized' volume in 1894, the second covering the subsequent period.

The first phase was a clear commercial failure. The first part had gone to the printers in June of 1891 and was published that year. Within a few months Palgrave was already alert to its lack of success in the market. In a letter to Macmillan dated 14 March 1892 he expresses himself 'extremely disappointed to find that the sale of the Dictionary has been so small'. At about the same time, the publishers began to suggest abandoning the existing publishing plan, in favour of a format more like that which actually appeared. Initially, Palgrave held out against these suggestions. But the similarly disappointing sales of the second and third parts, which appeared in 1892, seems to have reconciled Palgrave to a change of plan. In November of that year little sign remains of the vigorous defence he had made of the earlier plan just a year before. Instead he writes: 'I do not wish *myself* to suggest a change from parts of volumes, but . . . as you appear to have this in your mind, I have now planned out the work as far as the next volume would extend, should *you* desire it be dealt with *as a whole*'.

The professional reaction to the *Dictionary* was generally favourable, as might have been expected given the fact that almost all economists of any repute had already endorsed the enterprise by agreeing to contribute. Of course, any encyclopedia is vulnerable to criticism. Why one particular title for an entry, rather than some other? Why include some unimportant subject or author, and neglect other more worthy ones? There was also some critical comment on the work's sequential appearance. Ever a supporter, Edgeworth effectively put paid to this avenue of attack: 'not even Homer brings forward all his Greeks at once, but makes one the hero of the third, another of the fifth book' (1892, p. 525).

Probably more to the point, some reviewers were wary of the presence in the *Dictionary* of so much material on legal matters, current commercial practices and international treaty arrangements (a hangover from McCulloch's *Commercial Dictionary* perhaps?) and statistical information. This sentiment was shared even by Henry Higgs, who in the editorial preface to his edition of the *Dictionary* remarked that most of this is 'only remotely connected to economics'. The presence of these subjects probably reflected in substantial measure the tastes of Palgrave himself, a commercial banker.

Two specific and less favourable reactions to the *Dictionary* must be singled out, the first contained in an essay by E.R.A. Seligman (who would later edit the *Encyclopedia of the Social Sciences*) that appeared in two parts in the *Economic Journal* for 1903 under the title 'On Some Neglected British Economists'. The second reaction was that of Alfred Marshall.

Seligman's article (in Seligman 1925, pp. 65 ff.) seems to have been an impetus to some of the revisions which Palgrave began shortly after the third volume had appeared. Seligman used the *Dictionary* to exemplify his claim that insufficient attention had been given to a number of British economists: Torrens, W.F. Lloyd, Bailey, Longfield, Read, Craig, Butt and George Ramsay. The cases of Torrens, Lloyd and Longfield were compelling, and Palgrave sought remedy in the appendices. The cases of Craig, Butt and Ramsay were much less so, and Bailey had in fact been the recipient of a generous notice by Edgeworth in the original (where Read had been noticed by James Bonar).

Marshall's reaction, though contained only in asides in correspondence, was unambiguously negative – at one point he makes a play on Palgrave's initials (RIP) in regard to his expectations for the fate of the enterprise. This might help explain why Marshall's name is the most glaring absence from the list of contributors to the *Dictionary*. It was certainly not because he was not asked – it is clear from Palgrave's correspondence with Macmillan that Marshall was approached. In the end the *Dictionary* had to wait for a contribution which bore the signature of Marshall until the Higgs edition of Volume I in 1925. Even then, it was merely a note on the teaching of economics at

Cambridge, not written originally for the *Dictionary* in any case.

The judgement of the profession on his *Dictionary* is probably best summed up in a letter published in the *Economic Journal* for September 1917, congratulating Palgrave on reaching his 90th birthday. For there even Marshall's name appears among the distinguished list of signatories.

Little need be said here of the Higgs edition of the *Dictionary*, which for the first time formally added Palgrave's name to the title (though Edgeworth had done so informally in his review of its second and third parts in 1892), but which made few changes to its structure or contents. Like its predecessor the Higgs edition also appeared sequentially, though not in alphabetical order. Volume II appeared first, in 1923, Volume I followed in 1925, and Volume III in 1926; just why, is not known.

Palgrave was already in his sixties when he began the *Dictionary*, and was in his eighties when it was done – an act of dedication to the discipline unlikely to be replicated. As Edgeworth presciently remarked when reviewing its second and third parts in the *Economic Journal* for 1892, it 'will remain a monument of what may be accomplished by individual initiative and energy'.

Governor of the Bank of England from 1830 to 1833, Palmer was a significant participant in 19th-century controversies concerning the Bank's proper management. In 1802 he entered into a partnership with two others as East India merchants and shipowners, and remained active in business until weeks before his death in 1858. '[A] vigorous, outspoken man' (Clapham 1944, vol. 2, p. 114), he was first elected a director of the Bank in 1811 and was regularly re-elected thereafter except for the usual hiatus every third year before 1828 and again in 1845–6. By 1857, when his service terminated, he was the senior director of the Court.

Palmer's view over the period from 1832 to 1857 may be gleaned from his answers to questions addressed to him by Parliamentary committees, three pamphlets he published in 1836 and 1837, and correspondence. Among the central issues he discussed were the nature of the Bank's responsibilities, its relation to the London money market, the joint stock and country banks, its role in stabilizing domestic economic conditions, and how it operated on the exchanges.

Palmer's initial statement of the principles that guided the Bank's policy became known as the Palmer rule or the rule of 1832: the Bank's duty in ordinary times, when the reserve was at a maximum and exchange rates were at par, was to maintain its bullion reserve at one-third of its liabilities, the sum of deposits and note issues. At such times the Bank should hold interest-earning assets of government stock and other long-dated securities equal to two-thirds of its liabilities. Thereafter the portfolio should be maintained unchanged so that as gold was withdrawn from or brought to the Bank, the public would reduce or increase notes and deposits. Changes in the Bank's liabilities would thus arise at the public's, not the Bank's initiative. A loss of bullion would be matched by a reduction in notes and deposits with no change required in the portfolio to reduce the supply of funds in the money market. Palmer held that the Bank should set its rate above the market rate so that in normal times it would not be competing for discounts with London bankers. 'At times of discredit', however, when the market rate rose to the level of Bank rate, the Bank should discount bills of exchange, selling off government securities as discounts increased. (Palmer did not recognize that selling securities would offset the provision of funds to the discount market.)

The validity of the Palmer rule was challenged by both contemporary and later critics (Loyd 1837; Viner 1937), although some modern students (Horsefield 1949; Matthews 1954) regard it as essentially sound. A different line of criticism, occasioned by financial market stringency in 1836–7 and again in 1839, was that in practice the Bank did not observe the rule. Palmer defended the Bank, arguing that in face of deposit declines at other banks associated not with gold drains but with transfers to the Bank – he was referring to East India and other special deposits, 1833–7, and to seasonal Exchequer deposits – it was proper for the Bank to increase its portfolio to offset the extra funds it held. Similarly, the increase in the Bank's portfolio in 1836–7 was the correct response to an internal drain of gold, as it was also in 1839 to an external drain, none of these ordinary years in which the rule applied.

Palmer's arguments failed to convince his interlocutors. He himself retreated from some initial positions. In 1848 he qualified the rule governing reserves in relation to total liabilities. External drains affecting exchange rates, he noted (British Sessional Papers 1847–8, VIII, Pt. 1, 167–8), might be related to political factors abroad rather than to domestic circulation and deposits. As reserves of London bankers gradually came to be held at the Bank rather than as Bank notes, he shifted from a view of Bank rate as the means for influencing note issues to the view that it was the means for influencing the money market. Initially insistent that the Bank must have a monopoly of the note issue – he claimed in 1837 that the issues of many newly formed joint stock banks in 1835–6 had nullified the Bank's contraction of its issues (clearly not true) – in 1848 he did not object to unrestricted country bank note issues provided they were adequately secured.

On other matters, Palmer's views held firm. He believed that changes in Bank rate in relation to rates abroad could control international trade and capital movements. He was a critic of the Bank in the 1840s for too often changing Bank rate and failing to maintain it above market rates. Despite acknowledging the Bank's influence on economic affairs, he denied that it was answerable to anyone but its proprietors, or that publication of a statistical account of its actions was desirable. He opposed separation of the Bank into Issue and Banking Departments before and after the Act of 1844 became law.

Horsley Palmer's name survives as a spokesman for the proper conduct of monetary policy in a period of imperfect understanding of the Bank of England's responsibilities. By asserting that the Bank ought not to compete with other banks in discounting commercial bills in ordinary times, he centred attention on the position of the Bank as distinct from that of other institutions in the money market. He recognized the primacy of its central banking function as lender of last resort during financial stringency. His advocacy of setting Bank rate above market rates hastened the demise of the Usury Laws. For modern observers of the instability that discretionary central bank policies at times have produced, his rule of a constant portfolio has resonance.

Panic of 1907

The Bank Panic of 1907 was the final banking crisis of the National Banking Era (1863–1913); it was significant in that it led to the Federal Reserve Act. The panic began when the spectacular attempt by F. Augustus Heinze to corner the stock of United Copper Company collapsed on 16 October 1907. The collapse revealed the extensive links of Heinze to another notorious financier in the New York City banking community, Charles F. Morse, a man O. M. W. Sprague (1910, p. 248) describes as having 'an extreme character, even by American speculative standards'. Solvency concerns led to a series of bank runs at several national banks controlled by the two men. Yet the turmoil surrounding the Heinze collapse did not produce a systemic panic in New York, because the New York Clearinghouse took prompt corrective actions on the member institutions.

But on Monday 21 October the National Bank of Commerce announced late in the afternoon that it would no longer clear checks through the New York Clearinghouse for the Knickerbocker Trust Company. The following day, Knickerbocker Trust faced a run on deposits that lasted three hours, and it suspended business just before noon after having paid out $8 million in cash. The next day, the *New York Times* reported that the Trust Company of America was the current 'sore point' in the panic, a report that magnified the run on the Trust Company of America. Over the next two weeks the Trust Company of America paid out $47 million to depositors.

J. P. Morgan, James Stillman of National City Bank, and George Baker of First National Bank arranged through the New York Clearinghouse to aid the Trust Company of America, other stricken trusts, and the stock market after it had been determined that Knickerbocker could not be saved. On 26 October the New York Clearinghouse authorized the issuance of clearinghouse loan certificates to make available otherwise illiquid reserves and assets as a substitute for currency in transactions between banks, currency that could then be paid out to depositors. In addition, the Clearinghouse authorized restrictions on the payments of cash from deposit accounts, thereby limiting the outflow of the means for payment finality from the intermediation system.

While private sector efforts succeeded in quelling the panic, it still altered how key New York bankers perceived their ability to manage the New York money market. New risks set 1907 apart from the earlier national banking era panics of 1893, 1890, 1884, and 1873. These new risks arose from the increased participation of trust companies and other intermediaries in the call money loan market, the overnight loan market for the New York Stock Exchange. By 1907 the New York trust companies had nearly 90 per cent of the loan volume of the New York national banks (Moen and Tallman 1992). As intermediaries outside the Clearinghouse such as foreign banks, national banks from the interior of the United States, and the New York City trust companies became more prominent in the call loan market, the New York bankers realized that their ability to manage that market during panics had diminished considerably.

Under normal financial conditions the call loan market had been reasonably stable, serving as an outlet for excess reserves accumulating in New York through the correspondent banking system. During bank panics, however, the call loan market magnified the scramble for cash as numerous banks tried to call in their loans simultaneously. Typically, interest rates would spike upward and the value of the stock collateral would start to fall as borrowers as a group sold off their collateral to pay call loans. Until 1907, however, such a catastrophe had been averted because the New York national banks, acting through the Clearinghouse, jointly responded to mitigate disruptive contractions of call loans. The collective action of New York national bankers through the issuance of clearinghouse loan certificates and the partial suspension of convertibility of deposits into cash succeeded when clearinghouse banks provided the largest source of funds for the call loan market. The New York banks had been the main suppliers of call loan money since the inception of the stock market, which motivated them to preserve both the stock and call loan markets.

Outside intermediaries like the trusts, having no collective concern for the call loan market, began calling in large numbers of loans on 24 October 1907 (van Cleveland and Huertas 1985). Stock equity values began falling precipitously. Depressed stock values threatened the financial condition of both borrowers and lenders of call loans, including the national banks. The positive correlation between changes in collateral values and the changes in the creditworthiness of borrowers and lenders (sometimes referred to as covariance risk) transmitted the financial shock faced by trusts throughout the financial system to the national banks. Early in the panic there were reports of New York Clearinghouse member banks taking over a large volume of call loans made by trust companies to prevent the collapse of the call loan market and, hence, the stock market. By the end of the panic, loans (and deposits) at the New York national banks increased by nearly ten per cent, in contrast to the 37 per cent contraction of loans at trusts. No similar pattern was seen in the earlier panics (Moen and Tallman 1992).

Contemporary observers applauded the leadership of New York Clearinghouse banks. Sprague (1910) noted how the national banks forbore on calling in loans that were technically insolvent, expecting them to recover as conditions returned to normal. Woodlock (1908) noted the increasing and destabilizing role of outside lenders in the call loan market, lenders like the trust companies that were outside the influence of the Clearinghouse. New York Clearinghouse bankers lost confidence that they alone could reliably alleviate stress in the call loan market during a panic. The movement to establish a centralized system of reserves or a central bank gained momentum after the Panic of 1907 because the New York Clearinghouse banks were no longer willing to bear all the risks alone.

JEL Classifications

B31

Italian economist and politician, Pantaleoni was born in Frascati (Papal States) on 2 July 1857 and died in Milan on 2 October 1924. His career as a university teacher in economics was rather stormy on account of his impatient rejection of any attempt to interfere with his teaching and the free expression of his thought. Elected in 1900 as a radical to the Italian Parliament, he resigned shortly afterwards.

In 1920 he was appointed to manage the finances of d'Annunzio's Free State of Fiume, and in 1923 was nominated a member of the Italian Senate by the Fascist government, of which he was a supporter. His contribution to scholarship may be divided into three parts. First, a famous textbook, *Principii di economia pura* (1889), which contributed to the introduction of marginalist ideas into Italian economic thought and which, in its English translation (1898), made a considerable impression outside Italy as well. Second, a monograph on applied economics on the fall of the 'Credito Mobigliare', which Piero Sraffa aptly compared to Bagehot's *Lombard Street*. And third, a long series of papers, some of which may be regarded as seminal, on a wide variety of topics in both economics and at the interface with other social sciences. His lectures at the University of Rome, transcribed and published by his students, are also worthy of mention.

Much of Pantaleoni's writing has been brought together in anthologies and Pantaleoni's thought has been the subject of much comment; however, no persuasive, thorough, study has yet appeared. The man and the scholar emerge most vividly from his correspondence with Vilfredo Pareto.

The most distinctive feature of Pantaleoni's theoretical work is his tendency to generalize across disciplinary boundaries. Economics, sociology, anthropology and psychology form a kind of unified field within which Pantaleoni, while still employing the style of reasoning of the economist, moves freely and creatively, without shrinking from paradox and logical extremes. His great friend Vilfredo Pareto reproached him in 1898: 'the advancement of scholarship lies in creating new distinctions and not, as you seek to do, in reducing their number.' In apparent contradiction to this extreme tendency towards generalization is Pantaleoni's capacity for minute and piercing analyses and broad and brilliant syntheses of given concrete situations.

How far Pantaleoni may be classified as a genuine marginalist is still an open question. Musgrave and Peacock (1967) wrote that 'one of the first attempts at dealing with the determination of the tax-expenditure plan as a problem of economic value appears in Pantaleoni's essay of 1883'. They refer to the early Pantaleoni paper, 'Contributo alla teoria del riparto delle spese pubbliche', later republished in the *Scritti vari* anthology.

It is true that his extreme subjectivism brings him close to the 'classical' marginalists (though he was very critical of Menger at times), but his eclecticism – in a half-Marshallian vein – about the theory of value, and his acceptance of many of the concepts typical of evolutionist sociology (for example, his distinction between predatory, parasitical and mutualistic settlements), incline one to define him as unclassifiable except in the historical context. His relationship to the thought of Edgeworth and Marshall comes out clearly from the following letter to Edgeworth: ‘you are the closest approximation of a match for Marshall living in England. You know that to my mind, Marshall is simply a new Ricardo who has appeared in the field.’

If we look at Pantaleoni’s mature work, we can conclude, with G. di Nardi, that ‘the Pantaleonian essays following *i Principii,* place him outside orthodox marginalism and made of him a very acute forerunner of contemporary critical schools’.

Pantaleoni’s many disciples have helped to consolidate the profound imprint left by him (much deeper than that of Pareto, though the latter is better known nowadays outside Italy) upon Italian economic thought, especially upon general economic theory and the theory of public finance. Pantaleoni can also be considered among the founders of the modern Italian statistical school and a true forerunner of regional economics. A good example of the most typically Pantaleonian style of reasoning is given by his analysis of the concepts of ‘strong’ and ‘weak’ in economics, so alive and thought-provoking a century later.

Papi, Giuseppe Ugo (Born 1893)

F. Caffé

Born in Capua on 19 February 1893, Papi graduated in law in 1913 and pursued an academic career. From 1927 onwards he taught economics as Professor of Political Economy first at the universities of Messina, Palermo and Pavia, and finally in the Faculty of Law at the University of Rome. During his career he was General Secretary of the International Institute of Agriculture from 1938 to 1948, and, subsequently, General Secretary of the Italian committee of the Food and Agriculture Organization. These interests were reflected in the monographs Papi wrote, especially those on the vital importance of agriculture in the process of economic development, and on the emphasis given to free international exchange.

His main contributions were to the theory and politics of the economic cycle, international economics, the theory of the economic behaviour of the state, and the problem of international economic cooperation. In all these areas he remained faithful to his belief in the importance of real factors and of the microeconomic roots of economic phenomena, as compared with the monetary explanations of the trade cycle and of macroeconomic trends. It was characteristic of Papi that while he had no extended knowledge of the new Keynesian theories which dominated the major part of his working life, he continued to believe in the importance of factors governing the allocation of scarce resources and productivity. He believed that these forces could bring about an effective growth in real income.

The idea of a paradigm, in the sense of a dominating principle governing a whole area of scientific research, was invented by Thomas Kuhn (1962), a historian and philosopher of science. One of his starting points was Karl Popper's view of science, according to which the best scientific theories are falsifiable, viz., such theories could, at least in principle, be refuted by empirical evidence. Popper has argued that theories such as those of Freud and Marx, and the central assumptions of astrology, were unfalsifiable, and that in consequence they were inferior to Newtonian and Einsteinian physics, for example. Kuhn, however, pointed out the already well-known fact that the leading theories of the physical sciences are not straightforwardly falsifiable. On the contrary, a theory such as Newton's typically requires auxiliary assumptions before it can make any empirical predictions. If such predictions turn out to be false, then logic alone does not determine whether the main theory or one or more of the auxiliaries is at fault, and a person is then at liberty to retain the central theory and to reject one or more auxiliary.

Indeed, according to Kuhn, this is roughly what scientists generally do. Kuhn was particularly impressed by the way in which the Copernican and Ptolemaic theories, which provided rival accounts of the planetary system, were each sufficiently flexible to account for any astronomical observations. New observations that did not match expectation could always be reconciled with either the Copernican or the Ptolemaic theories by adjusting the system of epicycles, equants, and so on, upon which the planets were supposed to revolve. Kuhn concluded from this that no objective method could determine which theory is the right one or the better one, and that the transfer of allegiance from the earth-centred Ptolemaic to the sun-centred Copernican hypothesis was not based on the rational method of comparing the relative empirical support enjoyed by the two theories: 'the real appeal of sun-centred astronomy was aesthetic rather than pragmatic' (Kuhn 1957, p. 172).

Kuhn described the Copernican and Ptolemaic programmes as rival paradigms. A paradigm, for Kuhn, is a '[way] of seeing the world and of practising science in it' (Kuhn 1970, p. 4). Thus a paradigm incorporates a set of assumptions, especially assumptions about the fundamental nature of some aspect of the world, such as whether there are atoms or not. These assumptions are accepted unquestioningly by adherents to a paradigm. Scientific research is normally conducted in the context of such a paradigm, but it is not directed towards testing the paradigm; on the contrary, it consists in 'a strenuous and devoted attempt to force nature into the [paradigm's] conceptual boxes' (1970, p. 5).

Paradigm-directed research was dubbed 'normal science' by Kuhn to indicate that most work in science is of this kind. Normal science involves fact-gathering activities such as the determination of specific physical quantities (for example, stellar positions), and experiments designed to check theoretical predictions; it also 'consists of empirical work undertaken to articulate the paradigm theory, resolving some of its residual ambiguities and permitting the solution of problems to which it had previously only drawn attention' (1970, p. 27). The crucial feature of normal science is that it is directed to 'puzzle-solving', and 'not [to] major substantive novelties' (1970, p. 35), and predictive failures are normally blamed on the scientist rather than on the paradigm itself.

In addition to a set of assumptions, a paradigm comprises prescriptions for research; however, the precise character of a paradigm is impossible to state. According to Kuhn, the nature of a paradigm resembles the meanings of words, as Wittgenstein characterized them. According to Wittgenstein, a word like 'game' cannot be defined fully and explicitly, its meaning can only be intuited or grasped. One learns the meaning of such words by exposure to examples or paradigm uses. The same applies to a scientific paradigm, which is taught through exemplary or paradigmatic applications of a theory to a concrete range of phenomena. A similar view was held by Polanyi (1958).

How is one paradigm supplanted by another? Kuhn claimed that this is not done by the careful weighing of evidence for each and the selection of the one with the greater empirical support. He argued that this would not be possible, first of all because of the inarticulable and elusive character of a paradigm and secondly because paradigms are 'incommensurable', in that they are really dealing with quite separate phenomena. Kuhn claimed that the observations made by scientists are never 'pure' or 'theory-free', but are always interpreted in terms of the prevailing paradigm. In Kuhn's view, this means that there can be no data that would facilitate a comparison between two paradigms (Kuhn 1970). Hence, Kuhn argued, a rational comparison of the two paradigms is impossible and 'communication across the revolutionary divide is inevitably partial' (1970, p. 169).

Kuhn likened a change of paradigm, or scientific revolution, to a gestalt-switch, calling it 'a transition between incommensurables' (1970, p. 50). After a prolonged period of repeated failures to resolve anomalies in accordance with a paradigm's internal criteria, a time of 'crisis' sets in. Scientists are then prone to change paradigm all of a sudden, after which they see the world in terms of a new paradigm. Sometimes the 'shape of the new paradigm is foreshadowed' during the period of crisis. More often, though, 'the new paradigm, or a sufficient hint to permit later articulation, emerges all at once, sometimes in the middle of the night, in the mind of a man deeply immersed in crisis' (1970, pp. 89–90).

Some aspects of Kuhn's view of science have been widely accepted, in particular, his claim that theories may be tenaciously upheld in the face of apparently unfavourable evidence and that such theories often generate a long programme of research, in which they are defended and extended to new areas.

Other Kuhnian claims have, however, been contested, especially the idea that the nature of a paradigm is inarticulable and that apparently competing paradigms are incommensurable. Lakatos argued that paradigms, or research programmes, as he called them, could be accurately described. In his view, they consisted of a set of unfalsifiable theories (or a 'hard core'), together with a heuristic, or instructions and hints on how to apply the hard core theories to specific explanatory tasks.

The idea that different paradigms are incommensurable has been criticized in a number of ways. The most telling objection is this: although two theories, such as the Newtonian and Einsteinian theories, describe the world in terms peculiar to each and so, in a sense, are disconnected, when combined with appropriate auxiliary assumptions, they may each make predictions that are comparable. Such predictions are not expressed in a pure observation language, but they may be expressed in terms common to both paradigms, and this, contrary to Kuhn's claim, is all that is needed for a comparison of the explanatory powers of rival paradigms. For example, Newton's theory and Einstein's made different predictions over the rate of precession of the perihelion of the planet Mercury and this may be described in a way that is valid and comprehensible, whichever of these theories one favours.

It has been argued that such comparisons permit the relative merits of paradigms to be *rationally* assessed, and allow one to conclude that one of them is 'objectively' the better. Thus Lakatos spoke of a research programme that consistently leads to successful novel predictions as 'progressive', and those that produce a string of failures as 'degenerating'. Lakatos believed that he could advance beyond Kuhn by exploiting this dichotomy to supply rational criteria for paradigm choice. However, he was unable to justify this claim.

Treating scientific research in terms of paradigms or programmes is certainly a useful historiographical tool of analysis. However, there are often difficulties in determining the boundaries of a paradigm. This difficulty means that one often cannot be sure whether a change of view amongst scientists constitutes a revolution, that is, a replacement of one paradigm by another, or whether it is merely a change within a single, more general paradigm (Toulmin 1970).

Perhaps the most significant development in economics that resembles a paradigm is that of marginalism, in particular, the subjective theory of value and the associated methods of marginal analysis. This became the dominant approach of economists from the 1870s on (see Schumpeter 1954, ch. 7). However, a number of authors have picked out parts of this general approach as constituting separate paradigms, or research programmes. For instance, Latsis has given a detailed account of the hard core and heuristic methods of the neoclassical theory of the firm. And Blaug has outlined the paradigm of 'economic equilibrium via the market mechanism', which he traced to Adam Smith. De Marchi has described the Ohlin–Samuelson approach, in which the relative commodity outputs of different nations are connected to factor endowments, as a paradigm. Within macroeconomics there are competing paradigms, namely that which assumes continuous market clearing based on rational expectations (new classical macroeconomics), and that which is based on the old and neo-Keynesian approaches (see Klamer 1984).

A disadvantage of Kuhn's and Lakatos's views is that they suggest that the rules of science allow any group of theories to be set up as the basis of a paradigm. This has led to some areas of inquiry, especially those dealing with social phenomena, mistakenly being regarded as scientific, simply because they are dominated by some tenet that is dogmatically upheld against all difficulties. That such conditions are insufficient for a theory to be acceptable as science has been argued by Dorling (1979). Proceeding from the assumption that theories are judged by their probabilities, in the light of the available evidence, Dorling demonstrated the conditions under which a theory may remain very probable, even when the combination of that theory with some auxiliary hypothesis has been refuted. Redhead (1980) showed how this fact could lead to some theories forming the basis of a paradigm, and how, after a number of unsuccessful predictions, confidence in the assumptions of the programme would gradually be eroded. Thus the crucial characteristics of paradigms may be explained and rationalized.

Paradox originally meant contrary to accepted opinion. In logic something more precise is usually intended. A paradox is involved, for example, if we are led to a contradiction by sound reasoning. Economists on the whole seem to have stayed closer to the original sense. We can use this fact to claim that there is ground for treating economists' paradoxes simply as puzzling outcomes. There have been rhetorical appeals to 'paradox', as we shall see; but there are also numerous examples of substantive puzzles. They are to be expected as the limits to existing ways of explaining are explored. This usage has the advantage therefore of allowing us to treat paradoxes as a normal aspect of ongoing inquiry, and it shifts the focus of interest in them away from a status as intellectual curiosities to a status as stimulant to further research.

Anomaly, in the physical and biological sciences, is used to refer to an observational irregularity, or an exception. Economists are reluctant to claim a similar implied degree of regularity, or reliability in estimation. There are, however, at all times facts which resist ready incorporation within existing ways of explaining. We may reserve the term anomaly for these, to indicate the empirical origin of the puzzles which they pose. For the rest, however, there seems little reason to distinguish sharply between paradox and anomaly.

An Interpretative Framework

To make much sense of how paradoxes and anomalies relate to change and progress in economics, we need a framework. It seems probable that economists, like other scientists, are more disposed to admit corrections that they can deal with without altering too radically their existing theories. Challenges which threaten precipitate depreciation of their human capital are likely to be resisted. Furthermore, challenges to 'hard core' propositions, to use Lakatosian terminology, will be resisted absolutely. (This has certain implications for the way 'core' change, if it comes, will be experienced, but these need not occupy us here.) Challenges within the 'protective belt' (in the 'demi-cores', as Remenyi (1979) refers to them, or at the subdisciplinary nodes) will be dealt with more flexibly, but we may expect a different response according to whether the challenge is empirical or analytical in *origin*. Theoretical challenges, so long as they are less than 'core'-threatening, actually provide occasions for the display of ingenuity, and are a major vehicle for change. Empirical puzzles, on the other hand, for reasons that are pretty well understood (but will be reviewed below) seem generally to be regarded as less compelling. The accumulation of empirical anomalies which eventually become so numerous as to crush a theory by sheer weight, and to which Thomas Kuhn (1970) points as a major precipitating factor in revolutions in physical science, is not at all familiar in economics. Gross anomalies, of course, such as unemployment in the 1930s or stagflation in the 1970s, may provoke basic rethinking; but these are not our concern here.

If these suggestions broadly capture the situation and behaviour of economists, we would expect to observe little impact of empirical anomalies on preferred ways of thinking, and relative autonomy in theoretical developments. As Lakatos puts it (Lakatos 1970, p. 136): 'if the positive heuristic is clearly spelt out, the difficulties of the programme are mathematical rather than empirical.'

Such expectations merely reflect the rationalistic conception of their discipline that many economists seem to hold. Historically, that mindset derives from John Stuart Mill. Mill, though in principle a radical empiricist (V.R. Smith 1985, pp. 269–77), managed nonetheless to formulate an economic methodology in which there is no uncertainty, merely incompleteness. This accords well with the hypothetico-deductive model of explanation which economists have known since Mill and have found attractive as re-formulated in recent decades by Sir Karl Popper. On this view, science progresses by the making of bold conjectures, boldness meaning that there is much in the world of 'facts out there' that could refute them; and by subjecting these conjectures to factual tests to identify and help eliminate falsehood. Economists' Millian inheritance leads them to put a particular gloss on this: given our inability to conduct controlled experiments, we tend to look for certainty in premises that we 'know' to be true, by reason of introspection or casual observation. Hence we reason downward *from* truth. In this model, factual evidence can only be at odds with theory if our variables are incorrectly measured, or if we have failed to incorporate all those which are relevant to an explanation, or if the empirical model supposedly corresponding to our theory is incorrectly specified. These attitudes infused the early work of econometricians (Morgan 1984, chs 5, 7); and even the sophisticated methodology of the Cowles Commission in the 1940s used economic theory in a peculiarly Millian manner, to provide a priori grounds for rendering the problems of structure and causation operationally tractable.

With these general considerations in mind we turn to paradoxes and anomalies. What follows is not a survey, nor is there space to examine any single instance in detail (though several receive fuller attention elsewhere in this Dictionary). The instances mentioned serve us as illustrative material and are drawn together in this way in the hope of stimulating further exploration. We shall look at three categories: rhetorical paradoxes; 'fact of life' paradoxes, such as the failure of aggregation rules; and the main group, theoretical paradoxes and empirical anomalies. This last we shall split, as far as seems sensible, into challenges to the hard core and positive heuristics of the dominant neo-Walrasian style of analysis or research programme (for which see Weintraub 1985, ch. 7) and challenges within the protective belt.

Rhetorical Paradoxes

Here use is made of terminological fuzziness, or a premise is left unstated, so as to excite puzzlement and interest in the reader. Adam Smith's *diamonds and water paradox* is of the first sort. Neoclassical economists have, on the whole, viewed the puzzle as emanating simply from a confusion of total with marginal utility. An example of the second sort is again provided by Smith. When he avers that 'it is not from the benevolence of the butcher, the brewer, or the baker, that we expect our dinner, but from their regard to their own interest' (Smith 1776, vol. 1, pp. 26–7), the air of paradox is deliberate. It is dispelled when he goes on to relate the proposition to the principle of occupational specialization. Paradox was a favourite literary device in an earlier age. Donald McCloskey (1985) has recently alerted us to many others in the writings of modern economists.

Paradoxes Arising from the Absence or Failure of an Aggregation Condition

Examples here are the *paradox of thrift, Mandeville's paradoxes* about private vices (for example, profligacy) leading to public virtues (jobs) and *Arrow's impossibility theorem.* The first two, like Smith's paradox of self-interested behaviour leading to socially beneficial results or the Austrian view of social outcomes as complexes of individual choices which interact unpredictably, are instances of unintended consequences. Economists have failed to provide convincing reductionist accounts of aggregative behaviour and tend to take unintended consequences as a fact of economic life. Consistently with the dominant commitment to the neo-Walrasian approach, but paradoxically from any other point of view, this does not stop them from employing micro-motives to account for aggregate relations whose entities they cannot explain. (Excellent discussion of these things is to be found in Elster 1978, ch. 5, and in Nelson 1984.) Arrow's theorem, in so far as it is regarded as a generalization of the paradox of voting (as he himself is inclined to view it) creates difficulties at different levels in different problems (Sen 1985); but far from issuing in defeatism or the rejection of economic rationality it has given rise to a whole new sub-discipline, social choice theory.

Challenges to the Neo-Walrasian Hard Core and Positive Heuristics

Here we shall consider examples of both theoretical and empirical origin and note responses within the profession.

Take first the possibility of *capital reversal* or *reswitching*. In considering an array of techniques in a two-factor, two-product model, capital reversal occurs if, as the wage rate rises (interest rate falls), a less capital-intensive technique is chosen. A far-reaching implication is contained in this simple possibility. If there is no strictly monotonic relation between interest and the capital–labour or capital–output ratio, then it is conceivable that a more, then a less, then once again a more capitalintensive technique is the more profitable as the interest rate declines. This undermines the traditional demand curve for 'capital', negative in the interest rate, since relative goods prices may differ as between two interest rates at which the same technique may be equally profitable. There is then no unambiguous way to value 'capital' (Blaug 1985, pp. 523–8). The very possibility seems to render unserviceable the traditional aggregate production function. Neo-Walrasian economists in effect concede all of this yet go on using devices like the factor-price frontier, suggesting something like absolute resistance to challenges to the basics of the dominant research programme.

A curious instance with somewhat similar implications is the *Giffen paradox.* The positively sloped demand curve was thought of by Marshall as an empirical anomaly, and 'discoveries' of such phenomena by early econometricians led to identification and other 'correspondence' problems being defined (Morgan 1984, ch. 6). It has always been doubtful whether there are any actual observations of Giffen goods, and the strong presumption of theorists and theoretically influenced econometricians has been that, in Stigler's words, 'experience and common sense are opposed to the idea of a positively sloped demand curve' (Stigler 1965, p. 384). Thus even the standard price-theoretic rationalization in terms of a negative income effect dominating weak substitution effects (possibly due to strong rivalry between goods) is quite unaffected by the fact that tests normally turn up positive income effects.

This merely confirms the theorist's suspicion. While the case of Giffen goods is not all that significant, the typical theorist's attitude in this instance is interesting because it is wholly in line with what is observed elsewhere: within the programme, theoretical developments are relatively autonomous. Tests of demand theory were reported in 1975, for example, which in the words of the authors 'make possible an unambiguous rejection of the theory of demand' (Christensen et al. 1975, p. 381). The authors, however, did not refer to their own results as puzzling or anomalous, and their frontal assault also went unremarked.

A third example, involving experimental evidence, is the *preference reversal paradox*. Experimental trials conducted in the 1970s and 1980s have caused consternation by consistently implying intransitivity between individuals' direct preference rankings over risky prospects and the respective certainty equivalents they assign to them. Individuals will choose a high probability of low gain over a low probability of high gain while assigning a higher monetary value or certainty price to the second. This evidence appears to undermine all theories of choice which require transitivity (Machina 1983, pp. 76 ff.). As Imre Lakatos points out, however, 'there is no falsification before the emergence of a better theory' (Lakatos 1970, p. 119); and economists who use standard choice theory have remained impassive in the face of this evidence. The literature openly addressing the matter is apt to challenge the experimental design or to argue that intransitivity of certainty equivalents does not imply intransitivity of preferences (Safra and Karni 1984).

Challenges in the Protective Belt

Here we are much more likely to see positive responses to puzzling outcomes since there is more room for theoretical manoeuvre. Well-known examples among challenges of this sort include the *St Petersburg paradox*, the *Allais paradox*, the *Gibson paradox* and the *Leontief paradox*.

The Bernoulli solution to the St Petersburg paradox has been amended by placing bounds on the utility function. The Allais challenge to the independence axiom of expected utility theory has produced some modification in the specification of the subjects' choices – questioning the experimental design is something of a standard defence – but has issued mainly in the development of non-expected utility models (Schoemaker 1982). It is perhaps worth noticing that the Allais results might have been taken as a challenge to choice theory as much and therefore as threatening to the hard core; but turning the issue into one of model choice has deflected the threat into the protective belt. The Leontief paradox was explained initially as very largely due to omitted or improperly specified variables (De Marchi 1976), but more recent work has focused on a full articulation of the theory that would suffice to generate trade-revealed factor abundance (Leamer 1984, pp. 50 ff.). The Gibson paradox – an observed close correlation between long series of prices and bond yields – was given a complex explanation by Keynes in terms of market interest rate stickiness relative to the natural rate (Keynes 1930, vol. 6, pp. 182–3). Keynes thought of his account as rejecting the simple quantity theory account of the matter; but more recently Gibson's observations have simply been absorbed into the infinite time-horizon, intertemporal choice models of macroeconomics embodying a modified quantity theory approach.

What we see at work in all four of these cases is the emergence of a paradox being taken as an occasion for further theoretical refinement. Only one challenge was analytic in origin, but the three instances of empirical anomaly were treated as invitations to amend theory rather than to abandon it, and in this sense they were subsumed under the power of the positive heuristic. The difference between the way empirical anomalies are handled when the hard core is threatened and when it is not does not turn on any weakening of the rationalistic presumption that theory is the true arbiter. It is simply a methodological choice that is made: challenges to the hard core are inadmissible; challenges to theories in the protective belt allow of a more positive reaction.

Methodological Reasons Why Empirical Results Are Less Compelling

Finally, it is worth asking again why empirical tests result which look 'wrong' generally seem to be judged so, rather than to be taken as falsifications of theory. Theory may be modified by empirical challenges in the protective belt, but is unlikely to be rejected.

One problem is the economist's special version of the Duhem–Quine thesis to the effect that one never tests an hypothesis in isolation, but always in combination with a host of background conditions. Because it is often difficult to know the exact translation of theoretical terms in economic theories into empirical counterparts, and because the data often are not quite what the theory requires, tests are mostly joint tests of theory *and* the adequacy of proxies. A major reason, in turn, why the translation is not clear cut is that economic theories tend to be generic (choice theory, for example). It is possible to model such theories in many, many specific ways; but a negative test result for any one such specification has no implications for the generic theory. A third reason is that we do not observe in economics the constants of physical science. Especially in policy contexts it tends to be the case that altering a parameter of interest causes changes in other parameters. This is a particular form of what Klant has called the *parametric paradox* (Klant 1984, ch. 4.9). Here, and in much comparative statics analysis, our 'constants' are algebraic rather than numerical: they actually function as variables. This robs our models of predictive content unless very special restrictions can be devised (such as cross-equation restrictions in macro policy models) and rendered operational.

In sum, paradoxes, regarded as puzzling outcomes, are normal occurrences in the ordinary line of economic inquiry. Where they impinge on those basic commitments that determine what is 'acceptable' in a line of research there is every incentive to dismiss or ignore them. This is true for analytical puzzles (for example, reswitching) as well as for those in the form of anomalous empirical findings (for example, experimental results indicating preference reversal; Giffen goods; and contrary tests of basic demand theory). It is much easier to modify specific theories in the protective belt, though responses to challenges occurring there will still be driven by the positive heuristics of the research programme (as in the case of the Leontief and Allais paradoxes). The presumption even at this level is that theory arbitrates. There are good reasons for this in the generic nature of economic theories, in the specific difficulties of translating theory into an empirical model and in getting appropriate observations, and in the fact that genuine constants have not been found in economics.

Pareto as an Economist

A. P. Kirman

It is remarkable that as recently as 1968, Allais in his survey of the contributions of Vilfredo Pareto was able to say that: 'His influence on the development of economics as a science was felt only after considerable delay and has largely been confined to Italy and France.'

While the first part of this statement is not open to objection, most modern economic theorists now regard Pareto as one of the founders of 'economic science'. To see how this reevaluation has taken place, we need to examine Pareto's general approach to economics, certain of his specific contributions and his relationship to the work of his contemporaries and his predecessors. What is clear is that while Pareto's reputation has considerably increased in recent years, this reputation is now built on a very limited part of his work. Thus as he has become better known, the extent of his contribution has been less appreciated. Pareto's professional activity as an economist did not start seriously until 1892 although he had published several articles before that date. This late start, together with the general intellectual environment of the period, explains the curiously varied quality of his work. Although he condemned literary economists out of hand and professed to be interested only by a strictly scientific approach to economics, he frequently made normative judgements and indulged in casual empiricism. Yet his work contains pieces of serious and careful analysis, rigorously worked out, which have had a profound and lasting impact on economics. The three major contributions to economics are the *Cours d'économie politique* (1897), the *Manuale d'economia politica* (1906) revised and translated as the *Manuel d'économie politique* (1909) and his article 'Economie mathématique' in *L'Encyclopédie des sciences Mathématiques* (1911). To these, must be added his articles, in particular those collected and published later as *Marxisme et économie pure* (1966) in the *Oeuvres complets* (1964–84) together with the *Trattato di sociologia generale* (1916) which, with *Les systèmes socialistes* (1902–1903) includes a substantial body of economic analysis. Of these contributions, the first, the *Cours*, originally published in two volumes, contains an exposition of economic theory illustrated with numerous empirical facts. The theory is presented in a more precise and refined way than that of his intellectual predecessor Walras and the emphasis is consistently and unequivocally on the interdependence of economic phenomena and the idea of general equilibrium. Nevertheless, the *Cours* does not seem, to modern eyes, well organized, gives the strong impression of having been assembled from course notes, sometimes without a great deal of reflection, and periodically indulges in direct pleading for the 'liberal' cause. It should, however, be remembered that while so much of the material that Pareto discusses is now standard and has been refined by successive generations of economists, much of it was new, recent, or even original for him and it should be judged in context. What is remarkable is that Pareto, although one of, if not the, founder of the school which culminated in the Arrow–Debreu model, did not hesitate to cast his net wide. He included empirical observations and examples of economic phenomena for which he was able to develop little satisfactory theory. Much of the statistical material in the *Cours* had, according to Pantaleoni (1924), been gathered whilst Pareto was a business man and this fact may have some bearing on its presentation.

The *Manuel*, a deeper and more complete book, illustrates the coexistence of philosophical reflection, empirical observations and rigorous analysis in Pareto's work. Of this book, it is the last section, the 'Mathematical Appendix' (in the French edition, pp. 538–671) which has come to be thought of as Pareto's basic contribution to the theory of general equilibrium and to what we now call 'Pareto optimality' but which he referred to as 'The maximum of society's ophelimity'. This appendix was considerably modified and rewritten for the French edition, in large part as a result of Volterra's (1906) comments on the Italian edition. Although the appendix with its formal analysis is the most widely cited part of the *Manuel*, it makes up less than a quarter of the volume. The rest of the work gives an insight into the more general view that Pareto had of economics.

The first two chapters give his views on the scientific status of the social sciences. He argued strongly that in economics and in the social sciences in general, there were underlying laws and structures which had to be determined, specified and tested by scientific methods. He was contemptuous of the work of his more literary contemporaries and felt that economics should be committed to a positive and minimalist approach. The third chapter is devoted to an introduction to the idea of equilibrium. In chapters 4 and 5, he then separates consumption and production and reduces the individual's problem to one of constrained optimization. In the sixth chapter, he then brings the markets together to talk of the general equilibrium of the system and to discuss its efficiency properties. Two things are worth noting in passing. Pareto was well aware that the important thing for the individual was to maximize subject to the constraints that he perceives, which might or might not be the ones he faces in reality. Secondly, he systematically considered the possibility of monopolistic competition in parallel with that of perfect competition although it is his treatment of the latter that is remembered today.

The chapters following those on economic equilibrium deal with demographic problems and their consequences for the labour force, with many factual illustrations, with natural resources, in particular land, with capital and savings and with monetary problems. All the latter problems are dealt with summarily and consist often of observations based on specific facts. The last chapter is devoted to 'concrete economic phenomena' although these already figure largely in the two preceding chapters.

Ordinal Utility

One of Pareto's major contributions has long been considered as that of establishing that, even though utility may not be measurable, an ordinal notion is sufficient for the construction of equilibrium theory. This important aspect of modern theory was not immediately recognized by Pareto. It was only with his article (1900) that he started to develop a fully ordinal theory. Whether Pareto actually rejected the idea of 'measurable utility' or whether he thought that it was simply impossible to identify the appropriate function is an interesting question. Although he was very clear that any one of the 'indices' of utility would suffice for his analysis, several remarks and a comment of Volterra (1906) lead one to suppose that Pareto had not completely broken with the earlier tradition. Indeed, his discussion of cycles of choice leads him to state that 'In certain cases they would permit knowledge of the value of ophelimity' (*Manuel*, mathematical appendix). Pareto develops in the *Manuel*, his analysis of 'indifference curves' contrasting his approach to that of Edgeworth who started with 'ophelimity' or 'utility' and obtained expressions for the indifference curves' (*Manuel*, p. 540, footnote 1).

In the case of two goods, consider x and y the quantities consumed of those goods and consider the quantities dx and dy which, when added to x and y, leave the consumers' satisfaction unchanged. This gives an equation:

$$f_1[x,y]\mathrm{d}x + f_2[x,y]\mathrm{d}y = 0$$

This equation for the 'indifference line' gives us the expression: d$F[x,y] = 0$ which is satisfied by an infinite number of F, and Volterra (1906) now remarks that 'Ophelimity is one of these functions F'.

Whether or not the notion of the 'true utility function' lingered, as Volterra pointed out, Pareto's treatment required further work if it was to be extended to the case of three or more goods. Pareto's reply to this was his well known 1906 paper on 'Ophelimity in non-closed cycles'. Although this paper has been regarded as an attempt to solve this 'integrability problem', as Chipman (1971) points out, it is really devoted to a treatment of the measurable utility problem.

There is, first of all, as in several of Pareto's works, a preoccupation with the order in which goods are consumed which, to modern eyes, confuses the discussion. Strictly speaking, all goods are dated and hence changing the order of consumption changes the specifications of the bundle of goods in question. The dating convention was not established in Pareto's time so he devotes considerable time to discussing the 'paths of consumption'. Early on (1900) Pareto simply assumed that the order of consumption was the optimal one. However, in his 1906 paper, he argues as follows: if utility depends on the path leading to the final consumption whereas, at the final point, changes in utility resulting from perturbations of that point depend only on the total quantities consumed then, utility is measurable. In fact, as Chipman (1971) points out, in the case discussed by Pareto, utility is independent of the path of consumption. The type of result he was aiming at is closely related to another case already treated by Fisher (1896). In this case, consider the marginal utility ('elementary ophelimity') of a good as dependent only on the quantity consumed of that good. The utility function obtained in this case is measurable, that is, it is invariant up to a linear transformation. Pareto's work here may thus best be regarded as an early attack on the problem of separable utility functions. What is clear is that while Pareto recognized that equilibrium analysis could be carried out using only ordinal utility, he still had not reached the point of abandoning measurable utility as a concept.

The integrability problem mentioned above, that of recovering an underlying utility function from demand behaviour, was already solved in large part by Antonelli (1886) in a paper which Pareto had in his possession, albeit briefly, since he commented on it in a letter to Pantaleoni in 1891. However, Pareto does not seem to have profited from Antonelli's work although Walras had already praised it. Thus for some reason, Pareto did not appreciate what had already been done and did not make any significant contribution in this direction despite assertions in the literature to the contrary.

Returning to the original point, it must be emphasized that Pareto arrived at conditions for economic equilibrium using ordinal utility alone and thus clearly marked out the trail for modern economic theory.

General Equilibrium

Pareto wrote down what are now considered to be the standard equilibrium conditions for the consumer side of economy, showing the equality of the marginal rate of substitution to the price ratio, normalizing the price of money, which he assumed to give direct utility, to one (Manuel, mathematical appendix). Taking these equations:

$$U_x = \frac{U_y}{P_y} = \frac{U_z}{P_z} \cdots$$

together with Walras's Law:

$$(x - x_0) + P_y(y - y_0) + P(z - z_0) \ldots = 0$$

and differentiating he found expressions for

$$\frac{\partial y}{\partial P_y} \cdot \frac{\partial z}{\partial P_z} \text{etc.}$$

These he had already set out in his 1892 article in the *Giornale degli Economisti*. He then shows that if goods are independent i.e.

$$U_{xy} = 0 \quad x \neq y$$

then the conditions $U_{xx} < 0$ $U_{yy} < 0$ etc. imply that demand for each good is a decreasing function of its own price (*Manuel*, Mathematical Appendix, section 53). This is a forerunner of more general but very recent results.

It is worth noting in passing some of Pareto's clarifications in the general context of Marshall's work. Firstly, he showed in the *Manuel* (Mathematical Appendix, section 56) that, in general, the marginal utility of money changes with prices. Thus it cannot arbitrarily be assumed to be constant.

He showed in his Encyclopaedia article (1911, section 23) that if the elasticity of demand for all goods is constant, then it is unity, and remarked that since Marshall had not imposed this restrictive condition his analysis was defective.

Lastly, he showed that the idea of estimating consumer surplus as the area under the consumer's demand curve above the exchange price was wrong unless the marginal utility of money happened to be constant (*Cours*, section 83).

Pareto then gives a numerical example of equilibrium with very special utility functions and a linear production function. The conditions for equilibria with production are dealt with in a much less satisfactory way. Indeed, Pareto's treatment of production has been the subject of much discussion and he has been criticized for having abandoned too easily the 'marginal productivity' approach. As Schumpeter (1954) points out, the case often considered by Pareto is only a limiting case of the standard one and the fact that one has to consider boundary cases does not exclude the appellation 'marginal productivity'.

In fact, much of the difficulty in appreciating Pareto's contribution to equilibrium theory stems from his analysis of production. He dealt with both variable and fixed coefficients in production without separating them clearly, as he might have done, into considerations of the long and short term. He repeated explicitly in the *Cours* (section 714) the hypothesis of constant returns to scale. Furthermore, he abandoned, by his introduction of fixed costs, the convexity of the production set which plays such an important role in later analysis (*Manuel*, ch. 5). Finally, what seems to have escaped attention is the effort that Pareto made to discuss what has come to be called 'monopolistic competition' and its introduction into equilibrium analysis (*Manuel*, chs. 3, 5 and 6). Recognizing that individuals can influence prices and that this should be taken into account led him to try to take explicit account of the demand with which they are faced. This merits two comments. Only recently has the introduction of 'monopolistic competition' into general equilibrium models resurfaced and the article by Negishi (1961), which uses rather arbitrary assumptions, is generally cited as the first example. Thus Pareto was already dealing with a problem which has still not been really satisfactorily treated.

Secondly, the confusion as to the nature of time in all of Pareto's analysis is clear. Indeed, he recognizes this himself, when talking of the passage from an initial position to an equilibrium, when he says (*Manuel*, ch. 3, section 171), that the issues he discusses fall into the domain of dynamics rather than statics. The modern convention that the adjustment process to equilibrium is instantaneous and that long-term dynamics consist of the passage from one equilibrium to another is far from that adopted by Pareto.

Pareto did not make a clear distinction between the question of existence and the question of stability. He regarded equilibrium as the terminating point of a process and this is brought out in the *Cours* and particularly in the *Manuel* (ch. 3, sections 110–15 for example). The time taken for this process was not specified but is certainly not regarded, even conventionally, as negligible. He described the passage or path from the initial position to the final position under assumptions of perfect competition with tâtonnement and non-tâtonnement processes and considered the monopolistic competition case, although rejecting it as too difficult to handle. He did, however, enter into a discussion as to how individuals could push the economy towards a preferred equilibrium in the case of multiple equilibria and showed how they would try to manipulate the terms of exchange along this path (*Manuel*, p. 197) and discussed how individuals would benefit from doing this. Furthermore, in the light of this manipulation he suggested that certain equilibria would be stable. Thus Pareto recognized explicitly that stability is a property of a particular process.

Given this vision of equilibrium, Pareto did not try to show the existence of equilibrium as such except by counting equations and unknowns (*Manuel*, Appendix). In effect, he said that since one could find the conditions for equilibrium, an interesting possibility would be to solve explicitly all the equations necessary to determine the equilibrium. However, as he pointed out (*Manuel*, ch. 3, section 217) 'If we take into account the fabulous number of equations that a population of forty million individuals and several thousand goods would give, it would not be mathematics that would come to the aid of economics, but economics that would come to the aid of mathematics' since such a system would be beyond human capacity to solve. Thus Pareto assumes from a simple argument the existence of a solution and simply dismisses the practicality of finding it for a large economy even if all the relevant equations were known.

Thus the preoccupation with the formal establishment of equilibrium which was later to dominate mathematical economics was not shared by Pareto. Although relatively rigorous, he failed to specify various assumptions such as differentiability and only considered interior solutions to the maximum problem.

Before leaving Pareto's treatment of equilibrium, it is interesting to note that he was clearly aware of the possibility of multiple equilibria and in his diagrams in the *Manuel* (p. 192), he seems to have realized that 'in general, the number of equilibria would be odd', a result proved only very recently.

Pareto also seems to suggest that a socialist state would be better able to lead its economy to an equilibrium than an economy based on private property. The reasoning given for this is based on Pareto's particular view of production and this assertion is also heavily qualified (*Manuel*, ch. 6, sections 58–61). Nevertheless, it is interesting to note this contrast with the view of Pareto as an unqualified liberal.

Efficiency or Pareto Optimality

Of all Pareto's contributions to economics, it is this notion of 'optimality' or efficiency that has made the greatest impact.

Yet it was not he who first gave a definition of a situation corresponding to the modern definition. Edgeworth (1881) clearly defined a situation in which the utility of each individual is maximized given the utilities of the others. Although this definition is given in the context of an exchange economy, its extension to more general cases was not difficult.

It was not so much the introduction of the idea but the use that Pareto made of it which makes his contribution important.

Thus, although he had read Edgeworth, his definition which also includes production is an integral part of his own work.

Pareto defined a notion of surplus or gain which was maximized at an optimum. The real insight that Pareto had was that his notion of efficiency or optimality was independent of all institutional arrangements and of all distributional considerations (*Cours*, vol. 2). Pareto then went on in the *Manuel* (ch. 6 and Mathematical Appendix, sections 145–52), to establish the 'first theorem of welfare economics' that a competitive equilibrium is a Pareto optimum and a tentative version of the 'second theorem' that any Pareto optimum can be obtained as a competitive equilibrium from an appropriate distribution of initial resources. The latter result is only suggested and is never clearly stated. Furthermore, both results are incomplete and even incorrect as a result of the confusion in the treatment of production.

Pareto's ideas on the nature of efficiency evolved over time and in the *Trattato* (sections 2128–39), he showed that the maximization of any social welfare function W which was an increasing function of individual utility functions U_i.

$$W = F(U_1, U_2, \ldots)$$

whether the U_i were defined over the consumption of all individuals or, just restricted to individual consumption gave an optimum. Now as Pareto states (*Trattato*, pp. 1342–3), it is clear that in defining W a government would have to give weights to the different individuals. The idea of including the consumption of other individuals in the utility functions extends the scope of normal economic analysis to what were considered at the time and are still often thought of as 'sociological' considerations.

Pareto did not observe that by appropriately modifying F, all optima could be generated. As Allais (1968) suggests, it is not clear that Pareto was fully aware of the impact of this contribution.

Income Distribution, Pareto's Law

One of Pareto's most remarkable contributions was his development of a 'law' governing the distribution of income. It is significant both as a pioneering piece of applied econometrics and for the controversy that its social implications have aroused. His initial work was published in an article in the Giornale degli Economisti in 1895 then in a memoire (1896) on the 'income distribution curve'. Detailed discussion is given in the Cours (sections 957–65) and in the Manuel (ch. 7, sections 2–31).

Three formulae were proposed by Pareto and the first and most widely cited of these is given by:

$$N(x) = \frac{A}{x^a}$$

where $N(x)$ is the number of people having an income greater than or equal to x. As has been frequently pointed out it has obvious problems where either x tends to zero, or one increases x so that $N(x)$ goes to zero. Nevertheless, Pareto obtained values for α in particular for data for the UK collected by Giffen and obtained for 1843: $\alpha = 1.5$ and for 1879/80: $\alpha = 1.35$. Further computations for Prussia, Saxony, Paris and several Italian cities gave values around 1.5 with a maximum of 1.73. Pareto denied that his 'law' had the status of a physical law, and stated in an article in the *Journal of Political Economy* (1897b) that 'I should not be greatly surprised if some day, a well authenticated exception were discovered.' Nevertheless, he believed that the values of α that he found, α itself being a statistic, were sufficiently close for his law to be 'provisionally accepted as universal'.

Pareto also estimated a distribution of the form:

$$N(x) = \frac{A}{(x+a)^{\alpha}} 10^{-\beta x}$$

where a and β like α are constants. He found a value of β so low that he concluded that a distribution of the form

$$N(x) = \frac{A}{(x+a)^{\alpha}}$$

would suffice.

It is not the universality or otherwise of 'Pareto's law' that has provoked so much controversy, and it has been widely recognized since that other distributions provide more satisfactory fits for particular income data.

It is the relation between 'Pareto's law' and the problem of income inequality that has been the subject of dispute. Pareto says that if the number of individuals with an income over a certain level x in relation to the number of those below that level increases, then inequality diminishes (*Manuel*, ch. 7, section 24). Unfortunately, there was a printer's error in the *Cours* and there, the opposite is stated, although from the footnote (*Cours* Livre III, section 965), it is clear what Pareto intended. There has since been considerable confusion about what Pareto actually said.

Let $N(h)$ be the number of individuals with income above h (the 'minimum income') and $N(x)$ the number above x with $x > h$. Then, as Pareto says, if we define

$$U_x = \frac{N(x)}{N(h)}$$

then, 'income inequality will decrease as U_x increases' (*Cours* Livre III, section 965) (*Manuel*, p. 390, footnote 2).

Allais interprets Pareto as saying the opposite, perhaps following the error in the *Cours*. Yet if we now proceed and assume that 'Pareto's Law' holds, then we have:

$$U_x = \left(\frac{h}{x}\right)^{\alpha}.$$

Since $x > h$ by hypothesis, U_x decreases when α increases and income inequality increases. Allais makes an error in his argument and states that:

$$\frac{N(h)}{N(x)} = \left(\frac{h}{x}\right)^{\alpha}$$

an error identical to that made by Roy (1966). Since both Roy and Allais had started from the original mistake in the *Cours*, this further error should have led them to the same final conclusion as Pareto that income inequality varies in the same direction as α. Roy indeed arrives at this conclusion and contrasts it with the work of Gini and others. Allais made a further error and stated that Pareto believed that income inequality varied inversely with α. All this gives some indication of the sort of confusion that has surrounded Pareto's contribution.

Nevertheless, several remarks are in order. 'Pareto's Law' gives empirically a satisfactory fit for the upper tail of the income distribution (the top 20 per cent according to Lydall 1968) but is clearly inconsistent with the lower end. If α were a constant, then there would be little hope for policies aimed at reducing income inequality, as Pareto pointed out to those in favour of the socialist position. Lastly, Pareto's Law has the peculiar feature that the ratio of the average income above x say $m(x)$ to x itself is a constant given by:

$$\frac{m(x)}{x} = \frac{\alpha}{\alpha - 1}.$$

Allais suggested that this might be taken as Pareto's index of inequality. If this were so, then it would decrease with α the opposite of what Pareto intended.

Economics and the Social Sciences

Pareto's vision of the nature of the social sciences is reflected in his works on sociology (in particular the *Trattato*) and a certain number of his positions mark him out from his contemporaries and his successors. He developed and reinforced his idea that such sciences should be positive and went as far as criticizing his earlier work, taking the 'author' of the *Cours* to task for mixing ethical and positive considerations (*Manuel*, Preface). His defence of positivism was clearly associated with Comte's position (1830) and he was interested in developing a 'positive theory of economic policy'. He argued that 'laws' or relations deduced from specific assumptions should be tested empirically against 'observed statistical laws'. He went further, however, and unlike J.S. Mill (1844) who asserted that to verify hypotheses was not part of the business of science, a position supported by Friedman (1953) and Machlup and others, later, argued that assumptions should be examined to see how reasonable they are (*Trattato*, section 59). The importance of Pareto's statistical work which reflected his standpoint has tended to be overlooked and has been dominated by analysis of his purely theoretical contributions.

His approach to economics reflected a double position. Firstly, he shared Marshall's opinion that economic theory should be aimed at examining 'man as he is' and should not become an abstract intellectual exercise. Secondly, however, while he wished economics to be a relevant science, he condemned attempts to apply too readily economic theory to real problems. He believed that much harm had been done to the cause of 'scientific economics' by such hasty applications.

Finally, it should be remembered that while Pareto was with Weber among the first to expound the principles of 'positive social science', his view of the status of economics was ambiguous. He believed fundamentally, and in this he shared Comte's view, that there should be a universal scientific approach to social science. Yet he recognized the need for, and desirability of specialized disciplines and he was persuaded that economics had a special advantage in that it is by nature a more quantifiable science than the other social sciences. His contributions make it clear, however, that he was not prepared to isolate man's economic activity from his other functions.

Conclusion

Pareto's economic contribution has acquired an increasing reputation over time, unlike his sociological work. Yet as was suggested at the outset, it is disappointing that this reputation should be constructed on the basis of such a small part of his work. His strictly theoretical contributions are an essential part of modern general equilibrium theory. Yet here his education and training pushed him towards an equilibrium notion close to those of classical mechanics and in a certain sense, he helped to lock economics into an unhappily rigid framework.

His more imaginative contributions, his analysis of conflicting interests, his concern with statistical verification and his preoccupation with the place of economics as just one part of a larger structure, have all been left aside.

Thus, paradoxically, Pareto's stature as one of the major economic figures of his time with Walras and Fisher, has been diminished by recent over-emphasis of his most formal contributions.

The Greeks lamented the passing of the universal athlete who was replaced by the almost deformed specialist in each individual sport. Pareto's work should place him clearly as one of the last in the former category but the importance that has been attached to part of his mathematical economics is likely to condemn him unjustly to being described as one of the first of the 'specialists'.

Using certain data on personal income V. Pareto (1897) plotted income on the abscissa and the number of people who received more than that on the ordinate of logarithmic paper and found a roughly linear relation. This Pareto distribution or Pareto law may be written as

$$x = ay^{-\alpha} \text{ or } \log x = a' - \alpha \log y \qquad (1)$$

where α (the negative slope of the straight line) is called the Pareto coefficient. The density of the distribution is

$$dx = a\alpha y^{-\alpha+1} dy$$

The Pareto coefficient is occasionally used as a measure of inequality: The larger α the less unequal is the distribution. According to Champernowne (1952), α is useful as a measure of inequality for the high income range whereas for medium and low incomes other measures are preferable.

α takes only positive values. If $\alpha < 2$ the distribution has no variance; if $\alpha < 1$ it has no mean either. In practice the Pareto law applies only to the tail of the empirical distributions i.e. to incomes above a certain size. Thus the law (1) is valid asymptotically as $y \to \infty$. The range in which the empirical distributions conform to the law is different in different cases. It seems to be larger for wealth than for income (perhaps because we have data only for large wealth) and even larger for towns. In the case of firm sizes only very large firms are covered by the law.

In the case of the distribution of towns by size of population the rank-size relation has been used (Zipf 1949) which is the same as the Pareto distribution except that it uses rank as a measure of the tail (instead of the number of towns above a certain size) so that the higher the rank (beginning with rank one for the largest town) the smaller the size of the town. Zipf believed (incorrectly) that the coefficient α is always about one so that the product of rank and size is constant. But Pareto, of course, was even more 'out' with his belief that the Pareto coefficient for income α always equals unity. In highly industrialized countries today it is above 2 and sometimes above 3.

The main interest of the Pareto distribution lies not in its rather limited use as a measure of inequality but in the explanations it has provoked, naturally so since regular patterns are felt to be a challenge to the mind. There are two types of approach to the problem. That of Champernowne, Yule and Simon explains the characteristic pattern as the steady state of a stochastic process which has been evolving in time, so that the pattern reflects something which has been going on in the past. In contrast, Mandelbrot has been looking for a 'synchronic' explanation which does not depend on a process in time. He is mainly concerned with the reproductive quality of the Pareto distribution: If a large number of independent random variables is identically distributed according to Pareto's law then the sum of these random variables will also be distributed according to this law. Thus it could be expected that the income of the various counties in England would be Pareto distributed because it results in each case from the addition of individual incomes which are Pareto distributed.

Champernowne's pioneering work (1953) in essence goes back to his fellowship dissertation of 1936, published in 1973. He builds on a tradition which explains the normal distribution as the result of the addition of random unit steps (left or right) on the line over a long time (random walk; for the terms and concepts relating to random processes, see Feller, Vol. I). If the random walk takes place on the logarithmic scale the distribution of the sum of steps will tend to log normality. This does not give, however, a stable distribution, because the dispersion will go on increasing all the time. Champernowne chooses the technique of the Markov chain: Each year's income depends only on the previous year's income plus a random increment proportionate to last year's income; the probability of various increments remains constant from one year to the other. This feature is called the law of proportionate effect. Thus the required data will be embodied in a matrix which contains the probabilities of transition from one income in one year to another income in the following year. The number of income receivers remains stable in Champernowne's model because each exit is assumed to be automatically compensated by a new entry. To guarantee that the system reaches a steady state it is assumed that on the average the change of income is downwards; this is necessary to compensate the tendency of the system to diffusion which is characteristic of the unrestrained random walk. The assumption reflects the low income of new entrants.

In fact the role of new entry is crucial not only in this model but in other applications as well (size of firms, towns, wealth).

H. Simon (1955) studied the number of times a particular word (vocable) occurs in a text. The number of vocables which occur with a given frequency decreases with that frequency in a Pareto-like fashion. Simon's treatment is based on the work of Yule (1924), who dealt with a biological problem: the frequency of genera with different number of species which is distributed according to Pareto. He explained this pattern by means of a pure birth process deriving from this the Yule distribution with density

$$f(n) = \alpha\Gamma(1+\alpha)n^{-1-\alpha} \text{ as } n \to \infty.$$

The model of evolution assumes that mutations occur randomly with a frequency g per time unit, creating new genera, and with a frequency s per time unit creating new species, where $g < s$. Since each species has the same chance of creating a new species we have here a proportionate growth, in analogy to the law of proportionate effect. The steady state is produced by the emergence of new genera. The Pareto coefficient equals the ratio of the frequencies with which the two kinds of mutations appear, that is g/s. Simon, whose merit it is to have drawn attention to this brilliant work, has suggested application to incomes (not very convincingly) and has himself applied it to firm sizes (1967). A very direct application relates to the size of towns (Steindl 1965). If the number of towns grows at the rate of μ and the number of inhabitants of the town grows at the rate of ρ then after a sufficiently long time there will be a steady state distribution with Pareto coefficient μ/ρ.

Mandelbrot (1960, 1961) deals with the problem from the point of view of a mathematician and therefore on a very general level. He starts from the concept of stable laws (compare Feller, Vol. II, ch. VI). If a sum of independent identically distributed random variables is distributed in the same way as its components, except for a scale factor and possibly of a location factor, then this distribution is stable. The best-known example is the normal distribution. It has been shown by *P.* Lévy that there is a class of distributions with infinite variance which are stable and which converge to the law of Pareto when the variable in question (say, income) tends to infinity. The Pareto law in this context is confined to the range $1 < \alpha < 2$. Mandelbrot surmises, owing to the reproductive quality, in the above sense, of the Pareto law, that its importance empirically must be very great. He also considers that this must have implications for some statistical methods which depend on the assumption of normalcy.

As to income, Mandelbrot suggests that it can be regarded as composed of a number of independent elements which are identically distributed. We can easily imagine a decomposition into a few parts such as earned income, property income and transfer income. Mandelbrot requires, however, in order to assure convergence, a large number of components, and these, as he admits, have hardly any counterparts in reality (1961, p. 525). The explanation is analogous to the well known explanation of the stature of adult men as a random variable composed of a great number of independent small random variables; this explains the normal distribution of height. The precise identity of these small random variables is, here again, not specified and rather speculative. This may perhaps explain why this ‘synchronous’ approach has not, so far, found much resonance among economists.

The interest of the alternative approach (Champernowne or Yule) of explaining the law as a steady state of a stochastic process is that it establishes a relation between the stratification found in a cross section and the past history which has produced it, and which is mapped in the cross section. This is analogous to the stratifications in geology or the rings in the trunk of a tree. Irregularities or shifts in the empirical distributions can according to this view be explained by major disturbances of the process in certain points of time in the past.

Concretely, the Pareto distribution has been shown, in the case of a birth and death process model, to depend on growth; in an economy which has always been stationary it would not exist (Steindl 1965). The Pareto coefficient in such models is usually a ratio of growth rates; thus in the case of firm size it is a ratio of the growth rate of the number of firms to the growth rate of the firms themselves (Steindl 1965). The importance of new entry as a factor making for less inequality has also been shown, *inter alia* in the case of wealth (Steindl 1972).

The stochastic models have often been criticized for their lack of economic content. Perhaps it has been overlooked that they only represent the first steps in a new and exceedingly difficult terrain. It may be thought that the work of Champernowne, Yule, Simon and Wold and Whittle contains the seed of future studies which will reveal their full potentiality only when they are extended to distributions in several dimensions.

Few concepts are more widely used within economics than that of 'efficiency'. It usually means not wasteful, or doing the 'best' one can with available resources. However, there are specialized usages; for example, the concept of efficient markets in the finance literature, or Leibenstein's concept of X-inefficiency. Not all these meanings, even in academic work, have a common provenance. However, the concept as used in neoclassical economics has a precise but rather narrower meaning, given to it by Pareto, the Italian economist and sociologist, in his works *Course in Political Economy* and *Manual of Political Economy* around the turn of the twentieth century. He suggested the following definition: an allocation of resources in the economy was optimal if there existed no other productively feasible allocation which made all individuals in the economy at least as well-off, and at least one strictly better off, than they were initially. Although Pareto actually used the word 'optimal', this is really a definition of efficiency, as a Pareto-'optimal' allocation of resources is 'good' only in the limited sense that not everybody can be made better off. It may in fact be very undesirable in some other way, for example, very unequal. It is not surprising, therefore, that the word 'Pareto-optimal' has gradually been replaced by 'Pareto-efficient'.

There are several points to note about this definition. First, it is only well defined within a neoclassical framework, that is, where the preferences of individuals and the technical possibilities of production are taken as the ultimate data of economic analysis. Secondly, even within this framework, it is an ordinal concept of efficiency, as it does not rely on any intensity of preference, interpersonal comparability of utilities, or commensurability of different inputs or outputs for its definition. This is no accident; Pareto was a convinced ordinalist, who believed that the utilitarian concept of introspective utility was unscientific (see for example Pareto 1927, p. 113). Thirdly, while it provides a ranking of allocations of economic goods between individuals, it does not permit a ranking of all such allocations, that is, there are many different allocations that are Pareto-optimal and which differ with respect to the distribution of real income (that is, utility) among the individuals in society.

Simple and limited idea though this is, it has had an enormous influence on the development of neoclassical economics. First and foremost this is because Pareto did not simply present this notion of optimality as an abstract criterion, but showed that competitive equilibrium would yield an optimal allocation of resources in this sense, thus making precise the notion of the 'invisible hand'. It is no exaggeration to say that the entire modern microeconomic theory of government policy intervention in the economy (including cost–benefit analysis) is predicated on this idea. It also stimulated other debates, such as the one over 'market socialism' in the 1930s, which led to modern theories of economic planning. However, it has by its very success inhibited investigation of other criteria for the performance of economic systems. More radical commentators argue that Pareto, and what followed after, also serves an ideological purpose, namely, to show that capitalism is inherently self-regulating, with phenomena such as unemployment being explained as deviations from an 'ideal' equilibrium rather than inherent structural problems. In this article, we briefly review the historical evolution of the idea, and then attempt a critical assessment.

As already remarked above, the context in which Pareto first presented his concept of optimality was in demonstrating that competitive equilibrium was optimal, of efficient. This crystallized the notion, present at least since Adam Smith, that free trade has (possibly unintended) beneficial consequences. His arguments were much refined and extended over the years by figures such as Barone, Lerner, Hicks and Samuelson, although it took some 20 or 30 years after the *Manual of Political Economy* was published for the 'new' welfare economics to become common currency. The current version of the proposition is essentially based on the work of Arrow and Debreu (for example, Debreu 1959) who generalized and clarified the mathematics of the result. They showed that it is in fact a twofold proposition; under certain conditions, competitive equilibrium is Pareto-efficient, and second, the additional assumption of non-increasing returns to scale, any Pareto efficient allocation of resources may be decentralized as a competitive equilibrium. These statements are known collectively as the two theorems of welfare economics.

Before going on to discuss them, one should note that there is, to begin with, a problem with the notion of 'competitive'. By this, we simply mean here that all firms (or more generally, all agents) take prices as given, not necessarily that they are 'small' relative to the economy. The problem is that the former is not generally plausible behaviour unless the latter is true. Therefore, the result should really be thought of as approximate – that is, with price or quantity-setting firms equilibrium is approximately competitive, and hence approximately optimal when firms are 'small' – although it is not usually presented in this way.

Now, given price-taking behaviour, the sufficient conditions for the first theorem are (i) that there are no externalities and (ii) that there are complete contingent markets for all commodities (apart from externalities), that is, markets at all present and future dates and states in all contingencies. Implicit in (ii) is the assumption that all agents are equally and perfectly informed about all aspects of their environment. The reason why the first condition is sufficient (and, generally, necessary) is simply that externalities such as air pollution, are in this framework goods (or, more properly, 'bads') for which no markets exist, so there is no mechanism for the marginal benefits of the externality-producing activity to be equated to the marginal damages they impose on others.

The role of complete contingent markets, however, is not so immediately apparent. The reason is as follows. Consider, for example, a two-period economy with spot markets, but no means of transferring income from period to period (that is, no securities or money). Then, clearly, individual marginal utilities of income will not be equalized in the two periods. Equalization is, however, a necessary condition for full Pareto efficiency, as otherwise a reallocation of income between periods can make at least one agent better off than in the original position. The same argument applies *a fortiori* if there are no, or limited, means of transferring income between different states of the world. If there are complete contingent markets, however, this problem cannot arise.

Some, however, have suggested that, with incomplete markets, full Pareto efficiency is too demanding a performance criterion, and have suggested that one should reformulate the concept to take into account the inherent restrictions on allocation of resources when markets and information are incomplete. This is sometimes called constrained Pareto efficiency. The problem with such an approach is that the exact definition of constrained efficiency is often arbitrary. To take an example, Hart (1975) proposed the definition that a competitive equilibrium with incomplete markets was constrained Pareto-optimal if there was no other competitive equilibrium relative to the same allocation of endowments which Pareto-dominated it. This seems a weak criterion, (for a start, it only has force when there are multiple equilibria), but nevertheless he showed surprisingly that not all equilibria were Pareto-efficient even in this sense, that is, that multiple equilibria could be Pareto-ranked. On the other hand Gale (1982) has proposed an even weaker notion of Pareto efficiency relative to which the first theorem is true, and there is no way of deciding which 'the' correct measure of performance is. In addition, the issue becomes even more complex in the more interesting case where information is asymmetric, with the concomitant phenomena of signalling, adverse selection, moral hazard, and so on. Here, competitive equilibrium may 'fail' in a number of new ways; for example, resources may be wasted on signalling. In summary, Pareto's argument is not general; the invisible hand becomes very shaky when unrealistic assumptions are dropped.

Therefore, very few people take the theorems of welfare economics seriously as descriptions of the real world. The main significance of the two theorems has been in generating a framework for evaluation of government intervention in the economy: this framework has dominated neoclassical thinking about public policy. One can distinguish two types of policy analysis. The first, which we can call 'market failure' analysis, abstracts from distributional considerations by supposing that the government can lump-sum tax individuals in the economy. The procedure is to compare the 'real' economy to the complete contingent markets economy, which is known to be efficient, and on the basis of this prescribe policies that either mimic or replace markets to some extent, or more generally alleviate the inefficiency. The classic example of this approach is in the externalities literature, which proposes either the creation of artificial markets in the externalities via the assignment of property rights (à la Coase), or the imposition of corrective taxes (à la Pigou). This kind of prescriptive analysis may seem excessively utopian; however, some have used the market failure paradigm descriptively to explain the existence of various institutions as replacements for markets, a classic example being Arrow's (1963) discussion of health care.

The second type of policy analysis is concerned with the 'problem of redistribution' or how to redistribute pre-tax incomes to satisfy distributional objectives without the benefit of lump-sum taxation, that is, using income or commodity taxes, and so on. In this case, the first theorem says that the initial no-tax equilibrium is efficient, but, given that redistribution involves distortionary taxation, with redistributive taxes competitive equilibrium will be Pareto-inefficient. Hence, there is a trade-off between Pareto-efficiency and distributional objectives. The literature has, in the main, been concerned with characterizing those tax structures that are 'second best' Pareto-efficient, that is, such that there is no change in the available taxes such that all agents can be made better off. There is now a large literature on such optimal redistributive taxation (see for example Mirrlees 1986).

There are, of course, major problems with the actual implementation of the policy prescriptions that arise from this analysis. First, usually the policy recommendations depend on the taste/technology specification of the models (for example, optimal taxation formulae depend crucially on the functional forms chosen for labour supply and commodity demands) and the latter are only testable to a very limited extent. Second, as Lipsey and Lancaster (1956) showed, the 'optimal' policies are also generally sensitive to assumptions made about the existing 'distortions' in the economy (for example, taxes, monopolies, and so on) if these are not also controllable by the government or planner. For, as they showed, it may not be desirable to substitute lump-sum taxation for a tax on one commodity if there is a preexisting tax on another. Finally, the characterization of the trade-off between Pareto efficiency and distribution needs to be complemented by a distributional judgement to provide concrete policy recommendations, for example, a rate of income tax.

The alternative approach to policy, of course, is to suppose that the planner is interested in pursuing a number of 'intermediate' objectives such as maximizing the growth of national income or employment, or reduction of inequality of income, or inflation, or some weighted combination of these. However, while these objectives are undoubtedly more operational, and perhaps more philosophically appealing as they do not commit one to a utility-based view of welfare, the above problems will still arise with intermediate objectives.

Therefore, the Paretian approach to policy may have a role to play, especially (i) when Pareto-efficient policies are relatively robust to the structure of tastes/technology and distributional goals as are for example some shadow-price rules for cost–benefit analysis (see for example Drèze and Stern 1987, pp. 49–62) and (ii) to critically analyse the basis for the choice of intermediate objectives; for example, why is inflation 'costly'? When Pareto presented his original proof of the efficiency of competitive equilibrium, he seemed also to assert that these conditions could only be attained in a decentralized economy; 'if one could know all these equations (which describe the optimum) the only means to solve them which is available to human powers is to observe the practical solution given by the market' (Pareto 1927). Nevertheless, Barone pointed out explicitly shortly afterwards that the same efficient allocation of resources could be achieved by an omniscient central planner in a 'socialist' economy, that is, one where the means of production were collectively owned. This, and other subsequent contributions provoked a debate between, among others, von Mises, Lange and Hayek (see for example Lange 1936, or von Hayek 1940) about how – if at all – in practice the Central Planning Board (as Lange called it) could achieve this. Lange, for example, proposed a price-based iterative procedure where the CPB effectively replaced the Walrasian auctioneer. Other solutions were also proposed, and since the 1950s these have been extended and formalized by Arrow, Hurwicz, Malinvaud, Heal and others (see for example Heal 1986). All these schemes, however, essentially use the price system as a means of transmitting information to the central planner. In the end, though, it is questionable whether the market socialism debate has had any real impact on the adoption of market socialism in centrally planned economies.

The concept of Pareto optimality, while simple, almost trivial in itself, has had an enormous impact on economics. However, by providing an apparently precise measure of the efficiency of an economic system, independent of distributional questions, it has, in my view, inhibited discussion of distributional questions and alternative criteria of efficiency. One reason for this, however, may be that within the ordinal neoclassical paradigm Pareto's definition is the only tenable concept of efficiency; that is, any other concept of efficiency, once reformulated in a neoclassical model, will eventually reduce to it.

An example of this is Leibenstein's (1966) notion of X-inefficiency. When Leibenstein introduced the idea, he sharply distinguished it from the notion of Pareto efficiency. The former was inefficiency in the process of production due to the fact that contracts for labour are incompletely specified, the 'production function' is not known, and so on, and so derived from bounded rationality. However, Hart (1983) attempted to capture the notion of X-inefficiency in a fully rational, maximizing model; he identified it with the loss of output due to the fact that managers' efforts cannot be perfectly observed by shareholders. In this framework, X-inefficiency reduces to Pareto inefficiency relative to the full-information equilibrium. A similar fate befalls Schumpeter's definition of efficiency (see Schumpeter 1942, p. 188), which emphasizes the long-run performance of the economy – capital accumulation, technical progress, and so forth. He proposed that perfect competition, which is Pareto-efficient in a static sense, would not be efficient in this long-run sense compared with monopolized industries, as the latter survive better in the 'gale of creative destruction', as he describes capitalism. However, this concept of long-run efficiency reduces to Pareto efficiency if one writes down a dynamic model of competition. This is not to say that Schumpeter's ideas can all be adequately modelled in a neoclassical framework – they cannot – but simply that no other concept of efficiency can sensibly be formulated within this framework.

Therefore, Pareto efficiency and the neoclassical paradigm go hand in hand. If one rejects some aspects of the paradigm, then Pareto efficiency may not have much meaning. For example, some (for example, Galbraith) have argued that, in practice, there is little consumer sovereignty; if desires are manipulated and fears exploited by advertising and so on, the Pareto criterion is of little use in gauging how well real wants are satisfied. Some Marxists (see for example Rowthorn 1980) go further than this, and argue that Pareto's proof of optimality serves an ideological purpose, by presenting a picture of capitalism as a harmonious enterprise and distracting attention from its exploitative nature.

Pareto Principle and Competing Principles

Louis Kaplow

Abstract

The Pareto principle, the seemingly incontrovertible dictum that if all individuals prefer some regime to another then so should society, may conflict with competing principles. Arrow's impossibility theorem and Sen's liberal paradox are two notable examples. Subsequent work indicates more broadly that the Pareto principle conflicts with all non-welfarist principles. This essay surveys these results, including various extensions thereof, and offers perspectives on the conflict, drawing on classical and contemporary work in political economy and economic psychology.

The Pareto (1906) principle holds that, if all individuals strictly prefer one state, regime, or policy to another, then that selection is deemed socially preferable as well. Because of the power of unanimous endorsement, the Pareto principle has understandably been important in normative economic analysis. Even though strict Pareto dominance is unlikely to prevail when society is deciding among plausible competing alternatives (for this would require that literally each of millions preferred the same outcome), the Pareto principle nevertheless offers important guidance. In particular, the principle may help in choosing among or ruling out various other evaluative notions; principles that turn out to conflict with the Pareto principle may accordingly be rejected. Alternatively, if some competing principles seem compelling, they may raise doubts about the ostensibly incontrovertible Pareto principle.

The first sections to follow review two well-established conflicts between the Pareto principle and certain competing principles: Arrow's (1951) impossibility theorem and Sen's (1970) liberal paradox. The succeeding section presents more recent work that establishes a general conflict between the Pareto principle and all non-welfarist notions, whether they concern rights, justice, or other conceptions of fairness (apart from those pertaining only to the distribution of welfare itself). A final section examines classically grounded strands of literature on political economy and economic psychology that help reconcile the tension between the seemingly unimpeachable Pareto principle and conflicting non-welfarist principles, many of which have appeal to the public, policymakers, and economists as well. (The Pareto principle is also important in normative economic analysis, notably with regard to the two fundamental theorems of welfare economics, a subject not considered in this article.)

Arrow's Impossibility Theorem

Perhaps the most famous instance of conflict between the Pareto principle and competing principles is Arrow's (1951) impossibility theorem. Arrow considered social choice procedures designed to generate a consistent social ordering (a complete and transitive ranking) from purely ordinal information about individuals' preferences. In one formulation of Arrow's theorem, the assumptions of universal domain (no restriction on individuals' preferences), independence of irrelevant alternatives (the social ordering of any two alternatives depends only on individuals' orderings of those two alternatives), non-dictatorship (no one individual's preferences completely determine social preferences), and the Pareto principle imply that such a social ordering is impossible.

A large subsequent literature explores whether relaxing some of Arrow's assumptions modestly would make possible procedures that yield robust social orderings. Of particular relevance here are attempts to weaken the Pareto principle. As surveyed in Campbell and Kelly (2002), these efforts have been largely unsuccessful: either there are frequent violations of the Pareto principle or a single individual will have substantial, even if not completely dictatorial, influence.

Nevertheless, Arrow's theorem does not rule out the class of standard, individualistic social welfare functions (SWFs), mappings from individuals' utilities to a measure of social welfare, that are fully consistent with the Pareto principle. Consider the discrete case, in which there are n individuals, $U_i(x)$ is the utility of the ith individual, and x is a complete description of the pertinent state. Then we can define $W(\mathrm{U}_1(x),\ldots,U_n(x))$ as an individualistic SWF (so called because it depends only on individuals' utilities). Assuming, as is standard, that W is increasing in each individual's utility, it follows that, for any set of individuals' utility functions $\{U_i(x)\}$, W provides a complete and transitive social ordering of all possible social states that is independent of irrelevant alternatives, non-dictatorial, and satisfies the Pareto principle. The classical utilitarian criterion, $W = \Sigma U_i(x)$, is an example of such an SWF.

The possibility of an SWF is restored by altering Arrow's framework to allow the domain of social choice procedures to consist of individuals' utilities rather than just their orderings. This approach entails interpersonal utility comparisons, which during the mid-20th century (and to an extent thereafter) were eschewed in welfare economics, following the argument of Robbins. As Robbins (1935, vii–x, 1938) himself clarified in the second edition of *An Essay on the Nature and Significance of Economic Science* and a subsequent essay, however, his argument was not that interpersonal comparisons should not be made – indeed, they were inevitable – but rather that they involve value judgements rather than scientifically verifiable statements. Much modern welfare economics has pursued analysis of SWFs that depend on individuals' utilities and not just orderings, presumably because of a belief that preference intensities matter and that interpersonal comparisons are required if distributive judgements are to be made.

Sen's Liberal Paradox

In 'The impossibility of a Paretian liberal', Sen considered whether the Pareto principle conflicts with a specific notion of liberalism, subsequently described by many (including, on occasion, Sen himself) as a species of libertarianism. His condition stipulates that there exist certain choices about which the social ranking should reflect that of a particular individual, regardless of other considerations, including effects on the utility of others. This conception and Sen's analysis thereof is well illustrated by considering his much-discussed example. One individual, whom we shall call Prude, abhors erotic literature, and a second, Lewd, adores it. Both individuals' preferences, moreover, are assumed to be meddlesome in the following manner. Prude would be more upset by Lewd's reading a certain lascivious novel than reading it himself, and Lewd would get more pleasure from Prude's reading the novel than reading it herself. Therefore, as between just Prude reading the novel and just Lewd reading it, both prefer the former. However, Sen's liberal principle insists that the latter be the social choice: Prude's preference against his own reading of the book, ceteris paribus, dictates socially that Prude should not read the book, and likewise Lewd's desire that she read the book, ceteris paribus, dictates socially that Lewd should read it. Hence, the choice that Sen's liberal principle deems socially best is one that would be rejected under the Pareto principle.

Analytically, Sen's result can be understood by reference to the familiar concept of externalities. Lewd's reading the book involves a negative externality on Prude, whereas Prude's reading the book involves a positive externality on Lewd. (Compare the case in which Lewd moderately enjoys loud parties that greatly annoy his neighbour Prude, and Prude would rather not bother to replace his weed-ridden garden with flowers that would greatly delight his neighbour Lewd.) Failing to regulate externalities obviously may violate the Pareto criterion. Furthermore, in Sen's example, the two individuals – if left to themselves – would wish to enter a Coasian bargain under which Prude, rather than Lewd, reads the book (just as, in the variation, Lewd should agree to refrain from loud parties if Prude agrees to replace his weeds with flowers). Sen's principle implicitly prohibits both government regulation and private exchange in which individuals mutually relinquish their posited liberal rights. Preventing mutual waiver both by vote and by contract may hardly seem liberal, as argued by Gibbard (1974) and many others in a highly elaborated literature, surveyed by Suzumura (forthcoming). Indeed, any notion that conflicts with the Pareto principle must embody an underlying opposition to freedom since a violation of the Pareto principle entails contravention of unanimous choice. Some of Sen's subsequent writing (for example, 1992, pp. 144–6) defends his original liberal principle on grounds of practicality and concern for governmental abuse of power. As explored below in the final section, however, such Millian (Mill 1859) justifications for rights may be powerful but are not, at root, inconsistent with the Pareto principle.

Conflict Between Pareto Principle and All Non-welfarist Principles

Sen showed that one particular formulation of a libertarian principle, which carries the implication that externalities of a sort may not be regulated, violates the Pareto principle. Subsequently, it has been asked more broadly which notions of right, justice, and fairness conflict with the Pareto principle. The answer, it turns out, is that essentially all such notions do, as long as they do not depend exclusively on individuals' utilities – that is, unless they are a reformulation of welfarism.

To state the matter more precisely, we can contrast the individualistic SWF introduced previously, $W(U_1(x),\ldots,U_n(x))$, which by construction depends only on individuals' utilities, with the more generalized SWF, $Z(x)$, which also may be written as $Z(U_1(x),\ldots,U_n(x),x)$. Under the latter, social welfare may depend on anything and, in particular, need not depend exclusively on how the pertinent state x affects individuals' utilities. For example, notions of merit or desert concern whether certain actions or attributes are rewarded, principles of corrective or retributive justice demand that specific norm violations be followed by compensation or punishment, and so forth. Under each of these non-welfarist criteria, knowing each individual's utility in state x is insufficient information to form a social judgement.

Kaplow and Shavell (2001) prove that, if an SWF is not individualistic, then it violates the Pareto principle, if one makes a certain continuity assumption. The assumption is not that the SWF is continuous in all respects. (It is allowed, for example, that infinitesimal violation of some right might cause a discrete reduction in social welfare.) Rather, it is assumed that there exists some good that, if all individuals are given more of it, ceteris paribus (for example, holding rights violations constant), all will have a higher utility and, moreover, the value of the SWF changes continuously as the amount of that good is changed.

The proof is roughly as follows. First, if the SWF does not depend only on individuals' utilities, there must exist two states that are evaluated differently despite everyone's utilities being the same. That is, the non-welfarist SWF is supposed, in at least one instance, to rank states differently on account of a non-welfare difference. Now, taking whichever of the two states ranks lower, we can increase slightly everyone's allotment of the aforementioned good. By continuity, if that increase is sufficiently small, the lower-ranking state must still be ranked lower. However, since all individuals had equal levels of utility in the two initial states, every individual in the modified state now has greater utility, making it Pareto preferred despite the fact that the posited non-welfarist SWF ranks it lower. Hence, the Pareto principle is violated.

One way to understand the conflict between the Pareto principle and all non- welfarist principles is to reflect on the fact that a non-welfarist SWF by definition gives some weight in some instances to a factor independent of its effect on individuals' utilities. We can compare a state that is preferred on account of this non-utility factor to a state that is otherwise identical except that all individuals are slightly better off with respect to some commodity. In other words, a non-welfarist SWF, by its nature, sometimes sacrifices welfare, and nothing in logic rules out the possibility that the welfare sacrifice is borne pro rata.

Subsequent work has generalized and extended this theorem. Campbell and Kelly's (2002) survey notes that the proof in Kaplow and Shavell (2001) does not require the SWF to be a function rather than a binary relation; that this relation need not be fully transitive, only acyclic; and that only lower continuity is required. In a different vein, Suzumura (forthcoming) derives a sort of converse, namely, given Pareto indifference (if everyone is indifferent then society is indifferent – a principle implied by welfarism), social choice must respect the weak Pareto principle (the version defined at the outset of this entry) as well as the strong Pareto principle (if everyone weakly prefers one alternative and at least one individual strictly prefers it, then it is socially preferred). This theorem requires two additional assumptions: positive responsiveness of the social decision to individual preferences, and that, ceteris paribus, any utility level for an individual can be reached by adjusting the amount of a particular divisible good received by that individual.

Kaplow and Shavell (2002) also offer a complementary demonstration of the conflict between all non-welfarist principles and the Pareto principle. If one restricts attention to symmetric settings – those in which all individuals are identically situated – then any non-welfarist principle conflicts with the Pareto principle in every instance in which its ranking differs from a purely welfarist one. Because everyone is affected identically, it must be that, whenever any amount of aggregate welfare is sacrificed, each and every individual's welfare is sacrificed. The significance of this result is that many traditions favour assessing principles for guiding society in hypothetical situations that, because they are designed to create an impartial perspective, have a symmetric character. Consider, for example, the original position of Rawls (1971) – with important prior formulations thereof by Harsanyi (1953) and others – in which individuals are taken to have no knowledge of their own characteristics. Likewise, the injunctions of the Golden Rule and, relatedly, of Kant's (1785) categorical imperative demand, in essence, that one examine rules as if both positive and negative consequences were borne symmetrically by all. Since, as noted, all choices in symmetric settings involve strict Pareto rankings (except in cases in which all are indifferent), admitting a non-welfarist principle entails the view that the socially preferred state is systematically one in which everyone is worse off.

Perspectives on the Conflict

The Pareto criterion is a bedrock principle. Yet it conflicts with all non-welfarist principles – whether they pertain to rights, justice, or fairness – and some of these principles have apparent appeal. How may this tension be reconciled? That the Pareto principle should be seen as paramount is suggested by the rhetorical question: To whom is one doing right, providing justice, or being fair if every possible beneficiary is thereby made worse off? Additionally, as Sidgwick (1907) and others have queried, if something like utility does not underlie rights and related concepts, by what criterion is the proper list of rights determined in the first instance, and how in principle should the inevitable conflicts between different rights be resolved? A possible reconciliation is suggested by lines of thinking that trace their roots to prominent political economists of a prior era (among others), as more recently elaborated in Kaplow and Shavell (2002).

The relationship between the Pareto principle and other seemingly appealing principles can be understood by reference to what are known as two-level moral theories. (Act utilitarianism versus rule utilitarianism comes to mind, although that somewhat problematic distinction is subtly different from the one under consideration.) As suggested by Hume (1751), Mill (1861), and Sidgwick (1907), one can envision a first-level principle (such as utility) that provides our ideal assessment of states (corresponding to an SWF) and also numerous second-level principles (for example, that one should keep promises, tell the truth, not kill others) that are used as guides by individuals in their everyday conduct. Subsequent prominent statements of this view include Harrod (1936), Rawls (1955), and, most extensively, Hare (1981).

Put in a more explicit optimizing framework, the first-level principle serves as the objective function, and possible second-level principles constitute the universe of feasible policies. This feasible set is assumed to be constrained by limits of human nature and human institutions. Accordingly, the optimal scheme – taken here to consist of the optimal subset of second-level principles – will be only second best. The aforementioned limits render any attempt at direct implementation of the first-best criterion – commanding that everyone in their individual or institutional capacity act always so as to maximize social welfare – inferior to employment of second-best principles that, inevitably, deviate from the first-best criterion (welfare) in some instances. Two sets of rationales for this conception of the social maximization problem have been offered.

The first sort of justification is based on decision-making costs, complexity, limited information, limited self-control (for example, myopia), and so forth. Such considerations imply that all manner of behaviour, including some types that have no interpersonal effects, should be guided by rules. Moreover, given the nature of the problems that such rules are designed to address, it is inevitable that the rules will not require performance of a complete social welfare calculus and hence will sometimes command behaviour that differs from the first-best outcome. This conflict hardly makes the first-best principle any less of an ideal, just one that is not perfectly achievable in practice.

Second, the nature of human motivation, particularly the problem of cabining self-interest, provides another reason that sensible individual and institutional commands sometimes deviate from a pure concern for individuals' utilities, and thus offers another account of the conflict between the Pareto principle (viewed here as an aspect of the first-level social objective) and alluring non-welfarist principles (understood as second-level rules). Emphasized by Hume, Mill, and Sidgwick, and also by Smith (1790) and Darwin (1874), this strand of thinking is rooted in what may be called moral psychology. As a consequence of biological and social evolution, human emotions may help to channel behaviour in a positive fashion. Opportunism – whether through cheating, theft, or aggression – may be constrained by the prospect of guilt feelings or social disapprobation. Cooperation may be encouraged by anticipated positive internal sentiments or praise by others. Two familiar examples are the retributive urge, the prospect of which may deter aggression, and the desire for social approval, which may inhibit opportunism and encourage constructive collaboration. Given the limitations of biological evolution (limits on altruism as well as the tendency of evolved mechanisms to be specialized), constraints on social inculcation (including the fact that much is directed at young children), and the factors mentioned with regard to the first rationale for second-level rules, it is unsurprising that the resulting precepts sometimes deviate from the first best. Once again, this gap does not call into question the supremacy of the first-best ideal as a matter of principle. (Interestingly, however, this second explanation suggests that emotional force will be associated with moral criteria – various notions of what is right, just, or fair – that conflict with the Pareto principle, which helps explain why our intuitions may be in tension with pure welfarism in some settings.)

Both of these enduring strands of thought that help to reconcile the conflict between the Pareto principle and non-welfarist notions are related to the more recent upsurge of interest at the intersection of economics and psychology, often under the rubric of behavioural economics. Just as Tversky and Kahneman (1974) have stimulated research on heuristics and biases in a range of economic settings, Baron (1993) and others have documented similar phenomena – such as overgeneralization – in individuals' moral thinking. Likewise, many researchers, including Frank (1988) – following intervening provocative statements by Darwin (1874) and Wilson (1975) – have reinvigorated Smith's interest in human emotions as forces that guide human behaviour, although not always in an ideal manner.

The foregoing discussion suggests that, in regulating individuals' behaviour, various normative criteria that conflict with the Pareto principle may nevertheless usefully advance welfare and thus, at root, be consistent with the underlying force for that principle. These non-welfarist notions may also be relevant to the promotion of welfare for other, related reasons. As argued at length by Bentham (1822–23) in his constitutional writings and Mill (1859) in *On Liberty,* second-best rules obviously may play an important role in constraining government officials. In addition, since many of the non-welfarist criteria exist because of their relationship with the promotion of welfare, they may be useful proxy standards in some settings. Finally, due to the affective aspect of many non-welfarist principles, a complete welfarist account would incorporate them because they are in part constitutive of individuals' utilities. Note that, in each instance, because the relevance of non-welfarist criteria lies in the advancement of welfare, there is no conceptual inconsistency with the ultimate motivation for the Pareto principle even though the non-welfarist second- level rules on their face deviate from the posited first-level ideal.

In sum, a complete understanding of the relationship between the Pareto principle and other, possibly competing normative principles involves many dimensions. Formal analysis of these principles reveals the existence of an underlying, logical conflict. Examination of literatures in other fields of economics and in other disciplines, however, suggests a fundamental harmony.

Pareto, Vilfredo (1848–1923)

Alan Kirman

Abstract

Pareto made major contributions to a wide range of subjects covering mathematical economics, statistics, sociology and many others. In economics his name is mainly associated with general equilibrium, welfare economics and ordinal utility. Yet he insisted on the need to confront economic theories with empirical data as his work on income distribution shows. Furthermore, he was far from convinced of the rationality of individual economic behavior. Yet these aspects of his work have been put one side and he is now regarded essentially as the forerunner of the axiomatic school which reached its zenith in the Arrow–Debreu model. This is paradoxical for the latter has been shown to provide no empirically falsifiable propositions.

Vilfredo Pareto's name is one of the most familiar in economics, with the universal use of 'Pareto optimality' and the Pareto distribution. Yet in 1968 Allais said, in his biography of Pareto, 'His influence on the development of economics as a science was felt only after considerable delay and has largely been confined to Italy and France'. There are several explanations for this neglect. First, as Chipman (1976) in his admirable survey of Pareto's contributions suggested, it has become less and less fashionable to cite early scholars. Second, Pareto spread his net wide and his persistent desire for empirical verification led him to explore the sociology of human behaviour. This part of his work had some success among sociologists, but interest in it has waned. Third, among theoretical economists Pareto's lasting contribution has come to be regarded as that which helped the evolution of economic theory on the path from the contributions of his predecessor Walras to the full axiomatic formulation of the Arrow–Debreu model. Yet this was but a small part of his overall contribution and of interest to an elite of theorists. Finally, Pareto has been wrongly described as the originator of some ideas and yet has not been credited with certain ideas which he did originate.

All of this explains why his reputation in economics was limited for a long time and has fluctuated considerably since his death in 1923.

Vilfredo Pareto was born in Paris in 1848 where his father, a follower of Mazzini, had exiled himself for political reasons and returned to Italy when Pareto was four years old. His family moved to Florence in 1862. In 1864 Vilfredo Pareto finished school at the early age of 16 and entered the University of Turin where he studied mathematics. He then went on to do a doctorate in engineering and his thesis was entitled, 'Principi fondamentali della teoria della elasticita dei corpi solidi e ricirche fondamentali sulla integrazione delle equazione diffenziali che ne differiscono l'equilibrio'. The fact that it was on the equilibrium of a physical system is, of course, significant for his later economic work.

Pareto then took up a post as an engineer for a railway company in Florence and continued in this work for three years. In Florence he became a member of the Accademia deo Georgofili and during this period he wrote a number of pieces in economics on such varied topics as the comparison of the advantages of publicly and privately owned railway systems, the merits of proportional representation and the state of the Italian industrial system. He was an ardent campaigner against any form of state interference with the market system and was one of the founders of the Adam Smith Society in Ferrara. As a consequence of their activity he developed a network of contacts in the fields of economics and politics. In 1880 and 1882 he was a candidate for member of parliament as an exponent of free trade, but was unsuccessful. In 1875 he was appointed as technical director of an ironworks in Florence. When raising the capital necessary to modernize the plant he travelled widely in Europe meeting bankers and financiers.

Through his intellectual activities, he established a relationship with Pantaleoni, who later held a chair at the University of Geneva and who introduced him to Walras in Switzerland in 1891. Pantaleoni then, in 1892, recommended him as a worthy successor to Walras at Lausanne when it became clear that the latter's health would not allow him to continue teaching. (See Walras 1965, vol. 2, p. 455, letter no. 1015.) He took up the chair in Lausanne in 1893 and his vision of the state of the field at that time is illustrated by his inaugural lecture in which he said.

> Nous ne connaissons la théorie d'aucun phénomène naturel dans tous ses details; nous connaissons seulement des théories des phénomènes ideaux, qui se rapprochent plus ou moins du phénomène concret.

After eight years at the university during which he produced his first major contributions to economics and was involved both in the activities of the university and of the canton de Vaud, he bought a villa near Geneva at Celigny. Here he progressively isolated himself from the university although, despite various health problems, he continued to teach in Lausanne till 1911. (Despite the fact that Schumpeter 1949, describes him as having had a 'vigorous and fertile old age', it is clear from his correspondence with the Dean of the Faculty at the university that Pareto was constantly preoccupied by health problems, in particular a heart ailment. See the letters from the archives of the law faculty cited by Biaudet 1975.)

The university organized a 'jubilee' in his honour in 1917 which was attended by a large number of distinguished social scientists and included an official delegation from the Italian government. The latter did something to offset Pareto's feeling that his own country had treated him badly.

While it is customarily asserted that Pareto did not start his work in economics until he reached the age of 45, he would obviously not have been offered a chair with no justification as to his ability in that subject. In fact, for well over ten years prior to his nomination in Lausanne Pareto had been interested in and had contributed to economics.

From the outset, Pareto was preoccupied by the idea of the economy as a complete system and by the interaction between the various sectors of the economy. In this, he was completely in line with the approach developed by Walras and far from the predominantly partial equilibrium analysis of his English contemporary, Marshall. What he was interested in was providing rigorous but parsimonious models of individual economic behaviour and then constructing from these a model of the economy as a whole. He was interested in the 'points of rest' of his system and their welfare characteristics.

It was his background as engineer and mathematician that led him to adopt a formal approach to the subject and his frustration with his inability to explain empirical facts that later led him to extend his analysis to sociology. This last phase of his career should not be construed as a disillusionment with the mathematical approach but rather as an attempt to include the other phenomena which he thought might account for the failure of economics to explain empirical facts. In particular he sought to include in his analysis the idea that people could make, from an economic point of view, 'irrational choices'. In so doing he anticipated the modern 'cognitive' approach to economics by a century. His overall aim was therefore to broaden his analysis and eventually to construct a system of laws capable of describing the behaviour of society as a whole, an enterprise that Schumpeter (1949) dismissed as a 'complete delusion'.

As has been observed his work received rather little attention for a long while. Allais (1968) lamented the failure of the economics profession to recognize the pioneering work of Pareto on the idea of social surplus. (This reflected, in part, his frustration with the lack of recognition of his own work in this area, which was later to be corrected by the award of the Nobel prize.) Georgescu-Rogen (1975) said, ‘There is no denying that Pareto’s own ideas met with an incredible lack of attention from most economists during his life as well as for many years after.’ Hicks (1932) wondered why economists had been so hesitant to study Pareto’s work and suggested that it was perhaps ‘the sheer impressiveness of his achievements’ that discouraged them. However, later Hicks (1975) himself, observed that the origins of Pareto’s contributions on the social optimum form could be traced to Edgeworth rather than to Pareto himself. Yet Malinvaud (1993) asserted that Pareto is now unanimously regarded as one of the founders of the Arrow–Debreu approach to theory. To see how this re-evaluation has taken place, we need to examine Pareto’s general approach to economics, certain of his specific contributions and his relationship to the work of his contemporaries and his predecessors.

It is worth observing at the outset that, while he condemned literary economists out of hand and professed to be interested only by a strictly scientific approach to economics, he, nevertheless, frequently made normative judgements and indulged in casual empiricism. This was, in part, a reflection of a world in which academics would feel much freer to express themselves on a wide variety of subjects without the many constraints that govern academic publication today.

Yet, despite a period in the desert, perhaps due to his having formed almost no students, some of Pareto’s main contributions have come to be recognized as having had a profound and lasting impact on economics. The three contributions to economics which have best stood the test of time are the *Cours d’économie politique* (1897), the *Manuale d’economia politica* (1906) and his article ‘Economie mathématique’ in *L’Encyclopédie des Sciences Mathématiques* (1911). In addition to these one has to mention his articles, in particular those collected and published later as *Marxisme et économie pure* in the *Oeuvres complètes* (1964–84) together with the *Trattato di sociologia generale* (1916) which, with *Les systèmes socialistes* (1901c) includes a substantial body of economic analysis.

The Cours

Of these contributions, the first, the *Cours*, originally published in two volumes, contains an exposition of economic theory illustrated with numerous empirical facts. The theory is presented in a more precise and refined way than that of his intellectual predecessor Walras and the emphasis, in the theoretical analysis is consistently and unequivocally on the interdependence of economic phenomena and the idea of general equilibrium. However, it should be noted that only 75 of the 800 pages are devoted to pure theory and that there is very little that is completely original. At least in Bousquet’s (1928a) eyes the theory was better presented than in Walras’s *Eléments* (1900) where he suggests the exposition is so tedious as to deter anyone from reading it. Nevertheless, the organization of the *Cours* is curious and, as Cirillo (1979) remarks, it is odd that production is treated after banking and social evolution. Of course, given its title and Pareto’s new responsibilities it is not surprising that it gives the strong impression of having been assembled from course notes, and that the order and content of these left something to be desired. (Pareto’s teaching cannot have been quite as discouraging as some have suggested since he wound up with 56 students in 1893 as opposed to the six who attended Walras’s last courses.) It is also somewhat odd that, given Pareto’s strong feelings about the importance of a positivist approach to economics he periodically indulges in direct pleading for the ‘liberal’ cause. It should, however, be remembered that, while so much of the material that Pareto discusses is now standard and has been refined by successive generations of economists, much of it was new, recent, or even original for him and it should be judged in context. What is remarkable is that Pareto, although one of the founders (if not *the* founder) of the school which culminated in the Arrow–Debreu model, did not hesitate to move beyond the strictly theoretical framework. He included empirical observations and examples of economic phenomena for which he was able to develop little satisfactory theory. Much of the statistical material in the *Cours* had, according to Pantaleoni (1924), been gathered while Pareto was a businessman, and this fact may have some bearing on its presentation. However, the *Cours* did also contain the first material on income distribution, a subject which will be examined below in more detail. This material provoked a great deal of comment and criticism from such authorities as Edgeworth (1925), and the latter was some 20 years later to comment ironically both on the universality of the law and on the character of its proponent.

The *Manuel*

The *Manuel* marks, as Ingrao and Israel (1990) suggest, a watershed between Pareto's involvement in economics and his move into sociology. (The reader seeking a detailed and rigorous account of Pareto's main theoretical contributions in the *Manuel* need look no further than Malinvaud 1993.) It illustrates the coexistence of philosophical reflection, empirical observations and rigorous analysis in Pareto's work. It explicitly acknowledges errors in the *Cours*, in particular that of taking too dogmatic a position in favour of free trade. While still accepting the theoretical arguments in favour of the free trade position, Pareto now had doubts as to the practical value of these arguments. He was no longer convinced that 'homo oeconomicus' was useful as anything other that a theoretical construction. He goes even further and even suggests that theoretical economics have not had, from a practical point of view, 'any great utility so far' (pp. vi–viii). This did not lead him, however, to abandon theory and he continued to develop his 'successive approximations' approach which he thought would lead from a highly abstract theory to a closer approximation of reality.

Of this book, it is the last section, the 'Mathematical Appendix' (in the French edition, 1909, pp. 538–671) which has come to be thought of as Pareto's basic contribution to the theory of general equilibrium and to what we now call 'Pareto optimality' but which he referred to as 'The maximum of society's ophelimity'. (This appendix was considerably modified and rewritten for the French edition, in large part as a result of Volterra's 1906, comments on the Italian edition.) Although the appendix with its formal analysis is the most widely cited part of the *Manuel*, it makes up less than a quarter of the volume. The rest of the work gives an insight into the more general view that Pareto had of economics.

The first two chapters give his views on the scientific status of the social sciences. He argued strongly that in economics and in the social sciences in general, there were underlying laws and structures which had to be determined, specified and tested by scientific methods. However, he, himself, was later to become more and more frustrated with the failure of economic theory to explain empirical facts. The third chapter provides an introduction to the idea of equilibrium which he now saw as a sort of balancing between 'tastes' and 'obstacles.' In this he had moved on from a more static concept as envisaged in the *Cours* and thought of a situation in which the 'obstacles' reacted to the 'tastes' and sought a resting point for these competing forces. (He does seem to have thought of his own approach, even in the *Cours*, vol. 1, p. 18, as being more dynamic than that of Walras, but it is difficult to see it as other than the solution of a static set of equations.) In Chapters 4 and 5, he then separates consumption and production and reduces the individual's problem, in each, to one of constrained optimization. Consumers follow paths of increasing utility until they are brought to a halt by the resistance of the 'obstacles'. Producers seek profit but face technological constraints. (These do not, in current terms, define a convex set. The introduction of fixed costs which cause this complication did, however, allow Pareto to reconcile zero profits and profit maximization.) In the sixth chapter, he then brings the markets together to talk of the general equilibrium of the system and to discuss its efficiency properties. Indeed the 'first theorem of welfare economics' makes its first clear appearance here. Two things are worth noting in passing. Pareto was well aware that the important thing for the individual was to maximize subject to the constraints that he perceives, which might or might not be the ones he faces in reality. Second, he systematically considered the possibility of monopolistic competition in parallel with that of perfect competition, although it is this treatment of the latter that is remembered today. In the case of imperfect competition the 'obstacles' change as the result of the individual's actions.

The chapters following those on economic equilibrium deal with a variety economic problems. Pareto deals with demographic problems and their consequences for the labour force but does not pursue the analysis of resultant effects on the labour market. He uses many factual illustrations, in dealing with these problems as well of those of natural resources, in particular land. He also treats capital and savings and the theory of the interest rate. The latter reveals an interesting discrepancy between Pareto's treatment of consumption and that of capital. When dealing with capital he clearly expressed the idea that goods are dated and that the rate of interest can therefore be deduced from the differences in successive prices. Yet when dealing with consumption the notion that the dates at which goods are available is part of their definition is much less clear. He then goes on to deal with monetary problems, but is clear that money can only be introduced once the general equilibrium problem has been fully analysed. All the latter problems are dealt with summarily and consist often of observations based on specific facts. The last chapter is devoted to 'concrete economic phenomena', although these already figure largely in the two preceding chapters.

Other Contributions by Pareto

There is little point in simply cataloguing Pareto's numerous other contributions but there are one or two specific items which cast light on the evolution of his thought. One aspect of his work that has been lost from sight is that on international trade, and yet his two articles on that subject had a clear influence on the major figures in the field. Ohlin (1924) went as far as to say that had he read Pareto earlier he would have saved himself a great deal of time and effort. Haberler (1965) said, 'But the only important theoretical advance has been the application, notably by Pareto, of general equilibrium analysis to the problems of international trade.' In particular, in marked contrast to the standard view that he was an unalloyed free trader, he used a sort of 'infant industry' argument in favour of protectionism for this, he thought, would lead to the emergence of a vigorous and productive class which would by its activities lead to a long-run gain which would more than offset the short-term loss from the absence of free trade. (This argument may be found in Chapter 9 of the *Manuel* and in the *Trattato.*) This, of course, was strongly related to his sociological theories, particularly that concerning the 'circulation des elites'.

A second and interesting aspect of Pareto's work was his concern with the origin and nature of economic cycles and crises. This does not fit well in a framework which is essentially static but he had the clear idea as early as the *Cours* that there was a certain overshooting in individuals' adaptation of their expectations. Thus he thought that people move too far from optimism to pessimism and that this leads to the sort of cyclical behaviour we observe in economies. In this he was arguing for a vision different from that of the 'rational expectations' school of today and rather more in line with the idea of 'adaptive expectations' but with coefficients which lead to over-adaptation.

Pareto examined socialism as a system for allocating resources in the *Systèmes socialistes* (1901c). Pareto saw socialism on the one hand as a threat to private property with its desire to extend the role of the state to the detriment of individual liberty but on the other as a force for change in society. He was, for example, not convinced by the redistributive goal of socialism. This was coloured by his own work on income distribution and the constancy that he thought he had found under many different institutional arrangements. The relation of this work to that of Barone is interesting. Pareto saw a role for a 'Ministry of Production' as a way of overcoming the difficulty of fixed costs in production. He envisaged a system of taxes on consumers to cover these costs, and goods would then be sold at cost price. This, he maintained, would restore efficiency despite the non-convexities present in the system. The shift in Pareto's ideas away from the purely liberal view towards a more subtle view of the role of the state is intimately linked to the evolution of his thoughts on sociology. He had what has been described as a 'clientelist' view of the organization of society. In his view, the mechanics of government intervention are governed by its need to satisfy its clients and not, as in the collectivist state view, to allocate resources efficiently and equitably.

This analysis together with Pareto's later emphasis on the non-rational, from an economic point of view, elements of choice led to his considering the achievement of any sort of economic efficiency, through a market system alone, as a utopian dream. He was, therefore, highly critical of those who insisted on applying economic theory without taking the whole political and social system into account.

From the economics point of view these contributions are not regarded as major and it is those that are regarded as of lasting importance that will be reviewed in the remainder of this contribution.

Ordinal Utility, Measurable Utility and the Integrability Problem

One of Pareto's major contributions has long been considered as that of establishing that an ordinal notion of utility is sufficient for the construction of equilibrium theory. The importance of this step for the development of modern theory was not immediately recognized by Pareto. It was only with his article (1900) that he started to develop a fully ordinal theory. Whether this led Pareto actually to reject the idea of 'measurable utility' is an interesting question. One suggestion is that he still adhered to the idea of some 'true measure' of utility but that he thought that is was simply impossible to identify the appropriate function. In fact, there is no logical contradiction between the observation that ordinality suffices to establish equilibrium and the idea that utility has some cardinal sense. Indeed, although he was very clear that any one of the 'indices' of utility would suffice for his analysis, he stated that 'In certain cases they would permit knowledge of the value of ophelimity' (*Manuel*, Mathematical Appendix).

Before returning to the measurability problem let us first examine how Pareto developed his ordinal approach. In the *Manuel*, he explicitly contrasts his analysis of 'indifference curves' which are constructed without reference to any utility function to that of Edgeworth who started with 'ophelimity' or 'utility' and obtained expressions for the indifference curves (*Manuel*, p. 540, n. 1).

Pareto proceeds as follows. In the case of two goods, consider x and y the quantities consumed of those goods and consider the quantities dx and dy which, when added to x and y, leave the consumers' satisfaction unchanged. This gives an equation:

$$f_1[x, y]\,dx + f_2[x, y]dy = 0.$$

This equation for the 'indifference line' gives us the expression: $dF[x, y] = 0$ which is satisfied by an infinite number of F, and Volterra (1906) remarked that 'Ophelimity is one of these functions F′.' (Whether this remark should be interpreted as meaning that any of these functions would serve as a utility function or whether the idea was that amongst these functions was the 'true utility function' is an interesting question.) In any event, as Volterra pointed out, Pareto's treatment required further work if it was to be extended to the case of three or more goods. The problem here is a simple one. The equations that Pareto wrote down define the tangent hyperplanes to the true indifference surfaces at each point in the consumption space, and what Volterra observed was that there may be no utility function compatible with these equations. This 'integrability problem' has preoccupied theorists until recently, although Allais (1973) dismisses it as a red herring.

Pareto's well-known (1906b) paper on 'Ophelimity in non-closed cycles' has generally been regarded as an attempt to solve this problem. There are many interpretations of this but one is that it revealed that convexity can replace transitivity. (However, Chipman 1971, suggests that Pareto's real aim was to give a full treatment of the measurable utility problem and Malinvaud 1993, regards it as a straightforward attempt to deal with the problem of the transitivity of preferences which in turn is directly linked to the problem of the existence of a utility function. Without entering into the details it is worth observing that Sonnenschein 1971, showed that the assumption of the convexity of preferences and hence of the quasiconcavity of the utility function could be substituted for transitivity. Thus transitivity of preferences is not a necessary condition for equilibrium analysis. Pareto himself, as Malinvaud 1993, indicates, glimpsed the importance of convexity and discusses it in Section 4 of the *Manuel* and in Sections 44–50 of the mathematical appendix.) Indeed convexity of preferences is, in a certain sense, a natural condition. This is simply because a great deal of theoretical work in economics boils down to looking at the solution of the maximization of a concave or quasi-concave function over a convex set, and for this most economists have settled for an examination of the firstorder conditions for such a maximum. Here the function in question is the utility function and the convex set is provided by the budget constraint or, in Pareto's terminology, the 'obstacles'. Given this, by now standard view, it is easy to understand why Pareto's 1906 contribution seems so convoluted and makes such difficult reading.

One of the problems is that there is, as in several of Pareto's works, a preoccupation with the order in which goods are consumed which, to modern eyes, confuses the discussion. In modern general equilibrium theory, all goods are dated and hence changing the order of consumption changes the specifications of the bundle of goods in question. Indeed, Pareto, unlike the other economists of his time, did, at some points in his analysis, explicitly adopt the idea of dating goods in order to reduce a temporal problem to a static one. But he also devotes considerable time to discussing 'paths of consumption'. (Detailed analysis of Pareto's analysis of the 'order of consumption' problem can be found in Chipman 1971, and Malinvaud 1993.) Thus, individuals move along a path improving their welfare until they arrive at the best bundle given their constraints. Was this how individuals actually behave as he originally indicated or did he, as in his 1906 paper, regard consumption paths as only involving time in an abstract and 'virtual' sense.

Pareto also considered explicitly in this context the measurability of utility. As it happens, as Chipman (1971) points out, in the specific case discussed by Pareto, utility is independent of the path of consumption. In this case, consider the marginal utility ('elementary ophelimity') of a good as dependent only on the quantity consumed of that good. (The type of result Pareto was aiming at is closely related to another case already treated by Fisher 1896.) The utility function obtained in this case is measurable, that is, it is invariant up to a linear transformation. Pareto's work here may thus best be regarded as an early attack on the problem of separable utility functions. Given this, it seems that, while Pareto recognized that equilibrium analysis could be carried out using only ordinal utility, he still had not reached the point of abandoning measurable utility as a concept, and still attached importance to the idea that the difference between the utility obtained in two situations had some significance. Thus, perhaps paradoxically to modern eyes, having liberated the theory of general equilibrium from the notion of cardinal utility Pareto continued to concern himself with the idea of measurable and comparable utilities.

The integrability problem mentioned above, that of recovering an underlying utility function from demand behaviour, was already solved in large part by Antonelli (1886) in a paper which Pareto had in his possession, albeit briefly, since he commented on it in a letter to Pantaleoni in 1891 (letter no. 39 in Pareto 1960). However, Pareto does not seem to have attached much importance to Antonelli's work, although Walras had already praised it. Thus, for some reason, Pareto did not profit from what had already been done and did not make any significant contribution in this particular direction despite assertions in the literature to the contrary. This may have been because of the brief acquaintance that he had with Antonelli's contribution, or may rather be, as Chipman maintains, because he was less concerned with this problem than with that of the measurability of utility.

To conclude the discussion of this part of his contributions, it is worth emphasizing that Pareto arrived at conditions for economic equilibrium using preferences alone and thus clearly marked out the trail for modern economic theory, but that he did not abandon his interest in the nature of utility and its measurement, and indeed it was as a result of this dual preoccupation that he adopted the curious term ‘ophelimity’.

Lastly, it is worth mentioning that Hutchison (1953) asserted that Pareto had anticipated Slutsky’s income and substitution effects. This would indeed have been a major achievement, but, as C. Weber (2002) has shown, a careful reading of the appropriate passage shows that this is not the case. This is yet another example of the inappropriate attributions involving Pareto’s work.

General Equilibrium

There can be few who have studied general equilibrium theory without using the famous Edgeworth box. This graphical trick which was for a period, unjustifiably called the Edgeworth–Bowley box, actually first appears in its modern form in Pareto (*Manuel*, 1906, p. 355). This was used by Pareto to motivate his ‘proofs’ of the welfare theorems in the general case. The box is the simplest case of what was Pareto’s constant preoccupation, namely, the economy as a complete system. He can be thought of as regarding the economy as one market rather than as many individual markets which could be studied, as in the Marshallian tradition, separately. He wrote down what are now considered to be the standard equilibrium conditions for the consumer side of economy, showing the equality of the marginal rate of substitution to the price ratio, normalizing the price of money, which he assumed to give direct utility, to one (*Manuel*, Mathematical Appendix). (Paradoxically, as Hildenbrand 1994, points out, these conditions are absent from the final culmination of Pareto’s theoretical work, the Arrow–Debreu model, and Debreu dismisses the use of calculus and confines himself until much later to convex sets and separating hyperplanes.)

Taking these equations:

$$U_x = \frac{U_y}{P_y} = \frac{U_z}{U_z} \dots$$

together with Walras’s Law:

$$(x - x_0) + P_y(y - y_0) + P(z - z_0) \dots = 0$$

and differentiating, he found expressions for

$$\frac{\partial y}{\partial P_y} \cdot \frac{\partial z}{\partial P_z} \text{ and so on.}$$

These he had already set out in his 1892 article in the *Giornale degli Economisti.* He then shows that if goods are independent, that is

$$U_{xy} = 0x\,\pi y,$$

then the conditions $U_{xx} < 0$ $U_{yy} < 0$ and so on. imply that demand for each good is a decreasing function of its own price (*Manuel*, Mathematical Appendix, section 53). This is a forerunner of more general but very recent results.

Pareto’s introduction of money into the utility function is in the spirit of his time and in so doing he was able to clarify some of Marshall’s analysis. Firstly, he showed in the *Manuel* (Mathematical Appendix, section 56) that, in general, the ‘marginal utility of money’ changes with prices. Thus it cannot arbitrarily be assumed to be constant.

Secondly, in *Cours*, section 83, he showed that the idea of estimating consumer surplus as the area under the consumer’s demand curve above the exchange price was wrong unless the marginal utility of money happened to be constant which, as we have just seen, it is not, in general.

Finally, he showed in his Encyclopaedia article (1911, section 23) that, if the elasticity of demand for all goods is constant, then it is unity, and remarked that, since Marshall had not realized that he had to impose this restrictive condition, his analysis was defective.

An important aspect of Pareto’s work that seems to have escaped attention is the effort that Pareto made to discuss what has come to be called ‘monopolistic competition’ and its introduction into equilibrium analysis (*Manuel*, chs. 3, 5 and 6). Recognizing that individuals can influence prices and that this should be taken into account led him to try to take explicit account of the demand with which they are faced. This merits two comments. Only recently has the introduction of 'monopolistic competition' into general equilibrium models resurfaced, and the article by Negishi (1961), which uses rather arbitrary assumptions, is generally cited as the first example. Thus Pareto was already dealing with a problem which has still not been really satisfactorily treated. The way in which the individuals have an effect on prices is revealed in his treatment of the 'obstacles' or constraints. As an individual modifies his demand he might be thought of as moving to the appropriate point on his budget hyperplane, thus as making a linear movement. But what if his displacement itself influences prices? In this case his movement will be nonlinear. Once again one can think of all these movements as being virtual and only the final result counting. Alternatively, one can think of a non-tâtonnement process in which individuals trade until they hit a constraint. In the Negishi style, non-tâtonnement process prices are still called centrally and then traders exchange and terminate before their desired bundle if they are not at the equilibrium prices. In Pareto's analysis trade is pairwise and there is rationing, leading Malinvaud (1993) to suggest that this is an early foretaste of the rationing literature associated with the names of Benassy, Drèze and Malinvaud. Nevertheless, it is clear that Pareto in this respect made a step in the direction of greater realism of the adjustment process.

A difficulty with all of Pareto's analysis is the confusion as to the nature of time. Indeed, he recognizes this himself, when talking of the passage from an initial position to an equilibrium, when he says (*Manuel*, ch. 3, section 171), that the issues he discusses fall into the domain of dynamics rather than statics. The modern convention that the adjustment process to equilibrium is instantaneous and that longterm dynamics consist of the passage from one equilibrium to another is far from that adopted by Pareto in this part of his analysis.

Pareto did not make a clear distinction between the question of existence and the question of stability. He regarded equilibrium as the terminating point of a process and this is brought out in the *Cours* and particularly in the *Manuel* (ch. 3, sections 110–15, for example). As has been suggested, the time taken for this process was not specified but is certainly not regarded, even conventionally, as negligible. Having described the passage or path from the initial position to the final position under assumptions of perfect competition with tâtonnement and pairwise non-tâtonnement processes, he then considered the monopolistic competition case, but rejected it as too difficult to handle. He did, however, enter into a discussion as to how individuals could push the economy towards a preferred equilibrium, from their point of view, in the case of multiple equilibria, and showed how they would try to manipulate the terms of exchange along this path (*Manuel*, p. 197) and discussed how individuals would benefit from doing this. Furthermore, in the light of this manipulation he suggested that certain equilibria would be stable. Thus Pareto recognized explicitly that stability is a property of a particular process.

Although he wished to consider equilibrium as the resting point of a process, Pareto did not try to show the existence of equilibrium as such except by counting equations and unknowns (*Manuel*, Appendix). In effect, he said that, since one could find the conditions for equilibrium, an interesting possibility would be to solve explicitly all the equations necessary to determine the equilibrium. However, as he pointed out (*Manuel*, ch. 3, section 217), 'If we take into account the fabulous number of equations that a population of forty million individuals and several thousand goods would give, it would not be mathematics that would come to the aid of economics, but economics that would come to the aid of mathematics' since such a system would be beyond human capacity to solve. Thus Pareto assumes from a simple argument the existence of a solution and simply dismisses the practicality of finding it for a large economy even if all the relevant equations were known. (This is in no way surprising since we now know that proving the existence of equilibrium is equivalent to proving the existence of a fixed point and the first fixed point theorem was proved by Brouwer in 1910.) (Pareto would have much appreciated Scarf's computational approach to the finding of equilibrium; Scarf and Hansen 1973.)

Thus the preoccupation with the formal establishment of equilibrium which was later to dominate mathematical economics was not shared by Pareto. Although relatively rigorous, he failed to specify various assumptions used for his approach, such as differentiability and only considered interior solutions to the maximum problem.

Before leaving Pareto's treatment of equilibrium, it is interesting to note that he was clearly aware of the possibility of multiple equilibria and in his diagrams in the *Manuel* (p. 192), he seems to have realized that 'in general, the number of equilibria would be odd', a result proved only very recently. An antecedent for this can be found in Edgeworth (1881), who explicitly talks about several equilibria and the fact that they will 'alternate' in terms of stability.

Pareto also suggests, as mentioned, that a collectivist state would be better able to lead its economy to an equilibrium than an economy based on private property. The reasoning given for this is based on Pareto's particular view of production and his introduction of non-convexities. This assertion, given Pareto's natural aversion to state intervention, is also heavily qualified (*Manuel*, ch. 6, sections 58–61). Nevertheless, it is interesting to note the contrast with the view of Pareto as an unqualified liberal.

Efficiency or 'Pareto Optimality'

Of all Pareto's contributions to economics, it is this notion of 'optimality' or efficiency that has made the greatest impact.

Yet it was not he who first gave a definition of a situation corresponding to the modern definition. Edgeworth (1881) clearly defined a situation in which the utility of each individual is maximized given the utilities of the others. Although this definition is given in the context of an exchange economy, its extension to more general cases was not difficult.

It was not so much the introduction of the idea but the use that Pareto made of it which makes his contribution important. Thus, although he had read Edgeworth, his definition, which also includes production, is an integral part of his own work.

Pareto defined a notion of surplus or gain, which is what is now referred to as 'equivalent surplus', this is, the amount of a given numeraire good which would leave the individual indifferent between his original bundle together with this quantity of numeraire and his original bundle together with some proposed change in all the commodities. At an optimum or efficient point there is no surplus. Put alternatively, one could think of the economy as moving along paths as individuals seek to profit from the surplus that exists until no further such change is possible. Thus an efficient situation is one in which no feasible change exists which would correspond to a positive surplus. The originality and correctness of Pareto's contribution has been questioned and Samuelson (1947) suggested that it was Barone (1908) who first dealt with this point correctly. In fact, as Allais (1973) points out, Barone acknowledged Pareto's priority and furthermore developed a less adequate, price-dependent, version of surplus.

The real insight that Pareto had was that this notion of efficiency or optimality was independent of all institutional arrangements and of all distributional considerations (*Cours*, vol. 2). Pareto then went on in the *Manuel* (ch. 6 and Mathematical Appendix, sections 145–52), to establish the 'first theorem of welfare economics', that a competitive equilibrium is a Pareto optimum and a tentative version of the 'second theorem', that any Pareto optimum can be obtained as a competitive equilibrium from an appropriate distribution of initial resources. The latter result is only suggested and is never clearly stated. Furthermore, both results are incomplete and even incorrect as a result of the confusion in the treatment of production. There are also a number of simple errors that creep into the exposition which confuse the argument. To take a simple example at two points in the *Manuel* (Appendix, sections 45 and 89) he says that some people will necessarily be better off and others worse off. Did he here envisage only movements along the efficient surface and therefore rule out changes which would make everyone worse off? This is not clear for at another point (*Manuel* (ch. 6, section 37) he clearly envisages everyone's welfare as declining. The key here is that he makes the correct statement in the case of a finite move but rules out the possibility of everybody being worse off in an infinitesimal move. It was Wicksell (1897) who pointed this out and Chipman (1976) mounted a rigorous defence of Pareto.

Pareto's ideas on the nature of efficiency evolved over time and in the *Trattato* (sections 2128–39), he showed that the maximization of any social welfare function W which was an increasing function of individual utility functions U_i

$$W = F(U_1, U_2, \ldots)$$

whether the U_i were defined over the consumption of all individuals or just restricted to individual consumption gave an optimum. Now as Pareto states (*Trattato*, pp. 1342–3), it is clear that in defining W a government would have to give weights to the different individuals. The idea of including the consumption of other individuals in the utility functions extends the scope of normal economic analysis to what were considered at the time and are still often thought of as 'sociological' considerations.

Pareto did not observe that by appropriately modifying F all optima could be generated. As Allais (1968) suggests, it is not clear that Pareto was fully aware of the impact of this contribution.

In addition to these contributions to welfare economics Pareto has been credited with the founding of the 'New Welfare Economics'. In particular, it is argued that in his 1894b article 'Il massimo di utilita dato dalla libera concorrenza' he introduced the Hicks–Kaldor compensation principle. However, as Kemp and Pezanis-Christou (1999) point out, Pareto argued that compensation should only be a consideration if it was actually carried out, and not just potentially possible. He spelled out the way in which it could be achieved by transfers between individuals, but did not go as far as saying that situation X is better than situation Y if transfers could be made from Y that would make everybody better off than in X.

Income Distribution, 'Pareto's Law'

One of Pareto's major contributions was to propose a 'law' governing the distribution of income. Here by distribution of income is meant the distribution of personal income amongst individual economic units and not the distribution of income between factors of production. The latter line was developed by Ricardo, in particular and was, of course, at the centre of the Marxian, neoclassical, and Keynesian debates. Pareto's interest and motivation were very different. On the one hand, it has often been suggested that his work in this area reflected the search for some sort of universal principles underlying economic behaviour. This would not explain why he chose this particular domain. The reason for his initial interest was rather his disagreement with the socialist proposals to undertake institutional reforms to make the distribution of personal income more equal. His initial work was published in an article in the *Gironale degli Economisti* in 1895 then in a memoire (1896b) on the 'income distribution curve'. Detailed discussion is given in the *Cours* (sections 957–65) and in the *Manuel* (ch. 7, sections 2–31).

In the course of analysing different data, Pareto was led to believe not only that he had established a functional form for income distributions which was essentially independent of institutional considerations but, even more remarkably, that the parameter of that function might well be the same across all countries and thus also independent of institutional arrangements. This would be enough to make any attempts to achieve a significant redistribution of income impossible. It is not surprising, given its social implications, that his contribution has been the source of controversy. Second, this work can be thought of as a pioneering piece of applied econometrics and not therefore as in keeping with the rather abstract image that is often painted of Pareto's work.

Three formulae were proposed by Pareto and the first and most widely cited of these is given by:

$$N(x) = \frac{A}{x^a}$$

where $N(x)$ is the number of people having an income greater than or equal to x. As has been frequently pointed out, it has obvious problems where either x tends to zero, or one increases x so that $N(x)$ goes to zero. Pareto's proposed a second form which mitigated these problems and which was to replace x by $x + q$ where q is a constant. Using his original form, Pareto then estimated values for *a* in particular for data for the UK collected by Giffen (reproduced in Giffen 1904). He obtained for 1843: a = 1.5 and for 1879/80: a = 1.35. Further computations for Prussia, Saxony, Paris and several Italian cities gave values around 1.5 with a maximum of 1.73. Pareto denied that his 'law' had the status of a physical law, and stated in an article in the *Journal of Political Economy* (1897b) that 'I should not be greatly surprised if some day, a well authenticated exception were discovered.' Nevertheless, he believed that the values of *a* that he found, *a* itself being a statistic, were sufficiently close for his law to be 'provisionally accepted as universal'. This statement is not wholly unambiguous since closeness of the estimated parameter values is not an indication that the functional form itself corresponds well to the data. Nevertheless, Pareto asserted that the values he obtained which he considered to be remarkably close, despite the different origins of the data, could not be attributed to chance.

Pareto was well aware that other functional forms might also fit the data well; for example, he estimated a distribution of the form:

$$N(x) = \frac{A}{(x+a)^{\alpha}} 10^{-\beta x}$$

where *a* and *b* like *a* are constants. He found a value of *b* so low that he concluded that a distribution of the second form that he had proposed

$$N(x) = \frac{A}{(x+a)^{\alpha}}$$

would suffice.

It is worth noting, in passing, that the three forms proposed by Pareto have a number of particular properties. The third form has finite moments for all r whereas this is only true for the first and second forms for r < *a*. When *a*. is less than or equal to 2 the first form has infinite variance and 'Pareto's law' is characterized by a fat right tail. In this case both the first and second forms belong to the Pareto-Lévy class of stable distributions. Indeed, Barbut (2000) has pointed out that the reason that distributions of the Pareto type occur so frequently was shown by Paul Lévy (1937). He showed that stable distributions other than the normal exhibit asymptotic behaviour of Pareto's second form with $0 < a < 2$. Hence, a central limit theorem of a certain type exists for heavy tailed distributions to which the standard central limit theorem does not apply. Pareto was thus credited with having removed the stranglehold of the Normal distribution!

It has been widely recognized since Pareto's time that other distributions provide more satisfactory fits for particular income data. Nevertheless, 'Pareto's law' gives empirically a satisfactory fit for the upper tail of the income distribution (the top 20 per cent according to Lydall 1968) but is clearly inconsistent with the lower end. This has resulted in a search for distributional forms which are close approximations of the Pareto form for the upper tail.

However, it is not the adequacy of Pareto's income distribution as a description of empirical data that has been controversial, it is rather the relation between 'Pareto's law' and the problem of income inequality that has been the subject of dispute. Pareto says that, if the number of individuals with an income over a certain level x in relation to the number of those below that level increases, then inequality diminishes (*Manuel*, ch. 7, section 24). Unfortunately, there was a printer's error in the *Cours*, and there the opposite is stated, although from the footnote (*Cours*, Livre III, section 965), it is clear what Pareto intended. There has since been considerable confusion about what Pareto actually said.

Let $N(h)$ be the number of individuals with income above h (the 'minimum income') and $N(x)$ the number above x with $x >$ h. Then, as Pareto says, if we define

$$U_x = \frac{N(x)}{N(h)}$$

then, 'income inequality will decrease as U_x increases' (*Cours*, Livre III, section 965; *Manuel*, p. 390, n. 2).

Allais (1968) interprets Pareto as saying the opposite, perhaps following the error in the *Cours*. Yet if we now proceed and assume that 'Pareto's law' holds, then we have:

$$U_x = \left(\frac{h}{x}\right)^{\alpha}.$$

Since $x > h$ by hypothesis, U_x decreases when a increases and income inequality increases. Allais makes an error in his argument and states that:

$$\frac{N(h)}{N(x)} = \left(\frac{h}{x}\right)^{\alpha},$$

an error identical to that made by Roy (1966). Since both Roy and Allais had started from the original mistake in the *Cours*, this further error should have led them to the same final conclusion as Pareto that income inequality varies in the same direction as a. Roy indeed arrives at this conclusion and contrasts it with the work of Gini and others. Allais made a further error and stated that Pareto believed that income inequality varied inversely with a. All this gives some indication of the sort of confusion that has surrounded Pareto's contribution. An explanation of these different interpretations can, however, be found and is that the authors mentioned were working with different basic hypotheses. If two distributions with the same mean income are compared, then the view that inequality increases with a is correct. If, on the other hand, one compares two distributions with the same minimum income, then Pareto's view is the appropriate one.

If a were a constant, then there would be little hope for policies aimed at reducing income inequality, as Pareto pointed out to those in favour of the socialist position. Lastly, Pareto's law has the peculiar feature that the ratio of the average income above x say $m(x)$ to x itself is a constant given by:

$$\frac{m(x)}{x} = \frac{\alpha}{\alpha - 1}.$$

Allais suggested that this might be taken as Pareto's index of inequality. If this were so, then it would decrease with a, the opposite of what Pareto intended.

Economics and Physics: Pareto's View

What is clear from both Pareto's analysis and that of many of his contemporaries such as Edgeworth, Jevons and Fisher is that they all shared a conviction that there was an analogy between economic systems and those of classical mechanics. Edgeworth (1881) was quite explicit in suggesting that a 'mécanique sociale' would take its place alongside the 'mécanique celeste'. Jevons (1905) said that economics resembles physics in that 'the equations employed do not differ in general character from those which are really treated in many branches of physical science'. Another contemporary, Cairnes (1875, the citations from Cairnes and Edgeworth are taken from Cohen, 1994) was even more explicit. He asserted that 'Political Economy is as well entitled to be considered a "positive science" as any of those physical sciences to which this name is commonly applied.' He went on to argue that the principles of economics have identical features to those 'of the physical principles which are deduced from the laws of gravitation and motion.'

The validity and consequences of such assertions have been examined at length by Mirowski (1989), Ingrao and Israel (1990) and Cohen (1994). The extent to which the analogy between physics and economics has ensnared economics in a position which it could have avoided had it found its source of inspiration elsewhere – for example, in biology, as Marshall suggested – is well documented by these authors.

Pareto himself made the remark that when examining the equations which have to be solved to determine an economic equilibrium someone well versed in mathematics or physics would say, 'These equations do not seem new to me, they are old friends. They are the equations of rational mechanics.'

He went so far, in the *Cours*, as to draw up a table of analogies between the two disciplines.

What is most interesting about this table is not the analogies themselves, which are, in some cases, inaccurate and misleading, but rather the caveats that are provided by Pareto. He seemed to be well aware, even at his early stage in his writings, of the dangers of taking the analogy too literally, and in this he distinguished himself from a number of his contemporaries. He understood that, when extended to the full social system, the physical analogy was highly tentative. Yet he had no other formal frame of reference within which to model the socioeconomic system. This led to his increasingly cautious attitude in using equations from physics, but did not deter him in his goal of modelling the whole social system rigorously. Given the reservations expressed by Pareto it seems unfair to lay the blame for the domination of classical mechanics as a mathematical framework for economics at his door. This only partially absolves him, for his attitude was essentially that physics provided an analogy but those parts of it that were inappropriate could be put to one side. As Mirowski (1989) points out, it is a common error to believe that all parts of the physics metaphor are equally dispensable. This misunderstanding has led, in part, to the persistence of the metaphor for it seems that we are free to weaken it as much as we wish till it is suitable for our purposes. Had this been recognized as erroneous economists might have strived harder for an alternative metaphor.

Economics and Its Relationship with the Other Social Sciences

Pareto's vision of the nature of the social sciences is reflected in his works on sociology (in particular the *Trattato*) and a certain number of his positions mark him out from his contemporaries and his successors. He developed and reinforced his idea that such sciences should be positive and went as far as criticizing his earlier work, taking the 'author' of the *Cours* to task for mixing ethical and positive considerations (*Manuel*, Preface). His defence of positivism was clearly associated with Comte's position (1830) and he was interested in developing a 'positive theory of economic policy'. He argued that 'laws' or relations deduced from specific assumptions should be tested empirically against 'observed statistical laws'. He went further, however, and unlike J.S. Mill (1844), who asserted that to verify hypotheses was not part of the business of science, a position supported by Friedman (1953) and Machlup (1955) and others, later argued that assumptions should be examined to see how reasonable they are (*Trattato*, section 59). The importance of Pareto's statistical work which reflected his standpoint has tended to be overlooked and has been dominated by analysis of his purely theoretical contributions. It cannot be repeated often enough that Pareto insisted on what he called the 'experimental method' as the *only* appropriate method appropriate for the social sciences and would not countenance wholly theoretical work which could not be empirically tested.

His approach to economics reflected a double position. Firstly, he shared Marshall's opinion that economic theory should be aimed at examining 'man as he is' and should not become an abstract intellectual exercise. Secondly, however, while he wished economics to be a relevant science, he condemned attempts to apply too readily economic theory to real problems. He believed that much harm had been done to the cause of 'scientific economics' by such hasty applications. This was, he thought, particularly dangerous since economic considerations could not be isolated from more general sociological concerns and to do so would lead to misleading and erroneous conclusions. His preoccupation with the analysis of nonrational behaviour adds force to this view.

Finally, it should be remembered that, while Pareto was with Weber among the first to expound the principles of 'positive social science', his view of the status of economics was ambiguous. He believed fundamentally, and in this he shared Comte's view, that there should be a universal scientific approach to social science. Yet he recognized the need for and desirability of specialized disciplines, although he regarded these as building blocks for a general approach. Thus while he was persuaded that certain aspects of economic phenomena are more quantifiable than many social phenomena, he was not prepared to isolate man's economic activity from his other functions. It should clearly be recognized that Pareto himself (Pareto 1917) considered his *Trattato* as his most important work and that he came to believe that the non-economic component of social phenomena dominates the economic part; and as he said, 'The most important error of the so-called liberal economist is not to recognise this.' Thus Pareto was progressively more convinced of the importance of the non-economic in explaining the evolution of society.

Conclusion

Pareto's economic contribution has acquired an increasing reputation over time, unlike his sociological work. Yet, as was suggested at the outset, it is disappointing that this reputation should be constructed on the basis of such a small part of his work. His strictly theoretical contributions are an essential part of modern general equilibrium theory. Yet here his education and training pushed him towards an equilibrium notion close to those of classical mechanics, and in a certain sense he helped to lock economics into an unhappily rigid framework.

Pareto's work covered a wide range of subjects. Within the field of economic theory, not only did he examine the nature and existence of a general equilibrium but he also considered what we would now refer to as the problem of 'imperfect competition', that is, the analysis of directly and consciously conflicting interests. Furthermore, his concern with statistical verification and his constant references to the idea that economic theories should be confronted with economic facts as in his examination of the problem of the form of income distributions are all central to an understanding of his contribution. He was preoccupied with the idea that economic theory fails to explain many phenomena, not because the theory itself is inadequate, but rather because that theory is just one part of a larger theoretical structure which should incorporate all social phenomena.

All of this illustrates the richness and diversity of Pareto's work. It is therefore paradoxical that, as Pareto's stature as one of the major figures in the development of economics has grown in recent years, most of this increased recognition has been based on a limited part of his most formal contributions. As has been observed, Pareto came to emphasize more and more the role of the non-economic in explaining social phenomena, yet he has come to be remembered essentially as the forerunner of the axiomatic school of economics where rationality is rigidly imposed. Perhaps the most ironic aspect of the evolution of Pareto's reputation is the current state of general equilibrium theory. While the most refined version of Pareto's theory, the Arrow–Debreu model, has been shown, thanks to the Sonnenschein–Mantel–Debreu results, to provide no empirically falsifiable propositions, Pareto himself was impatient with the idea of purely theoretical models which were not subject to falsification. How would he have reacted to the idea that his reputation was to be essentially based on his contribution to the construction of such a model? How far he was in spirit from the theory that he is claimed to have founded can be understood from a remark he made to a specialist in mathematical logic.

> I cannot admit that there is any rational method which is superior to the experimental method: I do not accept that one can study what should be; I, on the contrary, try to find out what exists in reality. (Pareto, 1964–84, vol. 19, 1027)

Parnell, Henry Brooke (1776–1842)

Barry Gordon

A significant figure in the history of economic policy, Parnell was an Irish landowner, baronet (1812) and first Baron Congleton (1841). He was associated with the liberal wing of the Whig party in the British parliament. During the period that David Ricardo was in the Commons (1819–23), he lent strong support to Ricardo’s advocacy on economic policy issues. After Ricardo’s death, Parnell continued to press for tariff reform, repeal of the Corn Laws, and greater economy in government expenditure.

Parnell entered the Commons in 1802. Subsequently, he was a member of the Bullion Committee (1810), chairman of the Committee on the Corn Trade (1813), and chairman of the Committee on Public Income and Expenditure (the Finance Committee) from 1828. His motion of 1830 concerning the Civil List precipitated the resignation of the Duke of Wellington as Prime Minister. In 1831, Parnell was appointed Secretary at War, but was dismissed in 1832. Under Lord Melbourne, he became Treasurer of the Navy and Paymaster-General in 1835. He retained these posts until his death in 1842. For the last 20 years of his life he was an active member of the Political Economy Club.

A diligent committee man, Parnell also intervened frequently in economic debate on the floor of the Commons. Those interventions demonstrate considerable analytical ability as well as unswerving allegiance to the doctrines of economic liberalism. Particularly notable is his speech on the Customs Consolidation Bill (1825) in which he spells out what is required for a rational, utilitarian tariff reform according to Ricardian principles.

Publications by Parnell include several on currency and banking (1804, 1805, 1827 and 1832), and on the corn laws (1809 and 1814). His most influential work, however, was *On Financial Reform* (1830; 4th edn, 1832). This publication is a complement to his parliamentary efforts as chairman of the Finance Committee. Parnell was zealous for both the utmost economy in public spending and restructuring of the taxation system. Such restructuring, he believed, should include the removal of taxes on raw materials and semi-finished goods, general reductions in import duties, and the introduction of an income tax of between one-and-a-half and two per cent. These policy measures look forward to those of Sir Robert Peel in the 1840s and, even further, to those of Gladstone.

Parsons, Talcott (1902–1979)

J. Goodwin

Talcott Parsons was perhaps the most ambitious and influential sociologist of his generation. Parsons was born at Colorado Springs, Colorado, on 13 December 1902. He was educated at Amherst College (Massachusetts), the London School of Economics, and Heidelberg University, from which he received a doctorate in economics in 1927. Parsons served on the faculty at Harvard University from 1927 until his retirement in 1973. He played a key role in the organization of the interdisciplinary Department of Social Relations at Harvard (now defunct), serving as chair of that department from 1946 to 1956. Parsons was a prolific, if notoriously abstruse writer, producing more than a dozen major books and scores of articles on a variety of (mainly theoretical) subjects. His most influential works are *The Structure of Social Action* (1937) and *The Social System* (1951). Parsons died in Munich on 8 May 1979.

While at Heidelberg, Parsons came under the influence of Continental sociology, particularly the work of Max Weber and Emile Durkheim. Parsons was subsequently responsible, more than any other figure, for introducing the thought of these theorists into Anglo-American sociology. He translated Weber's famous essay on *The Protestant Ethic and the Spirit of Capitalism* into English in 1930; he analysed the work of Durkheim and Weber at length in *The Structure of Social Action* (1937); and his edited version of Weber's *Economy and Society* appeared in 1947 under the title *The Theory of Social and Economic Organization*.

Parsons himself attempted to elaborate nothing less than a comprehensive theory of society, a general theory of 'the social system'. He argued that the economy is a functional subsystem of the larger social system and that economic theory, consequently, is a 'special case' of the general theory of society. Parsons put forth the controversial claim that the thought of Marshall, Pareto, Durkheim, and Weber 'converged' on what he called a 'voluntaristic theory of action'. This theory emphasizes the normative and purposive dimensions of social (including economic) behaviour, rejecting purely utilitarian or interest-based accounts. Parsons also emphasized the importance of shared cultural values in his treatment of the 'Hobbesian problem' of social order and in his analyses of social change.

Parson's 'grand theory' continues to generate considerable debate. For his proponents, Parson's work ranks among the most sophisticated attempts to overcome the antinomies of modern social thought; for his critics, Parsons's ponderous prose conceals a simplistic and fundamentally conservative cultural determinism.

Partial Identification in Econometrics

Charles F. Manski

Abstract

Econometricians long thought of identification as a binary event: a parameter is either identified or not. Empirical researchers combined available data with assumptions that yield point identification, and reported point estimates of parameters. Yet there is enormous scope for fruitful inference using weaker and more credible assumptions that partially identify parameters. Until recently, study of partial identification was rare and fragmented. However, a coherent body of research took shape in the 1990s and has grown rapidly. This research has yielded new approaches to inference with missing outcome data, analysis of treatment response, and other important problems of empirical research.

Suppose that one wants to use sample data to draw conclusions about a population of interest. Econometricians have long found it useful to separately study identification problems and problems of statistical inference. Studies of identification characterize the conclusions that could be drawn if one were able to observe an unlimited number of realizations of the sampling process. Studies of statistical inference characterize the generally weaker conclusions that can be drawn given a sample of positive but finite size. Koopmans (1949, p. 132) put it this way in the article that introduced the term 'identification':

> In our discussion we have used the phrase 'a parameter that can be determined from a sufficient number of observations.' We shall now define this concept more sharply, and give it the name *identifiability* of a parameter. Instead of reasoning, as before, from 'a sufficiently large number of observations' we shall base our discussion on a hypothetical knowledge of the probability distribution of the observations, as defined more fully below. It is clear that exact knowledge of this probability distribution cannot be derived from any finite number of observations. Such knowledge is the limit approachable but not attainable by extended observation. By hypothesizing nevertheless the full availability of such knowledge, we obtain a clear separation between problems of statistical inference arising from the variability of finite samples, and problems of identification in which we explore the limits to which inference even from an infinite number of observations is suspect.

For most of the 20th century, econometricians commonly thought of identification as a binary event – a parameter is either identified or it is not.

Empirical researchers applying econometric methods combined available data with assumptions that yield point identification and they reported point estimates of parameters. Many economists recognized with discomfort that point identification often requires strong assumptions that are difficult to motivate. However, they saw no other way to perform inference.

Yet there is enormous scope for fruitful inference using weaker and more credible assumptions that partially identify population parameters. A parameter is partially identified if the sampling process and maintained assumptions reveal that the parameter lies in a set, its 'identification region', that is smaller than the logical range of the parameter but larger than a single point. Estimates of partially identified parameters generically are set-valued; a natural estimate of an identification region is its sample analog.

Until recently, study of partial identification was rare and fragmented. Frisch (1934) and Reiersol (1941) developed sharp bounds on the slope parameter of a linear regression with errors-in-variables, with refinement by Klepper and Leamer (1984) and others. Duncan and Davis (1953) used a numerical example to show that the ecological inference problem of political science is a matter of partial identification. Cochran et al. (1954) suggested conservative analysis of surveys with missing data due to non-response by sample members, although Cochran (1977) subsequently downplayed the idea. Peterson (1976) initiated study of partial identification of the competing risks model of survival analysis.

For whatever reason, these scattered contributions remained at the fringes of econometric consciousness and did not spawn systematic study of partial identification. However, a coherent body of research took shape in the 1990s and has grown rapidly. The new literature on partial identification emerged out of concern with traditional approaches to inference with missing outcome data. Empirical researchers have commonly assumed that missingness is random, in the sense that the observability of an outcome is statistically independent of its value. Yet this and other point-identifying assumptions have regularly been criticized as implausible. So it was natural to ask what random sampling with partial observability of outcomes reveals about outcome distributions if nothing is known about the missingness process or if assumptions weak enough to be widely credible are imposed. This question was posed and partially answered in Manski (1989), with subsequent development in Manski (1994, 2003, chs.1 and 2), Scharfstein et al. (2004), Blundell et al. (2004) and Stoye (2005).

Study of inference with missing outcome data led naturally to consideration of conditional prediction and analysis of treatment response. A common objective of empirical research is to predict an outcome conditional on given covariates, using data from a random sample of the population. Often, sample realizations of outcomes and/or covariates are missing. Horowitz and Manski (1998, 2000) and Zaffalon (2002) study nonparametric prediction when nothing is known about the missingness process; Horowitz et al. (2003) and Horowitz and Manski (2006) consider the computationally challenging problem of parametric prediction. Missing data on outcomes and covariates is the extreme case of interval measurement of these variables. Manski and Tamer (2002) study conditional prediction with interval data on outcomes or covariates, while Haile and Tamer (2003) analyse an interesting problem of interval data that arises in econometric analysis of auctions.

Analysis of treatment response must contend with the fundamental problem that counterfactual outcomes are not observable; hence, findings on partial identification with missing outcome data are directly applicable. Yet analysis of treatment response poses much more than a generic missing-data problem. One reason is that observations of realized outcomes, when combined with suitable assumptions, can provide information about counterfactual ones. Another is that practical problems of treatment choice as well as other concerns motivate research on treatment response and thereby determine what population parameters are of interest. For these reasons, it has been productive to study partial identification of treatment response as a subject in its own right. This stream of research was initiated independently in Robins (1989) and Manski (1990).

Subsequent contributions include Manski (1995, 1997a, 1997b), Balke and Pearl (1997), Heckman et al. (1997), Hotz et al. (1997), Manski and Nagin (1998), Manski and Pepper (2000), Moinari (2002), and Pepper (2003). The normative problem of treatment choice when treatment response is partially identified is studied in Manski (2000, 2002, 2005a, 2005b, 2006) and Brock (2005).

Another broad subject of study has been inference on the components of finite probability mixtures. The mathematical problem of decomposition of mixtures arises in many substantively distinct settings, including contaminated sampling, ecological inference, and conditional prediction with missing or misclassified covariate data. Findings on partial identification of mixtures have application to all of these subjects and more. Research on this subject includes Horowitz and Manski (1995), Bollinger (1996), Cross and Manski (2002), Dominitz and Sherman (2004), Kreider and Pepper (2004), and Molinari (2004).

There has been other research as well. In discrete response analysis, response-based sampling poses a 'reverse regression' problem in which one seeks to learn the distribution of outcomes given covariates but the sampling process reveals the distribution of covariates given outcomes. This problem has been studied in Manski (1995, ch. 4; 2001, 2003, ch. 6) and King and Zeng (2002). In econometric analysis of multi-player games, a long-standing problem has been to infer behaviour from outcome data when the game being studied may have multiple equilibria. Ciliberto and Tamer (2004) address this problem.

Whatever the specific subject under study, a common theme runs through the new literature on partial identification. One first asks what the sampling process alone reveals about the population of interest and then studies the identifying power of assumptions that aim to be credible in practice. This conservative approach to inference makes clear the conclusions one can draw in empirical research without imposing untenable assumptions. It establishes a domain of consensus among researchers who may hold disparate beliefs about what assumptions are appropriate.

It also makes plain the limitations of the available data. When credible identification regions turn out to be large, researchers should face up to the fact that the available data do not support inferences as tight as they might like to achieve.

The remainder of this article uses the problem of inference with missing outcome data and the analysis of treatment response to develop the common theme of recent research on partial identification and to give illustrative findings. Readers who aim to learn more may want to begin with two monographs that provide self-contained expositions with different audiences in mind. Manski (1995) presents basic ideas in a way intended to be broadly accessible to students and researchers in the social sciences. Manski (2003) develops the subject in a rigorous manner meant to provide the foundation for further study by econometricians.

Readers who prefer to learn about econometric methods through the study of empirical applications will find diverse case studies using observational data to analyse treatment response. Manski et al. (1992) investigate the effect of family structure on children's outcomes, and Hotz et al. (1997) analyse the effect of teenage childbearing. Manski and Nagin (1998) study the effects of judicial sentencing on criminal recidivism. Pepper (2000) examines the intergenerational effects of welfare receipt. Manski and Pepper (2000) and Ginther (2002) analyse the returns to schooling.

There have also been empirical studies of problems of partial identification that arise in analysis of randomized experiments. Horowitz and Manski (2000) study a medical clinical trial with missing data on outcomes and covariates. Pepper (2003) asks what welfare-to-work experiments reveal about the operation of welfare policy when case workers have discretion in treatment assignment. Scharfstein et al. (2004) analyse an educational experiment with randomized assignment to treatment but non-random attrition of subjects.

Inference with Missing Outcome Data

To formalize the missing data problem, let each member j of a population J have an outcome y_j in a space Y. The population is a probability space and y: $J \rightarrow Y$ is a random variable with distribution

$P(y)$. Let a sampling process draw persons at random from J. However, not all realizations of y are observable. Let the realization of a binary random variable z indicate observability; y is observable if $z = 1$ and not observable if $z = 0$.

By the Law of Total Probability.

$$\begin{aligned} P(y) = P(y|\, z = 1)P(z = 1) \\ + P(y|\, z = 0)P(z = 0). \end{aligned} \tag{1}$$

The sampling process reveals $P(y|z = 1)$ and $P(z)$, but is uninformative regarding $P(y|z = 0)$. Hence, the sampling process partially identifies P (y). In particular, it reveals that $P(y)$ lies in the identification region

$$\begin{aligned} &H[P(y)] \\ &= [P(y|\, z = 1)P(z = 1) + \gamma P(z = 0), \gamma \in \Gamma_Y], \end{aligned} \tag{2}$$

where Γ_Y is the space of all probability distributions on Y.

The size of the identification region $H[P(y)]$ grows with $P(z = 0)$, which measures the prevalence of missing data. The region is a proper subset of Γ_Y whenever the probability of missing data is less than 1, and it is a singleton when there are no missing data. Thus, $P(y)$ is partially identified when $0 < P(z = 0) <1$ and is point-identified when $P(z = 0)= 0$.

Means of Bounded Functions of y

A common objective of empirical research is to infer parameters of a probability distribution. The identification region for a parameter of $P(y)$ follows immediately from $H[P(y)]$. Let $\tau(\cdot):\Gamma_Y \rightarrow T$ map probability distributions on Y into a parameter space T and consider inference on the parameter $\tau[P(y)]$. The identification region consists of all possible values of the parameter. Thus,

$$H\{\tau(P(y))\} = \{\tau(\eta), \eta \in H[P(y)]\}. \tag{3}$$

Result (3) is simple but is too abstract to be useful as stated. Research on partial identification has sought to characterize $H\{\tau\ [P(y)]\}$ for different parameters. Manski (1989) does this for means of bounded functions of y, Manski (1994) for quantiles, and Manski (2003, ch. 1) for all parameters that respect first-order stochastic dominance. Blundell et al. (2004) and Stoye (2005) characterize the identification regions for spread parameters such as the variance, inter-quartile range, and the Gini coefficient; these authors apply their findings in empirical research assessing nationwide income inequality using surveys with missing income data.

The results for means of bounded functions are easy to derive and instructive, so I focus on these parameters here. Let R be the real line. Let $g(\cdot)$ be a function that maps Y into R and that attains finite lower and upper bounds $g_0 = \min_{y \in Y} g(y)$ and $g_1 = \max_{y \in Y} g(y)$. The problem of interest is to infer $E[g\ (y)]$.

The Law of Iterated Expectations gives

$$\begin{aligned} E[g(y)] &= E[g(y)|\, z = 1]P(z = 1) \\ &+ E[g(y)|\, z = 0]P(z = 0). \end{aligned} \tag{4}$$

The sampling process reveals $E[g(y)|z = 1$ and $P(z)$, but is uninformative regarding $E[g(y)|$ $z = 0$, which can take any value in the interval $[g_0,\ g_1]$. Hence, the identification region for E $[g(y)]$ is the closed interval

$$\begin{aligned} H\{E[g(y)]\} = [E[g(y)|\, z=1]P(z=1) \\ +g_0 P(z=0), E[g(y)|\, z=1]P(z=1) \\ +g_1 P(z=0)]. \end{aligned} \tag{5}$$

$H\{E[g(y)]\}$ is a proper subset of $[g_0, g_1]$ whenever $P(z = 0)$ is less than one. The width of the region is $(g_1 - g_0)P(z = 0)$. Thus, the severity of the identification problem varies directly with the prevalence of missing data.

Result (5) has many applications. Perhaps the most far-reaching is the identification region it implies for the probability that y lies in any non-empty, proper set $B \subset Y$ Let $g_B\ (\cdot)$ be the indicator function $gB(y) \equiv 1\ [y \in B]$; that is, $g_B(y) = 1$ if $y \in B$ and $g_B(y) = 0$ otherwise. Then $g_B(\cdot)$ attains its lower and upper bounds on Y, these being 0 and 1. Moreover, $E[g_B(y)] = P(y \in B)$ and $E[g_B(y)|z = 1] = P(y \in B|\ z =1)$. Hence,

$$H[P(y \in B)] = [P(y \in B|\, z = 1)P(z = 1),\\ P(y \in B|\, z = 1)P(z = 1) + P(z = 0)]. \qquad (6)$$

Observe that the width $P(z = 0)$ of this interval depends only on the prevalence of missing data, not on the form of set B.

When y is real-valued, result (6) immediately yields the identification region for the distribution function of y. Given any $r \in R$, it follows from (6) that

$$H[P(y \leq r)] = [P(y \leq r|\, z = 1)P(z = 1),\\ P(y \leq r|\, z = 1)P(z = 1) + P(z = 0)]. \qquad (7)$$

The feasible distribution functions are all increasing functions F(·) such that $F(r) \in H[P(y \leq r)]$ for all $r \in R$.

To go further still, result (7) may be used to obtain sharp bounds on quantiles of y, by inverting the bounds on the distribution function. Manski (1994) and Manski (2003, ch. 1) give alternative derivations of the results for quantiles.

Distributional Assumptions

Distributional assumptions may enable one to shrink identification regions obtained using the empirical evidence alone. One type of assumption asserts that the distribution $P(y|z = 0)$ of missing outcomes lies in some set $\Gamma_{0Y} \subset \Gamma_Y$. Then the identification region shrinks from $H[P(y)]$ to

$$H_1[P(y)] \equiv \left[P(y|\,z=1)P(z=1) + \gamma\left(P(z=0), \gamma \in \Gamma_{0Y}\right]. \qquad (8)$$

Assumptions of this type are not refutable; after all, the empirical evidence reveals nothing about $P(y|z = 0)$. A leading example is the assumption that data are missing at random. Formally, this is the assumption that $P(y|z = 0) = P(y|z = 1)$, which implies that $H_1[P(y)]$ contains the single distribution $P(y|z = 1)$.

A different type of assumption asserts that the distribution of interest, $P(y)$, lies in a set $\Gamma_{0Y} \subset \Gamma_Y$. Then the identification region shrinks from $H[P(y)]$ to

$$H_1[P(y)] = \Gamma_{0Y} \cap H[P(y)]. \qquad (9)$$

Assumptions of the latter type may be refutable: if the intersection of Γ_{0Y} and $H[P\,(y)]$ should be empty, then $P(y)$ cannot lie in Γ_{0Y} For example, let y be real-valued and consider the assumption that $P(y)$ is a symmetric distribution. Then $H_1[P(y)]$ is composed of all members of $H[P(y)]$ that are symmetric. If $H[P(y)]$ contains no symmetric distributions, the empirical evidence reveals that $P(y)$ is not symmetric.

Statistical Inference

The fundamental problem posed by missing data is identification, so it has been convenient in the above discussion to suppose that one knows the distributions that are asymptotically revealed by the sampling process, namely, $P(y|z = 1)$ and $P(z)$. An empirical researcher observing a sample of finite size N must contend with issues of statistical inference as well as identification. I shall not dwell on these here, but merely point out that the empirical distributions $P_N(y|z = 1)$ and $P_N(z)$ almost surely converge to $P(y|z = 1)$ and $P(z)$ respectively. Hence, a consistent estimate of the identification region $H[P(y)]$ is its sample analog

$$H_N[P(y)] = [P_N(y|\,z = 1)P_N(z = 1)\\ +\gamma P_N(z = 0), Y \in \Gamma_Y]. \qquad (10)$$

Moreover, a natural estimate of the identification region for a parameter τ is $\{\tau(\eta),\ \eta \in H_N[P(y)]\}$. Sample analogs may also be used in the presence of distributional assumptions.

Confidence intervals (CIs) may be constructed to measure the sampling variation in estimates of identification regions. Considering cases in which the identification region is an interval on the real line, Horowitz and Manski (2000) propose CIs that asymptotically cover the entire region with fixed probability. Chernozhukov et al. (2004) develop methods for construction of such CIs when the identification region is a general finite-dimensional set. Imbens and Manski (2004) develop a conceptually different confidence interval; rather than cover the entire identification region with fixed probability, their interval asymptotically covers the true value of the parameter with this probability.

Analysis of Treatment Response

Analysis of treatment response poses a pervasive and distinctive problem of missing outcomes. Studies of treatment response aim to predict the outcomes that would occur if different treatment rules were applied to a population. Treatments are mutually exclusive, so one cannot observe the outcomes that a person would experience under all treatments. At most, one can observe the outcome that a person experiences under the treatment he actually receives. The counterfactual outcomes that a person would have experienced under other treatments are logically unobservable.

For example, suppose that patients ill with a specified disease can be treated by drugs or by surgery. The relevant outcome might be lifespan. One may want to predict the lifespans that would occur if all patients were to be treated by drugs. The available data may be observations of the actual lifespans of patients in a study population, some of whom were treated by drugs and the rest by surgery.

To formalize the inferential problem, let each member j of a study population J have a response function $y_j(\cdot)$: $T \rightarrow Y$ mapping the mutually exclusive and exhaustive treatments $t \in T$ into outcomes $y_j(t) \in Y$. Let $z_j \in T$ denote the treatment that person j receives and $y_j = y_j(z_j)$ be the outcome that he experiences. Then $y_j(t)$, $t \neq z_j$ are counterfactual outcomes.

Let $y(\cdot)$: $J \rightarrow Y^{|T|}$ be the random variable mapping the population into their response functions. Let z: $J \rightarrow T$ be the 'status quo treatment rule' mapping the members of J into the treatments that they actually receive. Response functions are not observable, but realized treatments and outcomes may be observable. If so, random sampling from J reveals the status quo (outcome, treatment) distribution $P(y, z)$.

The Selection Problem

Analysis of treatment response seeks to predict the outcomes that would occur under alternatives to the status quo treatment rule. A leading objective is to predict the outcomes that would occur if all persons were to receive the same treatment. By definition, $P[y(t)]$ is the distribution of outcomes that would occur if all persons were to receive a specified treatment t. Hence prediction of outcomes under a rule mandating uniform treatment requires inference on $P[y(t)]$. The problem of identification of this distribution from knowledge of $P(y, Z)$ is commonly called the 'selection problem'.

The selection problem has the same structure as the missing-outcomes problem discussed above. To see this, write

$$\begin{aligned} P[y(t)] &= P[y(t)|\, z=t]P(z=t) \\ &\quad + P[y(t)|\, z \neq t]P(z \neq t) \\ &= P(y|\, z=t)P(z=t) \\ &\quad + P[y(t)|\, z \neq t]P(z \neq t). \end{aligned} \tag{11}$$

The first equality is the Law of Total Probability. The second holds because $y(t)$ is the outcome experienced by persons who receive treatment t. The sampling process reveals $P(y|z = t)$, $P(z = t)$, and $P(z{\neq}t)$, but it is uninformative about $P[y(t)|z{\neq}t]$. Hence, the identification region for $P[y(t)]$ if we use the empirical evidence alone is

$$\begin{aligned} H\{P[y(t)]\} = \{&P(y|\, z=t)P(z=t) \\ &+\gamma P(z \neq t), \gamma \in \Gamma_Y\}. \end{aligned} \tag{12}$$

This identification region has the same form as the region (2) for inference on outcomes with missing data, with $P(z \neq t)$ being the probability of missing data. Hence, all of the analysis of missing outcomes discussed above applies here as well.

Distributional Assumptions

A familiar 'solution' to the selection problem is to assume that the status quo treatment rule makes realized treatments statistically independent of response functions; that is,

$$P[y(\cdot)] = P[y(\cdot)|\, z]. \tag{13}$$

This assumption implies that $P[y(t)] = P(y|z = t)$. The sampling process reveals $P(y|z = t)$. Hence, assumption (13) point-identifies $P[y(t)]$.

Assumption (13) is credible when the status quo treatment rule calls for random assignment of treatments and all persons comply with their assignments. Indeed, the fact that (13) holds is the reason why randomized experiments are held in high esteem. However, the credibility of the assumption in settings without random assignment or full compliance almost invariably is a matter of controversy. This motivates interest in other assumptions that may be better motivated in practice.

There has been much study of assumptions that use an 'instrumental variable'; that is, an observable covariate whose value varies across the study population. Suppose that outcomes are real-valued. Manski (1990) poses the mean-independence assumption $E[y(t)] = E[y(t)|v]$. If outcomes are bounded with values normalized to lie in the unit interval, the resulting identification region for $E[y(t)]$ is

$$H\{E[y(t)]\} = [\max_{v\in V} E\{y \cdot 1[z = t] | v = v\}, \\ \min_{v\in V} E\{y \cdot 1[z = t] + 1[z \neq t] | v = v\}]. \tag{14}$$

Manski and Pepper (2000) study identification of $E[y(t)]$ when v is real-valued and the assumption of mean independence is weakened to state that $E[y(t)|v]$ weakly increases in v. Heckman and Vytlacil (2001) combine the mean-independence assumption with some of the structure of an econometric selection model and show that the identification region for $E[y(t)]$ remains (14).

Statistical independence assumptions are stronger than mean independence. Manski (2003, ch. 7) poses the assumption $P[y(t)] = P[y(t)|v]$ and shows that it yields this identification region for $P[y(t)]$:

$$H\{P[y(t)]\} = \bigcap_{v\in V} \{P(y | v = v,\ z = t) \\ P(z = t | v = v) + \gamma_v \cdot P(z \neq t | v = v),\ \gamma_v \in \Gamma_Y\}. \tag{15}$$

Balke and Pearl (1997) poses the yet stronger assumption $P[y(\cdot)] = P[y(\cdot)|v]$ and characterize its identifying power when outcomes are binary variables.

A different idea, developed in Manski (1995, ch. 6; 1997a) is to place assumptions on the shape of the response functions $y(\cdot)$. One may sometimes believe that treatment response is monotone, in the sense that outcomes increase with the intensity of the treatment. When the set T of treatments is ordered in terms of degree of intensity, the assumption of 'monotone treatment response' asserts that, for all persons j and all treatment pairs (s, t), $t \geq s \Rightarrow y_j(t) \geq y_j(s)$. If outcomes are bounded with values normalized to lie in the unit interval, the resulting identification region for $E[y(t)]$ is the interval

$$H\{Ey(t)\} = [E(y | t \geq z) \cdot P(t \geq z), P(t > z) \\ + E(y | t \leq z) \cdot P(t \leq z)]. \tag{16}$$

A narrower interval results if treatment response is assumed to be concave as well as monotone.

Shape restrictions on the response function and assumptions using instrumental variables illustrate the vast middle ground between inference from the empirical evidence alone and analysis predicated on assumptions that are strong enough to achieve point identification. As the study of partial identification continues to broaden and deepen, empirical researchers will be able to choose from a growing menu of inferential options. One should, however, not expect one uniformly best option to emerge. The appeal of any approach to inference necessarily depends on the objectives of the research, the available data, and the assumptions that are credible to maintain.

Partial Linear Model

Elie Tamer

Abstract

It is popular to summarize the relationship between an outcome variable y and a vector (x, z) through a linear mean regression where the mean of y is modelled as a linear function of both x and z. A more robust specification is called for in some situations where the imposed linear relationship between (the mean of) y and z is suspect. A partially linear specification allows for a regression function that maintains linearity in x but allows the effect of z to be nonlinear. This partially linear model has been widely studied in the statistics and the semiparametric econometrics literature.

A partially linear model requires the regression function to be a linear function of a subset of the variables and a nonparametric non-specified function of the rest of the variables. Suppose, for example, that one is interested in estimating the relationship between an outcome variable of interest y and a vector of variables (x, z). The economist is comfortable modelling the regression function as linear in x, but s hesitant in extending the linearity to z. One example, considered by Engle et al. (1986), is the effect of temperature on fuel consumption using a time series of cities. To do that, one can consider a regression of average fuel consumption in time t on average household characteristic and average temperature in time t. The analyst might be more comfortable with imposing linearity on the part of the regression function involving household characteristics but unwilling to require that fuel consumption varies linearly with temperature. This is natural since fuel consumption tends to be higher at extremes of the temperature scale, but lower at moderate temperatures. The regression function Engle et al. consider is:

$$y = x'\beta + g(z) + u \tag{1}$$

where x denotes a vector of household/city characteristics and z is temperature and u is a mean zero random variable such that is independent of (x, z). The function g(.) is unspecified except for smoothness assumptions. They term this *the semiparametric regression model.*

Another example is the demand for gasoline model used by Schmalensee and Stoker (1999). The primary interest in this paper is the age income structure of household demand for fuel. In particular, the authors want to estimate demand elasticities of age and income (do richer household consume more gasoline, and, if so, by how much?). Hence, their dependent variable is the logarithm of gasoline consumed and $g(.)$ is a function of both age and the logarithm of income. Schmalensee and Stoker also control for a set of other household characteristics. This partially linear model allows one to have a more robust model of the relationship between mean gasoline consumption and age and income.

The partially linear model can arise also as a special case of a censored sample selection model (see Heckman 1974). There, we are interested in estimating β in the equation $y^* = d * (x\beta + \varepsilon)$ where d is a binary observed random variable that indicates censoring: $d = 1$ the outcome y is uncensored, and $d = 0$ otherwise. The model above can be written as

$$E[y|\,w, x, d = 1] = x\beta + g(w).$$

If there is no overlap between x and w, this is an example of a partial linear model with a nonparametric selection mechanism. A more general version of this model is studied in Ahn and Powell (1993).

Partially linear models are more attractive than linear models especially in cases where the linearity assumption on a subset of the regressors is suspect. This more robust model allows for a more flexible parametrization for that part of the regression where the analyst is not convinced of the linearity. On the other hand, the main motivation for modelling the regression function as partially nonparametric, or semiparametric, as opposed to fully nonparametric, is the concern for the precision of the estimates. In particular, with more continuous regressors in the regression the 'curse of dimensionality' slows the rate of convergence, effectively reducing the usefulness of the regression in data-sets with moderate sizes. Hence, partially linear models provide another practical tool for analysts to use in regressions where linearity of part of the regression function is questionable and provides a middle ground between a completely linear regression that is less robust and one that is totally nonparametric but less practical.

There are many approaches to estimating β and g. For example, one can use a penalized spline regression similar to the one used in Engle et al. (1986), or use semiparametric sieve least squares by replacing the function f with an appropriate sieve that approximates the function space (where g lies) as sample size increases. The method we describe here uses kernel smoothing similar to the one used by Robinson (1988) and Speckman (1988). Notice that Eq. 1 above implies that

$$E[y|\,z] = E[x'|\,z]\beta + g(z). \tag{2}$$

Subtracting Eq. 2 from 1 we obtain

$$y - E[y|\,z] = \left(x - E[x|\,z]'\beta + u\right). \tag{3}$$

Hence, one can consistently estimate β by regressing ($y - E[y|z]$) on ($x - E[x|z]$) if the matrix $E[(x - E[x|z])(x - E[x|z])']$ is full rank. This procedure has some similarities to a linear regression where one is interested in a subset of the slope parameters. One can obtain this by regressing the dependent variable on residuals from a regression of the regressors of interest on the nuisance regressors. It is a regression of the outcome on what remains of the regressors after purging them of their linear component that is common with other regressors.

One problem in our set-up is that the regression in Eq. 3 is unfeasible since $E[y|z]$ and $E[x|z]$ are not known. These can be consistently estimated using a variety of methods like kernels or sieves. Robinson (1988), for example, replaces the conditional expectations by appropriate Naradaya–Watson kernel estimators where for a random sample of size N,

$$\widehat{E}[y|\,z] = \frac{1}{N}\sum_{i=1}^{N} w_{in}(z)y_i \tag{4}$$

where the weight function w_{in} is such

$$w_{in}(z) = \frac{K\left(\dfrac{z_i - z}{h_n}\right)}{\dfrac{1}{N}\sum K\left(\dfrac{z_i - z}{h_n}\right)}. \tag{5}$$

K(.) is a kernel function satisfying certain conditions (see Hardle 1991, for more on smoothing conditional expectations), and h_n is a bandwidth parameter that is positive and converges to zero as sample size increases. Conditions on the rate of convergence of this bandwidth are obtained to ensure desirable theoretical properties of the estimators (for example, on the conditional expectation case, we have $h_n = \lambda n^{-1/5}$ where $0 < \lambda < \infty$). Robinson then shows that the estimator $\widehat{\beta}$ of β is normally distributed asymptotically as sample size increases. (The estimator Robinson considers requires trimming those values of z that cause instability in the estimates in the 'random denominator' of the conditional expectation.) In particular,

$$\sqrt{n}\left(\widehat{\beta} - \beta\right) \rightarrow_d \mathcal{N}\left(0,\ \ \sigma^2 E\left[(x - E[x|\,z])\left(x - E[x|\,z]'\right]^{-1}\right). \tag{6}$$

This is derived on the assumption of homoskedasticity ($V(u|x) = a^2$), and other conditions guaranteeing well behaviour of the kernel estimators as sample size increases. As for estimating the nonparametric function g(.), one can use a feasible version of Eq. 2 to get

$$\widehat{g}(z) = \widehat{E}[y|\,z] - \widehat{E}[x|\,z]'\widehat{\beta}. \tag{7}$$

Under a set of assumptions, it can be shown that $\hat{g}\,(z)$ is a consistent estimator for $g\,(z)$. For example, in the case of scalar z that has support on [0,1], it can be shown that under appropriate assumptions,

$$sup_{t\in[0,1]}|\widehat{g}(t) - g(t)|\ \ = O\left(n^{-2/5}\log^{2/5}n\right).$$

In addition, Hardle et al. (2001) provide more consistency results for the nonparametric function g(.).

In practice, to implement a partially linear regression, three additional tasks remain. First, one needs to choose a kernel function. Second, although rates of convergence for the smoothing parameter h_n were given, those provide no guidance for choosing a particular value for this smoothing parameter with a given data-set. Third, and to account for sample variability, one needs to obtain estimates for the variance covariance matrix. As for the choice of the kernel function, one can use $K(u) = (2\pi)^{-1/2}\exp(-\frac{1}{2}u^2)$, $K(u) = \frac{1}{2}1[|\,u| \ \ \le 1]$ or a quartic kernel $15/16((1 - u^2)^2\ I\ (|u| \le 1))$ (see Hardle 1991, for more on kernel selection. Kernel selection does not seem to make a difference in practice). As for the choice of the smoothing parameter h_n, one method that can be used is *cross validation*. In particular, our estimators of β and the function g(.) obtained from Eqs. 3 and 7 can be written as $\widehat{\beta}(h_n)$

and $\hat{g}$ $(z) = \hat{g}$ $(z;\ h_n)$ which are functions of the smoothing parameter h_n. So, to choose h_n in practice, one can minimize the cross-validation function $cv(h_n)$ defined as

$$cv(h_v) = \frac{1}{N}\sum_{i=1}\left({}_i - x_i\widehat{\beta}(h_n) - \widehat{g}(z_i; h_n)\right)^2. \quad (8)$$

Finally, to estimate the variance covariance matrix in the homoskedastic case, one can replace $\sigma^2 E[(x - E[x|\ z])\ (x - E[x|\ z]')]^{-1}$ by its sample analog. In particular, an estimator $\widehat{\sigma^2}$ of σ^2 can be:

$$\widehat{\sigma^2} = \frac{1}{N}\sum_{i=1}^{N}\left(y_i - x_i\widehat{\beta} - \widehat{g}(z_i)\right)^2.$$

However, since the conditional mean is semiparametric, a better estimator for the variance matrix is one that is heteroskedasticity robust. This estimator is similar to the heteroskedasticity robust estimator in linear regression and can be written as

$$\widehat{V} = \frac{1}{N}\sum\left(x_i - \widehat{E}(x|\ z_i)\right)\ \left(x_i - \widehat{E}(x|\ z_i)\right)' \left(y_i - \widehat{\beta}x_i - \widehat{g}(z_i)\right)^2.$$

One can also approximate the finite sample distribution of the estimator by a bootstrapped distribution. After estimating β and $g(.)$, one obtains a set of centred residuals $e_i^*, i = 1, \ldots, N$ with distribution F_n^* from which one can draw a bootstrap sample, and then generate a sample of y's from which one can obtain one's bootstrap estimates. Hardle et al. (2001) contains consistency results for the bootstrap procedure in the partially linear model above.

Partially linear models are semiparametric linear regressions where the regression function contains a nonparametric function. These regressions are robust to the linear specification for part of the regressors. In addition, partially linear models provide a good alternative to fully nonparametric regression in settings where the data-set that is available is of moderate sample sizes and/or when one has to smooth over a set of continuous random variables of high dimension. Finally, one can also extend the independence (or mean independence) usually used in estimating partially linear models to conditional quantile restrictions and obtain a partially linear semiparametric quantile regression.

Pascal was born on 19 June 1623 in Clermont, France, and died on 19 August 1662. In 1631 his father Etienne Pascal moved to Paris in order to secure his son a better education. In 1635 Etienne was one of the founders of Marin Mersenne's 'Academy', to which he introduced his son at the age of 14, and Blaise immediately put this new source of knowledge to good use, producing (at the age of 16) his famous *Essai pour les coniques.*

In the succeeding years the young Pascal designed and had built the first mechanical adding machine (there is now a computer language called 'Pascal') and conducted experiments into the nature of a vacuum (the 'Pascal' is the S.I. unit of pressure), but his chief mathematical contribution was to lay the foundations of the theory of probability.

Before his time probability calculations amounted to no more than the enumeration of equally probable outcomes in games of chance, but Pascal introduced the important idea of expectation and used recursively the fact that if expectations of gain X and Y are equally probable, the expectation is $\frac{1}{2}(X+Y)$. He also introduced the binomial distribution for equal chances and with its help, and that of mathematical induction applied to expectations, solved the Problem of Points for two players.

This problem was the topic of correspondence between Pascal and Pierre de Fermat in 1654 which, together with Pascal's contemporary *Traité du triangle arithmétique,* includes three methods of solution. Two players stake equal money on being the first to win n points in a game in which the winner of each point is determined by the toss of a coin. If such a game is interrupted when one player still lacks a points and the other b, how should the stakes be divided between them?

Fermat and Pascal independently concluded that the problem could be solved by noting that at most $(a + b - 1)$ more tosses will settle the game, and that if this number of tosses is imagined to have been made, the resulting 2^{a+b-1} possible games (each equally probable) may be classified according to the winner in each case, the stakes then being divided accordingly. Thus the real game, of indeterminate length, is embedded in an imaginary game of fixed length. Apart from this novel idea, however, such a solution by enumeration was straightforward, but Pascal offered both an independent method based on expectations which is valid for any number of players, and, in the *Traité du triangle arithmétique,* the solution for two players in terms of the binomial distribution, proved by induction. He did not give the binomial distribution algebraically, but by reference to the 'arithmetical triangle' of binomial coefficients, whose properties he elaborated in his *Traité* (whence the name 'Pascal's triangle').

In the *Pensées* Pascal introduced his celebrated wager '*infini-rien*', in which he argued that we should wager for the existence of God since the stakes are finite (our lives) but there is an infinite prize (eternal life). The argument is that of modern decision theory, which it may be said to foreshadow. The 'states of nature' are the existence and non-existence of God whilst the 'decisions' are to act as if God exists and as if he does not. If God does exist and we act as if he does, the 'utility' is infinite, and thus so is the 'expected utility' of this course of action whether he exists or not, provided there is a non-zero chance that he does.

Patent Pools

Daniel Quint

Abstract

A patent pool is an agreement by multiple patentholders to share intellectual property among themselves or to license a portfolio of patents as a package to outsiders. Patent pools were common in the United States from the 1890s to the 1940s; since the mid-1990s, there has been a resurgence of patent pools tied to technological standards. I discuss the history and antitrust treatment of patent pools in the United States, and review the related academic literature (both theoretical and empirical).

A patent pool is an agreement by multiple patentholders to share intellectual property among themselves or to license a portfolio of patents as a package to outsiders.

Patent pools were common in the United States in the first half of the 20th century, and reemerged as an important institution in the mid-1990s; an estimated $100 billion worth of goods sold in 2001 were based at least partly on pooled patents.

History

The first patent pool emerged from infringement lawsuits won by Elias Howe, credited with inventing the sewing machine, who returned from marketing his invention in England in the 1840s to find that others had copied it. Following the lawsuits, Howe, Isaac Singer and two other manufacturers established a pool of sewing machine-related patents in 1856, with Howe receiving the bulk of the royalties.

Patent pools were commonplace in the United States from the 1890s to the 1940s. Lerner et al. (2007) identify 125 pools, most of them from this time; Lerner and Tirole (2007) claim that in the early 20th century, 'many (if not most) important manufacturing industries had a patent pooling arrangement'. (A partial list from Merges (2001) includes pools covering shoe machinery, automobiles, bathtubs, door parts, seeded raisins, coaster brakes, davenport beds, movie projectors, hydraulic pumps, and swimming pool cleaners; a longer list from Lerner et al. includes railroad couplers, television equipment, and plastic artificial eyes.) In 1917, with airplanes needed for the First World War, then Assistant Secretary of the Navy Franklin D. Roosevelt pushed eight aircraft manufacturers into a patent pool because patent litigation had shut down US aircraft production. A 1915 pool containing automobile patents had 146 initial members, but most of the pools examined in Lerner, Strojwas and Tirole started with six members or fewer.

Following Congressional hearings on patent pools in the 1930s and 1940s and several negative antitrust rulings, patent pools essentially vanished from the mid-1950s until the mid-1990s. In 1997, after extensive discussion with regulators, a pool formed containing patents essential to the MPEG-2 digital video standard. This was followed by pools tied to the DVD, Bluetooth, 1394 (Firewire), DVB-T, MPEG-4 (AVC) and 3G–Mobile standards. The MPEG-2 pool alone currently has 26 members, nearly a thousand patents, and over 1300 licensees and affiliates. Pools have also recently been discussed for the biotech and pharmaceutical industries.

Antitrust Treatment

For two decades following the passage of the Sherman Antitrust Act in 1890, patent pools appeared to offer a way to circumvent its prohibitions. In 1902, the Supreme Court upheld the legality of the National Harrow pool, which dominated the market for float spring tooth harrows. Among other things, the licensing terms required licensees to only sell particular products, and fixed the prices for these products. The Court wrote:

> The general rule is absolute freedom in the use or sale of rights under the patent laws of the United States. The very object of these laws is monopoly, and the rule is, with few exceptions, that any conditions which are not in their very nature illegal with regard to this kind of property… will be upheld by the courts. (E. Bement & Sons *v.* National Harrow *(186 US 70)*)

In 1912, however, the Court reversed itself, upholding a lower court's break-up of a pool with similarly restrictive licensing terms (*Standard Sanitary Manufacturing* v. *United States*). In the decades following, the court continued to focus on licensing terms, breaking up pools that fixed downstream prices or production, and allowing pools whose licensing agreements 'contained no restrictions as the quantity of goods to be produced, or the price to be charged, or the territory in which they might be sold by the licensee' *(Baker-Cammack Hosiery Mills* v. *Davis,* 181 F.2d 550 1950). In 1945, the Supreme Court ruled against the Hartford-Empire pool, which used licensing terms to set production quotas in the glassware manufacturing industry, claiming, 'The history of this country has perhaps never witnessed a more completely successful economic tyranny over any field of industry' *(Hartford Empire Co.* v. *United States*, 323 US 386). Although the Baker-Cammack ruling followed that, several other pools were broken up in subsequent years (*United States* v. *Line Material, United States* v. *U.S. Gypsum, United States* v. *New Wrinkle*), and Hartford-Empire was generally seen as signalling the end of favourable treatment toward pools; by the mid-1950s, pool formation had essentially ceased.

This changed following release of the Antitrust Guidelines for the Licensing of Intellectual Property by the Department of Justice and Federal Trade Commission in April 1995. Under the heading 'cross-licensing and pooling arrangements,' the Guidelines stated:

> These arrangements may provide procompetitive benefits by integrating complementary technologies, reducing transaction costs, clearing blocking positions, and avoiding costly infringement litigation. By promoting the dissemination of technology, cross-licensing and pooling arrangements are often procompetitive.

Department of Justice analysis, enunciated in business review letters of several proposed pools, focused on three questions: whether a pool would integrate complementary patent rights (as opposed to patents which would otherwise be in competition); whether it would foreclose competition in related markets; and whether it would discourage further innovation. In the cases of the MPEG-2, DVD, and 3G pools, the DOJ stated after review that it was 'not presently inclined to initiate antitrust enforcement action against the conduct you have described'. In 1998, the FTC did challenge a pool formed by Summit Technology and VISX, the only firms with FDA-approved technology for laser eye surgery, which was viewed to be functioning primarily as a price-fixing arrangement; the pool was dissolved as part of a settlement resolving the case. A 2007 DOJ/FTC report, which followed public hearings held in 2002, summarizes the current regulatory view.

Characteristics of Recent Pools

To address the first regulatory concern – the integration of only complementary patent rights – recent pools have been limited to patents deemed essential for standard compliance. The business review letter on the proposed MPEG-2 pool reads:

> The Portfolio combines patents that an independent expert has determined to be essential to compliance with the MPEG-2 standard; there is no technical alternative to any of the Portfolio patents within the standard. Moreover, each Portfolio patent is useful for MPEG-2 products only in conjunction with the others. The limitation of the Portfolio to technically essential patents, as opposed to merely advantageous ones, helps ensure that the Portfolio patents are not competitive with each other. . .. The continuing role of an independent expert to assess essentiality is an especially effective guarantor that the Portfolio patents are complements, not substitutes. (Joel Klein (Acting Assistant Attorney General), letter to Garrard Beeney, 26 June 1997.

Several of the recent pools include grantback provisions – pool participants and licensees agree to add to the pool, or to license to each other at reasonable terms, any future patents they receive that are judged to be essential. The pools also allow for separate licensing of individual patents – that is, licensing through the pool is not done exclusively. The majority of the recent pools allocate revenue in proportion to the number of essential patents that each firm has contributed to the portfolio, although some of the pools do attempt to account for patents that are more or less valuable.

One unusual case is the 3-G mobile standard. 3-G was designed to use five different radio interfaces, in order to be backward-compatible with five second- generation wireless networks. Antitrust concerns led to the establishment of five separate License Administrators to oversee licensing of patents essential for each interface, rather than a single platform or pool containing all of the relevant patents. (The 3-G platforms are different from traditional pools in that all licensing is done ‘a la carte’, at standardized terms set by each Administrator.)

Theoretical Literature

Shapiro (2001) employs a Nash-Bertrand model to show that pools result in lower prices and greater welfare when patents are perfect complements, by correcting the ‘complements problem’ of excessive prices; and higher prices and lower welfare when patents are perfect substitutes, by eliminating competition. Kim (2004) finds that when patents are perfect complements, the case for pools is even stronger in the presence of vertically integrated firms (patentholders who are also downstream producers). Choi (2003), on the other hand, shows that patent pools change the incentive for another patentholder or a potential infringer to challenge questionable patents in court, making pools of complementary but weak patents possibly welfare- destroying.

Lerner and Tirole (2004) introduce a more flexible model than perfect complements and perfect substitutes, and show that when patents are more substitutable, pools are more prone to be welfare-negative. They show that forcing pool participants to also make their patents available individually has a destabilizing effect on welfare-negative pools, but no effect on welfare-positive pools, and therefore propose compulsory individual licensing as a screen for efficient pools. Brenner (forthcoming) examines the equilibrium effects of different pool formation rules in the Lerner and Tirole framework, showing that endogenously occurring pools will be inefficiently small if patentholders can opt out individually without disrupting pool formation. My own work (Quint 2008) examines pools in a setting with both essential and nonessential patents; I find that pools of essential patents are always welfare-increasing, while pools containing nonessential patents have ambiguous welfare effects, even when they are limited to patents that are perfect complements. I also find that when a pool is welfare-increasing, agreements that ‘bind the pool’s hands’ with respect to pricing will reduce, and may even reverse, the welfare gains.

Empirical Literature

Merges (2001) discusses the workings of many historical pools. Gilbert (2004) discusses a number of important court rulings and how they hold up under economic analysis. Lerner et al. (2007) analyse the licensing rules of 63 patent pools, most from before 1950 but a handful from the 1990s; they find that, consistent with theory, pools containing complementary patents were more likely to allow independent licensing and require grantbacks. Layne-Farrar and Lerner (2008) examine arrangements for dividing pool revenue and its effect on participation; they also find that vertically integrated firms are more likely to join pools. Lerner and Tirole (2007) review current public policy and suggest certain changes.

Patent Races

Richard A. Jensen

Abstract

A patent race is a competition between two or more inventors, typically firms, to discover an invention first, thereby securing a patent which protects the invention from imitation. The date at which a firm discovers the invention is stochastic, but can be reduced in expectation by increased investment in research and development. Competition to win the patent leads firms to over-invest, compared with the outcome where they invest cooperatively and share the patent equally. However, the expected discovery date is later than socially optimal, so innovation is delayed, on average, compared with the social optimum.

A patent race is a situation in which two or more inventors, typically firms, compete to discover an invention first, thereby securing a patent which protects the invention from imitation or infringement.

The literature on patent races is predominantly theoretical. These analyses have two fundamental properties. First, for each firm, the discovery date of the invention is stochastic, and depends on the effort expended (or investment) by both itself and its rivals. It is common to assume the discovery date is a random variable that is exponentially distributed with a parameter that depends on the knowledge levels of the firms, which in turn depend on the cumulative research and development (R&D) investments of the firms. If firm i invests an amount $I_i(t)$ at date t, then the growth of its knowledge stock $K_i(t)$ is $K_i'(t) = I_i(t)$. The distribution of firm i's random discovery date t_i is $Pr\{t_i \leq t\} = F(K_i(t)) = 1 - exp\{-\lambda K_i(t)\}$, where $\lambda > 0$ is a parameter, noteworthy because the cumulative knowledge needed for discovery is exponentially distributed with mean $1/\lambda > 0$. The probability that i discovers at t, conditional on i not discovering before t, is $Pr\left\{t_i \in \left(t, t + dt\right] | t_i > t\right\} = \lambda I_i(t) dt$.Given n firms, if their research processes are stochastically independent, then the probability density that i wins the race at t is $\lambda I_i(t) exp\left\{-\lambda \sum_{j=1}^{n} K_i(t)\right\}$.

Second, the race is modelled as a game in which each firm chooses its R&D investment (effort) at each t to maximize the present discounted value of its expected profit, subject to knowledge growth $K_i'(t) = I_i(t)$ from an initial stock $K_i(0) = K_0 \geq 0$. If $V > 0$ is the value of the invention at its discovery date, $r > 0$ is the interest rate, and $c_i(x_i)$ is i's R&D cost function, then this expected present value is

$$\int_0^\infty exp\{-rt\} \times \left[\lambda I_i(t) exp\left\{-\lambda \sum_{j=1}^{n} K_i(t)\right\} V - exp\left\{-\lambda \sum_{j=1}^{n} K_i(t)\right\} c_i(x_i(t))\right] \times dt.$$

Research on patent races initially focused on the Schumpeterian hypothesis regarding the relationship between competition and the pace of innovative activity. In the seminal article on patent races, Loury (1979) assumes each firm chooses a lump-sum R&D expenditure at the start, so $c_i(x_i(t)) = x_i(t)$ where $x_i(0) = X_i$ and $x_i(t) = 0$ for $t > 0$. With no knowledge accumulation over time, the probability density of discovery becomes $h(X_i)$ $exp\left\{-\sum_{j=1}^{n} h(X_i)t\right\}$ where the hazard function $h(X_i)$, the probability that i discovers at t, given that it has not discovered before t, depends only on the lump-sum R&D expenditure. Thinking of invention as a stochastic production process, it is natural to assume that this hazard function is increasing in expenditure, possibly with initially increasing returns to scale, but necessarily with decreasing returns eventually. In this model, increased competition (an increase in the number of firms) reduces the Nash equilibrium expenditure of each firm. Given a fixed number of firms, however, each firm spends more than in the outcome where they invest cooperatively and share the patent value equally. Thus, with unrestricted entry, there are too many firms and too much aggregate R&D investment in the Nash equilibrium, compared with the cooperative outcome.

Lee and Wilde (1980) note that Loury's approach does not allow firms to invest in R&D over time. They assume instead that each firm initially chooses a level of R&D expenditure for each date until it or a rival discovers the invention, $c_i(x_i(t)) = x_i$ for all $t \geq 0$ before discovery and $c_i(x_i(t)) = 0$ thereafter. Again, with no knowledge accumulation, the probability density of discovery is $h(x_i)exp\left\{-\sum_{j=1}^{n} h(x_i)t\right\}$ where the hazard function $h(x_i)$ now depends only on current R&D expenditure. In this case, increased competition increases the Nash equilibrium expenditure of each firm.

For a fixed number of firms, each firm spends more than in the outcome where they invest cooperatively and share the patent value equally. And with unrestricted entry, there are too many firms, each of which spends too much on R&D, in the Nash equilibrium, compared with the cooperative outcome.

One notable difference between these studies is that competition increases R&D investment per firm in Lee and Wilde's approach. This arises from the different R&D strategies. In Loury's model, firms choose the scale of R&D effort with one initial investment, whereas in Lee and Wilde's model, firms choose the intensity of R&D effort per period. In the latter approach, firms can cut their R&D spending, and so their losses, after a rival discovers.

Both of these patent races are essentially static in that the firms choose the strategies at the beginning of the game, and there is no knowledge accumulation. Reinganum (1982) generalizes this by allowing firms to choose feedback strategies: each firm chooses its R&D investment at each date as a function of the observed knowledge stocks of all firms in the race. When patent protection is perfect, increased competition increases the R&D investment expenditure of each firm. However, the effect of increased competition on a firm's R&D investment is ambiguous when patent protection is not perfect. Finally, when the social value of the patent exceeds the private value to a firm in the race, the noncooperative growth rate of knowledge is less than socially optimal, and so innovation is delayed on average compared with the social optimum.

Subsequent research has sought to understand the effects of two types of asymmetries on patent race outcomes. The first type involves an incumbent who owns the current patent and a group of potential entrants vying for the patent to the next generation technology. There are two conflicting effects. First, there is a dissipation of monopoly rent if the incumbent loses. If the innovation is a non-drastic new process, and $M =$ monoply profit and $D =$ duopoly profit, then the incumbent earns $M - D$ if it wins, and the entrant earns D, where typically $M - D > D$. However, if the monopolist wins, it replaces itself as the monopolist (Arrow 1962). If the innovation is drastic and pre-innovation profit is π, then the monopolist's gain from winning is $M - \pi$, while the entrant's is $M > M - \pi$. Incumbents have a greater incentive to innovate when the rent dissipation effect dominates (Gilbert and Newbery 1982), but not when the replacement effect dominates (Reinganum 1983).

The second asymmetry involves a race in which one firm has a lead in the race. When the lead takes the form of greater accumulated knowledge, $K_i(0) > K_j(0)$ for all $j \neq i$, the laggards simply exit and concede the race to the leader firm i in the unique subgame perfect equilibrium. However, the laggards can and do remain in the race if there is some way that they can leapfrog into the lead, such as when the R&D process requires completion of several successive stages (Fudenberg et al. 1983).

Patent Valuation

Jonathan Putnam

Abstract

Agents routinely appraise and trade individual patents. But small-sample methods (generally derived from basic accounting and finance) are often crude, and their results may bear little relationship to economic fundamentals, especially in litigation. Meanwhile, large-sample methods usually lack much invention-specific data on which to condition value estimates. Regardless of sample size, proper valuation methods require both conceptual delineation and empirical ingenuity.

O31

The valuation of patent rights sounds like a simple enough concept. It is true that agents routinely appraise and trade individual patents. But small-sample methods (generally derived from basic accounting and finance) are often crude, and their results may bear little relationship to economic fundamentals, especially in litigation. On the other hand, large-sample methods usually lack much invention-specific data on which to condition value estimates. Regardless of sample size, proper valuation methods require both conceptual delineation and empirical ingenuity.

Concepts

Legally, a patent is the right to exclude others from making, using or selling an invention. In economic terms, that right is an asset, yielding a non-negative returns stream while it is enforceable. Because the right is a private means (increased exclusivity) to a public end (increased productivity), a patent's private value only partially conveys its market significance.

Unlike most property rights, patents do not comprise the affirmative right to use the invention. Absent the right to use, patents may generate private value only when combined with complementary assets, such as a licence under other patents. Contracting problems (for example, asymmetric information) may strongly influence value.

A patent may generate private returns apart from the right to exclude rivals. The patentee may use it: to monitor employee performance; to signal otherwise unobservable quality to prospective financiers; to enhance reputation; to signal a willingness to litigate; or to reduce the costs of settlement in the event that litigation occurs ('defensive patenting'). In large samples, it is usually impossible either to observe the magnitude and timing of these sources of value, or to decompose them.

Patents also impose unobservable private costs on the patentee. Chiefly, the inventor must disclose the means for reproducing the invention. Disclosure reduces the cost to rivals of reproducing the invention (static spillover) and conducting R&D (dynamic spillover). Apart from reducing the incentive to invent, these private costs imply social benefits not captured by the patentee.

Cross-sectionally, patents are usually modelled as having a one-dimensional 'quality' (which is either synonymous with, or a monotone function of, the patent's value). More precisely, a patent's private value depends significantly on the exclusivity conferred by its claims, but its uncaptured social value depends significantly on the scope of its disclosure (which must be at least as broad as the claims). For various reasons, including rival use of the patentee's disclosure to develop competing innovations ('creative destruction'), the social and private values of a patent may diverge. Thus, it is theoretically preferable, but empirically much less tractable, to model patents as having two-dimensional 'quality'.

Over time, because of ongoing research by the patentee and his rivals, the private returns to patent protection may fluctuate sharply up or down, in response to complementary or competitive discoveries. The variance is likely to be larger in a patent's early years.

Stylized Facts

The following stylized facts bear on the calculation of aggregate private patent values:

1. Whether aggregated by firm, industry or country, patent counts do not vary much from one period to the next.
2. The distribution of patent values is skewed.
3. Social and private patent values are imperfectly correlated.
4. *Ex ante* and *ex post* values are imperfectly correlated.
5. Most patents are not traded.
6. Samples are selected (not all innovations are patented; not all applications are filed in any single country; not all applications are granted).

Related Research

Proceeding in the direction of generally increasing complexity and structure, the following categories describe large-sample models that economists have developed to value patent rights. Lanjouw et al. (1998) surveys recent papers.

Patent Counts

A variety of models employ simple patent counts to indicate the value of patent rights. Strictly speaking, patent counts indicate quantities rather than values. Under certain assumptions, relative quantities may be proportional to relative values. For example, if two patent samples are drawn from the same value distribution, then the ratio of quantities is an efficient estimator of the ratio of values.

Griliches (1990) reviews a large number of studies that, implicitly or explicitly, rely on this assumption. Griliches' view of 'patent [counts] as economic indicators' is not encouraging ('The food here is terrible.' 'Yes, and the portions are so small.'). Stylized facts 1 and 2 combine to thwart inference. A firm facing a fixed budget constraint may patent its best *N* inventions, which implies little intertemporal variation in patent counts even if their realized quality varies markedly. Thus, patent counts are a *biased* measure of value. Because R&D outcomes are highly variable and skewed, patent counts are an *imprecise* measure of value. For these reasons, the assumption that patent samples are drawn from the same distribution is difficult to test, and often false.

On the other hand, fixed budget constraints for R&D and patenting imply that patent counts may proxy for the value of R&D *inputs*. Hausman et al. (1986) model the lag relationship between patent counts and R&D, and find an approximately contemporaneous relationship.

One may compute implied patent values by associating patent counts with other observable aggregates. On the macro level, McCalman (2005) employs the structural imitation model of Eaton and Kortum (1996) to determine international 'trade' in patents. He estimates that the worldwide value of patent applications filed by US inventors in 1988 was about $12.4 billion ($163,700 per application). The estimates for four other large patenting countries vary: France, $147,200; Germany, $82,200; UK, $53,100; Japan, $47,700.

At the firm level, Pakes (1986) constructs a time series model of patent applications, R&D and the stock market rate of return. Controlling for R&D expenditures, an unanticipated patent application implies an $800,000 increase in market capitalization. This relatively high value also reflects investors' revised expectations of research success, and the selection of publicly traded patentees (which are larger and more successful than average).

Patent Citations (Weighted Patent Counts)

Patent examiners cite prior patents when they decide whether to grant a patent application. Analysts count these citations to indicate the value of the cited patent. Patent counts are then weighted by the number of citations. A recent book-length treatment is Jaffe and Trajtenberg (2002).

This branch of the literature divides in two: estimates of the relationship between citations and patent value; and studies that assume that relationship. In the former category, Trajtenberg's (1990) pioneering study showed that citation-weighted patent counts perform better than unweighted counts in explaining aggregate patent value (see Harhoff et al. 1999). However, this and subsequent studies found that citations tend to indicate the social value of the patent rather than the purely private value (stylized fact 3). Private value is better captured by 'self-citations' from the patentee's own later inventions. Hall et al. (2005) show that weighted patent counts are associated with – and predict – higher stock market returns.

Assuming that citations proxy for value, Henderson et al. (1998) examine the contribution of university patenting to commercial technology; Trajtenberg et al. (1997) find that the 'basicness' of university patents relative to corporate patents has narrowed over time. Jaffe et al. (1993) model the spatial distribution of dynamic spillovers.

Other Indicator-Based Methods

Lanjouw and Schankerman (2004) construct a composite index of patent quality using several indicators (forward and backward citations, number of claims, and number of filing countries). This combination of *ex ante* and *ex post* measures (stylized fact 4) efficiently aggregates informationally distinct components of patent value. The composite also explains related *ex post* decisions (for example, patent renewal and litigation); forward citations (an *ex post* measure) demonstrate the greatest explanatory power.

Structural Models: Patent Renewals and Patent Applications

Although most patents are not traded (stylized fact No. 5), patent office rules effectively require patentees to make optimal investments to create and maintain patent rights. These investments reveal information about the expected value of the asset. The information is censored, however, because (conditional on choosing to invest) patentees make the same investment regardless of the expected value. Structural econometric models identify the underlying value distribution.

Most countries require that a patentee pay an increasing fee to keep a patent right in force. Beginning with Pakes and Schankerman (1984), so-called patent renewal models exploit the optimal stopping problem implicit in the annual investment decision. The *ex post* value distribution is identified from the shares of an annual cohort that are renewed each subsequent year when patentees confront known renewal fee schedules, observed over multiple cohorts. In relatively simple *deterministic* models (Schankerman and Pakes 1986; Sullivan 1994; Schankerman 1998), returns are assumed to depreciate at a known rate following an initial draw from the value distribution. In more complex *options* models (Pakes 1986; Lanjouw 1998), returns evolve stochastically. In both models, the average patent value is relatively low (for example, less than $20,000 in Europe during the post-war period). Lorenz plots reveal that the top 10% of patents account for about 47% of the total value distribution.

The value distribution may also be identified from cross-sectional information (Putnam 1996). Under international rules, patent applicants typically determine simultaneously whether to file in each jurisdiction outside their home jurisdiction. Applicants file if the capitalized value of net returns exceeds the application cost. Application models capture filing anywhere in the world, conditional on a common information set, which mitigates both intertemporal (stylized fact #4) and sample selection (stylized fact #6) problems. The *ex ante* value distribution is identified from the combination of filing countries, assuming that national returns are the product of a common invention-level 'random effect' and an idiosyncratic national market draw. Putnam (1996) values the mean German patent at about $69,000 in 1974, with the top 10% of patents accounting for about 70% of the value distribution.

Small-Sample Methods

Small-sample patent valuation typically occurs in a legal or quasi-legal context, such as licensing or litigation. In infringement litigation, the law typically allows one of three measures of damages: the patentee's lost profits; the infringer's incremental profits; or a 'reasonable royalty' (conceived as the outcome of a hypothetical licensing negotiation (Weil et al. 2001)). Typically, parties employ discounted cash flow methods and 'comparable' licence transactions to support valuation claims. Both *ex ante* and *ex post* methods are used, not always consistently. The law also allows limited consideration of an infringer's *ex ante* alternatives to infringement, such as inventing a substitute. Generally, the most difficult legal and empirical question is: What fraction of (actual or expected) profits should be imputed to the patent? While much damages jurisprudence remains economically ad hoc, courts are increasingly inclined to require the same market analyses that characterize antitrust law (*Crystal Semiconductor v. TriTech Microelectronics*, 246 F. 3d 1336, (Fed. Cir. 2001)).

Patents

Bronwyn H. Hall

Abstract

A patent is the legal right of an inventor to exclude others from making or using a particular invention. This right is sometimes termed an 'intellectual property right' and is viewed as an encouragement for innovation. This article gives a brief history of patenting, and discusses the legal and administrative process for obtaining a patent in the major world jurisdictions. Evidence on patent effectiveness in encouraging innovation is surveyed, and the article concludes with a discussion of the use of patent data in economic analysis.

A patent is the legal right of an inventor to exclude others from making or using a particular invention. This right is customarily limited in time, to 20 years from the date of the application submission in most countries. The principle behind the modern patent is that an inventor is allowed a limited amount of time to exclude others from supplying or using an invention in order to encourage inventive activity by preventing immediate imitation. In return, the inventor is required to make the description and implementation of the invention public rather than keeping it secret, allowing others to build more easily on the knowledge contained in his invention.

The economics of patents has two distinct components, one normative and one positive. The first is directed towards questions of optimal patent policy, the existence and strength of patents, and the design of the patent system. The second uses patent data as an indicator of inventive activity, relying on the fact that patent offices attempt to apply fairly uniform standards of novelty and inventive step when granting patents, so that counts based on them should reflect the innovative activity in a society or in a particular industrial or technology sector. The advantage of patent data is that they are available in great detail over a wide range of time periods, geographic areas, and technological sectors (Griliches 1990). Nevertheless, all patents are not equal, and it is important to understand the operation of patent systems throughout their history in order to make effective use of these data.

This article begins with a brief history of patents, followed by a discussion of the legal and administrative processes for obtaining a patent in the three major patent offices, the United States, European, and Japanese. Then the evidence on patent effectiveness in encouraging innovation is surveyed. The final section discusses the use of patent data in economic analysis.

Brief History

Patents have a long history, although some of the earliest patents are simply the grant of a legal monopoly in a particular good rather than protection of an invention from imitation. Early examples of technology-related patents are Brunelleschi's patent on a boat designed to carry marble up the Arno, issued in Florence in 1421, the Venetian patent law of 1474, and various patent monopolies granted by the English crown between the 15th and 17th centuries. The modern patent, which requires a working model or written description of an invention, dates from the 18th century, first in Britain (1718) and then in the United States (1790), followed closely by France (in both the latter two cases one of the consequences of a revolution). Many other Continental European countries introduced patents during the 19th century, as did Japan. During the 20th century, the use of patent systems became almost universal.

The French patent law of 1791 emphasizes the property right aspect of the patent rather than its use in promoting the useful arts: 'All new discoveries are the property of the author; to assure the inventor the property and temporary enjoyment of his discovery, there shall be delivered to him a patent for five, ten or fifteen years' (Ladas and Parry 2003). In contrast, the Japanese law of 1959 states that its goal is to encourage 'inventions by promoting their protection and utilization and thereby to contribute to the development of industry' (JPO 2006). Patents are enshrined in the US constitution with the sentence 'Congress shall have power . . . to promote the progress of science and useful arts by securing for limited times to authors and inventors the exclusive right to their respective writings and discoveries' (Article 1, Section 8, clause 8), which implicitly recognizes both goals of a patent system, namely, reward to the inventor and the promotion of inventive progress.

In 1883 the Paris Convention for the Protection of Industrial Property ensured national treatment of patent applicants from any country that was a party to it. Its most important provision gave applicants who were nationals or residents of one member state the right to file an application in their own country and then, as long as an application was filed in another country that was a member of the treaty within a specified time (now 12 months) to have the date of filing in the home country count as the effective filing date in that other country (the 'priority date'). This is an important feature of the patent system, and enables worldwide priority to be obtained for an invention originating in any one country, in addition to ensuring that in principle all inventors are treated equally by the system, regardless of the country from which they come.

Legal and Administrative

Although the process for granting a patent varies slightly according to the jurisdiction for which protection is desired, the adoption of the agreement on Trade-Related Aspects of Intellectual Property Rights (TRIPS) in 1995 ensures that it is approximately the same everywhere in the world. This agreement requires its member countries to make patent protection available for any product or process invention in any field of technology with only a few specified exceptions. It also requires them to make the term of protection available for not less than a period of 20 years from the date of filing the patent application.

The World Intellectual Property Organization (WIPO) has almost 200 member states and lists an equivalent number of national patent offices and industrial property offices on its website. In general, the patent right extends only within the border of the jurisdiction that has granted it (usually but not always a country). An important exception is the European system, where it is possible to file a patent application at the European Patent Office (EPO) that will become a set of national patent rights in several European countries at the time of issue (EPO 2006). A similar situation exists with respect to the African Regional Intellectual Property Organization (ARIPO). The exact number and choice of countries is under control of the applicant. Patents granted by the EPO have the same legal status as patents granted by the various national offices that are party to the European Patent Convention (EPC).

The Patent Cooperation Treaty (PCT) came into existence in 1978, and now has 133 countries as contracting signatories. Any resident or national of a contracting state of the PCT may file an international application under the PCT that specifies the office which should conduct the search. The PCT application serves as an application filed in each designated contracting state. However, in order to obtain patent protection in a particular state, a patent needs to be granted by that state to the claimed invention contained in the international application. The advantage of a PCT application is that fewer searches need to be conducted and the process is therefore less expensive. In fact, 87 per cent of the PCT applications go to one of three patent office for search: those in the United States, Europe, and Japan. Most of the other systems rely on them for the search process and follow them in a number of other areas. Therefore the brief account that follows focuses on these three major systems.

EPO patent grants are issued for inventions that are novel, mark an inventive step, are commercially applicable, and are not excluded from patentability for other reasons (Article 52, EPC). The statutory requirements for patentability in the United States are similar: ‘any new and useful process, machine, manufacture, or composition of matter, or any new and useful improvement thereof’ may be patented (35 US Code 101-103 and 112). By itself, this definition does not create a subject matter restriction, although it has long been held that laws of nature, physical phenomena, and abstract ideas are not patentable subject matter.

The origins of the Japanese patent system date back to the Meiji Era (1868–1912). Early patent laws in 1885 and 1899 were modeled on French, US, and then German patent law. In 1899, Japan acceded to the Paris Convention for the protection of industrial property. The patent law was completely revised in 1909, 1921, and 1959. Today, in Japan, patent rights are still protected by the Patent Act of 1959, frequently amended since then (JPO 2006; Kotabe 1992). Two important recent changes were the introduction of a product patent in 1976 and the switch to allowing multiple claims in a patent in 1987, both of which have the effect of bringing the system closer to those in Europe and the United States (Nagaoka 2006).

US patent applications must be filed within one year of the invention’s public use or publication – this year is called the ‘grace period’, intended to allow researchers some ability to publish their results as soon as possible. In Europe and other jurisdictions, there is no grace period. Alone among the world’s patent offices, the US Patent and Trademark Office operates a ‘first-to-invent’ rather than a ‘first inventor-to-file’ system. In either case, the applicant must be the inventor (except in certain special cases such as death or mental incapacity), but in the US system priority is assigned to the inventor who can show that he reduced the invention to practice first. Also unique to the United States is the fact that patent applications are not made public automatically. Ordinarily patent applications are published 18 months after their priority date, but in the United States an applicant may request exemption from this rule if he files an application on the equivalent invention only at the United States Patent and Trademark Office (USPTO) and in no other jurisdiction.

Many patent offices have a provision for challenging patents following their issue. In the United States, any third party may request re-examination of a patent during its lifetime, although for various reasons related to potential subsequent litigation this opportunity is rarely taken up. In Europe and Japan, robust patent opposition systems with limited time frames operate, and these systems are often used by rival firms as an alternative to more expensive litigation (Hall et al. 2003). In Europe this avenue of challenge is particularly attractive because it is the last opportunity to attack a patent at the European-wide level rather than in individual national courts.

Patents are valuable only if they can be enforced and this fact has a number of implications for their use. First, the ability of the courts to reach the ‘correct’ verdict with respect to infringement and validity will matter; in situations or jurisdictions where there is a great deal of uncertainty about the outcome, and even if both parties agree as to the merits of the case, it may be worth pursuing the issue further or in some cases, reaching a private financial settlement to avoid a random outcome in the courts. Second, the costs of litigation will matter: parties with deep pockets can threaten those with less access to resources, or where the opportunity cost of paying attention to a patent suit is high. On the other hand smaller parties with less to lose can also hold up firms with large sunk investments that they might lose. Finally, the threat of litigation may discourage firms from even entering certain areas, thus providing a disincentive rather than an incentive for R&D. Lerner (1995) documented this phenomenon for biotechnology. The degree to which these kinds of threats matter depends to a great extent on the costs and extent of litigation, both of which tend to be higher in the United States than in many other countries.

Research on patent litigation is difficult because of the data collection problem (it frequently requires accessing the records of courts in several different jurisdictions) but in recent years there have been series of studies of US patent litigation (Moore 2000; Lanjouw and Schankerman 2001; Bessen and Meurer 2005) and at least one of the German system (Cremers 2004). All of these studies document the fact that litigated patents tend to be the more valuable. The US studies also show that only about five per cent of such suits go to trial, with the remainder being settled before going to trial. They also show that whether patent litigation has increased depends on whether it is measured in aggregate or per patent. That is, the increase in patent litigation has roughly paralleled the increase in patenting, at least in the United States.

Economics of Patents

The economic view of patents is that they offer a bargain between society and the inventor: in return for a limited period of exclusivity, the inventor agrees to make his invention public rather than keeping it secret. Therefore, one of the central questions that arises when patents are used as a policy tool to encourage innovation is whether this tool is effective. The theoretical literature in this area produces somewhat ambiguous results. In the simplest case, where a patent corresponds to a single product and knowledge is not cumulative, clearly patents do encourage innovation. In fact, the early theoretical industrial organization literature on patent races seemed to suggest that patents produced too much innovation (Wright 1983; Reinganum 1989). However, models that incorporate the cumulative nature of innovation or the fact that production of something new frequently relies on patents held by a large number of entities produce more ambiguous results (Judd 1985; Bessen and Maskin 2006).

This question has also proved exceedingly difficult to answer empirically, largely because of the absence of real experiments. Some researchers have looked at historical eras when there were changes to the system and examined the consequences for subsequent innovative activity, measured either by patenting in a jurisdiction not affected by the changes to the system or by invention counts obtained independently (Lerner 2002; Moser 2005). A second widely used approach is to survey firms and ask about their patent use (Levin et al. 1987; Cohen et al. 2002; Arundel 2003). Using these kinds of survey data matched to R&D spending and innovation outcomes, more structural approaches have been pursued by Baldwin et al. 2000; Arora et al. 2003; and Bloom et al. 2005, among others.

A few conclusions emerge from this body of work. First, introducing or strengthening a patent system (lengthening the patent term, broadening subject matter coverage or available scope, improving enforcement) unambiguously results in an increase in patenting and also in use of patents as a tool of firm strategy (Lerner 2002; Hall and Ziedonis 2001). It is much less clear that these changes result in an increase in innovative activity, although they may redirect such activity toward things that are patentable and are not subject to being kept secret within the firm (Moser 2005). Sakakibara and Branstetter (2001) studied the effects of expanding patent scope in Japan in 1988 and found that this change to the patent system had a very small effect on R&D activity in Japanese firms.

The survey evidence from a number of countries shows rather conclusively that patents are not among the important means to appropriate returns to innovation, except perhaps in pharmaceuticals (Levin et al. 1987; Cohen et al. 2002; Arundel 2003). More important means of appropriation are usually superior sales and service, lead time, and secrecy. Patents are usually rated as important only for blocking and defensive purposes. Thus, if there is an increase in innovation due to patents, it is likely to be centred in the pharmaceutical and biotechnology areas, and possibly specialty chemicals. Arora et al. (2003) found that increasing the patent premium, which they describe as the difference in payoffs to patented and unpatented inventions, does not increase R&D much except in pharmaceuticals and biotechnology. Using aggregate data across 60 countries for the 1960–90 period, Ginarte and Park (1997) found that the strength of the patent system is positively associated with R&D investment in countries with high median incomes (that is, G-7 and others), but not in lower-income countries.

Recently it has been suggested that the existence and strength of the patent system affects the organization of industry by allowing trade in knowledge, which facilitates the vertical disintegration of knowledge-based industries and the entry of new firms that possess only intangible assets. The argument is that, by creating a strong property right for the intangible asset, the patent system enables activities that formerly had to be kept within the firm because of secrecy and contracting problems to move out into separate entities. Although limited, research in this area supports this conclusion in the chemical and semiconductor industries (Arora et al. 2001; Hall and Ziedonis 2001).

Economic analysis has also been used to address the optimal design of the patent system. The seminal work in this area was Nordhaus (1969), which considered two policy instruments: the length of the patent term and the breadth of the patent, that is, the range or scope of the inventions covered. The broader the scope of a patent, the larger the number of competing products and processes that will infringe the patent, and the larger the market power of the patentholder. Later work by Gilbert and Shapiro (1990) and Klemperer (1990) built on and extend his method of analysis. Unfortunately, even though all three sets of authors simplified the problem by assuming that a patent corresponds to a product and that there is no uncertainty, the welfare conclusions still turn on assumptions about the nature of the product market and the existence of close substitutes for the patented product. The main conclusion from this line of work is that optimal patent design is likely to depend on the nature of the product market and the technology, which is inconsistent with long-standing practice and policy in most patent systems. Historically, the only important exception to the homogeneous treatment of technologies is the extreme one of excluding some of them (such as pharmaceutical products, medical practices, or disembodied software) completely from the system.

Recent theoretical and empirical work on the patent system has focused on a set of questions that have increased in importance because of the complexity of modern technology and the growth in patent use in sectors that traditionally had paid relatively little attention to them. Briefly described, the new setting is one where a single product involves hundreds of patents, and where one innovation builds directly on many others. Neither feature is really new, but both have assumed increasing importance in a number of technology areas such as information technology and biotechnology. At a theoretical level, Scotchmer (1991, 2005) was the first to identify the problem that cumulative innovation creates for the patent system, in the sense that it is difficult if not impossible to set incentives at the correct level for both the first and subsequent innovators.

When development of an innovative product requires multiple patent inputs, Heller and Eisenberg (1998) have argued forcefully that the licensing solution may fail because of transactions costs if a large number of patentholders are involved. One consequence of this fragmentation threat may be increased defensive patenting by the product developer. Empirical evidence for this proposition has been provided by Ziedonis (2004) in the context of the semiconductor industry.

Using Patent Data

Researchers into the economics of innovation and technical change frequently find themselves in need of measures of innovative output or success, preferably classified by sector or technology. Many would also like measures of knowledge flow between individuals and firms, given the potential importance of spillovers in the production of knowledge. In recent years, the growth in importance of the knowledge economy worldwide has lead to an increased interest in such measures. As was noted long ago by such pioneers in the field as Schmookler (1966), patent data can be very helpful in constructing them. The primary advantage of patent data is that they are available over a wide range of countries and years, for detailed technology classes, and they contain information on inventor, geographic area, and owner (if there is one other than the inventor). Together, these data provide information on the locus and type of newly created knowledge. The second advantage is that they provide information on links between different quanta of knowledge via the citations to other patents and non-patent documents that they contain (see Jaffe et al. 2000, for further justification of the use of patent citations to model knowledge flow and for the limitations of the measure). With the possible exception of data on scientific paper publication, no other data source comes even close to providing this level and quantity of information about the creation and dissemination of new knowledge.

The use of patent data as a proxy for innovation output in the economic analysis of technological change dates back to the path-breaking analyses of Schmookler (1966) and Scherer (1965). An overview is given in OECD (1994). The availability of information from the US patent office in machine-readable form in the late 1970s enabled research using these data with much larger samples of firms; the resulting early work is reported in Griliches (1984) and then surveyed by Griliches et al. (1987) and Griliches (1990). At the same time, Schankerman and Pakes (1986) pioneered the use of renewal data from the patent offices of several European countries to estimate the value distribution of patents; at the time, such data were not available for the United States owing to the absence of renewal fees in that country.

The results of this early work were, first, to demonstrate a strong correlation between the size of a firm's R&D effort and its patenting output, with little evidence that smaller programmes and firms yielded more output per unit of input, once selection was controlled for. Second, the renewal data, along with pieces of evidence from some specific sectors such as pharmaceuticals (Grabowski and Vernon 1994) and medical devices (Trajtenberg 1990), suggested that the value distribution of patents was very skewed, with a few patents worth a lot and most patents worth nothing. Third, there was little evidence that patent outcomes added much predictive power to sales, profits, or market value equations in the presence of R&D expenditure (Griliches et al. 1991).

With the advent of the personal computer and the increased access to computing power on the part of economic researchers, it became feasible to construct data-sets containing patent citations in the late 1980s, leading to a second wave of research. Similarly to a research paper, the patent document contains a set of references to earlier patents and scientific literature on which it builds; a typical patent referenced approximate five earlier patents in the 1980s, and an increasing number as time passes. These citations can be used to give an indication of the impact of a patented invention on the inventions in subsequent patents and to investigate an additional set of questions related to the flow of knowledge across time, space and organizational boundaries. However, it is important to note that differences exist in citation practice between the US and other patent systems (see Webb et al. 2005; and Harhoff et al. 2006, for further discussion of this issue), and most of the validation of this methodology has been done using US data.

Researchers have used these data to explore questions involving spatial spillovers (for example, Jaffe et al. 1993), knowledge flows among firms in a research consortium (for example, Ziedonis et al. 1998), and spillovers from public research (for example, Jaffe and Trajtenberg 1996; Jaffe and Lerner 2001). In using citations as evidence of spillovers, or at least knowledge flows, from cited inventors to citing inventors, it is clearly a problem that many of the citations are added by the inventor's patent attorney or the patent examiner, and may represent inventions that were wholly unknown to the citing inventor. On the other hand, in using citations received by a patent as an indication of that patent's importance, impact or even economic value, the citations that are identified by parties other than the citing inventor may well convey valuable information about the size of the technological 'footprint' of the cited patent.

Beginning with Trajtenberg's (1990) study of the welfare impact of CAT scanners, there are by now a number of studies that 'validate' the use of citations data to measure economic impact, by showing that citations are correlated with non-patent-based measures of value. Hall et al. (2005) investigated the use of citations as an indicator of private invention value in a large sample of publicly traded US manufacturing firms and confirmed that, although patent yield conveys little information beyond that conveyed by R&D spending, citation-weighted patents are strongly related to market value in a nonlinear way, with very highly cited patents worth a great deal more than those with less than average citation.

Recent work by Lanjouw and Schankerman (2004) also uses citations, together with other attributes of the patent (number of claims and number of different countries in which an invention is patented) as a proxy for patent quality. They find that a patent 'quality' measure based on these multiple indicators has significant power in predicting which patents will be renewed and which will be litigated. They infer from this that these quality measures are significantly associated with the private value of patents. Similarly, Harhoff et al. (1999) surveyed 962 holders of German patents that had a priority date of 1977, asking them to estimate at what price they would have been willing to sell the patent right in 1980, about three years after the date at which the German patent was filed. They find both that more valuable patents are more likely to be renewed to full term and that the estimated value is correlated with subsequent citations to that patent. As in Hall et al. (2005, p. 23), the most highly cited patents are very valuable, 'with a single U.S. citation implying on average more than $1 million of economic value'.

Path Analysis

İnsan Tunali

Path analysis is a method for estimating and testing the internal consistency of models with a postulated causal structure. The postulated structure is displayed in the form of path diagrams, where one-way arrows link causal variables to their outcomes, and curved two-headed arrows connect related variables whose causal links are not under study. Estimation proceeds along the lines of method of moments and instrumental variables theory: the causal ordering of variables along distinct paths are exploited to express the unknown structural parameters in terms of the population moments of the observed and the unobserved variables. Estimating equations are obtained by replacing the population moments of the observed variables by their sample counterparts, which are then solved for the unknown parameters and the estimates of the moments of the unobservables (which themselves can be thought of as structural parameters).

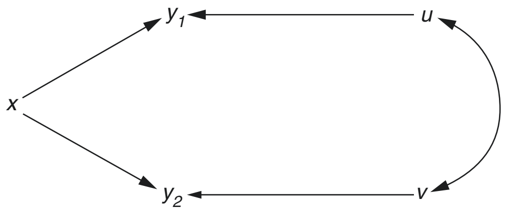
Consider the following simple example discussed in Wright (1960) and Duncan (1975). The structural model consists of

$$y_1 = \beta_1 x + u$$

Model (1)

$$y_2 = \beta_2 x + \upsilon$$

where y's denote the observed (endogenous) variables, x the observed (exogenous) variable, u and υ the unobserved (exogenous) variables or disturbances, and β's the unknown parameters. To keep the algebra simple, all exogenous variables are assumed to have zero means here and below. The disturbances are assumed to have non-zero variances and covariance, and are uncorrelated with x. The path diagram depicting the postulated causal structure is given in Fig. 1. The



Path Analysis, Fig. 1 The path diagram for Model (1)

relationships between the population moments and the structural parameters are easily derived to be

$$\sigma_{11}=\beta_1^2\sigma_{xx}+\sigma_{uu},\sigma_{12}=\beta_1\beta_2\sigma_{xx}+\sigma_{u\upsilon},\sigma_{1x}=\beta_1\sigma_{xx}$$
$$\sigma 22=\beta_2^2\sigma_{xx}+\sigma_{\upsilon\upsilon},\sigma_{2x}=\beta_2\sigma_{xx} \qquad (1')$$

where the variance–covariance structures of the observables y_1, y_2, x and the unobservables u, υ are respectively given by

$$\begin{bmatrix} \sigma_{11} & \sigma_{12} & \sigma_{1x} \\ & \sigma_{22} & \sigma_{2x} \\ & & \sigma_{xx} \end{bmatrix}, \quad \begin{bmatrix} \sigma_{uu} & \sigma_{u\upsilon} \\ & \sigma_{\upsilon\upsilon} \end{bmatrix}.$$

Inspection reveals that the five equations in (1′) will uniquely determine the five unknowns, β_1, β_2, σ_{uu}, $\sigma_{\upsilon\upsilon}$, $\sigma_{u\upsilon}$, using estimates obtained from a random sample on the observables to replace σ_{11}, σ_{22}, σ_{12}, σ_{xx}, σ_{1x} and σ_{2x}.

To see how path analysis can be utilized to test the internal consistency of a postulated structure, consider the same set of equations as in model (1), but omit the curved arrow from Fig. 1. This is equivalent to setting $\sigma_{u\upsilon} = 0$ in the equation system (1′). The five equations now over-determine the four unknowns, β_1, β_2, σ_{uu} and $\sigma_{\upsilon\upsilon}$. Simple algebraic manipulation of the covariance terms reveals that the solution to the system will be unique if and only if $\sigma_{12} = \sigma_{1x}\,\sigma_{2x}/\sigma_{xx}$. This condition (referred to as an 'over-identifying restriction' in the econometrics literature) can be tested using the sample counterparts of the population moments involved. Note that no such check on the internal consistency of the original model is available: Model (1) is 'just-identified'.

The preceding example illustrates the basic ideas behind path analysis, cast within the conventional linear regression framework. The method's origins, however, lie elsewhere. Path analysis was invented by the geneticist Sewall Wright, whose work in the 1920s foreshadowed the econometric literature on structural estimation. Wright formulated complex models with unobservables and wrestled with simultaneity and identification long before econometricians began their systematic study of these topics. Wright's main subject of study, heritability, offered him the necessary insights for modelling the links between cause and effect. His objective was to infer correlations between the traits of interest – bone sizes of rabbits, skin colour and birth weight of guinea pigs, etc. – across different generations in a population. Towards this end, Wright devised an algorithm for reading off the estimating equations directly from the path diagram. For a model which does not depict simultaneity, Wright described his algorithm as follows (cf. Wright 1960):

> The correlation between any two variables in a properly constructed diagram of relations is equal to the sum of contributions pertaining to the paths by which one may trace from one to the other in the diagram without going back after going forward along an arrow and without passing through any variable twice in the same path. A coefficient pertaining to the whole path connecting two variables, and thus measuring the contribution of that path to the correlation, is known as a *compound path coefficient*. Its value is the product of the coefficients pertaining to the elementary paths along its course. One, but not more than one of these, may pertain to a two-headed arrow without violating the rule against going back after going forward.

Since the analysis of correlations constituted his primary interest, Wright worked with standardized variables, having zero means and unit variances. His algorithm applied to the model above without standardization of the variances would yield the system in (1′). If standardized variables were utilized instead, the resulting equations would be in terms of simple correlations and beta coefficients, referred to as 'path coefficients' by Wright. It is a matter of simple algebra to convert the above equations to Wright's equations, and vice versa. For example, taking the first expression in (1′) above and dividing by σ_{11}, we get the equivalent representation.

$$1 = \left[(\beta_1)(\sigma_{xx}/\sigma_{11})^{1/2}\right]^2 + \left[(1)(\sigma_{uu}/\sigma_{11})^{1/2}\right]^2$$
$$= p_{1x}^2 + p_{1u}^2,$$

where p's denote the path coefficients. (Note that the structural coefficient of u has been entered as '1' in this expression.) Wright's representation has the advantage of providing a readily interpretable goodness of fit measure: p_{1x}^2 and p_{1u}^2 and p are respectively the proportion of the variation in y_1 that can be explained by x, and that which is left unexplained.

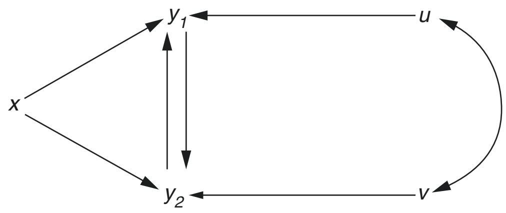
Path analysis is capable of handling a much more general class of problems than the one discussed above. To illustrate the nature of the extensions, we look at some other simple models. These and other examples may be found in Goldberger (1973) and Duncan (1975). We first consider the simultaneous equations model

$$y_1 = \gamma_1 y_2 + \beta_2 x + u$$

Model (2)

$$y_2 = \gamma_2 y_1 + \beta_2 x + \upsilon$$

where u and υ are unobserved, and are assumed to be uncorrelated with x. The associated path diagram is given in Fig. 2. It is straightforward to show that this model is not identified without further assumptions. Clearly, setting $\gamma_1 = \gamma_2 = 0$ gives model (1). Setting $\gamma_1 = \sigma_{u\upsilon} = 0$ (which is equivalent to removing the arrow going from y_2 to y_1 and the double-headed arrow connecting u and υ in Fig. 2) gives a recursive model, which can be shown to be just-identified. Recursive models have been studied extensively in the sociology literature, where Wright's work has had its significant impact (cf. Boudon 1965; Duncan 1966).



Path Analysis, Fig. 2 Path diagram for Model (2)

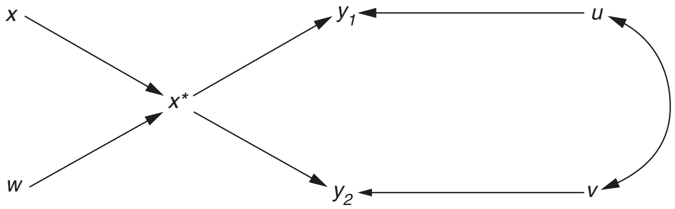
Next, we consider the latent variable model

$$\text{Model}(3) \qquad \begin{aligned} x^* &= \alpha x + w \\ y_1 &= \beta_1 x^* + u \\ y_2 &= \beta_2 x^* + \upsilon \end{aligned}$$

where y's are observed, x^* is unobserved, w is unobserved and uncorrelated with the other disturbances u and υ, and x is observed and uncorrelated with w, u, υ. The path diagram corresponding to this specification is given in Fig. 3.

It can be shown that Model (3) is not identified without further assumptions. Clearly, setting $\alpha = 1$ and $w = 0$ yields Model (1), which is just-identified. The versatility of path analysis can be underscored by nothing other versions of (3) that appear under various names in the literature on linear structural equation models. (We ignore the issue of identification for these models.) Setting $\alpha = 1$ we obtain an errors in variables (or measurement error) model. Dropping the x^* equation from (3), we get a factor analytic model, with x^* as the common factor, and u, υ as the specific factors. If we replace the scalars α and x by conformable vectors α' and x, we obtain a multiple indicator-multiple cause (MIMIC) model. Finally, note that the simultaneous equation model (2) and the latent variable model (3) can be combined to arrive at a more general structural model, widely known by the name of the computer program used for

Path Analysis, Fig. 3 Path diagram for Model (3)



estimating such models, LISREL (cf. Jöreskog and Sörbom 1981).

Path Dependence

Steven N. Durlauf

Abstract

Path dependence refers to the idea that 'history matters', that is, that various types of contingent events may have long-term consequences. This article provides some formalization of the concept and assesses its usefulness in elucidating economic phenomena.

Keywords

Ergodicity and non-ergodicity in economics; Multiple equilibria; Multiple steady states; Network externalities; Path dependence; QWERTY keyboard configuration; Reflection problem

Originating with work of Paul David (1985, 1986) and W. Brian Arthur (1989), there have been a number of efforts by economists to argue that path dependence exists in various socio-economic outcomes. Heuristically, path dependence is understood to mean that 'history matters' in the sense that certain long-term economic outcomes are contingent on particular events that themselves need not have occurred.

The canonical example of path dependence is that of the QWERTY keyboard configuration for typewriters, studied by David (1985, 1986). David argues that the emergence of the QWERTY configuration as the standard for typewriters was an historical accident in the sense it was the consequence of a set of decentralized, uncoordinated choices by different economic actors whose decisions were driven by network externalities. As such, the standard became locked in even though it was not socially optimal, that is, there existed an alternative configuration, the Dvorak keyboard, which was preferable in terms of typing efficiency. From this perspective, the QWERTY keyboard was simply one of several potential long-run standards that could have emerged, its actual emergence being a function of a particular set of contingent events, that is, shocks. Other cases where path dependence has been argued to occur include nuclear reactor technology (Cowan 1990) and railway gauge length (Puffert 2002). Arthur (1989) provides a formal model of path dependence which captures the logic of the QWERTY example; see also Farrell and Saloner (1985) for an early and important example in the industrial organization literature on network externalities which exhibits path dependence-type phenomena.

From the perspective of current economics, most of the path dependence literature is somewhat anomalous. While path dependence is often informally invoked to describe one phenomenon or another, there has been little systematic research on path dependence outside of economic history; in particular, there is a general dearth of formal theoretical and econometric analyses. As a result, discussions of path dependence are often very imprecise. Such imprecision may first be seen in definitions of path dependence. The term means different things in different writings, so that disagreements on its presence to some extent are simply disagreements about its definition.

Most discussions seem to equate path dependence with non-ergodicity. Consider a set of independent shocks ε_t and an outcome of interest x_t; let μ denote a probability measure. The process x_t is non-ergodic if for a fixed k, $\lim_{j\text{ß¥}} \mu\left(x_{t+j} | \varepsilon_0, \ldots, \varepsilon_k\right)$ depends on the realization of ε_0, …, ε_k. Such a definition captures some of the main intuition underlying qualitative discussions of path dependence in that for such processes history matters, that is, particular sets of shocks have long-run consequences. Theoretical models of path dependence such as Arthur (1989) have this property. It is worth noting that, from the perspective of those few formal theories that claim to model path dependence, the phenomenon is typically a form of multiple equilibria or multiple steady states, both of which occur in many contexts. See Blume and Durlauf (2001) for a conceptual discussion on how various deviations from the Arrow–Debreu baseline, when combined with complementarities (those of network externalities are simply one example), can lead to multiple equilibia or multiple metastable states, that is, states from which a system will emerge only after long epochs. What distinguishes theoretical models of path dependence appears to be the explicit attention to the consequences of individuals making decisions sequentially, so that dynamic forms of coordination failure can occur.

However, it is far from clear that such a notion of path dependence as non-ergodicity is sensible for the examples for which path dependence has been claimed to occur. While it is incontrovertible that technological standards are subject to strong network externalities, it is equally true that technological standards evolve over time. One early example of path dependence was the success of the VHS tape standard over Betamax. In light of the rise of the DVD, it is unclear in what sense the success of the VHS tape over a particular time horizon is evidence of anything deeper than network externalities per se. It is possible that a better definition of path dependence relates to whether shocks to a system are self-reversing. Suppose we consider a system where $\varepsilon_l = 0, \quad l > k$. If $\lim_{j\text{ß¥}} \mu\left(x_{t+j} | \varepsilon_0, \ldots, \varepsilon_k, \;\; \varepsilon_l = 0, \;\; l < k\right)$, depends on the realization of ε_0, …, ε_k, then one has a system in which shocks to a system can persist unless overcome by future shocks. This notion of path dependence may be more sensible for contexts such as technological standards as it respects the role of new technologies in undoing current configurations; in fact, it seems the more appropriate definition from the perspective of various examples in economic history. This definition of path dependence also has the advantage that it is meaningfully different from other mathematical concepts, that is, non-ergodicity, that have separately appeared in the economics literature. This suggests that theories of path dependence should focus on how systems can exhibit long passage times out of local basins of attraction rather than multiple equilibria or multiple steady states per se. This in turn would suggest that analyses of path dependence should focus on understanding aggregate nonlinearities rather than the persistence of shocks as has occurred historically. The reason for this is that the second definition does not imply that actual shocks have persistent effects, only that they could have them.

The definitional ambiguities associated with path dependence are mirrored in the substantive discussions that have been developed concerning the economic environments in which it is supposed to occur. Liebowitz and Margolis (1990, 1995) have challenged David's claims about path dependence and the QWERTY keyboard and indeed have questioned the general empirical relevance of the concept. The Liebowitz and Margolis arguments, in the context of QWERTY, largely amount to claiming that there is no good evidence that the Dvorak keyboard is superior and that, further, the historical record indicates that the emergence of the QWERTY standard was driven by competitive forces to a much greater extent than acknowledged by David (rebuttals to their claims include David 2001). This debate has not been resolved and has generally been unproductive. As discussed in Durlauf (2005), the main problem is the lack of careful attention to microeconomic behaviours when analysing the historical evidence. For example, to the extent that evidence of path dependence is equated with the possible stability of a technologically inferior standard, then what matters in evaluating the claim is the level of information that was available to the individual economic actors when they made their standard choices, not what was *ex post* true. This requires much more explicit attention to the decision problems of the individual actors whose choices are collectively said to produce path dependence as well as the way in which an equilibrium configuration of choices occurs at each point in time.

Put differently, the path dependence literature has generally reasoned from aggregate observations towards microeconomic conclusions, whereas a rigorous formulation and empirical evaluation of path dependence as the property of an economic system requires that one start with individual decisions and reason towards aggregate implications. What this means is that resolution of whether network externalities, for example, have produced multiple steady states in a particular market should be understood as claims about the nature of individual decisions and how aggregate equilibria emerge from them. It is well known, as a theoretical matter, that broad claims such as the assertion that markets select for rationality, efficiency and the like (cf. Blume and Easley 1992) depend on details of the economic environment under study. By implication, formal microeconometric analysis will be necessary for empirical adjudication of claims concerning path dependence.

The existing microeconometric literature makes it very clear that there exist deep difficulties in determining whether path dependence is present in a given environment. For example, without strong assumptions on the decision rules of individual agents, one cannot identify whether the equilibrium of a given model is or is not unique. Indeed, even with individual level data, so that the decision rules of the agents can in principle be estimated, identification of whether an environment can produce multiple equilibria is difficult (cf. Brock and Durlauf 2008; Tamer 2003). From the econometric perspective, one basic problem is that any argument that an equilibrium has emerged that is not unique implicitly requires identification of the strength of the interdependences in individual choices, for example network effects. These interdependences cannot be identified unless one is willing to make assumptions about the correlated (across individuals) unobserved components to the costs and payoffs of the choices that are made; some possibilities on how to do this appear in Brock and Durlauf (2008). Further, even when there are no such correlated components, there are cases where the degree of interdependence cannot be identified when there are correlated observables components; this was established in Manski (1993) who calls this the reflection problem. At the current writing, *none* of these issues has been explicitly considered in the study of path dependence.

Thus, the current path dependence literature has had mixed success. From the perspective of the identification of interesting facts and the description of candidate environments for multiple steady states, the path dependence literature has been quite stimulating. From the perspective of developing a new theoretical view of economic outcomes, something that the more grandiose writings on path dependence sometimes allege they do, the literature is still highly imprecise and speculative. Thus the contributions of path dependence research really amount to the delineation of interesting historical episodes, episodes whose interpretation has yet to be resolved.

Path Dependence and Occupations

Maristella Botticini and Zvi Eckstein

Abstract

Path dependence in occupations refers to the observed occupational distribution in a population or in a sub-population at a point in time that depends on changes that occurred years or centuries earlier. Path dependence in occupations can be the outcome of the cumulative concentration of certain productive activities in specific regions over time, it can emerge through the effect of parental income or wealth on offspring's occupations and incomes, or it can be the outcome of group effects. Some historical cases are selected to illustrate the various mechanisms through which path dependence in occupations can emerge or disappear.

Path dependence in occupations can be interpreted to mean that the observed occupational distribution in a population or in a sub-population at a point in time depends on changes that occurred years or centuries earlier (for example, a war that siphons off certain types of workers, the enactment of anti-discriminatory labour practices, a technological invention which is not gender- or race-neutral). This definition is consistent with the notion of path dependence suggested in the economic history literature by David (1985) with the example of the 'standard QWERTY' keyboard. Under this definition one can include both the cases in which particular innovations in the economy have permanent consequences and those instances in which particular shocks are not self-correcting, so that they remain permanent in the absence of some countervailing change.

To show that there is path dependence in occupations, one has to describe the exact sequencing of events related to the initial change and show that they had a permanent effect on the occupational choice and distribution observed later. In other words, one has to show that, at a given point in time, multiple occupational distributions were available for selection, and theory is unable to predict or explain the occupational structure that will be chosen. Then, a change occurs and an occupational distribution is favoured over competing ones. Finally, the selected occupational structure capitalizes on initial advantage and is stably reproduced over time.

The economics literature identifies a number of possible sources of path dependence (see for discussions Arthur 1989; David 1994; Liebowitz and Margolis 1995; Blume and Durlauf 2005). For example, the economic geography literature explains path dependence in occupations as the outcome of the cumulative concentration of certain productive activities in specific regions over time (for example, Krugman 1991b; Fujita et al. 1999). This literature highlights the potentially big impact of increasing returns and cumulative processes, which in turn can make the role of historical accidents decisive. Small changes in the parameters of the economy may have large effects. For example, if transportation costs, economies of scale, and the share of non-agricultural goods in expenditure cross a critical threshold, population may start to concentrate and regions to diverge; once started this process will feed on itself.

However, increasing returns are not necessary for path dependent processes (Bowles and Gintis 2002). For example, in models of intergenerational mobility where individual-level characteristics matter (for example, Becker and Tomes 1979; Loury 1981; Banerjee and Newman 1991, 1993; Galor and Zeira 1993; Eckstein and Zilcha 1994; Mookherjee and Ray 2002, 2003), the existence or absence of path dependence in relative economic status across generations emerges through the effect of parental income or wealth on offspring's occupations and incomes.

In contrast, starting from the seminal work of Shelling (1971), in membership models an individual's economic choices are influenced not only by his or her traits but also by characteristics of the group of individuals with whom the person typically interacts (see Durlauf 2006, for a discussion of these models and related empirical literature). Groups may differ in average level of schooling, cognitive functioning, occupational structure and wealth level. Some groups are exogenously determined, for example by ethnicity or gender. Other groups are endogenously determined. For example, individuals may be strongly influenced by groups such as residential neighbourhood, the schools attended, and the co-workers at various jobs. Group effects on economic success are well documented and may arise for a number of reasons, including discrimination, conformist effects on behaviour, differential access to information, and complementarities in production.

An exhaustive survey of historical and contemporary examples of path dependence in occupations is beyond the scope of this article. Instead, we selected some examples which illustrate the various mechanisms discussed above through which path dependence in occupations can emerge or disappear.

Jewish Economic History in the Past Two Millennia

At the beginning of the first millennium, an exogenous change in the religious and social norm that defined Judaism occurred as a result of the shift in the leadership within the Jewish community. Before the destruction of the Temple in Jerusalem in 70 CE, the Jewish population in Eretz Israel, which consisted mainly of farmers, was segmented in many religious groups. After the destruction of the Temple, many Jewish sects disappeared, whereas the Pharisees became the dominant group. They replaced sacrifices with the study of the Torah in the synagogue. The transformation of the religion created the need for the devoted Jews to be literate and to educate their children. In about 200 CE, the transformation of Judaism reached its full-fledged stage with the compilation of the Mishna. Also, a new social norm came to prevail according to which an illiterate Jewish individual was considered an outcast in the community.

Despite education being very costly and ‘useless’ in production for farmers, religious instruction and primary education became more and more widespread among the Jewish communities in Eretz Israel and Babylonia from the second to the seventh century. The spread of literacy among the Jewish rural population is even more impressive when compared with the literacy rates of the non-Jewish rural population in the same period. In the Roman, Byzantine, Christian and Persian worlds there was no mandatory primary education, and the non-Jewish rural population was almost entirely illiterate.

Before 400 CE almost all Jews in the three main centres of Jewish life in the classical period – Palestine, Babylonia, and Egypt – were farmers, exactly like the rest of the population. The transition away from agriculture into crafts, trade, and moneylending started in the Talmudic period (200–500 CE), especially in Babylon. In the fifth and sixth centuries, some literate Jews abandoning agriculture moved to the towns and became small shopkeepers, craftsmen and artisans. However, given the stagnant economies in the late Roman, early Byzantine and Persian empires in the fourth to the seventh centuries, the growing number of literate Jewish farmers could not find skilled occupations in the existing cities at that time and many of them converted out of Judaism. World Jewry was reduced from about 4.5 million in 70 CE to about 1.5 million in 600 CE, with 80 per cent living in Babylonia.

But in the eighth and ninth centuries, another exogenous event occurred: massive urbanization in the newly established Muslim empire under the Abbasid caliphate vastly increased the demand for urban, skilled occupations. The *literate* Jewish rural population in Iraq and later in the Abbasid empire as a whole moved to urban centres, abandoned agriculture, and became engaged in a wide range of crafts, local and long-distance trade, moneylending, tax-farming and the medical profession. This occupational transition took about 150 years, and by 900 CE almost all Jews in Iraq, Persia, Syria and Egypt, were engaged in urban occupations. In contrast, most non-Jews remained farmers, even though they could engage in any occupation in the regions under Muslim rule. These two facts identify the educational reform in Judaism around 200 CE as the key factor for the occupational transition of the Jewish people (Botticini and Eckstein 2005).

Judaism, with its costly religious norm regarding education, can thrive in the long run only if the Jews can find occupations in which their earnings significantly gain from literacy (Botticini and Eckstein 2006). The voluntary diaspora of the Jews to western Europe during the tenth to the 13th centuries, to eastern Europe in the 16th and 17th centuries, and then worldwide supports this argument. Other minorities within the Muslim empire under the Abbasid caliphate did not migrate to western Europe even though no prohibitions prevented them from doing so. The distinctive engine of the Jewish migrations to the West was the incentive to maximize the returns to their investment in education. Hence, these two facts identify the link between the 'historical accident' and the voluntary diaspora of the Jews in search of urban, high-skill and high-income occupations.

The large Jewish population of Iraq and Iran, which amounted to about 800,000 in 1250, almost disappeared when the Mongol invasions brought the Near East back to a subsistence farming economy. In contrast, the small Jewish population in Europe survived, kept its literacy and educational distinctiveness, and through urban and skilled occupations reached high standards of living.

These urban, skilled occupations remained the distinctive mark of the Jewish people throughout their history, as clearly highlighted by the data provided by Kuznets (1960): in the countries which hosted the largest Jewish communities in the early 20th century (countries in eastern Europe, Russia, the United States and Canada), between 96 and 99 per cent of the Jews were engaged in non-agricultural occupations even though no restrictions prevented them from being farmers. Chiswick (2005) documents the same occupational selection of the Jewish population in the United States as late as the year 2000. For example, about 53 per cent of adult Jewish men are engaged in professions such as law, medicine, and academia, whereas the percentage for white non-Jewish men is about 20 per cent. In contrast, only six per cent of adult Jewish men are employed in the construction, transportation, and production sectors in comparison with about 39 per cent of adult non-Jewish men.

Jewish economic history fits very well the multiple features of path dependence outlined in the introduction. On the one hand, two exogenous changes (the transformation of the religious norm in the first and second centuries CE and the urbanization in the Muslim empire in the eighth and ninth centuries) created a permanent effect on the occupational distribution among the Jews. On the other hand, the mechanisms through which these changes worked to affect the occupational structure of the Jews in the long run were twofold: the intergenerational transmission of skills and literacy from parents to children, and the peer pressure (social penalty) that the Jewish communities imposed on those who did not invest in their children's education.

Commercial and Trade Diasporas

As membership models would predict, ethnic groups can influence the occupational distribution of immigrants in a country and create occupational clustering by ethnicity. One of the most visible examples of this occupational clustering is offered by the so-called commercial and trade diasporas.

A diaspora is any ethnic group without a territorial base within a given polity, and whose social, economic and political networks cross the borders of nation states. In particular, trade and commercial diasporas are those diasporas whose members specialize in trade and commercial activities or, more generally, in urban, skilled jobs. Historical examples include the Jews in the last two millennia, the Parsi (Zoroastrian) diaspora from Iran, the Huguenots in early modern and modern western Europe, the Armenians, the Greeks of the Ottoman Empire, the Germans throughout eastern Europe in modern times, the Chinese in many areas of south-east Asia from the 15th to the 20th century, the Indian middleman minorities of east Africa and Malaya, the Pakistanis in Great Britain, and the Lebanese Christians in 18th-century Egypt and contemporary west Africa (Botticini 2003).

Commercial and trade diasporas – indeed, diasporas in general – have been characterized by strong linguistic skills, often including the ability to speak and write in both their own and alien languages. This enabled members of a diaspora to maintain communication networks within the group and to use alien languages for practical purposes. Maintaining the common original language is one of the means to enhance the organization of a diaspora. Others mechanisms include the establishment of communal institutions, such as the commercial coalitions among the Jews in the Mediterranean in the high Middle Ages (Greif 1989) or the Chinese societies known as *Houei;* the development of a common set of commercial laws or norms whose enforcement is delegated to courts within the communities; and strong endogamous marriage strategies.

In some cases, exogenous changes have created or reinforced occupational selection among ethnic or religious groups. For example, it has been often argued that legal prohibitions and the exclusion of Jews from guild membership in medieval and early modern Europe would account for their occupational selection into moneylending and the medical profession. Similarly, it has been pointed out that, after the revocation of the Edict of Nantes by King Louis XIV in 1685 that made Protestantism illegal, many Huguenots (French Protestants) emigrated to Ireland, England, Prussia, and America, where they contributed to the development of industries and trades. The Agricultural Law of 1870 in Indonesia against land ownership by ethnic Chinese has been cited to explain the exclusion of the Chinese diaspora from farming and agricultural activities.

In other instances, the occupational distribution was altered by rulers who substituted one diaspora for another if they perceived the change to be advantageous for them. Thus, in the Ottoman Empire, Catholic Levantines, who held the leadership in crafts and trade in the 15th century, were replaced by the Jews in the 16th and 17th centuries, followed by the Greeks until the beginning of the 19th century and Armenians during the 19th century.

Geography also played a role in the occupational specialization of some ethnic groups. With the European geographical expansions and the establishment of colonial rule in south-east Asia and west and east Africa during the 19th and 20th centuries, Lebanese Christians, Chinese, and Indians have contributed to the establishment of commercial economies in the European colonial empires.

The Manufacturing Belt in the United States

The establishment and remarkable persistence of the manufacturing belt in the United States is one of the most prominent examples of geographic concentration which in turn affected the occupational distribution of the US population.

Early in the history of the United States, when most of the population was engaged in agriculture, when transportation costs were high, and when manufacturing was characterized by few economies of scale, no concentration could occur. When the United States started to industrialize, manufacturing first developed in regions where most of the agricultural population outside the South was located. The manufacturing belt developed in the second half of the 19th century when economies of scale in manufacturing increased, transportation costs fell, and the share of the population in non-agricultural occupations rose. The initial advantage of the manufacturing belt was locked in, leading the bulk of US manufacturing to be concentrated in a relatively small part of the north-east and the eastern part of the Midwest. It persisted even as the centre of gravity of agricultural and mineral production shifted to the West. As late as 1957, the manufacturing belt still contained 64 per cent of US manufacturing employment (Krugman 1991a).

Intergenerational Occupational Mobility in Britain and the United States Since 1850

Unlike today, the United States in the 19th century was ‘exceptional’ in the occupational mobility experienced by its population (as well as in its geographic mobility) compared with Europe. As documented by Long and Ferrie (2005), this contrast is even more striking when 19th-century United States is compared with 19th-century Britain – the country with which it shared legal traditions and property rights systems and sources of labour, capital, and technology.

Differences have been attributed to a number of factors. First, the absence of feudalism and of strong craft guilds has been put forth as one reason for the higher occupational mobility in the United States. Second, at least some of the high mobility in 19th-century United States may result from it being at an earlier stage of development than 19th-century Britain, so its farm sector was relatively larger.

Third, the United States provided considerably more public education than Britain in the middle of the 19th century: the primary school enrolment rate was one and a half times greater in the United States than in Britain. The US educational system in the second half of the 19th century, though less extensive at the secondary and post-secondary levels than European systems, was considerably more egalitarian (Goldin and Katz 2003). To the extent that intergenerational mobility is greater where fewer parents are wealth-constrained, superior mobility in the United States may well have been a consequence of its educational system, which provided a public alternative to a private education that was outside the reach of many families.

Fourth, residential mobility to places that were growing more rapidly than others may have provided an alternative to direct investment in human capital. Cities (such as Chicago) sprang up initially to provide services demanded as the frontier expanded. Though US labour markets in the North were well-integrated at the regional level by the middle of the 19th century, differences across smaller units of geography may have continued to present opportunities for 'locational arbitrage' that provided a route to occupational change through the start of the 20th century (Long and Ferrie 2005).

The Feminization of Teaching and Clerical Work in the United States

Teaching Profession

Today in the United States the vast majority of elementary and secondary teachers are women. In 2000, the female proportion among teachers was 76 per cent. Much earlier in American history, however, this was not the case. The feminization of teaching occurred over the course of the 19th century and continued throughout the 20th century. Two exogenous factors changed the social norm and attitude towards female teachers in the United States and, therefore, significantly contributed to the feminization of teaching: (*a*) the ethnic, national, and cultural identity of the European settlers who established their communities in the Northern, Midwestern, and Southern states, and (*b*) the wars (especially the American Civil War and the First World War).

Relatively early in the 19th century, women came to dominate teaching in New England through the establishment of two educational institutions: the so-called 'dame schools' and a two-tier system divided into winter and summer sessions. The 'dame schools' were an educational institution imported by British settlers, in which women taught very young children as they were considered the natural carers for these children. The division into winter and summer sessions reinforced this gender-specific assignment of teachers to pupils according to age. As winter sessions were geared towards older boys, male teachers were considered to have greater human capital and skills to enforce discipline among them. Female teachers were considered better equipped to teach summer sessions attended by younger children. As population spread westward in the North, the female percentage in teaching increased in these states (Carter and Margo 2007).

In contrast, because of the different ethnic and national background of the European settlers who established themselves in the US South, neither 'dame schools' nor the two-tier system were developed and the percentage of female teachers remained much lower there until the Civil War. But even within the North itself, the role of culture and institutions in affecting the gender distribution in the teaching profession is illustrated by regional variation. In Illinois counties where the settlers were mainly Yankees, female teachers were quite common, whereas in those counties where the settlers were mainly Southerners, male teachers predominated (Carter and Margo 2007).

As Perlmann and Margo (2001) have shown, the American Civil War significantly contributed to the feminization of teaching. In 13 Northern and Midwestern states, the average share of female teachers rose from about 57 per cent in 1860 to 67 per cent in 1865 and 79 per cent in 1915. During the war women took jobs in teaching, substituting for men who were at war. When the war ended, there was some mean reversion, but not back to the original equilibrium.

The entry of many women into teaching during the Civil War changed the social norm and attitudes toward female teachers by making the bias against them gradually fade. In the earlier decades, the argument against hiring female teachers had been that, especially in winter classes when adult boys attended school, women lacked the skills to discipline these students. However, the entry of women in the teaching profession during the war to substitute for the male teachers gave them the opportunity to show that they could be as effective as their male colleagues in teaching and maintaining the discipline among students. This changed the social norm and attitude toward hiring female teachers, which increased the feminization of teaching in both the Northern states and in the South, where the share of female teachers reached unprecedented levels, rising from about 35 per cent in 1875 to 73 per cent in 1915 (Perlmann and Margo 2001, p. 169).

The First War World had a similar effect on the selection of women into the teaching profession, although on a smaller scale. After the Second World War, women entered many other occupations and professions. Yet the predominance of female teachers in primary and secondary schools holds to the present day.

Clerical Work

In 1870, fewer than three per cent of all clerical employees were women. In 1930, women made up over half (52.5 per cent) of the total clerical workforce, and today the clerical sector is one of the major employers of women. The most rapid increases occurred in two decades, 1880–90 and 1910–20, as the outcome of two exogenous shocks on the demand side of the labour market coupled with a profound transformation on the supply side of the same market.

On the demand side, Rotella (1981) has argued that the adoption and diffusion of the typewriter in the 1880s, the growth of large firms and the expansion of the government sector in the 1910s created a huge demand for clerical work. Specifically, the diffusion of the typewriter made the skills required of clerical labour no longer firm-specific, as it had been when employers preferred to hire male workers who were expected to have a long working life within the firm. With the development of the modern, mechanized office, employers could afford to hire young, educated women who had high expected turnover and who desired clean, high-status employment. Later, in the 1910s, the growth of large firms and the expansion of the government sector through regulation and tax laws greatly increased the demand for information and information processing within firms and government offices. Again, this shift in demand was not gender neutral: it favoured women, and women came to dominate office work, basically after about 1910.

On the supply side, Goldin (1986, 1990) has shown that the huge increase in high school attendance around the turn of the 20th century – the so-called ‘high school movement’ – dramatically increased the supply of young, educated women in the labour market. These women offered a relatively cheaper and easier to monitor labour force.

The Occupational Transition of African-Americans in the 20th Century

After the American Civil War, a steady stream of African-Americans moved out of the South to the North. It has been estimated that from 1870 to 1910 about 535,000 blacks emigrated from the South on the net as the outcome of the large wage differentials between the North and the South and of the increased human capital acquired by the first generations of blacks after the Emancipation (Margo 1990, ch. 7). This migration, though, did not have a huge impact on the overall occupational and residential distribution of African-Americans. In fact, in 1900 approximately 90 per cent of the blacks still lived in the South, and the majority of them worked in agriculture and were very poor.

In contrast, from 1910 to 1950 the Great Migration brought about 3.5 million African-American people out of the South mainly to the urban North. Even when migration occurred to rural areas in the North, it invariably involved a shift out of agriculture. The Great Migration represented a watershed in African-American economic history and implied a profound and permanent transformation of the occupational distribution of the blacks in the United States.

The relevant exogenous shocks that fuelled both the Great Migration and the permanent change in the occupational distribution of the blacks were the two world wars and a combination of government policies.

First, quotas set by the US government on foreign immigration after the First World War greatly accelerated the outmigration of blacks from the South in the 1920s, as blacks were substitutes for the foreign-born immigrants (Collins 1997).

Second, the Second World War was an even bigger exogenous shock. When the United States entered the war, demand for white workers in the war-industry sector increased at the same time as the military was siphoning off potential workers. US employers were faced with a tough choice: either to follow the prevailing taste for discrimination among employers and white workers and the social norm against hiring black workers, or to expand production and to gain profits by hiring black workers.

The enforcement by President Roosevelt of the anti-discriminatory policy amongst defence contractors through the Fair Employment Practice Committee (FEPC) established in 1941 was the exogenous change in government policy that helped employers choose the second option and hire black workers despite the prevailing taste for discrimination (Collins 2001). The impact of this government intervention was twofold. It made defence contractors hire black male workers who otherwise would not have been hired because of the hostility of white male workers towards hiring fellow black workers. At the same time, it started changing the social norm and attitude against hiring black workers in other firms and industries in those instances when the enforcement of the anti-discriminatory policy among the defence contractors sector had spillover effects on other firms' hiring practices.

The combination of the two exogenous shocks – the Second World War and the establishment of the Fair Employment Practice Committee – had a large impact on the occupational and residential transition of African-Americans. Between 1940 and 1950 the proportion of black male workers classified as operatives (semi-skilled) rose from 12.6 to 21.4 per cent, and the proportion in manufacturing industries rose from 16.2 to 23.9 per cent (Collins 2000). This transition into manufacturing and war-related industries greatly contributed to the economic progress of blacks, as the data on the substantial wage premium these workers earned indicate.

A similar effect occurred ten years later as the outcome of another major change in government policy. The *Brown vs Board of Education* Supreme Court's decision in 1954, which invalidated school segregation in the US South, the enactment of Title VII of the 1964 Civil Rights Act, which forbade discrimination in employment, the establishment of the Office of Federal Contract Compliance (OFCC), which monitored the anti-discrimination and affirmative action responsibilities of government contractors, and the passage of the Voting Rights Act of 1965 were the most famous among several government policies designed to eliminate discrimination against blacks. Donohue and Heckman (1991) show that a significant portion of the sustained improvement in the labour market status of black males from 1965 to 1975 (especially in the US South) was the outcome of these changes in government policies.

Poverty Traps

Intertemporal social interactions (that is, social interactions in which choices made at one time affect others made later) can create path dependence in occupations through a variety of mechanisms. Role models and peer group effect models are two examples of these mechanisms. Suppose, as role models do, that the decision to attend college by a young adult depends on the percentage of college graduates among adults in his community. Then two communities, one where the adults are all college graduates and the other where none are, can converge to different levels of college attendance in a steady state, leading to path dependence in occupational and economic segregation across long time periods and generations.

The persistence of ghettoes and poverty traps are the two most visible examples of the intertemporal effect of group membership on individual outcomes (Bowles et al. 2006). Poverty traps are situations where the evolution of individual wealth is governed by a path-dependent process such that, depending on initial conditions, otherwise identical individuals or groups (ethnic, linguistic, religious) may remain for long periods of time ‘locked into’ poverty. The key characteristic of a poverty trap is that the ‘good’ and ‘bad’ outcomes are self-enforcing, so that small interventions or chance events will not alter the long-term outcome. Recent evidence of the persistence of income differences between races, even after some of the structural determinants of inequality (such as colonialism, inequalities of educational opportunity, and de jure segregation) have been removed, point to the importance of historical contingency and ‘lock-in effects’ in the process that generates inequality (Loury 2002; Bowles 2006).

Path Dependence in Technical Standards

Douglas Puffert

Abstract

The value of standardization leads to the persistence of established technical practices despite, in some cases, imperfect adaptation to current exogenous conditions. Economic explanation of these practices therefore requires reference to history. The conditions leading to path dependence in technical standards, as well as path independence, are examined with reference both to economic theory and to case studies of the QWERTY keyboard, videocassette recorder systems, railway track gauge and other railway standards. The controversy over path dependence is discussed.

Path dependence is the dependence of outcomes on the course of previous outcomes, and thus on past conditions, rather than simply on current exogenous conditions. In a path-dependent process of economic change, choices motivated by transitory conditions can have results that persist long after those conditions change. The early conditions that have persisting effects could be systematic in nature, but the literature has focused more on the role of non-systematic 'small' events in selecting one potential path of later outcomes rather than another. A path-dependent process is non-ergodic, that is, its limiting distribution of possible outcomes changes as a function of its specific, evolving history. History matters for later outcomes, and economic explanation is incomplete without accounting for that history.

Early choices can have particularly strong effects in the context of technologies that exhibit ‘increasing returns to adoption’ (Arthur 1989), in that specific practices become more valuable to each user as the total number of users rises. These increasing returns often give rise to standards – rules or practices that enable adopters to pursue some sort of value-producing interaction with other adopters. For example, railway companies that adopt a common track gauge (width between the rails) can exchange cars without reloading, while typists who learn a standard keyboard layout can apply their skills in any office that uses standard machines. Increasing returns to adoption can arise either on the demand side or the supply side of a market. On the demand side, as in the cases of railway gauges and typewriter keyboards, adopters gain from participation in physical or virtual networks of adopters. On the supply side, learning effects – learning by doing or learning by using – reduce the cost or improve the characteristics of a product as cumulative adoption increases.

Quite often, a technology embodying increasing returns to adoption offers a range of specific practices that could form the basis for a standard. Railways have used track gauges ranging from about 600 mm (two feet) to 2140 mm (seven feet), and typewriter or computer keyboards could use 26-factorial (about 1026) different orderings of the letters. These practices may represent different, diverging, potential paths of outcomes. Once early adopters choose a particular practice, later adopters have an incentive to match those choices in order to gain the benefits of compatibility. Thus, increasing returns can give rise to positive feedbacks among agents’ choices. The selection process (or allocation process) that results does not converge to a unique equilibrium outcome. Rather, such a process has multiple potential equilibria or, rather, equilibrium paths. These equilibria could vary substantially both in their general efficiency (total payoffs) and in their distribution of payoffs among different agents. Which equilibrium is selected depends in large part on early choices.

Requirements for Path Dependence

Two things are necessary for path dependence to make a difference for outcomes (David 1999, 2001). First, the conditions or criteria that determine early choices – and thus one branching path rather than another – must not be closely correlated with the conditions or interests that matter later. Second, the selected path of outcomes must constitute a locally stable equilibrium, so that the selection process does not simply revert to an outcome that is determined by later conditions or interests.

Empirically, the most important reasons that early choices might not reflect later conditions are limited information and limited technical capability. These are common occurrences in the early stages of a new technology. Innovators must often engage in exploratory behaviour to learn the possibilities for both technological development and market application (Nelson and Winter 1977), and the effective choice of a standard practice may precede much of this learning. For example, the standard track gauge used in most of the world today was chosen during the 1820s, when railway cars were little more than road wagons and when locomotives were little more than small steam engines set on wagons and linked by crank to a wheel. The gauge was not optimized for what railways were soon to become, let alone for what they are 180 years later. Many engineers since the 1830s have believed that a broader gauge would be more efficient for most purposes (Puffert 2002, 2008). As another example, the ‘QWERTY’ standard typewriter keyboard was developed by rearranging letter sequences so as to minimize the jamming propensities of one short-lived typewriter design in 1873. Modern eight-finger typing methods emerged a decade later (David 1986), and keyboards designed for such methods offer about a 10% improvement over QWERTY in typing efficiency (Norman 1990).

A further reason that early choices might not reflect later conditions and interests is that later adopters may have different interests with regard to the content of a standard than early adopters, but high transaction costs (or simple lack of foresight) may prevent the later adopters from influencing the early choices that determine their later options. In addition, the discounting of future payoffs would lead even perfectly foresighted agents to place little value on distant outcomes.

The second requirement for path dependence to have consequential effects, again, is that a selected path of outcomes be locally stable. Part of the cause of such stability is increasing returns to adoption. Increasing returns lead new adopters to adopt a practice simply because it is the established standard with a large installed base, even if they would prefer some alternative practice if that were to have a comparable installed base. In such an instance the established standard is said to be ‘locked in’, both in the economics literature (Arthur 1989) and in the business world.

Another part of the reason for the stability of a path of outcomes is switching costs – the hardware conversion costs, retraining costs, and transaction costs (that is, information and coordination costs) entailed in converting from an established standard practice to a superior alternative. Users are often restrained from converting not only by irreversible investments in the established practice but also by the technical interrelatedness of system components (David 1986), which makes piecemeal conversion impractical. In a railway, for example, individual equipment and fixtures of one gauge cannot simply be replaced with items of another gauge when they wear out. Rather, new equipment must continue to match the installed base of old equipment, and a conversion requires that all equipment be converted together. Furthermore, the value of compatibility may mean that any conversion must be coordinated among many agents.

These two requirements are by no means always present as technical standards are formed. Foresight into the technological and market opportunities of a new technology is often sufficient to enable early adopters or product sponsors to choose, in effect, a superior path of later outcomes. As an example, Sony and Philips introduced the standard compact disc (CD) format in the early 1980s after digital audio sampling theory, other relevant technologies, and market requirements were already well known. The standard has served quite well. In such instances path dependence, as such, plays no role in the selection process.

Furthermore, if switching costs are sufficiently low, then a less preferred path does not constitute a stable equilibrium. Thus, the potential inefficiency of a path-dependent process is generally limited to the cost (including transaction costs) of carrying out a remedy for this inefficiency. A less preferred path of outcomes may become unstable through innovations or market developments that either reduce the costs or increase the benefits of transition to a preferred practice (Puffert 2004). For example, invention of the low-cost rotary electrical converter in the 1880s helped bring an end to regional lock-in to DC electrical power by facilitating the coupling of AC transmission networks with applications that required DC (David 1991). Similarly, in contemporary information technology, adapters or ‘gateways’ arise frequently to link otherwise incompatible networks (David 1987). Sometimes these techniques offer a migration path from an inferior or obsolete practice to a superior one, making the selection process ‘path independent’.

The Controversy Over Path Dependence

The concept of path dependence first gained widespread attention in economics through Paul David’s (1985, 1986) interpretation of the case of QWERTY and through a series of theoretical discussions by W. Brian Arthur (1989, 1994). David’s thinking grew out of an earlier literature on how technical interrelatedness can inhibit adaptation to changing conditions (Veblen 1915; Frankel 1955; Kindleberger 1964; David 1975). Arthur combined mathematical models of non-ergodic processes in the natural sciences with economic theory concerning how increasing returns can give rise to multiple equilibria.

Arthur developed models in which stochastic fluctuations in the market shares of alternative products or practices are magnified by positive feedbacks until one practice gains the whole market, becoming locked in as a de facto standard. In view of the subsequent controversy over path dependence, it is worth noting that Arthur's (1989) primary model used two key assumptions that obviated the need to consider expectations and forward-looking behaviour. First, he assumed that alternative competing practices are unsponsored, rather than promoted by suppliers. Second, he assumed that increasing returns to adoption are based simply on learning effects embodied in a practice at the time of adoption, so that each adopter's payoffs depend only on the number of previous adoptions, not the number of future adoptions. Arthur discussed only briefly how outcomes of his model would differ under alternative assumptions. He acknowledged that, if increasing returns were based on network effects rather than learning effects, then each adopter's payoffs would continue to rise after adoption as the number of adopters increased. He reasoned that expectations would then lead to earlier lock-in, but he did not carry his analysis further.

Stan Liebowitz and Stephen Margolis (1990, 1995) raised a substantive critique of David's and Arthur's writings, based partly on exploring the implications of assumptions other than those of Arthur's model. The central thrust of their argument was that purposeful, profit-seeking, forward-looking behaviour can override the mechanisms of path dependence whenever, in their view, outcomes truly matter. According to Liebowitz and Margolis (1995), if agents can foresee that some potential future outcomes offer higher payoffs than others, then they have a variety of means to steer the selection process toward the preferred outcomes. Suppliers of products that embody superior practices can profit by promoting those practices to become standards. Adopters can also conduct transactions among themselves, by direct communication or market mechanisms, to assure that they realize the highest available payoffs. According to Liebowitz and Margolis, if means such as these are unable to realize a putatively superior outcome, then that is only because the costs (including transaction costs) of pursuing that outcome are greater than the benefits. In other words, they argued, the putatively superior outcome is not really superior. Agents may come to regret that earlier choices, made in the absence of good foresight, had made some conceivable outcome unattainable. However, Liebowitz and Margolis argued, such regret is naive, a crying over spilt milk.

Liebowitz and Margolis concluded that path dependence is likely to affect only features of the economy that no economic agent has a real reason to care about – and that are not worth much attention from economists or economic historians. They set forth a taxonomy of 'degrees' of path dependence: first degree, in which alternative outcomes have no consequences for efficiency; second degree, in which different outcomes offer differing payoffs but imperfect foresight and transaction costs prevent purposeful behaviour to attain the highest payoffs; and third degree, in which there is sufficient foresight and scope for forward-looking behaviour to attain the superior outcome, but this outcome is somehow still not attained. Liebowitz and Margolis argued that only the third type of path dependence would offer a real challenge to what they called 'the neoclassical model of relentlessly rational behavior leading to efficient, and therefore predictable, outcomes'. They claimed, however, that this type is unlikely to arise empirically.

David (1997, 1999, 2001) responded that Liebowitz and Margolis had mischaracterized several of the issues at stake. Puffert (2000, 2002, 2004, 2008) responded to the critics by incorporating the issues of foresight and forward-looking behaviour explicitly into models and case studies, and he argued that such behaviour is fully compatible with path dependence. He maintained that Liebowitz's and Margolis's taxonomy of 'degrees' is incomplete, leaving out a great range of cases where agents are neither fully passive nor fully able to control outcomes. Such cases demonstrate a rich, complex interplay between forward-looking behaviour and the legacy of past events.

Although David and Arthur had not sufficiently examined the issues of foresight and forward-looking behaviour, they also had not fully neglected these matters. David (1986), indeed, attributed path dependence in typewriter keyboards to the lack of perfect futures markets. Kenneth Arrow stated in his foreword to Arthur's collected articles that much of Arthur's analysis applies specifically where 'expectations are myopic, based on limited information' (Arthur 1994). This is not how Arthur himself explicitly interpreted his models, but it is how he applied them. For example, Arthur (1989), as well as David (1987), argued that path dependence may be particularly relevant for policy when early information is imperfect. Government, they argued, might improve information and later outcomes by exploring the potential payoffs of alternative practices before one practice became locked in. Such a policy later proved its value when the US government sponsored a competition among alternative high-definition television systems, resulting in the accelerated development of a superior digital technology while preventing lock-in to a soon-to-be outmoded analog system.

The relevance of all these considerations must be judged empirically. We begin with the disputed case of QWERTY.

The QWERTY Keyboard

David (1985, 1986) argued that QWERTY gained a lead over rival keyboard systems due to the happenstance that instruction in eight-finger 'touch' typing was developed first for QWERTY during the mid-1880s. The best-trained typists used QWERTY, so office managers hired them and bought QWERTY machines to match. This, in turn, gave budding typists, typing schools, the writers of typing manuals, and typewriter manufacturers a further incentive to focus on QWERTY, to the exclusion of alternative systems. Positive feedbacks reinforced QWERTY's early lead until it gained virtually the whole market. The superior 'Ideal' keyboard layout, introduced in 1893, appeared too late to disrupt a lock-in to QWERTY.

David (1986) concluded, 'competition in the absence of perfect futures markets drove the industry prematurely into standardization on the wrong system'. Critical to both the emergence and persistence of QWERTY was that the 'larger system of production', comprising typists, employers, manufacturers, and typing instructors, 'was nobody's design'; it was characterized by decentralized decision making. Liebowitz and Margolis (1990) responded, in effect, that 'design' rather than positive feedbacks controlled the process that produced the QWERTY standard. Early typewriter manufacturers, they noted, competed vigorously on features of their machines, and they inferred from this that QWERTY succeeded due to a market test of its relative fitness. Positive feedbacks played no role, they argued, because typewriter suppliers had an opportunity to provide training to offices where they sold their machines. Suppliers could thus internalize, and profit from, the advantages of a superior keyboard.

David (1999, 2001) responded in turn that keyboards were never tested by the market in isolation from numerous other features of machines that varied among manufacturers. Furthermore, Liebowitz and Margolis offered no evidence that typewriter manufacturers found it practical to offer training in touch typing before the 1920s, long after QWERTY had become the established standard. Thus their argument has no empirical basis. Still, David's empirical evidence appears less than conclusive in light of the points raised by his critics.

Liebowitz and Margolis devoted most of their article to matters less relevant to David's argument. They refuted a popular account that QWERTY won 'once and for all' due to the publicity it received when a touch-typing QWERTY typist won a single typing contest in 1888. As they showed, non-QWERTY typists soon won other typing contests, so a single contest could not have been decisive. Their refutation did not, however, address David's argument that the contest in question had publicized the value of touch typing, which was being taught at the time only for QWERTY. Liebowitz and Margolis also refuted the mistaken story that QWERTY had been designed to slow typists down, but, again, this story was never part of the claims made by theorists of path dependence.

Liebowitz and Margolis did convincingly refute one claim about QWERTY that David had tacitly accepted – that the Dvorak Simplified Keyboard, invented in 1932, was so superior to QWERTY that the cost of retraining could be recovered in a period of weeks. As Liebowitz and Margolis showed, this claim was based on dubious experiments, and it does not stand the test of reasoned inference from users' behaviour. But David had mentioned the claim, in a single sentence, only to establish the extent to which the legacy of early events had mattered. His argument is little affected if the relative inefficiency of QWERTY is only on the order of 10%, as estimated by a leading researcher in industrial design and ergonomics (Norman 1990). David's claim about history mattering would, however, be affected if QWERTY's relative inefficiency is next to nothing, as Liebowitz and Margolis suggest.

Videocassette Recorders and Similar Cases

Another influential case study in path dependence was the competition between alternative videocassette recording systems from the mid-1970s to the mid-1980s. The VHS system of JVC (Japan Victor Corporation) became the standard, beating out Sony's Betamax. Arthur (1990) explained this as the result of positive feedbacks in the video rental market, as video stores stocked more film titles for the system that accidentally gained a larger user base, while consumers bought the system for which they could rent more videos. Liebowitz and Margolis (1995) pointed out, however, that Sony had actually been first to market. If positive feedbacks had mattered, they argued, then Sony should have won. They attributed the VHS victory to active product promotion and to the advantage of VHS in offering a longer playing time. In their view, purposeful, forward-looking behaviour had overridden positive feedbacks, ensuring the superior outcome. They offered substantial evidence against Arthur's suggestion that the winning system may have been technically inferior.

The extensively documented account of Cusumano et al. (1992) showed, however, that purposeful behaviour did not trump path dependence. There was indeed a positive-feedback dynamic in the video rental market, but this market emerged late, after VHS had already gained a strong lead. The onset of positive feedbacks turned Betamax's small but stable market share into a fast-declining one, forcing it to exit the market.

More intriguingly, Cusumano, Mylonadis and Rosenbloom attributed the earlier lead of VHS to path dependence in supplier choices. Manufacturers and distributors increasingly supported VHS over Betamax as they saw others doing so, increasing their expectations that VHS, not Betamax, would later become the standard. Ultimately, the authors argued, VHS won as the result of non-systematic differences in the promoters' early strategy choices. First, Sony initially pursued a go-it-alone strategy, while JVC built a coalition of suppliers in order to benefit from positive feedbacks. Second, JVC's partner Matsushita installed a large manufacturing capacity to solidify expectations among other suppliers. Third, Sony opted for a smaller cassette size, while JVC chose a larger cassette with longer playing time. In the event, a longer playing time proved more important to consumers in the early years, when only a VHS tape could record an entire American football game or a long movie. Distributors responded to this temporary advantage by joining the VHS coalition permanently.

This account shows that path dependence is fully compatible with forward-looking behaviour, provided that foresight is imperfect when early choices are made about strategy and product characteristics. Indeed, market participants recognized positive feedbacks, and they sought to influence the early events that would have a disproportionate effect on later outcomes.

Such behaviour is common in advanced-technology industries, and innovators whose forward-looking behaviour takes positive feedbacks into account are more likely to win their markets (Morris and Ferguson 1993; Shapiro and Varian 1998). Indeed, according to many observers, either IBM or Apple Computer rather than Microsoft could have become the dominant firm in microcomputers, controlling the key system standard (Rohlfs 2001; Carlton 1997). However, only Bill Gates of Microsoft had, and acted on, the foresight that control of a standard would matter. He became the world's richest individual as a result.

Such processes are path dependent when outcomes depend, in part, on nonsystematic choices and events. If general foresight is good, however, then systematic considerations may dominate. Market participants may agree on a superior outcome from the start, in the manner of a fulfilled-expectations process (Katz and Shapiro 1985). An example, again, is the CD standard.

What is at stake in a path-dependent process is not necessarily general efficiency or total payoffs. It may, rather, be the distribution of payoffs to different innovators and suppliers. Furthermore, in a path-dependent process, particular individuals can have lasting effects on later outcomes, for better and for worse.

Railway Track Gauge

One individual who made a lasting difference was railway pioneer George Stephenson. Stephenson transferred the gauge of four feet eight and a half inches (1435 mm) from the primitive mining tramways where he gained his early experience to the Liverpool and Manchester Railway. That line became the model of best practice for the earliest railways of Britain, North America, and Continental Europe (Puffert 2000, 2002, 2008). The Stephenson gauge became the standard over wider areas as new railways, interested in compatibility, adopted the gauge of prior neighbouring lines.

Engineers soon came to prefer broader gauges, and they introduced such gauges to new regions. A lack of foresight into the later importance of large-scale network integration led to the emergence of two regional standard gauges in Britain, six in North America, six in Continental Europe, and multiple gauges in Australia, India, and other intercommunicating regions. The cost of coping with or resolving this diversity was the main path-dependent inefficiency in track gauge, outweighing the minor inefficiency of the prevalent Stephenson gauge. Still, diversity was resolved most easily where it proved most costly, and the mechanism for resolving diversity was frequently the sort of coordinating behaviour discussed by Liebowitz and Margolis (1995). Much of Britain's and North America's diversity, for example, was resolved by emerging interregional rail systems that internalized the benefits of standardization.

Even so, these improvements in outcomes were a matter of 'path-constrained amelioration' (David 2001) rather than a complete break from the historical legacy. Britain made the Stephenson gauge its general standard at a time when the consensus of engineers favoured a gauge of five feet to five feet six inches (1524 mm–1676 mm), and North America did so when the consensus favoured five feet. Japan has long regretted its choice of a narrow standard gauge, three feet six inches (1067 mm).

Australia and India have only recently resolved much of their diversity, while the variant gauges of the Iberian peninsula and the former Russian and Soviet empires are becoming more costly as those regions are integrated economically into the core of Europe. However, the cost of this diversity is being reduced by innovative mechanisms that enable trains to change their gauge en route. The potential role of government mandates in improving on path-dependent outcomes was proved in Britain, where the 1846 Gauge Act led to some rationalization of gauges.

Other Railway Standards

Path-dependent diversity in regional standards has also proven costly in such matters as railway electrification systems, clearance dimensions ('loading gauges'), and train control and signalling systems. This diversity has hindered the formation of international high-speed train links in Europe (Puffert 1993).

Several railway standards that were well adapted to early conditions proved poorly adapted to later ones, but they continued in use due to the cost of converting the installed base. Examples reportedly include mechanical couplings and air brakes, as electrical systems would now be safer and less labour-intensive (Hilton 1990, p. 294).

A more famous example is what Veblen (1915) called the 'silly little bobtailed carriages' used in British goods traffic. A long literature has addressed how the historical legacy of interrelated freight handling facilities prevented the modernization of coal cars in particular (Kindleberger 1964, pp. 141–4). Recently, Van Vleck (1997) argued that small coal cars were well adapted to the larger system of distribution, chiefly by reducing the costs of small deliveries. Scott (2001) showed, however, that few coal users benefited from small car-size deliveries. Rather, the cars' small size, widely dispersed ownership (by collieries), antiquated braking and lubrication systems, and generally poor physical condition made them quite inefficient indeed. Replacing these cars and associated infrastructure with modern, larger wagons owned and controlled by the railways would have offered savings in railway operating costs of about 56%, yielding a social rate of return of 24% on the physical costs of conversion. Nevertheless they were not replaced until both the railways and the collieries were nationalized after 1945. Until then, regulations forced the railways to accept colliery cars at set rates or else offer high levels of compensation. Due to technical interrelatedness, the railways could not have saved much in operating costs until virtually all the antiquated cars were replaced, so high transaction costs prevented transition to a more efficient practice.

Further Cases

Cowan (1990) argued that transitory circumstances led to the establishment of the prevalent 'light-water' design for civilian nuclear power reactors. This design, adapted from nuclear submarines, was rushed into use due to the political value of demonstrating peaceful uses for nuclear technology. Thereafter, learning effects arising from engineering experience continued to make the light-water design the rational choice for new reactors. Cowan argued, however, that an equivalent degree of development would likely have made an alternative design superior.

Cowan and Gunby (1996) addressed farmers' choices between systems of chemical pest control and integrated pest management (IPM), which uses predatory insects to devour harmful ones. As the drift of chemical pesticides from neighbouring fields often makes the use of IPM impossible, IPM must be used on the whole set of farms that are in proximity to one another. Where this set is large, the transaction costs of persuading all farmers to forgo chemical methods often prevent adoption. In addition to these localized positive feedbacks, local learning effects also make the choice between systems path dependent. Local lock-in to each practice is sometimes upset by such developments as invasions by new pests and the emergence of resistance to pesticides.

Patinkin, Don (1922–1955)

Nissan Liviatan

Abstract

Don Patinkin’s main contributions are in monetary theory, including the topics of involuntary unemployment and the interpretation of the writings of J.M. Keynes. He criticized the classical and neoclassical monetary model for its ‘invalid dichotomy’ between the real and the monetary sectors. His main underlying concern was whether capitalism possessed an automatic mechanism for attaining full employment. He claimed that the real interest rate might be insufficiently flexible and the real

balance effect insufficiently powerful to allow any rapid convergence to equilibrium, rendering it politically unrealistic to rely on automatic forces to establish full-employment equilibrium in reasonable time.

Don Patinkin is regarded as the 'father of the economics profession' in Israel. Upon his arrival in Israel with his wife Dvora in 1949, he joined the Hebrew University and raised a generation of students trained in modern economics (known as the 'Patinkin boys'), who were to form the backbone of the economics departments in the various universities, the staff of Treasury and the Bank of Israel, the commercial banks and the other institutions that had a demand for economists. In spite of his young age, he was an economist with outstanding academic achievements, which marked him as a rising star in the economics profession. His choice to live in Israel was a source of much pride to the new state. He passed away in 1995, but the impact of his teaching and of his personality will linger on for many years.

The Chicago Days

Don Patinkin was born in 1922 in Chicago to an Orthodox Jewish family that lived in a predominantly Jewish neighbourhood. His early education was a combination of secular and rabbinical studies. In 1943 he enrolled in the economics department of the University of Chicago, obtaining his Ph.D. in 1947. This period left a deep impression on Patinkin and had a great impact on his future work. He was influenced not only by the Chicago Tradition of free-market liberalism, but also by the personalities of his prominent teachers Frank H. Knight, Jacob Viner, Henry C. Simons, Oscar Lange and Lloyd W. Mints. (See his account of his teachers in Patinkin, 1981b.)

In addition, he was awarded a fellowship with the Cowles Commission, then situated in Chicago, which hosted a remarkable number of prominent economists. Patinkin looked back to his Chicago days with pleasure and nostalgia, and considered himself lucky to have benefited from the contact with such 'giants'. His Ph.D. dissertation, 'On the consistency of economic models: a theory of involuntary unemployment', under the supervision of Jacob Marshak (the chairman of the Cowles Commission), is on a topic to which he returned many times over the years without being able to find a satisfactory solution (nor has any other economist).

The Years at the Hebrew University

In 1949 he accepted the proposal of the Hebrew University of Jerusalem to serve as a senior lecturer in the economics department. On his very first day Patinkin plunged into this task, directing the transition of the department from the Continental descriptive and institutional framework to the Anglo-Saxon tradition of analytical economics (Barkai, 1993). Professor Alfred Bonne, who chaired the traditional economics department, supported this move. In the first years he taught practically all the courses in microeconomics and macroeconomics, at all levels, and performed this task outstandingly.

It is remarkable that these years of great pressure were also the most fruitful of his career: he completed his monumental book *Money, Interest and Prices* (MIP, 1956) and wrote a number of influential papers in leading journals, usually rebutting criticisms on various topics related to the book (such as the invalid dichotomy, discussed later). In evaluating the numerous reviews of the book, Stanley Fischer (1993) states that practically all the reviewers recognized that they were dealing with a major work.

To build the foundations of the economics profession in Israel, Patinkin sent a group of graduates, whom he considered candidates for an academic career, for Ph.D. studies in the top universities in Britain and the United States. The building of foundations included also the construction of a statistical base of the Israeli economy. To perform this task he was appointed director of the Falk Institute of Economic Research Israel in 1956, where he continued the work of Daniel Creamer and Harold Lubell, the previous directors. It seems that Simon Kuznets, who was involved in formulating the programme of the Falk Institute, had a profound influence on Patinkin's interest in empirical research. In addition to directing numerous research projects at the institute, Patinkin himself wrote on the early years of the Israeli economy (*The Israeli Economy in the First Decade*, 1959a), where the elimination of the monetary overhang associated with repressed inflation fitted well with his model of the real balance effect.

Although he believed in, and represented, the Chicago pro-market creed, he never pushed this approach forcefully. The very first lesson in his celebrated course 'Introductory Economics', modelled on the famous textbook of Samuelson with application to Israel, was about the allocation of scarce resources among competing uses, which could in principle be performed by the market or by a central planning committee.

Patinkin completed his term of office as chairman of the department of economics in 1960, moving on to serve as the Dean of Social Sciences, and from there in 1980 to serve as Rector and finally as President of the Hebrew University. In all these years he maintained his touch with monetary economics, especially from the doctrinal aspect.

Patinkin participated actively in the debates concerning Israel's economic policy problems. In particular, he was critical of the way monetary policy was run. He served on a number of policy committees (for a thorough discussion of this aspect of Patinkin's activity, see Barkai, 1993) and contributed to the daily press of the early 1970s when the inflationary process began. In later years he preferred that the economists that he had raised should handle these matters.

On the occasion of Patinkin's retirement his colleagues organized a conference in his honour. The scientific works of the participants, who included many of the economists that he regarded highly, were published in *Monetary Theory and Thought* (Barkai et al. 1993), which covered topics related to Patinkin's work.

Patinkin's Contribution to Monetary Economics

Patinkin contributed to three main areas in economic theory: his criticism of neoclassical monetary theory, his treatment of involuntary unemployment and his work on the history of economic thought, in particular the writings of Keynes. Patinkin introduced some order into the vague (some may prefer the term 'chaotic') state of the monetary model that existed in his time. MIP stands out as a bridge between pre-Keynesian economics, Keynesian economics and the modern economic literature. Its economic rigour, building the macroeconomic model on micro foundations, was unprecedented in the literature on monetary economics.

Patinkin was very critical of the monetary model formulated by the classical and neoclassical theorists. In particular, he claimed that their theory was 'guilty' of the 'invalid dichotomy' between the determination of relative prices and the absolute price level. More specifically, the dichotomy relates to the separation between the real sector, where relative prices are determined, and the monetary sector, where the absolute price level is determined by some version of the quantity theory of money (the Cambridge equation). He claimed that this dichotomization is invalid because, by Walras's Law, the excess demand for money is just the sum of excess supplies in all other markets and hence must share the same parameters, in particular the money supply. The fact that in the neoclassical formulation the money supply appears only in the money market is self-contradictory. (In the second edition of MIP, 1965, Appendix to ch. 8, Patinkin pointed out that, when the real balance effect is confined to the bond market, it is possible to express the excess demand functions for commodities in terms of relative prices and the interest rate without referring explicitly to the real balance effect.).

To prove that the neoclassical monetary economists adhered in fact to the invalid dichotomy, Patinkin created a ‘database’ of the relevant writings of these economists (summarized in the first and second editions of MIP), and scrutinized carefully the suspect sentences to show that they were unclear and even reckless. There is no doubt that Patinkin was a master of the literature on monetary theory, and he used it effectively to support his arguments.

Since many people wrote without a formal analytical apparatus in those days, they often said contradictary things concerning the dichotomy, and Patinkin identified and stressed the inconsistencies. The mathematically inclined economists used the formulation of excess demand functions in terms of all the n prices ($p_1,\ldots,p_n$), which can be multiplied by a Lagrange multiplier λ, which could be any positive number. However, in order to reflect the fundamental property of zero degree homogeneity of real excess demand functions with respect to money prices and the nominal money supply, λ has to be set equal to 1/M, where M is the nominal money supply; then it would represent the real balance effect. But Patinkin insisted (and documented) that as a rule they thought of λ as $1/p_n$, that is, they thought of excess demand for commodities as dependent only on relative prices, without taking account of the real balance effect.

The preoccupation with the question of ‘what people really thought’ left a gray area of possible interpretations, which depended on subjective evaluations. Paul Samuelson (1968), who thought that in principle Patinkin’s criticism was well taken, nevertheless believed that Patinkin’s reading of the earlier theorists was not sympathetic. However, the examples of the articles of Hickman (1950) and Archibald and Lipsey (1958), who tried to defend the invalid dichotomy, made it clear that Patinkin’s tough criticism was justified from the point of view of improving professional rigour in economic science (see also Fischer, 1993).

Patinkin’s critical evaluation reflects the stringent criteria he applied to the work of his predecessors. He required of monetarist theorists who put money in the utility function to state explicitly the rationale for holding money; he insisted on an explicit reference to the real-balance effect, and he required an understanding of the difference between the individual and market experiments. In addition, he insisted on the incorporation of stability analysis of the money market in the same way as his predecessors analysed the stability of markets for ordinary commodities. He considered the fulfillment of all these criteria necessary for a full integration of money and value theory.

The ‘victims’ of this harsh criticism included such famous names as Walras, Fisher, Pigou and Cassel, in whose writings the presence of the invalid dichotomy was ‘highly probable’, as well as others who were more explicit about it, such as Lange, Modigliani, and Hickman (Patinkin, 1965, p. 175, n. 33).

Patinkin enjoyed the role of critical interpreter of texts, which he attributed to his training at the Yeshiva College in Chicago (1994). This perhaps explains his infatuation with Keynes’s writings in later years, and his preoccupation with the writings in the Chicago tradition. The former involved mainly the evolution of Keynes’s thoughts on effective demand and involuntary unemployment, and the latter focused on the interpretation of the quantity theory of money and the economic philosophy of his famous teachers at the University of Chicago.

The non-technical writings of Keynes (1936) were a fertile ground for interpretations and formulations of formal models attributed to his ideas, and it provided Patinkin with ample room for clarification of Keynes’s arguments. For example, he presented a diagrammatic exposition of the Keynesian theory in Patinkin (1982), especially Figures 5 and 6, clarifying the concepts of effective demand and aggregate supply in the Keynesian model. (In Figure 6 it is shown that effective demand is determined at the intersection of aggregate demand and supply – in terms of wage units – as functions of employment. In this diagram the real wage is endogenous to the level of employment on the assumption that firms are on the demand curve for labour. Thus the real wage is indirectly determined by aggregate demand. In this sense it is not a fixed-price model.) In his analysis of Milton Friedman's statement of the quantity theory of money (Patinkin, 1981) he contrasts it critically with what Patinkin considered the true Chicago tradition.

Involuntary Unemployment

While the task of putting the house of neoclassical monetary theory in order involved an in-depth analysis of the early literature, his other major preoccupation was in an area which required his own creativity – involuntary unemployment. This problem, which reflected the realities of the Great Depression of the 1930s, occupied Patinkin's academic interests from his Ph.D. dissertation and throughout his later work. Yet the problem of why the workers could not avoid unemployment by real wage cuts remains basically unresolved to this very day.

Patinkin first approached this problem in his famous early article in the *American Economic Review* (1948), where he claimed that the real interest rate and the real-balance effect might not be sufficiently flexible to allow an equilibrium solution, and even if they did it may take a long time (due to bankruptcies and pessimistic expectations). This may render it politically unrealistic to rely on automatic forces to establish full-employment equilibrium. Patinkin therefore considered unemployment essentially in the context of economic dynamics.

In Chapter 13 of MIP, Patinkin took an additional step in dealing with this issue, arguing that if firms cannot sell their optimal (competitive) output they will not employ their optimal labour input. This gave rise to a new area of research in macroeconomics, namely, disequilibrium models. Barro and Grossman (1971) combined this analysis with the Clower constraint, which postulates (as explained by Barro and Grossman) that, if workers cannot supply their optimal labour services they will not purchase their optimal (competitive) quantity of goods. Barro and Grossman go on to show how equilibrium can be established in the fixed-price model of this type. Over the years, the criticism of these models increased because they required arbitrary rationing rules (Drazen, 1980), and because they were too complicated technically. The disappearance of widespread involuntary unemployment in the post-Second World War era probably had something to do with the growing unpopularity of these models.

It is noteworthy that Patinkin refrained (in the second edition of MIP) from seeking a solution to the problem of involuntary unemployment in the domain of imperfect competition, in spite of Arrow's (1959) remark that in disequilibrium situations the competitive model is problematic. It seems that this is an indication of Patinkin's conservative approach to economic analysis.

Although most of MIP is devoted to the working of Patinkin's model in full employment, the more interesting implications of monetary policy were in connection with unemployment. The latter case gave rise to the fundamental question of whether the capitalist system possesses an *automatic* mechanism for attaining full employment, which is the basic problem that underlies much of Patinkin's work. Perhaps this explains why he was willing to take the risk of dealing with disequilibrium models, although he realized their limitations (1965, ch. 13, n. 9).

Some of the issues which were presented in MIP gave rise to criticism by prominent economists. But in all these confrontations Patinkin had the upper hand. One can cite as an example Hicks's (1957) criticism of Patinkin's interpretation of Keynesian unemployment theory; Patinkin's reply (1959b) in terms of the Hicksian IS–LM model suggested that Hicks did not fully understand Pigou's (1943) mechanism of the real-balance effect.

Patinkin's early work dealt solely with the static economy, while the profession was concerned in the 1960s with models of economic growth, including monetary growth. This led Patinkin to write a paper, with David Levhari (1968), on monetary growth in the fashion of Tobin's original contribution to these models.

Patinkin's own view of his early work and his critical reflections about the recent developments in economics are interesting. We have a glimpse of these in the introduction to his final, abridged edition of MIP in 1989, 23 years after the publication of the first edition. In this introduction he welcomes the progress that has been made in disequilibrium theory, although he realizes its limitations, since it contradicts some of the tenets of rational expectations. He also welcomes the renewed theoretical work by the neo-Keynesian economists on the rational basis of price and wage rigidities, and discusses the effect of the new developments related to rational expectations. His discussion is certainly very scholarly but short of the original insights that characterized his earlier writings. It seems that rational expectations represent a whole new philosophy that was absent in the writing of the 1950s and 1960s, which one might call the age of innocence.

B31

One of the most original and idiosyncratic American economists of his generation, Patten was born at Sandwich, Illinois on 1 May 1852 and studied at Jennings Seminary, Aurora, Illinois. There he met Joseph French Johnson, later a colleague at the University of Pennsylvania, whom he followed to Halle in 1876 after spending only 18 months as a freshman at Northwestern University. At Halle Patten obtained the Ph.D. degree remarkably quickly, in 1878, and he encountered two major personal influences, his teacher Johannes Conrad and a fellow American student, Edward Janes James, who was eventually instrumental in securing Patten's appointment at the University of Pennsylvania in 1888, where he remained throughout his academic career. In the intervening period, however, like Thorstein

Veblen, Patten had been unable to get a university post despite the publication of his highly original *Premises of Political Economy* (1885), and was obliged to work on a farm and teach in various public schools, partly because of his poor eyesight.

Once at Philadelphia, Patten proved to be a profoundly stimulating pedagogue and author of a series of unusual, even eccentric books that challenged, provoked and sometimes baffled his professional peers. In harmony with the Wharton School tradition, he was an ardent protectionist, believing that trade barriers would stave off the dangers envisaged by Ricardo and Malthus. Adopting an optimistic, teleological view of the prospects for American abundance, provided that crop variations could be developed to counteract soil exhaustion, Patten insisted that economic laws were not natural, but social. His conception of economics was broad, as in the German tradition, yet his own work was abstract and deductive rather than heavily empirical or statistical. Together with James, he tried in 1884 to form a Society for the Study of National Economy, modelled on Conrad's suggestions, but when this failed to gain sufficient support they joined Ely and others in launching the American Economic Association, of which Patten was elected president in (1908–9). Patten's concepts of the laws of pleasure and pain, his theory of consumption, and his idea of the social surplus were intriguing but puzzlingly novel and unsystematic, yet his awareness of the costs of growth and his concern for the environment anticipated late 20th-century anxieties.

Payment Systems

William Roberds

Abstract

Payment systems are arrangements that allow for the discharging of debts by the transfer of specialized claims. This article illustrates how payment systems can facilitate exchange in economic environments where enforcement of obligations is limited, and collateral is scarce.

A *payment* occurs when one party, the *payer*, transfers an asset to another party, the *payee*, for the purpose of discharging a debt incurred by the payer. Or, a payment may consist of the payer's instruction to a third party to make such a transfer, as is the case with a cheque payment. While in principle a payment may be made with any asset, in practice virtually all modern payments involve transfers of debt claims on either central banks (including 'outside money' in the form of both currency and deposits) or private banks ('inside money', today almost always in the form of deposits). Available evidence suggests that most payments are still made in cash, but these transactions tend to be for relatively small amounts. By value, the wide majority of payments involve transfer of bank deposits by various means.

A payment may or may not constitute *settlement*, a legal discharge of a debt. In most countries, for example, a payment by means of a transfer of claims on a central bank unconditionally settles a debt, whereas other types of payment settle a debt only after certain conditions have been fulfilled (for example, after a cheque has been honoured by the bank on which it is drawn).

A payment *system* is a collection of technologies, laws, and contracts that allow payments to occur and determine when a payment effects a settlement. Payment systems include currency, cheques, credit and debit cards, electronic funds transfers, and so on. Developed economies depend critically on the near-flawless operation of such systems. By offering debtors low-cost and trustworthy means of settling their debts, payment systems provide an important stimulus to the use of credit, and to economic activity more generally.

Some simple statistics illustrate these assertions: in the year 2003, 81 billion payments of $824 trillion were recorded in the United States, not counting payments made in currency (Committee on Payment and Settlement Systems 2005). Another way of framing these numbers is to note that they imply, on average, $75 in non-cash payments for each dollar of final output produced in the United States in 2003. During the same year each US resident made 278 non-cash payments on average. All developed economies display similar levels of payments activity.

Theory of Payments

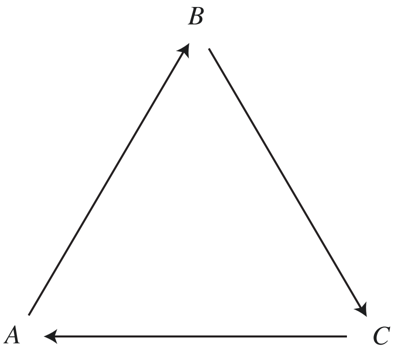
Despite their ubiquity and their obviously central role in modern economies, payments have only recently begun to make their way into mainstream economic theory. Payment systems do not exist in Arrow–Debreu economies, where transfers may always be made in kind, and promises to transfer are enforced by a social planner. In these economies there is no need for specialized assets to allow for payments, technologies for transferring these assets, or rules concerning when such transfers settle a debt.

Even if the planner's ability to enforce promises is limited, payments may still be inessential. Agents will have incentives to honour their obligations so long as they have access to sufficient amounts of collateral that can be attached by creditors after a default. Payment systems become relevant when enforcement is limited and collateral is scarce. In such environments, payment systems serve as devices that allow for enforcement of debts while making efficient use of available collateral.

One commonly available type of collateral is, of course, outside fiat money, but a discussion of the comparative payment roles of inside and outside money is beyond the scope of this essay. Two influential papers in this area have been Freeman (1996, see especially its discussion in Green 1999) and Cavalcanti and Wallace (1999). For the reminder of this article I will concentrate on payments in private debt.

An Illustration

To demonstrate the function of payment systems, I consider some models of payment based on the celebrated 'Wicksell triangle' depicted in Fig. 1. Each of the three agents is endowed with a unit of a generic numeraire good. Agent A has the possibility of converting this good into a 'customized' good that is (highly) desired by agent B, who can convert his numeraire into a good desired by agent C, who can produce a good that is desired by A.



Payment Systems, Fig. 1 Wicksell triangle

Barring difficulties in enforcement, efficiency would require each agent to produce the appropriate customized good and deliver it to the next agent. I call this allocation the *full-enforcement efficient* allocation.

The general goal of payment systems is to deliver an allocation that approximates this allocation, to the extent this is feasible under limited enforcement. I now consider to what extent various payment systems are able to do this. In each of these environments, any enforcement actions will occur through a fourth agent known as the *centre* or 'central counterparty', who has a restricted ability to punish agents who default on their obligations. Punishments may include limited fines, attachment of collateral, and public announcements of a default.

Payment Model 1: 'Netting'

Kahn et al. (2003) analyse the following version of the Wicksell-triangle environment. A, B, and C each consists of a buyer-seller pair who live at a separate 'location', meaning that trade occurs as bilateral encounters between buyer and seller. Agents are not particularly inclined to keep their promises, but may post some numeraire as collateral before trading begins. There is a single period during which sellers can visit buyers and transfers of customized goods can occur, and a subsequent period during which numeraire may be transferred. Prices of goods are given in numeraire and are determined through bilateral negotiations.

In this environment, it is easy to show that the amount of collateral required for trade can be minimized by the use of a payment system based on *net settlement.* However, as net settlement typically requires the diversion of resources in order to acquire and post costly collateral, its use will entail a welfare loss, relative to the full-enforcement efficient allocation.

Under net settlement, after trades have occurred, the central counterparty sums for each agent the amount the agent owes *to* the seller he bought from, minus the amount owed *from* the agent from the buyer sold to. If this sum is positive, the agent transfers numeraire to the central counterparty, and if the amount is negative, he receives numeraire from the central counterparty.

Payment in this environment simply consists of an agent's declaration of his intent to settle, and this occurs simultaneous with trade. *Settlement* is the two-stage process of (*a*) replacing gross obligations with net obligations and (*b*) discharging net obligations through transfer of numeraire.

A characteristic feature of net settlement is 'set-off,' under which a debt owed *by* party *X* is enforced by cancelling it ('setting it off') against its debt owed *to* party *X*. In this fashion, agent *X*'s creditor may exercise a de facto prior claim against *X*, even when other means of exercising priority are costly (such as posting additional collateral). Payment systems incorporating net settlement allow set-off to occur in a regular and predictable fashion.

Netting of obligations is an ancient method of payment, dating at least to the 13th century fairs of Champagne (Kohn 2001). It continues to be used extensively for settling high-value, recurring obligations such as those that arise between commercial banks (for example, the CHIPS system which operates in the United States). But there are certain limitations that prevent its more widespread use. The first is that there may be an inadequate legal basis for netting (Bliss 2003). Second, netting works well only if all parties involved are of roughly equal creditworthiness (Kahn and Roberds 2003). Finally, netting may require too much coordination in the sense that all parties must agree in advance to participate in the netting arrangement. These limitations have given rise to other forms of payment systems which, in effect, allow netting to occur in a more decentralized fashion.

Payment Model 2: 'Banknote'

Kiyotaki and Moore (2000) discuss a slightly different model from model 1 above. Suppose that preferences and endowments are the same as above, but that bilateral encounters between agents are separated in time: agent *C* first has an opportunity to buy his desired good from agent *B*, who then has an opportunity to buy from *A*, who can then buy from agent *C*. Agent *C* is known to be creditworthy but *A* and *B* are not.

In this model, the full-enforcement efficient allocation can be implemented if *C*'s debt can 'circulate'. More specifically, *B* receives debt from *C* in return for a customized good. Agent *B* then trades *C*'s debt to *A*, in return for *A*'s customized good. *A* then presents *C*'s debt to *C* for redemption. Finally, agent *C* completes the cycle of trade by transferring a customized good to *A*. *Payment* in this environment corresponds to either the issue (by *C)* or transfer (by *B*) of *C'*s debt. If *C* is sufficiently creditworthy, *B*'s transfer of *C*'s debt will also constitute a *settlement.* Otherwise settlement may not occur until *C* redeems his debt.

Under this arrangement it is not necessary for all parties to be creditworthy for trade to occur. Agent *C* may enjoy some natural advantage in this regard. This advantage could take the form of ownership of attachable assets or, in a dynamic setting, it could be that people have better information on the actions of *C* than on the actions of other agents (Cavalcanti and Wallace 1999). In this arrangement, *C*'s debt becomes a form of specialized asset for use in payment, a 'banknote'.

This is the basic model for many transactions using not only privately issued banknotes (which are rarely observed nowadays) but also other means of transferring debt claims. A retail store may not be willing to accept a customer's IOU in exchange for merchandise but is perfectly willing to accept a debt (that is, deposit) claim on a bank, transferred by means of a credit or debit card.

This form of payment also has a long history. One of the most famous early examples is from 15th-century Genoa. There, payments were commonly made using claims on an institution responsible for managing the debt of the state (the *Casa di San Giorgio*; see Kohn 1999). Under this arrangement agent *C* became, in effect, an agent of the state, whose creditworthiness derived from the taxation powers delegated to it. People owing taxes could use claims on the *Casa di San Giorgio* to discharge their own tax obligations, which generated a demand for these claims as payment instruments.

Note that model 2, like model 1, involves a form of netting. When a consumer purchases merchandise with, say, a debit card, the consumer is in effect netting out the debt he owes *to* the merchant against debt (deposits) owed him *by* his bank. In contrast to model 1, however, there need be no prior agreement between merchant and consumer, given sufficient trust in the banking system.

Payment Model 3: 'Bank Loan'

Model 2 illustrates how payment systems allow netting to occur in a decentralized fashion. This model is inadequate for some situations, however, because it does not explain the simultaneous existence of both liquid and illiquid debt. In particular, this model is inappropriate for production economies where a producer may require prompt delivery of an intermediate good now in order to produce a final good that can be sold only later. In such situations, working capital is typically provided by the issue of debt.

To remedy this shortcoming, some studies have attempted to modify model 2 in order to incorporate both transferable ('liquid') and non-transferable ('illiquid') debt. Kiyotaki and Moore (2000) consider a model which maps into the following variation. Suppose that the timing of the first two transactions in the Wicksell triangle is reversed, so that that agent *B* first has an opportunity to buy from *A*, then *C* from *B*, and finally *A* from *C*. This timing is natural if *B* uses *A*'s good as an intermediate good.

As in model 2, agent *C* is trustworthy but agents *A* and *B* may not be. In addition, Agent *C* enjoys a special privilege as a creditor, that is, an enhanced ability to enforce debts, and serves as 'banker' to agent *B*.

In this modified example, it is possible to show that the full-enforcement efficient allocation can sometimes be implemented through use of a combination of transferable and non-transferable debt. Specifically, suppose that *B* has an opportunity to meet with *C* before production of specialized goods can occur, and before trading begins. Agent *B* issues debt to *C*, and *C* in turn issues debt to *B*. When *B* then encounters *A*, he pays for *A*'s specialized good by transferring *C*'s debt to *A*. Agent *B* then has the opportunity to discharge his debt to agent *C* by transferring his specialized good to *C*. Finally, agent *A* presents *C* with his debt, and receives *C*'s specialized good. *Payment* and *settlement* are defined as in model 2.

In short, in this model agent *C* is engaged in 'liquidity transformation', which consists of holding *B*'s debt, which would be unenforceable by *A*, while issuing to *B* his own enforceable and therefore transferable debt. In practice, this liquidity transformation is usually provided by banks. This function of banks was already well established by the 14th century (Kohn 2001).

Payment Model 4: 'Bill of Exchange'

Model 3 allows for the coexistence of liquid and illiquid debt, but may not be appropriate for all circumstances. In some environments, there may be no agents with special enforcement abilities, such as agent *C* above. This is particularly true for economies with less developed legal and financial systems. Yet through the process of payment it may still be possible to economize on resources devoted to enforcement, by allowing for the discharge of one debt by the transfer of another.

Kahn and Roberds (2001) consider the following variation on model 2. The order of meetings is *A* with B, *B* with C, and *C* with *A*. The customized good produced by agent *C* is now valued by both *A* and *B*.

The full-enforcement efficient allocation can then be supported as follows. Suppose that agent *B* issues debt to *A* in the first transaction, and that agent *C* issues debt to *B* in the second transaction, which is subsequently passed to *A*. In the final transaction, *A* presents *C*'s debt to *C*, and *C* redeems his debt by providing the appropriate good to *A*. *Payment* in this environment again corresponds to the passing of *C*'s debt by *B* to *A*, and *settlement* occurs either simultaneously with payment, or when *C* redeems his debt.

The intuition behind the efficiency of this arrangement is as follows. Suppose that, instead of making use of transferable debt, trade is organized as a 'credit chain' (Kiyotaki and Moore 1997), in which *B* issues debt to A, C issues debt to B, and B promises to discharge his debt with A once he has collected from C. If enforcement is less than perfect and *B* also values C's customized good, then *B* may collect C's debt then 'take the money and run', that is, abscond with C's good. But if *A* requires an 'early' payment from *B* in the form of a transfer of *C*'s debt, *B*'s default can be averted, provided that *A* can respond to a failure to pay at this stage by preventing *B* from collecting with *C*.

As in the models above, enforcement of *B*'s obligation to *A* occurs through a form of netting. By requiring early payment from *B* in the form of *C*'s transferable debt, *A* is in effect forcing *B* to cancel one debt with another. The key distinction between model 4 and earlier models is that this cancellation is no longer instantaneous. In other words, even potentially bad credits such as *B* are allowed to issue debts as long as they agree to punctually pay them off using the debt of another, possibly stronger credit.

The work of economic historians (see Ashtor 1972) suggests that model 4 is also an ancient one. Its use in the West (in the form of bills of exchange and similar instruments) dates from the late 12th century, and likely arose from even earlier Middle Eastern precedents. Even in today's advanced economies, this model persists in the form of trade credit that is granted with the understanding it will be repaid in another form of debt, nowadays typically bank funds.

Payments and Networks

Payment systems based on the models discussed above have been in use for some time. Successful application of these models, however, requires some information which may not always be present in practice. At a minimum, participants in these arrangements must be able to distinguish the identity of their counterparties, and have some notion of their counterparties' ability to honour their debts. Historically, these requirements have often worked to limit the use of many forms of non-cash payments to established businesses, wealthy individuals, or parties already well known to each other.

These constraints have become less onerous with improvements in information technology. In particular, the years since 1960 have seen rapid development of electronic payment systems based on the use of cards (Evans and Schmalensee 1999). A noteworthy distinction between electronic systems and their paper-based counterparts is that the new systems require the use of specialized communications networks.

As is the case with other industries, the presence of 'network effects' in payment systems leads to complications (see Weinberg 1997). Baxter (1983) was the first to point out the essentially 'two-sided' nature of the service provided by these networks: that is, that efficiency in these networks may depend critically on the allocation of their costs between buyers and sellers. This insight has been subsequently expanded on by many authors (an authoritative survey is given in Rochet and Tirole 2004). Nonetheless, as of this writing, no consensus has emerged concerning efficient allocation of services provided by these systems (Evans and Schmalensee 2005).

Conclusion

Payment systems are an important component of decentralized exchange. This article has illustrated how the fundamental role of these systems is the reduction of chains of obligations to a smaller and more readily enforceable set of obligations. Ongoing improvements in information technology have the potential to increase the scope and efficiency of payment systems, and this will require economists to provide more precise models of their function and essential nature.

Pay-off Period

D. M. Nuti

The *pay-off period* of an investment project is the number of years over which the project pays for itself from the time of completion, i.e. the sum of undiscounted after-tax gross profits over the period are equal to total investment outlays. There is evidence that enterprises investing in plant and equipment, mostly in industry, require for a project to be undertaken that its pay-off period should be no longer than a *standard* period which is customary in the given sector of operation, ranging from under two to five years. If mutually exclusive projects are available, for instance if there are alternative techniques of production available for creating otherwise identical productive capacity, *ceteris paribus* the pay-off period of investment is not minimized but is brought closest to the standard pay-off period of the sector involved, which is not to be exceeded. It is an *average satisfying* condition, not a marginal condition for optimization. Its satisfaction for any given investment and current costs associated with it can be ensured by a corresponding appropriate mark-up on current costs in output pricing.

Early evidence of this kind of investment behaviour was documented by Henderson (1938), Meade and Andrews (1938), Brockie and Grey (1956). In general this criterion of investment choice tends to be discussed in business textbooks rather than in economic theory; a notable exception is Kaldor and Mirrlees (1962), where this investment criterion plays a major role in determining the economy's growth path.

The pay-off period criterion would appear to be at odds with discounted cash flows methods, whereby the present value of investment, i.e. the cumulative sum of discounted net cash flows at start, should be maximized, being tantamount to the increase in net wealth deriving specifically from undertaking the investment. Discounting methods lead to projects being undertaken if their present value is positive or – which mostly but not always gives the same result but not necessarily the same ranking of projects – if the discount rate expressing the opportunity cost of finance to the investor is lower than the internal rate of return on investment (i.e. the rate which, if it exists and is unique, would make the present value of investment equal to zero at the point of starting the investment; we neglect here the questions of multiple internal rates of return, variable cost of finance, optional investment lifetime and other complications of discount methods). The divergence between pay-off and discounting criteria is not, however, as great as it may seem.

First, usually the pay-off criterion is applied only to investments which satisfy the additional criterion of earning a minimum rate of profit over the investment lifetime higher than a target rate related to the opportunity cost of finance to the investor. However, the pay-off criterion is likely to be a stricter test than the minimum profit rate; Kaldor and Mirrlees (1962) assume that whenever the first is satisfied, the second is automatically satisfied.

Second, discounting procedures apply primarily to a world of certainty: to handle uncertainty those procedures require either adding a percentage risk factor to the interest rate, which unduly amplifies the weight attached to the riskiness of future distant events; or the comparison of 'certainty equivalent' present values, i.e. a purely subjective trade-off between mean present value and its standard deviation (or other measure of dispersion). The pay-off criterion is a rough and ready way of handling uncertainty, in particular about potential competition generated by new technology. The best explanation of the pay-off criterion, owed to Kaldor, is that the standard period is a parameter chosen by firms on the basis of experience in such a way as to meet the uncertainty due to obsolescence in different sectors and the time required by the introduction of new techniques. An entrepreneur undertaking a new investment is subject to the risk that technical advance in his field will make his investment obsolete cutting the flow of his profits. Cheaper substitutes for his product may be introduced, or he may be unable to take advantage of subsequent more efficient methods of making his product once he has committed his investment funds to a specific technical form embodying the best current practice. But it takes a certain number of years to develop a new process up to the point of industrial application on a large scale, and since he knows that for the time being there are no such new processes, he is prepared to invest in projects from which he expects to get his own money back within that number of years, whereas he is reluctant to risk investments which would normally pay for themselves over a longer period.

In the Soviet Union and other East European countries in the mid- and late-1950s official instructions were issued for the selection of investment projects which are formally similar to the pay-off criterion but are radically different in both theoretical meaning and empirical justification. Basically, if two alternative ways of producing the same new capacity were available, the more investment intensive project would be selected only if its current operating costs were so much lower that the *additional* investment expenditure could be recouped through current costs savings within a given number of years T fixed as 'standard' by central planners. Another way of putting this is that the more investment intensive project would be selected only if the sum of its operating costs and $1/T$ of its investment outlays were lower than for the other project; this leads naturally to the generalization of the principle, for any given new capacity to be generated, as the minimization of the sum of operating costs and $1/T$ of investment outlays. Thus investors obeying this rule effectively behaved *as if* they were subject to a capital charge equal to $1/T$ in spite of the fact that investment funds were obtained free of charge from the state budget (only subject to reimbursement of straight line depreciation). Given a uniform lifetime n of the investment plants a standard period T defines a shadow interest rate r implicit in the relationship

$$T = \frac{(1+r)^t - 1}{r \cdot (1+r)^t}$$

The standard period T in English-language literature is usually labelled 'recoupment period' (*rok okupoemosti* in Russian, *doba navratnosti* in Czech, *czas zwrotu* in Polish) and in spite of the non-existent nuance of meaning between 'recoupment' and 'pay-off' the maintenance of this convention to distinguish between the two concepts is essential in view of their radical differences.

The Soviet-type standard recoupment criterion is a marginal, not an average condition and is part of an optimization (i.e. cost minimization) procedure in an economy where otherwise there are no capital charges. It does not regulate whether or not the new capacity should be generated but it only regulates its technical form; thus it is insensitive to the relative price of output and inputs. For a single investment project a recoupment period cannot be defined and is not necessary once planners have decided to create that new capacity. The pay-off criterion of the capitalist firm on the contrary is an average not marginal condition and can only be regarded as an approximate rule of thumb in lieu of optimization. The pay-off period of a single investment can be defined and is certainly sensitive to the relative price of inputs and outputs. It regulates both whether new capacity is established and its technical form. The two criteria have in common the comparison of items of capital stocks and undiscounted flows and therefore also the common time unit but should not be confused (as they often have been in comparative literature).

The recoupment period criterion in the Soviet Union was officially codified in official investment regulations in 1960 and 1962, but had already been informally used in the infraministerial distribution of investment funds since the mid-1930s (for a discussion of early practices see Hunter 1949) as a way of ensuring efficiency in the absence of interest charges on investment (on early Soviet discussions on interest and capital charges see Grossman 1953). Similar criteria were introduced in Czechoslovakia (1961), Poland (1963) and Hungary (1963). Soviet and Czech rules added straight line depreciation percentages to $1/T$ in comparing investment alternatives; Polish and Hungarian rules did not. Soviet and Czech rules had different 'standard' recoupment periods in different industries, ranging from 4 to 10 years. The criterion rules on the technical form of investment and not on whether new capacity should be created at all, thus diversified recoupment periods by sectors cannot be regarded as an expression of central planner's sectoral priorities and have no justification. It is probable that in Soviet practice in each industry a standard period emerged to rationalize technical choice by engineers and projectdesigning organizations, but that softer financial constraints led to longer standard recoupment periods in priority industries – a practice later codified in both the Soviet Union and Czechoslovakia without consideration of the reasons for it. Polish procedures (1962) are the most elaborate and contain allowances for the freezing of investment resources during gestation, allowances for the impact of durability on both costs (given embodied technical progress) and output as well as a justification for the determination of the standard recoupment period (6 years throughout the economy on new investment) which was related to the recoupment period of labour-saving investment in modernization, thought to be recoverable in five years on a large scale (the difference between 5 and 6 years being accounted by the shorter lived nature of benefits deriving from investment in modernization). The original elements of the Polish investment rules were due to the work of Michal Kalecki and Mieczyslaw Rakowski (1959) which they embodied almost verbatim. In other East European countries similar rules were apparently used more or less officially (Katchaturov 1962; for a general discussion of these criteria see Dobb 1951; Zauberman 1955, 1962; Nuti 1971; for a criticism of the Kalecki–Rakowski approach see also Nuti 1986).

Harcourt (1968, 1969) has compared the impact of alternative investment rules such as discounted cash flow methods and recoupment periods. In the late 1960s and early 1970s new rules were issued in Czechoslovakia and Poland (see Nuti 1970, 1971) approaching more conventional Western type discounted cash flow methods – including emphasis on international prices as in standard OECD and UNIDO cost/benefit analysis, while the 1972 Soviet investment regulations maintained the earlier approach with small modifications. The 'recoupment period' approach – whatever the official permanence of regulations – has been made redundant by the appearance of interest-bearing investment credit (in Hungary and Poland on a large scale). Economic crisis in Eastern Europe at the turn of the 1980s has introduced emphasis on quickyielding investment, with versions of the capitalist pay-off criterion (especially for outlays and revenues respectively incurred and accrued in hard currencies) used to allocate investment funds among competing firms. This however is an indication of underpriced hard currency and external imbalance; it does not have the same rationale given above (i.e. technological uncertainty) for the capitalist pay-off criterion and it is part of an optimization attempt (maximize the flow of net export receipts) instead of being an average condition.

Payroll Taxes

Daniel S. Hamermesh

Taxes paid by employers based on the number of employees and the wages paid. These taxes are constructed by applying a *tax rate* to the per-period wage rate paid to the employee. The rate may differ among employees or across firms. In a few tax structures there is a *ceiling* on the total payroll tax bill assessed against the earnings of each employee.

Although historically not an important source of revenue for national governments, they became a major and increasingly important source of revenue for national governments after World War II. By 1980 payroll taxes accounted for 15 per cent of the tax revenue of the Federal government in the United States, 13 per cent in Great Britain, and 39 per cent in Sweden. Payroll taxes have several purposes. In many cases a payroll tax is explicitly designed to finance programmes viewed as benefiting workers. For example, payments to retirees under the United States Social Security Act are financed by a payroll tax (as well as by an earnings tax on workers). The tax may also be an instrument of economic policy, either *experience rated* – varying in amount with each firm's past record of generating benefits financed by the tax – or raised or lowered to affect employment over the cycle, across areas or among demographic groups.

The major economic issue of interest in the payroll tax is its *incidence* (see Musgrave and Musgrave 1980, for a discussion of incidence in a more general context). Stated most broadly, the question economists must answer is: what is the effect on the time path of factor and product prices and quantities of an increase in the tax assessed on the firm against the payroll of the workers it employs?

The most widely discussed issue under this general question is whether labour bears the payroll tax. (This is generally taken to mean whether net per-worker earnings after the payroll tax is assessed are equal to their pre-tax level minus the tax.) If the supply of labour to the market is completely inelastic, labour bears the entire tax; tax-induced shifts in labour demand merely move the demand curve along the vertical labour-supply curve. If the supply elasticity is non-zero, the elasticity of demand for labour will also affect the outcome. On *a priori* grounds the answer thus depends on one's beliefs about the empirical magnitudes of labour supply elasticities. Despite the centrality of labour-supply behaviour in resolving this question, most empirical research has focused on attempts to estimate directly the effect of differences in payroll tax rates on wage rates across subunits and over time. Thus one leading empirical study (Brittain 1972) estimates a CES production function across countries, modified to incorporate differences in payroll tax rates and their incidence, and finds full shifting onto labour. Other empirical studies, using data on individuals whose employers pay different taxes on their earnings because of ceilings on the tax (Hamermesh 1979), or using aggregate time-series data to examine how average wage changes respond to payroll tax changes (Beach and Balfour 1983), reach sharply differing conclusions. The conflicting evidence forces one back onto extraneous estimates of labour supply elasticities in order to reach conclusions about the burden of this tax. Since the best estimates of these suggest they are small but positive, and since the aggregate demand elasticity for labour is below unity, we may infer that labour bears most, but not all of the tax in the form of net wages only slightly greater than the pre-tax wage less the tax.

A second major issue is the effect of increased payroll taxes on the price level. In the popular press, and among some Keynesian economists, the increases are viewed as 'passed on' in the form of higher product prices. These views ignore the effect of monetary policy and spending policies on aggregate outcomes; they also implicitly assume that the aggregate demand is price inelastic. Payroll tax increases represent a negative supply shock that can be easily analysed in the standard aggregate demand/aggregate supply framework. As such, they produce a temporary decline in output and rise in price inflation, both of which are eventually removed as price expectations adjust. As with other negative supply shocks, the temporary decline in output can be mitigated, at the cost of more rapid inflation, by expansionary spending or monetary policy. Payroll tax increases are 'passed on' in the form of higher product prices, unless net wages fall by an amount equal to the tax increase. But the effect on prices is temporary unless the government accommodates the increase by stimulating aggregate demand. The arguments on the effects of payroll taxes on the macroeconomy hold in reverse for payroll subsidies.

A third issue under the general question of incidence is the effect of the tax on the distribution of net incomes. This problem is frequently dealt with in popular discussions of payroll taxes that embody ceilings, as such taxes are superficially regressive. Such discussions implicitly assume that labour bears the tax, and also assume the burden to be proportionate to the tax each particular worker generates. Perhaps even more important, they ignore the common link, either explicit or implicit, between the tax and the distribution of benefits of the programmes it finances. These are best viewed as a package; and there is no satisfactory evidence on the effect of the tax/benefit package on net incomes.

Most analyses of the incidence of payroll taxes are static and, like the discussion here, implicitly long-run. Even if the tax is eventually borne mostly by workers because the long-run supply of labour to the market is relatively inelastic, and even if there are no net effects on income distribution, labour-market dynamics can produce quite different short-run outcomes (Hamermesh 1980). While labour demand adjusts fairly rapidly to its long-run equilibrium, labour supply adjusts slowly because of lags in perception and in training. These lags are sufficient to make the incidence of payroll tax increases rest less heavily on workers for several years after they are instituted, and to give employers more incentive to attempt to raise prices (thus producing a larger negative supply shock).

Leaving the general question of incidence, we also know that the existence of different marginal payroll tax rates assessed on workers with different earnings rates and of ceilings on taxable earnings means that changes in payroll taxes will affect the mix of labour inputs. Thus, for example, an increase in the rate of a tax with a low ceiling effectively increases the fixed costs of employing workers, but does not raise the cost of adding another hour to the work week. It thus induces employers to substitute away from workers and toward hours along an isoquant. Similarly, a higher ceiling with an unchanged rate raises the relative cost of employing more skilled workers and induces substitution away from them, especially given the strong evidence that they and less skilled workers are substitutes in production. These and other examples indicate that payroll tax policy can be used as a tool of labour-market policy; and policy analysts have increasingly recognized that the impact of changes in the structure of payroll taxes on employment must be considered.

Experience-rated payroll taxes are designed to reduce the incidence of the activity that generates the payments the taxes finance. Periods of unemployment and workplace injuries are the best-known examples of these activities. Increasing the degree of experience rating in a payroll tax that finances these benefits will tend to reduce the incidence of the activity. A mass of empirical work is fairly conclusive on the validity of this theoretical proposition, though the range of estimates is so wide that one cannot infer the magnitude of the reductions in injuries and unemployment that could be induced by better experience rating of taxes. Instituting a system of benefits financed by a payroll tax that is not experience rated may actually *increase* the incidence of the loss. To the extent that workers derive some utility from the consumption of leisure financed by unemployment benefits, they will supply their labour more cheaply to the firms that offer such leisure. The combination of lower wages and the same payroll tax bill leads such firms, those that generate substantial unemployment, to expand, thereby increasing the total variability of employment.

Peacock, Alan T. (1922–2014)

Martin Ricketts

Abstract

The central concern of Alan Peacock's work was in public finance. He defended the traditions of classical liberal political economy against the claims of 'The New Welfare Economics' to represent the only theoretically rigorous approach to public policy. His contribution was not focused on either positive or normative economics, but on what John Neville Keynes (1891. *The scope and method of political economy*, 1st ed. London: Macmillan) called the 'art of economics' – the translation of normative principles into policy action given the constraints presented by practically feasible institutions governing both private and public choice. His policy interests were wide and ranged from the big questions of the size and scope of government to more specific issues such as the structure of the social security system, the finance of education, the public support of the arts generally and the finance of the BBC in particular.

Born in Ryton on Tyne, Alan Peacock was educated in Dundee after his father moved from Armstrong College in Newcastle to become Professor of Zoology at the University of St Andrews. Alexander Peacock was an entomologist who had studied mosquitoes in West Africa and the lice that were the cause of trench fever while he served as a soldier on the Western Front during the First World War. Alan Peacock grew up, therefore, in an environment that heavily emphasised the social responsibilities attached to receiving a higher education and, as he wrote in a 'quasi-autobiographical' book *Anxious to do Good* (2010, p. 10), his father 'was a particularly hard act to follow so far as "doing good" is concerned'. His parents' desire for reconciliation with the Germans after the horrors of the First World War led to holidays in Germany and to his studying German at school – a fact that played a significant role in Peacock's later career.

Peacock's studies at the University of St Andrews (1939–42) were interrupted by the Second World War. His knowledge of German led to the role of a sea-going Intelligence Officer of the 'Y' service in the Royal Navy, decoding enemy communications, an account of which appeared as *The Enigmatic Sailor* (2003). In this capacity he took part in Operation Tunnel, in which his ship, HMS *Limbourne*, was torpedoed and sunk along with HMS *Charybdis*. The likelihood of available information being overlooked or misinterpreted had a significant effect on the young Peacock (the captain of *Charybdis,* for example, had not fully appreciated the source of information from *Limbourne* and mistook 'Y' information for the less technically specific 'my' information [Peacock (2003, p. 41)]. Peacock went on to serve on operations protecting the Arctic Convoys taking assistance to Russia via Murmansk and was awarded the Distinguished Service Cross in 1945.

After the war he completed his degree in Economics and Political Science at St Andrews and, following a brief spell as a lecturer there, moved to the London School of Economics in 1948 where he was influenced by Lionel Robbins and Friedrich Hayek. In later years he was to become Reader in Public Finance at the LSE (1951) and to hold Professorships at Edinburgh (1956–62), York (1962–78) and Buckingham (1978–84). He remained Professor Emeritus at Buckingham until his death. He also played a large part in establishing the David Hume Institute at Edinburgh.

The Growth of Government

Peacock's early work was on National Insurance and the analysis of the Beveridge Report (1942) that formed the basis for the growth of the post-war Welfare State in the UK. Beveridge was a Liberal academic at the London School of Economics from a tradition that emphasised personal independence and responsibility, but his reforms were implemented by a Labour administration in difficult economic circumstances and in a world that had become increasingly used to high levels of state intervention and planning. Coming from Scottish Liberal political circles, Peacock was concerned with the problem of reconciling the aims of social security provision with the maintenance of a liberal economic order in the classical sense.

In the post-war environment of the UK, critical analysis of social policy did not rank highly in academic circles. Peacock (2010, p. 45) records that in the period 1925–1955, of one thousand articles in the *Economic Journal*, only ten concerned the social services. He therefore began researching the institutional background and financing of pensions, unemployment insurance, 'national assistance' (as transfers to those in poverty were then termed), and provision for sickness and disability. Beveridge had recommended an 'insurance' based system of social support with premiums payable by all (if necessary supported by the taxpayer). By the 1950s it was clear, however, that the state, whether controlled by Labour or Conservative governments, was to play a dominant role on the supply side and that the system as a whole was becoming highly centralised and collectivised. It was also becoming clear that the National Insurance Scheme was not simply about creating 'insurance' markets that might not evolve without state encouragement, but was part of a broader policy towards the redistribution of income.

Criticism of both these trends provides the two main leitmotifs of Peacock's professional writing. His Scottish Liberalism as well as his classical liberalism led to profound suspicion of state monopoly provision as well as a preference for redistributional instruments that gave the recipients a degree of freedom of choice and the chance to avoid dependency. Much of his early work involved mastering the national accounts (still a relatively new framework for the collection and organisation of economic data at the time) and considering how these would be affected over time by demographic trends, changes in the rules of entitlement to benefits and trends in economic growth. This resulted in an early paper on the National Insurance Funds (1949) in which he proposed integrating National Insurance with the accounts of the public sector and giving up 'the pretence that the scheme is based on insurance principles'. This was followed by a more extensive study questioning the National Insurance system (1952), an article projecting the likely strain on the state's budget up to the 1980s of existing policies (1954a, with Frank Paish) and a book specifically on the techniques of national income accounting (1954b, with Harold Edey).

During this early period Peacock had also been involved as a Liberal party advisor. He was a member of the 'Unservile State Group' of academics and others sympathetic to the Liberal Party, which was set up in 1953 and produced a report entitled *The Unservile State: Essays in Liberty and Welfare* in 1957. He also provided research assistance for a report (1950) on the *Reform of Income Tax and Social Security Payments*. This was based around the work of Lady Juliet Rhys Williams and proposed a 'negative income tax' (later associated with Milton and Rose Friedman (1962)) by which minimum levels of income might be guaranteed to families through the normal operation of the fiscal system. An allowance would be paid to families (whether in or out of work) financed out of the taxation of income in excess of this level. It drew stark attention to the implied trade-offs between higher minimum standards and the possible adverse effects on work incentives and growth of the tax rates required to achieve them. Peacock was involved in providing estimates of the tax rates required to finance the scheme – though estimates of the incentive consequences were highly conjectural. The Liberal Party report proved to be at odds with the temper of the times and was considered but rejected by the Royal Commission on the Taxation of Profits and Income that received evidence in 1951. The old radical and individualist traditions going back to John Stuart Mill were increasingly supplanted by a more interventionist and paternalist philosophy, both within the Liberal Party and more generally.

Peacock's interest in social policy and involvement in Liberal politics had brought him to consider a major component of the growth of public expenditure. As an academic public finance economist he was also interested in placing these developments in redistributional finance in the context of normative and positive theories of government growth more generally. With Richard Musgrave (1958) he edited a collection of *Classics in the Theory of Public Finance*. This included contributions from Adolf Wagner (1883), Knut Wicksell (1896) (translated by the later Nobel prize-winning economist James Buchanan), Erik Lindahl (1919) and other articles translated from German, Italian and French. Samuelson (1954) had clarified the technical conditions for the efficient provision of 'public goods', but the older literature, with its emphasis on consensus (Wicksell) or bargaining over cost shares (Lindahl), draws greater attention to the institutional problems of collective choice and the possibility that actual results will depart substantially from the ideal.

Peacock wrote with Jack Wiseman (1961) a study of the *Growth of Public Expenditure in the United Kingdom* which charts the historical trends and considers the various possible explanations for them. In particular, this study is celebrated for its critique of Wagner's 'law' of increasing state activity (pp. 16–24) and the investigation of two hypotheses – the 'displacement effect' and the 'concentration process' (pp. 24–30). Peacock and Wiseman were critical of some of Wagner's arguments for a rising share of public in total expenditure – such as the inherent superiority of public over private corporations in producing economic stability. But they advanced alternative explanations of their own for particular periods of public sector growth in the UK. Public expenditure was 'displaced' upwards after periods of social stress, such as wars or severe social disturbance. Higher levels of taxation were tolerated under extreme conditions 'and this acceptance remains when the disturbance itself has disappeared' (p. 27). The concentration process referred to a tendency for larger and more centralised delivery mechanisms to evolve partly in response to economies of scale, but also to political demands for uniformity of standards.

These two hypotheses seemed descriptively to fit the story of 20th century developments in the UK. But, as Peacock and Wiseman themselves emphasised, they did not constitute a fully developed theory of government growth. The main influence on Peacock's work during and after the 1960s was the advance of public choice theory associated with Downs (1957), Buchanan and Tullock (1965), Breton (1974), Olson (1974) and Niskanen (1971). These offered a much more systematic analysis of collective choice by looking at the individual incentives faced by economic agents within a range of constitutional or organisational settings.

Two factors were paramount in Peacock's later writing about the growth of government. The first was the tendency within democracies for particular interests and pressure groups to divert resources in their favour through the regulatory as well as the fiscal system. On the demand side, this was partly the result of the ability of relatively poor voters in a democracy to load the tax costs of public activities onto richer voters through progressive tax systems. But it was also related to the ability of smaller cohesive interest groups, facing relatively low costs of collective action, to exert pressure on politicians and legislators in representative democracies. The second important factor concerned the 'supply' side of the political market. Legislators and bureaucrats were themselves operating within an institutional and organisational context that would be expected to lead to expanding public spending.

Peacock's work in Public Choice provides an interpretative commentary rather than theoretical novelty. As a classical liberal he was always interested in the historical origins of ideas about the role and growth of the state. He wrote a set of lectures (1992a) on *Public Choice in Historical Perspective* in which he pointed to de Tocqueville's (1965) work (also in Peacock (1978a)) as a prologue to much modern theory (pp. 42–53). In the same lectures he returned to the Italian tradition in public finance, which he much admired, and in particular the contribution of Amilcare Puviani (1903) on fiscal illusion (pp. 96–102).

Although he would occasionally specify a theoretical model in formal mathematical terms, his efforts were usually directed at discussing the problems of interpretation, the difficulties of defining and measuring the arguments of the utility or production functions used, the possibility that important elements of the problem had been omitted and so forth. The Economics of Bureaucracy, for example, might find it convenient to summarise the objective of senior administrators as maximising their budgets. Peacock (1978b) accepted that this might be a useful first approximation (although still probably culturally specific), but matters such as reputation with colleagues, professional pride, the desire for a quiet life, pure laziness, personal ambition or an idealistic wish to serve the public needed to be borne in mind when applying the theory in particular cases.

It would be a mistake to regard Peacock's commentary on Public Choice as representing an attack on formal theory by the easy paths of questioning assumptions, complaining about lack of completeness or lack of descriptive realism. He admired many of the theorists, quoted their work extensively and was well aware of methodological defences to quite abstract and 'unrealistic' theory. His contribution, however, was not in positive theory itself, but in using the theory to cast light on the whole process of policy formulation and execution. This 'art of economics' requires a more classical approach to the subject. Peacock's economic agents whether business people, voters, politicians, bureaucrats, lobbyists or indeed academics were those of Adam Smith – broadly self-interested, but hard to sum up in a simple utility function – and 'the situation in which they are placed', as Smith put it, was more complex than could be summarised in a set of known resource constraints.

Lack of information or the possibility that it might be systematically distorted also played a large part in Peacock's view of policy leading to an awareness, more normally associated with 'Austrian' economists, of the unintended consequences of intervention. He was also wary of theoretical approaches that viewed people as 'passive adjusters' to policy instruments instead of active bargainers. This can be seen in the titles of articles and books – *The Regulation Game* (1984), *The Heritage Game* (2008), 'Bargaining and the regulatory system' (1986) – and in papers (1981) emphasising that taxpayers can respond not merely by avoidance or evasion, but with various forms of political action.

The Critique of Welfare Economics

Peacock's classical liberal approach to public policy had a direct bearing on his suspicion of Welfare Economics. By the 1950s the New Welfare Economics deriving from Vilfredo Pareto, based upon the inadmissibility of interpersonal comparisons of utility and the concept of 'Pareto efficiency', had become the established paradigm in normative theory. It had been saved from its seemingly highly restrictive applicability (most policy changes would make some people worse off and others better off, thus requiring the forbidden interpersonal comparisons of utility in any final assessment) by the development of the Hicks (1939)–Kaldor (1939) compensation tests. Where the gainers from a change from one social state to another could compensate the losers there was a 'potential Pareto improvement' in social welfare, and it increasingly became accepted (in practical policy discussion if not in purely philosophical discussion) that changes of this nature were desirable (even if compensation were not actually paid). In essence, the pursuit of 'economic efficiency' came to be treated as a dominant aim of public policy, while the ability to characterise these Pareto efficient states in mathematical terms lent a spurious 'scientific' credibility to the resulting policy proposals.

The value judgements underlying Paretian welfare economics were widely considered very weak and indeed perfectly consistent with liberal principles. However, the pursuit of 'efficiency' through public policy was not always consistent with the tenets of classical liberalism conceived of as the defence of negative freedom. Much of Peacock's writing is based on this essential point. In Peacock and Rowley (1975) the theme was set out at length. 'It is an illusion to infer that Paretian welfare judgements lead to non-authoritarian solutions in matters of economic policy simply because they are derived from individual preferences' (p. 2). The whole book is an attempt to re-establish a 'classical political economy with modern trappings' (p. 3) against the claims of Paretian welfare economics that had established a 'dangerous hegemony in the economic theory of public policy'.

Ultimately the critique is founded on a rejection of 'welfarism' – the idea that social welfare should be derived entirely from the self-assessed utility of individuals. In Peacock (1992a, p. 104), for example, he explicitly remarks that 'it is amazing to me how often it is taken for granted that if by some miraculous device, all preferences for social goods could be known . . . an imposed solution is then considered justified'. The actual taking part in a process of political decision-making is important – just as the exercise of judgement in matters of private exchange is important in developing people with qualities that permit the exercise of personal responsibility. The use of non-utility information to assess policy involves value judgements quite distinct from the idea that 'individuals are the best judges of their own welfare'. Outcomes alone (and their consequences for the utility of individuals) are not all that count from a liberal perspective or indeed from the perspective of other radical and 'New Left' critiques of static welfare theory (see Peacock and Rowley 1975, pp. 69–76).Sen's (1970) celebrated proof of the impossibility of a Paretian liberal, while clearly drawing attention to potential conflicts between formal social choice theory and liberalism, is nevertheless criticised by Peacock and Rowley (pp. 80–3) for advancing an inadequate condition of 'minimal liberalism'.

Although Peacock saw the classical liberal approach to both private and public choice as supporting the claims of negative liberty, he was not a fully fledged 'process liberal', such as Ludwig von Mises. Mises and others of the 'Austrian School' conceived economic life as entirely about change and dynamic market processes. These processes would never come to rest and the time path could not be determined in advance. Normative assessment could therefore not be in terms of the achievement of particular end states, but had to rely on the compatibility of the process itself with desirable features – such as the maintenance of an open society and individual liberty.

Peacock had greater affinity with the German neo-liberals, whom he categorised as 'end state' liberals (Peacock and Willgerodt 1989b, p. 3). His knowledge of German and his acquaintance after the war with Herbert Giersch at the LSE introduced him to the work of Walter Eucken and other 'ordo-liberals'. Ludwig Erhard, one of the main architects of West German post-war reform, was associated with the neo-liberals and is widely credited with the implementation of the *Soziale Marktwirtschaft* (a term coined by Alfred Müller-Armack). Peacock and Willgerodt (1989a) edited a set of translations of some of the major contributors to this German neo-liberal tradition including Walter Eucken, Franz Böhm, Wilhelm Röpke, Alfred Müller-Armack and others.

The distinguishing feature of the ordo-liberals compared with the more libertarian followers of Mises and Hayek was their conviction that the state had a crucial role to play in ensuring that various undesirable outcomes were avoided. A central task, for example, was to ensure that market processes did not lead to excessive accumulations of private monopoly power. Such power was dangerous because it could be used to establish political privilege and undermine the competitive liberal order. Mises and others might argue that no position was immune from new entry and technical change in the very long run, but this would not be true if the state itself began to fall under the influence of powerful private interests. Similarly, intervention to try to place some limits on income inequality was accepted as a necessary part of maintaining political support for an essentially liberal economic system. This went further than measures to relieve abject destitution, but not as far as a comprehensive 'social welfare state' – which itself would be a threat to liberalism (Peacock and Willgerodt (1989b, p. 12). Maintaining a reliable and non-inflationary currency was also a matter of central importance to the neo-liberals, as the disastrous consequences for liberalism of the Weimar inflation were still a matter of recent experience.

Where, or within what limits, in the interventionist spectrum the liberal order might find a sustainable location was a matter for continuing investigation and argument. But the desire, for example, to maintain competition by preventing mergers above a certain size or by forbidding particular restrictive agreements (even if these were entirely voluntary in nature) implies that certain types of social 'outcomes' matter. In this sense classical liberals such as Adam Smith and John Stuart Mill were 'end state' liberals even if their ultimate interest was to defend a system of 'natural liberty' that gave maximum scope for market processes and the exercise of individual choice.

Peacock fitted into this 'classical' historical tradition. It was a tradition deeply suspicious of Welfare Economics. His support for competition, for example, did not derive from the First Theorem of Welfare Economics that a perfectly competitive equilibrium (in the absence of externalities) was Pareto efficient. Nor did he think that it made any sense for policy to aim at approximating perfectly competitive conditions – which would have the effect of expunging conscious rivalry from the economic system. The case for competition in classical liberalism was based on a suspicion of concentrated private power and a desire to see these subject to new entry in the interests of economic progress. It was not concerned with the pursuit of limiting cases where universal price taking (the absence of all economic power) became the aim of policy.

Policy Areas

Education

The 'big questions' of government growth and the role of the state may have formed the thematic material that permeates Peacock's work, but it was his interest in particular areas of policy for which he is best known. He had a lifelong interest in education, perhaps because, as a liberal, he saw it as a means of enabling the population to live independently, supporting human capital accumulation, and resisting the rise of dependency and the purely redistributional state. He also accepted that there were particular problems in education markets related to the public benefits associated with a well-educated population and the transactional hazards encountered in educational finance.

His paper with Jack Wiseman (1964), 'Education for democrats' advocated the development of a voucher scheme that would give parents the financial resources to purchase educational services from competing suppliers. On the demand side it was opposed by those who thought that parents could not be trusted to make such important decisions on behalf of their children, and on the supply side it was challenged by an educational establishment that, like all producer interests, preferred its customers not to have access to possible alternatives. State paternalism and state supply were to win the day for many years to come and Peacock moved away from any advisory capacity in Liberal party circles.

He did not withdraw from the debate however, and in 1978 took up a post at the University College at Buckingham, an institution that rejected direct government finance and relied upon student fees. He was Principal of the College (1980–83) and upon achieving a Royal Charter became the first Vice-Chancellor of the University. At some professional risk to himself, Peacock signalled his view that financial support for human capital accumulation in higher education should be directed through the students and not be assigned by bureaucratic and centralised formulae direct to the institutions themselves. Given the introduction of student loans in recent years he could at least reflect on the advance of this principle in higher, if not in primary or secondary, education.

Devolution

Peacock's liberalism showed itself consistently in his continuing defence of devolved decision making – if possible to the level of the individual. He was a member of the Royal Commission on the Constitution (the Kilbrandon Commission) that reported in 1973. Essentially, the majority report recommended directly elected Scottish and Welsh assemblies with specified devolved powers – a model that was eventually adopted in the Scotland Act 1998 and the Government of Wales Act 1998. With Lord Crowther-Hunt, Peacock wrote a Memorandum of Dissent to the 1973 report advocating greater decentralisation using a federal model closer to the German system. In addition to assemblies for Scotland and Wales there would be five further assemblies for regions in England – all with more substantial powers than those recommended by the majority report.

Amongst the arguments motivating the note of dissent Peacock particularly emphasised two. As he put the case 25 years later (1997a, p. 267) 'I still hold that partial devolution is an essentially unstable position'. The English regions would not long tolerate the greater influence exerted by devolved Scottish or Welsh governments. Of even greater importance, however, was his view that devolving the existing (and over-extended) functions of government would do little to empower individuals. Another political and bureaucratic layer of government controlling expenditure flows might simply empower the new representatives and officials and embolden local rent-seeking behaviour. 'The possibility was not considered that some of these functions might be carried out in different ways . . . or might be returned to the private sector' (Peacock 1976, p. 217).

Pensions

The same theme of encouraging personal responsibility and choice is revealed in Peacock's role as a member of the Inquiry into Provision for Retirement in 1984. Although he accepted that the economist as a technician should not have a privileged role in setting policy objectives, he also took the view that the clear articulation of the normative principles underlying policy was essential to any rational consideration of alternatives (1992b). When committee members were invited to list their own preferred criteria for pensions policy, Peacock (1997a, p. 320, 1997b) specified a system compatible with consumer sovereignty, based upon a minimum required standard for pensions, permitting personal saving to meet the standard, encouraging low transactions costs and, finally, conducive to the mobility of capital and labour.

Once more, Peacock's willingness to extend choice in this area by encouraging personal and portable pensions above a minimum standard met with resistance, although the committee agreed on a proposal to abolish the State Earnings Related Pension Scheme (SERPS). This was opposed by the Treasury at the time, although a highly complex system of 'contracting out' was devised. SERPS was eventually abolished in 2002 and greater flexibility and consumer choice have characterised the reform of retirement provision in the second decade of the 21st century.

It is pertinent to note that personal payments by the relatively poor into pensions or education would be assisted by the state, and Peacock was attracted by the use of finance raised at death. Here he followed J. S. Mill in favouring a tax structure that encouraged wide dissemination of estates and taxation according to the circumstances of the beneficiary rather than the donor. Peacock and Rizzo (2002) also discussed the proposal of the Italian writer Rignano to tax inherited property at progressively higher rates on successive transfers at death. Many of these ideas Peacock considered impractical, but the aim was clear – 'to produce greater equality in the distribution of wealth for the purpose of giving individuals the means to investment according to their own assessment of their welfare' (Peacock 2010, p. 137).

Broadcasting and the Arts

In 1986 Peacock was appointed Chairman of the Committee on the Financing of the BBC. It was widely assumed that, as a noted economic liberal, he had been appointed to recommend the abolition of the licence fee and its replacement by advertising revenue. In fact the report (Home Office 1986) concentrated more on the development of competition in the production of public service content and the facilitation of subscription and pay per view services that rapid technological change was making possible. Important recommendations for example were that the more popular BBC Radio 1 and Radio 2 stations should be privatised and that both ITV and the BBC should source at least 40 per cent of their output from independent producers. The licence fee was to be retained for a further period of time, but capped and indexed to inflation.

In his later writing (1997a, 2004) Peacock's suspicion of state-sponsored monopoly and his support of the normative principle of consumer sovereignty led him to oppose the channelling of licence fee revenue exclusively through the BBC. This in no way implied that he rejected out of hand the case for public service broadcasting. Various educational and other cultural objectives might lead to a case for assistance to certain types of output. He therefore recommended (2004, p. 45) that public service broadcasting should be financed through a hypothecated 'licence fee' replacement. The allocation of the available budget would then be overseen by a new council with representatives of viewers and listeners making up half of its membership. Crucially, bids for resources could be made not merely from the main terrestrial channels, but also from cable and satellite channels and for a range of purposes – including making marginal changes to the quality or accessibility of particular projects. Peacock argued that such a system would be more conducive to new entry, technical progress and 'workable competition'. The system by which the BBC received licence fee revenue and a few other broadcasters with public service requirements were regulated separately harked back to an era when spectrum scarcity severely curtailed the number of suppliers and technical non-excludability made it hard to charge for services in the market.

This liberalisation of public service broadcasting did not imply privatisation of the BBC and its transformation into a public limited company. Apart from any other consideration, property rights in past programmes financed by generations of licence fee payers would give a powerful competitive advantage to the BBC. The international reputation of the BBC in areas such as news and current affairs was also an asset that required protection. Peacock suggested that a preferable route would be to transform the BBC into a non-profit-making corporation similar to the National Trust.

To understand Peacock's approach to broadcasting it is necessary to bear in mind that he saw 'public service' elements as inextricably linked to related issues such as education, the preservation of the cultural heritage and the encouragement of the arts more generally. As noted above, he supported the idea of vouchers in education and extended this idea to consider the possibility of vouchers for museums, art galleries, concerts, libraries and a whole range of other 'cultural' activities (1993, pp. 122–8). He speculated that technical advance might even permit consumers to access a certain quantity of public service programming within a competitive environment in which pay per view television became the norm.

In general Peacock preferred subsidies to go to people rather than organisations, and this led him into continual conflict with vested interests in the world of the arts, culture and the media. In a chapter entitled 'How to lose friends and alienate people', Peacock (1993) describes his membership of the Arts Council of Great Britain and Chairmanship of the Scottish Arts Council 1986–92. He entirely endorsed John Maynard Keynes's view that the education (and hence preference formation) of the public was the main objective, and that subsidies to single companies 'were only temporary devices, rather like research and development expenditure, to give them a start in life' (1993, p. 118). Giving people the ability to access cultural events at subsidised prices would help, as experience accrued, to change preferences and lead to expenditure on the arts becoming self-sustaining.

This view of arts subsidies simply reflected his approach to the welfare state as a whole. 'The true function of the welfare state is to create the circumstances which render it unnecessary' (2010, p. 140). Hard to identify in particular policy areas and, in the eyes of many, doomed to fail in the face of the realities of democratic politics and public choice, this youthful statement of the classical liberal ideal nevertheless provides the key to Peacock's entire corpus of work in the economics of public policy.

Peak-Load Pricing

Jack Wiseman

Abstract

The present-day theory of peak-load pricing is concerned with the identification of the optimal pricing structure for a particular class of products: essentially, commodities the demand for which is episodic (variable by time of day, season, or whatever) and whose technical conditions of production make storage difficult and/or are discontinuous in terms of volume.

The present-day theory of peak-load pricing is concerned with the identification of the optimal pricing structure for a particular class of products: essentially, commodities the demand for which is episodic (variable by time of day, season, or whatever) and whose technical conditions of production make storage difficult and/or are discontinuous in terms of volume.

An adequate exposition of the nature and problems of the literature concerned with this specialized problem requires that it be placed in historical perspective. There are two convergent lines of thought. The direct one originates in the discussion by Dupuit of the pricing of such services as those of bridges, Marshall's discussion of the case for the subsidization of diminishing average cost industries, and the questioning by Hotelling of the pricing of products such as railway services by the principle that 'each tub should stand on its own bottom'. For present purposes, it is enough to point out that one attempt to solve the central dilemma, identified as the need to relate price to marginal cost but yet meet all relevant opportunity costs, has been the use of multi-part pricing (a) 'standard charge' to meet overhead costs, and a 'per unit' payment (price) related to volume of consumption). Peak-load pricing can be seen as a further refinement of this line of thought, in that it seeks to relate prices to variations in the opportunity-cost situation of the producer at different points (e.g. time-periods) of consumption.

The second, distinct but clearly related historical development was the debate concerning collectivist economic planning. The question addressed in this debate is whether in a liberal collectivist economy (one in which capital is not privately owned but which is concerned to satisfy consumer choices), resources can be efficiently allocated between uses. The solution propounded is that the absence of a market in capital can be overcome by instructing all producers to equate marginal costs and prices, so replicating the outcome of perfectly competitive markets in a private capitalist economy. The theory of multipart and peak-load pricing can be seen as an extension of this specification of the optimum allocative conditions to the special circumstances of the specified industries, in which the 'competitive' solution is argued to be excluded by the technical conditions of production. It follows from this specification that the problem (and theory) has relevance irrespective of the means being adopted to allocate resources elsewhere in the economy. If the relevant technical conditions pertain, a separate 'solution' is needed whether or not competitive markets or other means are utilized to seek optimum allocative efficiency elsewhere.

The theory of peak-load pricing can be discussed in two related contexts: a narrow one concerned with the technical characteristics of the problem within the defining constraints explained above, and a much broader one concerned with the relation between this narrow specification and the wider questions raised by the theory of public utility pricing and collectivist economic planning. This in turn will provide the material for a concluding evaluation of the current state, policy-relevance, and political development of the theory of peak-load pricing.

It is of interest that the specialist literature concerned with peak-load pricing has come to be preoccupied with what are seen as essentially practical problems. Writers are concerned to develop the theory of marginal cost pricing in ways that will contribute to the specification of optimal tariff structures for the supply of actual products which are perceived to have) 'peakload' characteristics: there is a whole sub-literature, for example, concerned with electricity prices. A useful introduction to this 'narrow perspective' literature, providing also ample further references for the interested reader, is provided in a Symposium in *The Bell Journal of Economics* (1976). The introductory article by Joskow (1976) in this Symposium provides a useful taxonomic survey. He distinguishes three broad approaches, labelled 'somewhat artificially' the American, British and French. All three approaches find their intellectual heritage in the theory of public utility pricing, which is to say that the writers concerned would accept, as the hallmark of an 'efficient' pricing and investment structure, conformity with the 'optimum conditions of choice' of mainstream welfare economics (Joskow 1976, describes an) 'implicit social welfare function' in a fashion that exemplifies this). They are distinguishable rather by their emphasis and coverage, which in turn it is perhaps not too fanciful to relate to the typical form of national industrial organization: regulated private monopoly in the USA, nationalized industry in the UK, state enterprise within an indicative plan in France.

The American approach specifies an enterprise with homogeneous productive capacity. If the location and magnitude of the peak is not affected by the relative prices charged in peak and off-peak periods, then the efficient solution is a two- (or multi-) part tariff which separates capacity and operating costs and allocates the marginal opportunity-cost of capacity to peak users. That is, off-peak users pay marginal operating costs, but peak users also pay marginal capacity costs. This solution requires that the relevant physical capacity be not indivisible in the relevant respects.

If these conditions are not met (if demand at peak or off-peak is sensitive to relative prices: if the off-peak load utilizes plant to capacity when charged at short-run marginal cost), then a problem of 'shifting peaks' emerges, and the identification of the efficient tariff becomes much more complex. Detailed information is needed about both production costs and about the character and inter-relationships of period demand-functions. This information is the input requisite for a formal ('welfare-optimizing') solution which maximizes net benefits (total revenue plus consumers' surplus less opportunity costs) and needs further to be supplemented by the assumption (value judgement) that individual gains and losses can be weighted equally.

The British literature is concerned with a more sophisticated technology: it postulates a mix of units of physical capital with different investment and operating costs and maintenance requirements. The purpose is to determine the optimum utilization of the capital stock by identifying the long-run marginal costs relevant to the fixing of prices to meet a fixed set of consumer demands.

Peak and off-peak periods are determined by the variations in both demand and in the type of capacity available. The analysis is more sophisticated (and realistic) than the American in its handling of the technology of production, but less satisfactory in dealing with (or, rather, failing to incorporate) the problems of shifting peaks.

The French contribution comes largely from economists with industrial rather than university academic affiliations. This is very much in the Dupuit tradition, which in the present instance has given technically sophisticated economists considerable practical influence over electricity pricing and investment policy. This is reflected in a concern for operational relevance. The defining characteristic of their contribution is that it attempts to develop the American and British approaches in ways that facilitate the practical application of the constructs to the actual determination of electricity prices. Joskow (1976) identifies three important contributions.

First, they are concerned that demand may be uncertain as well as periodic, with the implication that (unforeseen) demand may exceed current capacity and/or standby capacity must be kept available. Second, any curtailment of supply because of uncertainty may itself impose costs on both the demand and the supply side, and these 'marginal curtailment costs' have to be seen as a further element in the determination of the efficient pricing-and-investment plan. Third, an efficient tariff structure must embrace all opportunity-costs incurred up to the point of consumption. This is no trivial matter: the question has traditionally been seen as concerned with the relation between a production supply technology and a variable consumption demand. But in the case of electricity, for example, the distribution system may account for around half of total costs. The pricing structure thus needs to integrate a centralized generation system with its related technological problems and diversities, and a dispersed distribution network directed to the satisfaction of the disaggregated consumption demands of individuals and small groups.

The literature under review is most satisfactory when it is concerned with what is essentially an 'engineering' problem, and becomes progressively less persuasive as we move from this restrictive context towards the requirements of a 'political economy' model bearing on economic (pricing) policy in the real world. Even at the restricted level, our survey suggests that there are significant outstanding problems to be solved: the complementary insights of the British and American approaches, for example, await integration in a common construct that can incorporate both technological diversity and shifting peaks. More important, the writers themselves recognize that the 'engineering' approach can be translated into pricing policy recommendations only if a solution can be found to related valuation problems which tend to be dealt with by essentially arbitrary assumptions. There is recourse to such concepts as consumer surplus and opportunity-costs, value judgements about the weighting of gains and losses, and so on, with little recognition of the essentially subjective nature of these concepts, and the difficulties that this creates for the translation of an objectively specified (engineering) formulation into a system of pricing rules/procedures. The French approach, with its emphasis on uncertainty, underlines these difficulties. How to write into a peak-load pricing model, for example, individual judgements as to the possibility that within the next decade someone will invent an efficient generator that can be housed in the family basement?

The contribution and limitations of the peak-load pricing literature can be most easily summarized by relating the description so far to the broader streams of thought referred to at the outset: those of public utility pricing and of collectivist economic planning. In respect of the former, the peak-load literature does nothing to resolve the fundamental logical problem that arises even within the welfare economics model of which that literature is a special part. That is that *all* scarce resources have opportunity-costs over an appropriate period of time; that is the implication of scarcity. If prices reflect all these opportunity costs, then the problem of conflict between average and marginal costs disappears: there will be as many (opportunity-cost) prices as there are relevant time-periods. If the price structure differs from this (which is the conclusion of the ‘orthodox’ analysis), then that is because some relevant opportunity-costs are being ignored. The) ‘deficit’ that this is argued to imply must be borne by someone, and the decision about how it ‘should’ be borne is effectively a policy (distributional) value judgement about which the economist *qua* economist can have nothing to say (Wiseman 1957). The peak-load pricing literature contributes nothing to the resolution of this prior problem.

An even more fundamental difficulty surfaces when the literature is placed in the broader, economy-wide context of the collectivist economic planning debate. Essentially, the liberal collectivist solution to the resource-allocation ‘problem’ consists in the replacement of the competitive search for profit in the capitalist economy by obedience to a ‘cost rule’ (‘make marginal cost equal to price’) in the collectivist one. What is identified as a characteristic of the *outcome* of the capitalist process becomes a rule of cost-behaviour in the collectivist one. For the cost-rule to be operationally plausible, it is necessary that the costs concerned should be objective, since otherwise the instruction to make marginal cost equal to price amounts simply to an exhortation to the decision-taker to choose the plan he believes ‘best’. Effectively, *any* pricing and investment decision could be made to appear consonant with such an instruction: and if the *content* of the marginal cost) ‘plan’ is specified for the manager, then the effective allocation decision is simply shifted to those who give the instructions, and their subjective evaluations then determine the content of) ‘marginal cost’.

In briefest summary of a complex literature, once it is recognized that the opportunity-costs that determine resource-allocations through time are the subjective evaluations of future possibilities of those who make the relevant decisions, there can be no ‘objective’ way to determine prices by reference to costs. The money outlays into which opportunity-costs are commonly translated must in a policy context be predicted future money outlays, and so must be someone’s opinion rather than have ‘objective’ or ‘scientific’ status (Wiseman 1983). If this is true of costs (and cost-rules) generally, it must be true equally of those particular costs that are the concern of the multi-part pricing literature.

The literature is not without interest or potential practical utility, provided that it is treated as no more than a particular input to the subjective opportunity-cost plans bearing on a special set of products. There are incidental recognitions of this, and it is clearly a plausible inference from the French development of the problem. But until there is an explicit recognition of the need to integrate the technological (‘engineering’) characteristics into a subjective opportunity cost framework, any claim that the literature enables the identification of economically or socially-efficient pricing structures must be treated with caution.

A peasant is someone who lives in the country and works on the land (the word derives from the French *paysan*). Taking this definition, the topic 'peasant economy' concerns the analysis of the economic decisions and interactions of peasants, their relations with other agents and the rest of the economy, the determinants of the general level and distribution of their economic welfare, and how their position might move over time or be affected by policy. As such it is very broad in scope, involving the study of the economic life of around half the world's population. The term 'peasant' is sometimes used in a somewhat narrower sense in economics to mean the small farmer (tenant or smallholder) as opposed to the agricultural labourer or very large landowner. The peasant economy would then be one where farming was conducted mainly by tenants and smallholders. Even under this narrower definition it is clear that vast numbers of individuals are included.

There are fundamental differences amongst economists in their views of the way in which the peasant economy functions and these underlie many of the strong disagreements over policy. The main sources of the differences concern views on the 'rationality' of economic behaviour by individuals, the competitiveness and efficiency of markets, the importance and implications of the distribution of power and wealth, and the role of institutions, cultures and beliefs. Whilst we cannot provide a detailed description of these general views we shall try to give a flavour of their diversity and focus on the basis of their differences. We shall then examine some specific issues and problems including the objectives of peasants and others in terms of profit, utility and attitudes to risk; labour markets; credit; sharecropping; and relationships between size of holding and productivity. Concentration will be on the literature since the Second World War, although many of the issues concerned and divided some of the outstanding economists of the 19th and early 20th century.

One of the most clearly stated and definite views places the peasant economy firmly within the standard competitive analysis; see for example Schultz (1964). Within the constraints of their knowledge, it is argued, participants in the peasant economy make the best use of the assets available to them. Each agent makes production, working and spending decisions to maximize utility or profit. This is essentially the notion of rationality in this context: individuals have preferences and act according to them. Markets for labour, land, credit, inputs and outputs, consumer purchases and so on function competitively and efficiently. The outcome for the usual reasons is therefore a Pareto efficient allocation. The role of policy is then to improve knowledge, increase assets and, if desired, to improve the distribution of income.

At another extreme we find the views of those such as Myrdal (1968), who believes that markets and prices play a minimal role. He argues that few people calculate in terms of costs and returns and that, even if they do, such calculations are not the primary determinants of their behaviour. Further, he argues that many transactions are not of the market type at all, and where markets do exist they are very far from perfect. He pleads for an institutional analysis of behaviour and the workings of the economy. Further, he suggests direct controls to implement policy; he calls these non-discretionary controls as opposed to the manipulation of prices, where individuals are left to take their own decisions.

Away from these extremes we have varying emphases on the role of rational behaviour, incentives and market structure. For example, Lewis (1955) regards institutions, legal structures and political and religious attitudes and practices as major determinants of the form of incentives. Thus he suggests that land reform may be a prerequisite to successful agricultural extension if, without it, farmers believe that others will reap the fruits of their improvements. Since the 1970s there has been substantial concentration on the forms of peasant arrangements for cultivation, the incentives which they give and the reasons for their selection. A central example (discussed briefly below) has been the study of sharecropping following the questions and analysis of Marshall in Chapter X, Book VI, of his *Principles of Economics*. In this context individuals are seen as rational but face problems of information and supervision in designing and implementing agreements for the use of land, labour and other inputs.

Marxist writers have emphasized property and power. For example, Bhaduri (1973) suggests that landlords manipulate indebtedness over their labourers and tenants to maintain a very tight hold over their freedom. He argues from his model that landlords have an incentive to block technical change and that progress requires expropriation.

These views are generalizations about the world and no single study could provide a conclusive test between them. An empirical judgement should be based on the accumulated experience of detailed studies. Here economists have not been as active as perhaps they should in conducting economic studies of peasant societies to examine how the theories they are discussing fare in the field (compare the many studies by anthropologists; see, for example, Srinivas 1960 and 1976, and Wiser and Wiser 1971). Nevertheless, many studies are available (see for example, Bailey 1957; Epstein 1962; Haswell 1975; Bell 1977; Bliss and Stern 1982, and for further references Binswanger and Rosenzweig 1984; see also the bibliographies of village studies prepared at the Institute of Development Studies, Sussex – Lambert 1976 and 1978). One should not perhaps expect a clear, single picture to emerge; people and societies vary considerably. However, it seems that neither of the simple descriptions of Myrdal and Schultz are remotely adequate as generalizations. The institutional structure and conventions concerning the disposition of land and labour (for example, the form of ownership and duties of owners, structure of tenancy agreements, restrictions on the obligations of labourers and so on) will be of considerable importance in determining cultivation decisions. Individuals vary greatly in their ability to make the most of their circumstances. Nevertheless, most of the studies point to strong economic responses and these are often rapid and subtle: the Myrdal picture is clearly unacceptable.

We comment briefly on some of the particular positive issues that have been prominent in theory and applied work. The objectives of peasants have been modelled in terms of profit and utility and in varying ways relative to uncertainty (for an early discussion see Chayanov 1925). Thus, for example, Hopper (1965) suggests that simple maximization of expected profit provided a good description of farming decisions in the village he studied in North India. This seems implausible in a poor society and for a risky activity, and a number of models of behaviour under uncertainty have been considered. These include the standard model of expected utility maximization and 'survival algorithms' where individuals attempt to minimize the probability of falling below 'disaster level'. The implications can be very different from simple profit maximization. Under expected utility maximization with risk aversion the expected value of the marginal product of an input would, in equilibrium, be above the price of the input (possibly well above) whereas with profit maximization we must have equality (see, for example, Bliss and Stern 1982).

Two central issues in discussion of the labour market have been, first, the relationship between wages and the marginal product of labour and, second, migration. On the former some appear to have argued that the marginal product is zero. This receives little empirical or theoretical support in that an extra hour of work in agriculture usually has some contribution to production. The question of whether the withdrawal of an extra person from agriculture reduces output and by how much depends on the response to the departure by others. Whilst the marginal product of an hour or day is unlikely to be zero, it is quite possible that it may be less than the wage in the case of family labour where there are perceived costs in working for others or of hiring labour (see for example Sen 1975).

Migration decisions have been examined extensively, both in theory and practice, in terms of expected differences in net incomes or utility from making a move. Of particular influence was the paper by Todaro (1969) in which he proposed a model where the probability of employment in the town was equal to the number of jobs divided by the number of seekers. If rural and urban wages and urban employment are fixed, the number of seekers adjusts to make, in equilibrium, the expected urban wage equal to the rural wage. If we associate the job seekers with the employed plus the unemployed then this is a theory of urban unemployment with the striking implication that an increase in the number of urban jobs increases unemployment. The model has been extended, elaborated and tested by many authors (see, in particular, Fields 1975; Sabot 1982; Todaro 1976).

The role of credit, for example, the much easier access and cheaper rates available to the richer farmers (Griffin 1974) and its use in manipulation and control (Bhaduri 1973) have been major issues. It is an area where data are particularly difficult to collect and good empirical studies are rare (a notable exception in the context of fishing is Platteau et al. 1985).

Share-cropping was discussed carefully by Marshall in his *Principles*. Following the book by Cheung (1969), it has become a popular issue in recent research. Cheung contrasted his view of sharecropping as an efficient arrangement (with the tenancy contract clearly defined to stipulate inputs) with that of Marshall, who had pointed to the possibility that the tenant who receives half the output may not push the level of an input as far as someone who receives the full amount of the marginal product. Many of Cheung's arguments were, however, anticipated by Marshall in his account which contains a description of how the landlord might try to enforce higher input levels. More recently attention has been focused on sharecropping as a means of sharing risk between landlord and tenant and as providing incentives for the tenant which would not be present under simple wage labour (see Binswanger and Rosenzweig 1984, for references).

The proposition that larger holdings may have lower output per acre has been the subject of much theoretical and empirical discussion. In Indian studies it receives more support for comparisons across districts than within villages. Possible reasons for the phenomenon, where it occurs, include more labour input per acre on smaller family plots (where labour may be applied beyond the point where the marginal product is equal to the wage) and faster population growth (and thus greater subdivision of holdings) on fertile land. For further discussion, see Sen (1975).

On the policy side some of the major issues have been land reform, the dissemination of technical change, the pricing of output and the supply and pricing of crucial inputs such as water, fertilizer and draught power. We shall be very brief since our main emphasis has been on the functioning of the peasant economy. Land reform in the sense of redistribution has been very difficult to achieve, in part because many of those who have it will make great efforts to resist losing it. It has sometimes been argued that the (supposed) inverse relationship between size of holding and land productivity will imply that a more egalitarian distribution of land will yield higher total output. Agricultural extension has long been seen as part of government policy, but it has become particularly prominent with the arrival of the newer varieties of seeds (the so-called 'Green Revolution') which are particularly responsive to water and fertilizers. Of special concern has been the differential impact of the advances on different groups in the population and how the changes might be influenced to provide greater benefits to the poor.

The relative price of food and the implicit or explicit taxation of peasants have been seen as critical aspects of the availability of food (and its price) to the rest of the economy as well as influencing growth within and outside peasant agriculture. Much turns on the assumed elasticity of response. A further important feature of government policy concerns the pricing and supply of inputs. The effects on agricultural production and on the welfare of peasants and labourers can be substantial, the most obvious example being irrigation.

The study of the peasant economy is a subject for which careful economic theorizing is critical since transactions can have special structures, uncertainty will be central, and economic relations will be strongly influenced by institutional arrangements. And those theories should be tested against, and arise from, detailed empirical observation since the successful application of the theories turns on which of the structures are relevant for the particular peasant economy under examination.

Peasants

Keijiro Otsuka

Abstract

While traditionally peasants are regarded as subsistence-oriented, full-time, and small-scale farmers, many small-farmers are part-time farmers engaged in both cash-and food-crop farming and non-farm jobs. Therefore, peasants may be defined as small-scale, family based farmers, including both owner cultivators and tenants. A major question is whether the peasant mode of production is socially efficient. Because of the absence of scale economies, the advantage of risk sharing under share tenancy contracts, and the inefficiency of agricultural labour contracts due to the difficulty of supervision, small-scale family based farming system, including share tenancy, is a socially efficient system in low-wage economies.

Defining who 'peasants' are is not an easy task for social scientists interested in rural economies and their transformation over time. The traditional image of peasants may be small-scale, full-time farmers, who have some access to land, depend largely on family labour, and produce food primarily for home consumption. The main characteristics of peasants, however, have changed over time in the process of economic development that has accompanied the penetration of markets into rural areas. Many of them are part-time farmers engaged in both farming and non-farm jobs, and produce cash crops in addition to food crops. Yet family farms continue to dominate throughout the world, contrary to the traditional view that they are remnants of feudal society and are bound to disappear as modernization proceeds (Hayami 1996). Therefore, in order for the concept of peasants to be relevant to the present world, it seems sensible to define peasants simply as small-scale, family based farmers.

Thus, we exclude agricultural labourers dependent on wage employment, and 'capitalist' farmers, large landlords, and plantation owners who operate large farms using hired labour. The major categories of peasants are owner-cultivators and tenants, and tenants can be further classified into leaseholders (or fixed-rent tenants) and share tenants (or sharecroppers). Commonly these peasants are managers of farms, engaged in multiple farm tasks such as land preparation, fertilizer application, and the supervision of wage workers hired for simple tasks such as weeding and harvesting. Tenants are subject to terms of contracts, which are often unwritten and implicit such as the careful maintenance of irrigation facilities and diligent work on assigned tasks. Being small-scale, efficient farm production for food security is a major concern in a peasant society.

We also regard small cultivators in customary land tenure areas as peasants, even though they are neither owner-cultivators nor tenants. These cultivators have the use right on land as long as they continue to cultivate it, but typically they do not possess ownership rights. Thus, for example, once land is put into fallow, the cultivator tends to lose the use right. The future use of land, as well as the inheritance of land use rights, is determined by the leader of the extended family or the village chief. Such insecurity of tenure arising from the uncertain access to land in future may reduce incentives to invest in the long-term improvement of land, because those who invest may not be able to reap the benefits in the future. Although it may appear that the same argument applies to tenancy contracts, so long as the landowner has the right to terminate the contract, it is landowners, but not tenants, who make long-term investment decisions in the case of tenancy. Thus, whether the tenure insecurity results in underinvestment in land improvement is a major empirical question particularly relevant to customary land tenure areas (Besley 1995). A critical question in the study of customary tenure institutions is whether efforts to invest in land – for example, tree planting and terracing – confer strong individualized land rights *ex post,* so as to provide proper incentives to invest *ex ante* (Otsuka and Place 2001).

Peasant farms are small because scale economies are absent under the prevailing labour-intensive farming systems, which are characterized neither by indivisibility caused by large-scale mechanization nor by the specialization and division of labour among farm workers. Thus, the optimum farm size is likely to be small. In Asia, the average size of rice-growing farm households seldom exceeds two hectares, and it can be as low as 0.5 hectares in Java, Bangladesh, and China (David and Otsuka 1994). Extremely large farms, including haciendas, plantations, and estates, were created by force by colonial governments, not by market forces. Once they are created, however, they tend to persist, even though their sizes exceed the optimum, primarily because the land sales market does not function due to imperfect credit markets (Binswanger and Rosenzweig 1986). The inverse correlation between farm size and productivity, often measured by yield per hectare, is widely observed in South Asia, which indicates the existence of scale diseconomies (Otsuka 2007). Such scale diseconomies are likely to arise from the difficulty faced by large farmers in supervising hired workers in spatially wide and ecologically diverse farm production environments.

It is widely believed that peasants are poor but efficient in resource allocation – the ‘efficient but poor’ hypothesis of Schultz (1964), which argues that investments in human capital and the dissemination of new technologies are the keys to improving their livelihood. A major challenge to the Schultz thesis is the so-called Marshallian inefficiency of share tenancy. According to this theory, a share tenant does not work as hard as an owner-cultivator or a leasehold tenant, because he receives only a fraction of the value of the marginal product of labour. Inexplicably, output sharing rate under share tenancy is fifty–fifty not only historically in France, Italy and the antebellum South in 19th century United States, but also in many contemporary developing countries (Hayami and Otsuka 1993). If sharing rate is not fifty–fifty it is two-thirds for the tenant and one-third for the landlord almost without exception. It is argued by the advocates of the Marshallian thesis that output-sharing is like the imposition of proportional income tax on a tenant, which discourages him from working hard. For this reason, share tenancy is prohibited by land reform laws in a number of countries in Asia.

It must be pointed out that Marshall himself (1890) did not necessarily support the Marshallian thesis: he pointed out the major shortcomings of this argument in a footnote, which was later elaborated upon by Johnson (1951) and Cheung (1969). The main point is that both the landlord and the tenant can be made better off by adopting a fixed-rent contract, which does not distort work incentives as the tenant receives the entire marginal product of labour, and then by sharing the larger ‘pie’ between the two parties. Marshall argued that, if the work effort of the share tenant can be monitored costlessly by the landlord, the share tenant will be forced to work as hard as a fixed-rent tenant. The implication is that share tenants tend to shirk unless they are effectively monitored or provided extra incentives to work harder. It is also generally agreed that, despite such problems, share tenancy is prevalent because of the risk sharing advantage; the production risk is shared between share tenants and landlords, unlike with fixed-rent contracts in which all the risk is shouldered by the tenants. This argument is plausible considering the absence of insurance markets and the existence of substantial production risk in poor agrarian communities.

Because of the existence of monitoring costs, share tenancy is inefficient in the literal sense of the word. One may argue, however, that since we cannot avoid monitoring costs in the real world, it is misleading to argue that share tenancy is inefficient; it is ‘second-best’ efficient, even if a tenant shirks. Unlike other areas of contract studies, there have been a huge number of empirical studies comparing yields per hectare between share tenancy and owner-cultivation or fixed-rent tenancy. According to a summary of earlier empirical studies by Hayami and Otsuka (1993) and a number of subsequent empirical studies, the difference in yield is found to be generally insignificant, suggesting that resource allocation under share tenancy is not significantly different from the ‘first-best’ efficiency. It is true that the differences in land and labour qualities are not properly controlled for in some studies, so that their yield comparisons are not as rigorous as they ought to be. However, since there is no reason to believe that share tenants are endowed with greater human capital and cultivate higher-quality land, the empirical evidence can be taken to imply that share tenancy is efficient, or at least not as inefficient as the Marshallian thesis assumes.

Hayami and Otsuka (1993) argue that significant shirking by share tenants is prevented by multifaceted, enduring personal relationships between tenants and landlords and the community mechanism of contract enforcement. More often than not, the landlord selects the share tenant, who is deeply related by kinship or community ties. Therefore, if the dishonest behaviours of a tenant are detected, he will be penalized not only by the termination of the share contract but also by the discontinuation of multifaceted personal relationships. Furthermore, he will not be able to find other landlords in the same community who are willing to offer new share contracts because of the loss of reputation as an honest and hard-working tenant. In this way shirking is prevented, which supports the Schultz thesis.

The above argument implies that if the share contract is deemed to be short term – for example, one season or one year – the share tenant is likely to shirk because, regardless of whether he shirks or not, the contract will be terminated at the end of the cropping season. Indeed, according to Hayami and Otsuka (1993), significantly lower crop yields under share tenancy are typically found in India, where large landlords rotate share tenants season after season in order to avoid the implementation of the 'land-to-the-tiller program', which attempts to transfer land to the tenant. Since the presumption of the land-to-the-tiller program is that there is a single tenant on each piece of land, its implementation becomes difficult if there are many tenants.

If share tenancy is not significantly inefficient, we should not observe the inverse correlation between farm size and productivity, because larger and less productive farmers can gain by renting out a part of their lands to smaller and more productive share tenants. Indeed, in general, the inverse correlation is seldom found in South-east Asia, where tenancy markets are generally active, whereas it is often observed in South Asia where tenancy markets tend to be suppressed or discouraged by land reform laws (Otsuka 2007).

In theory, it is considered that a fixed-rent contract will be chosen only if the tenant is risk neutral, because it provides proper work incentives to tenants who are willing to assume production risks. It is, however, highly unlikely that tenants, who are often landless and poor, do not care about the production and income risks. Although rigorous analysis is required, casual observation as well as a brief literature survey suggest that fixed-rent tenancy is more common than share tenancy in sub-Saharan Africa, unlike Asia where share tenancy is dominant. Since African farmers are poorer, it seems unreasonable to assume the risk neutrality of fixed-rent tenant farmers in sub-Saharan Africa. Indeed, they grow multiple crops presumably to diversify the production risks. One missing factor that possibly affects the contract choice is the cost of metering output under share tenancy. Since a share tenant has an incentive to under-report the amount of output to increase his share of income, the landlord must be able to meter the output effectively in order to prevent the tenant's cheating. In the case of rice farming in Asia, either the landlord himself watches the harvesting or he sends some dependable person, like his son, to the field on the designated harvesting days. The cost of watching the harvest will be high for absentee landlords and widows who have no farming experience. This is one of the reasons why such landowners usually offer fixed-rent contracts.

The importance of the cost of metering output in contract choice is illustrated by the case of the share contract of cocoa farming in Ghana, whose harvesting season lasts for more than a few months; instead of sharing output, the tenant and the landlord share the ownership of the land after the tenant finishes planting the cocoa trees (Otsuka and Place 2001). One plausible hypothesis is that a precondition for share tenancy to be adopted is a short harvesting season, so that the cost of measuring output for the landlord is reasonably low. This hypothesis may explain why share tenancy is common in Asia, where rice and wheat are the major crops, whereas fixed-rent contracts are common in sub-Saharan Africa where maize, cassava, and other food crops which are harvested for prolonged periods are the major crops. Interestingly enough, in Ethiopia, where wheat, barley, and teff (a uniquely grain grown in this country alone) are the major crops, share tenancy is common (Benin et al. 2005). It is, however, fair to say that how crop choice and contract choice are related is an important empirical question to be investigated further.

As the population pressure on limited land resources increases in developing countries, land becomes scarce and tenancy becomes important in achieving the efficient allocation of land among farm households by transferring cultivation rights from land-rich to land-poor households. Also becoming increasingly important are non-farm jobs, as small-scale farming subject to seasonality cannot ensure a decent living standard. Thus, the development of the rural non-farm economy is the norm rather than the exception throughout developing countries (Haggblade et al. 2006), in which members of small-scale family farms are engaged not only in food production but also the production of cash crops and, more importantly, in non-farm jobs (Bliss and Stern 1982; David and Otsuka 1994; Hayami and Kikuchi 2000; Quisumbing et al. 2004). Thus, the conventional characterization of peasants as self-sufficient food production units as envisaged by Chayanov (1966) is no longer valid.

This does not imply, however, that markets work competitively in rural economies, so that rural households allocate labour time among food production, cash crop production, and non-farm activities, purchase all factors of production freely so as to maximize profits, and purchase goods and services so as to maximize utility. This separability of production and consumption decisions does not hold if markets are imperfect (Singh et al. 1986). Therefore, in a Chayanovian world, production and consumption decisions must be made simultaneously.

Although many commodities and factors of production can be purchased and sold at competitive markets, there are also serious market failures. First of all, insurance markets fail to develop, as bad harvests negatively affect the income of all farmers in the locality (Binswanger and Rosenzweig 1986). Second, credit markets tend to be imperfect primarily because of the lack of collateral, except for owner-cultivators who can use land as collateral. Third, labour markets, in general, do not function efficiently because of the difficulty in labour supervision. Thus, the labour market is typically thin or hired labour is employed only for such simple tasks as weeding and harvesting, activities which can be monitored easily (Hayami and Otsuka 1993). If hired labour is employed for tasks which require care and judgment, such as water management, land preparation, and fertilizer application, the farm operation becomes inefficient. This is likely to be the main reason for the inverse correlation between farm size and productivity, in view of the fact that the suppression of land tenancy transactions forces large farmers to employ seasonal labour, often called ‘permanent’ labour, for tasks requiring care and judgement in South Asia.

If the labour market fails, the response of peasants to new marketing opportunities and new technologies can become sluggish or even perverse (de Janvry et al. 1991). For example, when the price of cash crops increases, their supply may not increase much, because farmers must depend solely on family labour without employing additional hired labour, which ought to be available at constant wage rates in the presence of a competitive labour market. Similarly, technological change in the food sector may not lead to large increases in the market supply of food if labour markets fail and food markets do not function effectively.

In view of the increasing involvement of peasants in market transactions, it is critically important to strengthen the efficiency of marketing sectors through investing in roads, communication facilities, and marketing information, such as the establishment of quality standards for farm products, in order to improve their well-being. According to Hayami (1996), peasant entrepreneurs significantly contributed to the development of rural commerce and industries in the process of economic development in East Asia.

It must be emphasized that, given the difficulty in labour supervision, we can hardly expect the farm labour markets to function efficiently. In all likelihood, it is more realistic to promote efficient tenancy transactions, be it share or fixed-rent tenancy, if we hope to develop peasant sectors in the rapidly globalizing world where markets penetrate increasingly into rural areas. Efficient tenancy markets will increase the responsiveness of peasant sectors to new market and technological opportunities by facilitating the reallocation of land from households endowed with meagre family labour relative to land to those with an abundant supply of family labour.

The importance of tenancy transactions will continue to increase as an economy develops further. An efficient farm size expands with an increase in the wage rate, which makes it profitable to introduce large-scale mechanization to save labour. The traditional peasant mode of labour-intensive production on small farms, therefore, will no longer be sustainable in high-wage economies. Because of the scale economies associated with large-scale mechanization, viable farmers accumulate large cultivation areas through land tenancy. The practical question is at what farm size we can legitimately claim that farmers are no longer peasants. Although a clear and unanimously acceptable answer can hardly be given, I would like to propose that the issue of peasants ceases to be relevant when the issue of food insecurity associated with small farm size is resolved through farm size expansion, as well as the development of efficient marketing systems and technological changes in food production.

Pecuniary and Non-pecuniary Economies

J. de V. Graaff

The term *pecuniary* economies is probably due to Viner (1931), who distinguished them from *technological* ones. It is the latter that are often referred to as *non-pecuniary* economies. It is helpful to start by distinguishing internal economies from those that are external to the firm, and to deal with them separately.

Economies *internal* to the firm may be classified as pecuniary or non-pecuniary without much difficulty. Both (unless offset by diseconomies) give rise to falling unit costs as output is expanded. The former result from the firm's being able to negotiate lower prices for inputs bought in quantity; the latter from fuller utilization of 'lumpy' inputs such as buildings, machines and the services of specialists. In short, pecuniary internal economies have to do with factor prices; non-pecuniary ones with indivisibilities.

Economies *external* to the firm may also be classified into pecuniary and non-pecuniary (or technological), but there is scant connection with the previous definitions and some doubt as to the appropriateness of the nomenclature. In what follows we take the non-pecuniary ones first, as they give fewer difficulties; and use *economies* in a sense wide enough to include *diseconomies*.

Non-pecuniary external economies exist when there is technological interdependence between firms in the sense that it is not possible to specify one firm's production function without knowing at least one of the inputs or outputs of another firm. There are numerous wellworn examples in the literature, and many more in actual life. Among them are: (i) two wells on a single oilfield, the yield of the one depending on the rate at which the other is pumped; (ii) effluent from a pulp mill, increasing the purification costs of a brewer drawing downstream water; and (iii) a heavier crop of fruit in an orchard, resulting from better pollination by bees from a neighbour's apiary.

These examples illustrate some of the many sorts of technological inter-relationships that are possible between firms. All of them represent non-pecuniary external economies and (if, as in the examples, they operate at the margin) will produce divergences between marginal private and marginal social costs. These divergences give rise to certain problems in connection with the optimal working of the market mechanism that can be resolved by merger, by negotiation (if transactions costs are not too high) or by other measures such as taxes and subsidies.

Pecuniary external economies comprise the last of the four categories. They have been defined differently by different writers but are in essence what Marshall had in mind when he described external economies (he did *not* use the word) 'pecuniary') as 'those dependent on the general development of the industry' (1920, p. 266) or on 'advances made by subsidiary industries' (1920, p. 614). The examples that used to be given include the development of transport and telephone services, the growth of a skilled labour supply and such unlikely oddities as the appearance of a trade journal. Typically, they operate through time rather than in a framework of static equilibrium.

Viner (1931) made an attempt at formalizing the definition. For him pecuniary external economies exist when decreasing unit costs for a firm result from reductions in the prices paid by it for its factors of production when the industry of which it is a part grows as a whole. Most of these price reductions would presumably be due to internal economies in other firms; but Viner also has the rather fanciful illustration of labourers having a preference for working in an important rather than a minor industry and therefore being willing to accept a lower wage as their chosen one expands. Nevertheless, his definition gets close to Marshall's original idea.

Scitovsky (1954) makes his definition turn on profits rather than prices. Pecuniary external economies exist for him when a firm's profits depend 'not only on its own output and factor inputs but also on the output and factor inputs of other firms'. No treatment in terms of profits can exclude price changes, so the two definitions are not necessarily incompatible, although Scitovsky's is much wider. It is indeed so wide that it includes *non*-pecuniary external economies. It also includes all the aspects of mutual interdependence through the price system that are normally treated in General Equilibrium studies. There is very little that is left out. One is left wondering why one should be asked to call almost everything an external economy.

A possible reason is that the concept of pecuniary external economies has found its chief use in the field of economic development. There one is not dealing with equilibrium studies but with the growth of a whole economy over a broad front. It is difficult for private entrepreneurs to get sufficient information to coordinate their investment plans from current market prices. What they really would need would be a complete set of forward markets in 'future' goods through which the mutual interdependence of the various projects could find expression. In the absence of such markets there is a case for some form of central planning. The recognition of a need for planning is often regarded as an admission of market failure. But external economies of the technological kind are known to lead to market failure. So let us call both causes of failure by the same name: external economies.

That seems to be how the terminology has developed. Clarity would be served by reversing the process and speaking instead of technological interdependence (of production functions) on the one hand, and market interdependence (via the price system) on the other.

Pecuniary Versus Non-pecuniary Penalties

Dan Kahan

Abstract

'Pecuniary' penalties (fines) seem underutilized relative to 'non-pecuniary' penalties such as imprisonment, since they are ceteris paribus cheaper for society to impose. But the public preference for imprisonment over fines might reflect the value that the public attaches to the condemnatory meaning that imprisonment, unlike fines, conveys. An economic theory of punishment should include this sensibility in the social welfare calculus used to appraise the efficiency of various forms of punishment. The expressive utility of imprisonment might more than offset the higher cost of imprisoning offenders who could just as effectively be deterred by fines.

The topic of 'pecuniary' and 'non-pecuniary' penalties involves a distinction easily grasped but also a puzzle not easily solved. The distinction is between fines and all other types of criminal punishments, most conspicuously imprisonment. The puzzle arises from the seeming underutilization of pecuniary penalties, especially relative to imprisonment, in the American criminal justice system.

An economic theory of law furnishes a straightforward case for the use of pecuniary penalties. From an economic point of view, it is assumed that an individual will refrain from criminality when the expected cost of lawbreaking exceeds the expected gains (Bentham 1843). The law can raise the expected cost by divesting offenders of either their liberty or their monetary assets. Depriving them of the latter, however, is much cheaper for society: whereas imprisonment demands an immense expenditure of resources, fining involves a transfer of wealth from offenders to the state. Accordingly, whenever a fine of a particular size and a prison term of a particular length would impose equivalent disutility on offenders, the state, in the interest of efficiency, should select the fine (Becker 1968).

But as cogent as it might be, this economic defence of pecuniary penalties has had strikingly little influence on the law. Non-violent offenders, who could be fined rather than imprisoned consistent with public safety, make up over half the American prison population. Many of these non-violent offenders are likely to be poor and thus effectively immune to the threat of massive fines (Shavell 1985). However, the possibility of 'day fines' – a procedure, common in Europe, whereby fines are meted out over time based on ability to pay – would make stiff penalties feasible even for offenders of relatively modest means. Based on these considerations, there is widespread expert consensus that American jurisdictions rely far too heavily on imprisonment relative to pecuniary penalties, particularly for white-collar offenders, who are obviously the least violent and the most credibly threatened with large fines (Morris and Tonry 1990; Posner 1980).

Confronted with this tension between theory and practice, one might be tempted to shrug one's shoulders at the seeming economic irrationality of the law and move on. But before doing so, it is worth considering whether the relative underutilization of pecuniary penalties might itself be explained in economic terms – ones that the conventional defence of pecuniary penalties overlooks.

Perhaps surprisingly, the key to a more complete economic analysis is rooted in a distinction that sociologists and philosophers draw based on the *social meanings* that legal impositions convey. 'Prices', on this account, refer to pecuniary exactions that connote an intention to levy a tax on an activity that society views as morally permissible; 'sanctions', in contrast, connote punishments that the state imposes on activities that are morally forbidden (Cooter 1984). Criminal fines, particularly for offences that seem to involve a serious flouting of societal norms, often strike members of the public, dissonantly, as mere 'prices'. Imprisonment, in contrast, unambiguously registers as a 'sanction'; by virtue of the veneration of individual liberty in American society, taking a person's liberty away conveys a highly condemnatory intent on the part of the law (Kahan 1996).

Is there any reason, economically speaking, to prefer sanctions to prices? Perhaps. Again, from an economic point of view, a person will refrain from criminality when the expected cost exceeds the expected gain. If that is correct, then the law can discourage criminality not just by increasing an offender's estimation of the costs but also by diminishing his or her valuation of the gains associated with lawbreaking. It is often argued, in fact, that the law plays a vital role in inculcating preferences that conduce to law-abiding behaviour (Andenaes 1966; Dau-Schmidt 1990).

On this account, one economic defence of imprisonment in preference to fines would be that sanctions are more effective than mere prices in instilling law-abiding preferences. Imposing a sanction, such as imprisonment, on an act would impart information – that the act is morally frowned upon – whereas a mere price, such as a fine, would not. On the assumption that individuals adapt their values to those expressed in law, the threat of imprisonment would in these circumstances more effectively suppress a potential offender's estimation of the gain associated with a particular criminal act than would the threat of a fine. If this characteristic of imprisonment is sufficiently pronounced, it might result in behavioural effects that more than compensate for the additional cost of imprisonment (Kahan 1997).

But such an argument is speculative. There is some empirical evidence that the perceived justice of legal outcomes and procedures influences persons' disposition to obey (Tyler 1990; Nadler 2005), but none to show that the form of punishment (abstracted from its severity) does.

In addition, the claim that the law prefers imprisonment to fines because of its superior preference-shaping effect has a 'just so' quality. Aside from the implicit and by now largely rejected assumption that the law tends naturally toward efficiency, the preference-shaping defence offers no explanation of how this supposed feature of imprisonment figures in the political economy of punishment selection. Accordingly, this argument does not offer a particularly satisfying solution to the puzzle of why American jurisdictions so decidedly favour pecuniary over non-pecuniary penalties.

The real contribution the 'price-sanction' distinction makes to solving this puzzle consists in its power to illuminate an otherwise obscure element of the public demand for punishment. Criminal punishments, that distinction reminds us, do more than protect society from harm; they also evince a societal attitude towards criminal wrongdoers. The preference for imprisonment over fines, then, might reflect the immense value that the public attaches to the condemnatory meaning that sanctions, relative to mere prices, express.

This hypothesis finds ample empirical support. Some of it is experimental: even when fines are perceived as imposing levels of disutility comparable to particular terms of incarceration, members of the public reject fines as lacking the power to express moral condemnation (Marinos 1997). Analysis of the reasoning of legislators, judges, and ordinary citizens confirms that it is this sensibility that causes legal decision-makers to resist substituting fines for imprisonment as a punishment for white-collar offences and for other serious but non-violent common crimes (Kahan 1996).

The public demand for expressively satisfying punishments arguably helps to acquit imprisonment of the charge that it is less efficient than fines. Members of the public clearly value criminal punishment not only as a device for protecting them from harm but also as a ceremonial gesture for proclaiming the deviant status of those who violate societal norms (Garfinkel 1956). There is no reason, economically speaking, to exclude this sensibility from the social welfare calculus used to appraise the efficiency of various forms of punishment. If the value that members of society obtain from the expressive utility of imprisonment is sufficiently high, that species of well-being might more than offset the higher cost of imprisoning offenders who could just as effectively be deterred by fines (Kahan 1998).

Even more importantly, the contribution that the 'prices-sanctions' distinction makes to solving the puzzle of non-pecuniary penalties suggests insights into how, from an economic perspective, the law might be profitably reformed. Once the full dimensions of the social welfare function of punishment is discerned, it becomes clear that making law more efficient requires identifying relatively cheap punishments that, unlike fines, are comparable to imprisonment in *both* their expressive *and* their deterrent value. Because the expressive inadequacy of fines is also what constrains their political acceptability, expressively adequate alternatives to imprisonment also stand a much better chance than do fines of being adopted in the political process. These arguments have been used to defend the advent of *shaming* punishments – another non-pecuniary penalty – for white-collar criminals and other common offenders (Kahan and Posner 1999).

The desirability of shaming or any other non-pecuniary penalty is obviously open to debate, economically and otherwise. What should not be, however, is the proposition that the perfection of economic analyses of law depends on their cognizance of the full range of societal benefits, including expressive ones, that the law secures.

Pennington, James (1777–1862)

Murray Milgate

Keywords

Bank of England; Currency principle; Fullarton, John; Pennington, James; Tooke, Thomas

Pennington may be credited with having been among the first to produce a concise statement of the so-called currency principle which formed the basis of the thinking behind the Bank Charter Act of 1844. Pennington's proposal appeared in the form of a privately printed *Memorandum* issued in 1827. This tract actually contained two memoranda, separated by a reply to the first (of 1826) from Huskisson. Much of the material from the memoranda was subsequently reissued by Pennington himself in 1840 as part of his larger *Letter to Kirkman Finlay, Esq., on the Importation of Foreign Corn*. It seems likely that the first memorandum was written at the suggestion of Thomas Tooke.

Pennington's argument was that by bringing under the direct control of the Bank of England the entire note issue, and by restricting that issue to the amount of specie reserves of the central bank so that, as Pennington put it, 'in all cases paper would contract and expand according to the increase or diminution of its bullion', monetary stability would be ensured. The similarity between this proposition and the practices which were emerging in the Bank of England itself at roughly the same time is worth noting. The so-called 'Palmer rule' differed from Pennington's only in as much as that under its operation the monetary magnitude that was to be tied to the Bank's specie reserves included not only notes and coin but also deposits. However, unlike the Palmer rule, Pennington's proposal entailed control by the central bank over the independent note-issuing activities of the country banks.

Though Pennington's proposal did not gain much public notoriety at the time, by the early 1830s Pennington had become an occasional adviser to ministers of state and to government departments. By 1844, it would seem that Pennington was sufficiently close to the government to have been asked to assist in drafting the technical details of the Bank Charter Act. The evidence currently available, however, suggests that this assistance was requested after Peel had decided upon the main provisions of that Act.

It must be remembered that although an advocate of the currency principle, Pennington actually opposed the division of the Bank of England into separate Issue and Banking departments (as was done under the provisions of the Act of 1844). A note to this effect written by Pennington was appended by Tooke to the first volume of his *History of Prices*. The curious fact that the most famous opponent of the currency principle should have appended to his celebrated study a note by the originator of that principle, was used to humorous effect by some of Tooke's adversaries (in particular, Torrens) in subsequent controversy over the consistency of Tooke's arguments. There is a comment on this aspect of the debate by Fullarton in his *Regulation of Currencies* (1844; 2nd edn 1845, p. 191).

Pennington was born at Kendal on 23 February 1777, and died at Clapham Common on 23 March 1862. There is an admirable and thorough survey of Pennington's life and work written by R.S. Sayers to accompany his edition of Pennington's economic writings, in which can be found all of the tracts referred to above. It may be of anecdotal interest to record that Hayek has conjectured that Pennington's brother may have been the apothecary who attended Henry Thornton during his final illness in 1815 (1939, p. 33n).

Edith Penrose had a distinguished career in economics teaching, research and administration in the USA and the UK. From Johns Hopkins University she went to London University, where she became a professor; later she was Associate Dean of Research and Development at INSEAD in France. In administration she also rendered valuable service to the UK as chairman of the economics committee of the British Social Sciences Research Council. She retired in the mid-1980s.

In research, in the final part of her career, she concentrated on the oil industry and on multinational companies generally. Her place in the history of economic thought, however, lies in a single book *The Theory of the Growth of the Firm,* published in 1959. The review in *The Economic Journal* (1961) predicted that the book would prove one of the most influential books of the decade: this proved an understatement.

In Edith Penrose's conception, a firm is an administrative organization representing a collection of human and material resources for the purpose of producing goods and services for sale on the markets. It is essentially directed and controlled by its managers who will for various reasons be strongly motivated towards growth. The firm is not confined to any one product or market, but may diversify as its managers think fit. Profits, as seen by Penrose in her original book, were essentially a means to that end, a necessary condition for expansion.

There were, however, important administrative restraints on the rate of growth. Human resources required for *the management of change* (*growth*) were firm-specific and therefore, at any one moment, internally scarce. Expansion, however, included recruitment of additional high level human resources, that is, recruitment of additional growth-creating capacity. Therefore, subject to the dynamic constraint, there need be no ultimate limit on size. More generally, the relationship can be stated as a proposition that the *level* of current efficiency will, beyond a point, diminish with the rate of change of size: fast growth has a price.

The book was also rich in many associated and diverse ideas which cannot be set out in detail. The administrative 'Penrose effect' has been generally accepted and incorporated into a variety of micro-and macroeconomics, especially in the field known as 'the Corporate Economy'. The idea was most especially used in Robin Marris in *The Economic Theory of Managerial Capitalism* (1964) and by Hirofumi Uzawa in a significant contribution to macroeconomics a few years later (Uzawa 1969).

The total effect of Edith Penrose's work was that of destruction of the neoclassical model of the firm, followed by reconstruction. In the following years, however, despite the wide recognition the work received, classroom microeconomic theory, and also classroom industrial organization, often seemed to continue as if nothing had happened.

Pension Systems: Principles, Debates and Analytical Errors

Nicholas Barr

Abstract

Many countries face problems financing pensions in the face of population aging. There is controversy about the underlying economic theory, the extent of the problem and the best mix of policies to protect old-age security. This article sets out the economic analytics of pensions, discussing in turn their multidimensional nature, principles of analysis, the reasons why government gets involved, and debates and analytical errors. Those analytical errors matter, because they lead to policy errors. A central conclusion is that although there are sound principles of pension design, there is no single best pension system for all countries.

This article discusses the multidimensional nature of pensions, principles of analysis, the reasons why governments get involved, and debates and analytical errors.

A Multidimensional Set of Issues

Analysis of pension systems has to accommodate different ways of organising pensions, multiple objectives, multiple risks, different ways of relating contributions and benefits, and different ways of adjusting contributions and benefits over time.

Multiple Ways of Organising Pensions

Pensions can be fully funded, pay-as-you-go (PAYG), or partially funded.

Fully-funded pensions are paid from an accumulated fund built up over a period of years out of contributions by and/or for members. Funding is thus a method of accumulating financial assets, which are exchanged for goods at some later date.

PAYG pensions are paid out of current contributions. They are usually run by the state, on the basis that the state can, but does not have to, accumulate assets in anticipation of future pension claims, and can tax the working population to pay the pensions of the retired generation. From an economic viewpoint, a publicly organised PAYG system can be looked at in several ways. As an individual contributor, a worker's claim to a pension is based on legislation that, if she pays contributions now, she will receive a pension in the future. From an aggregate viewpoint, the state is taxing one group of individuals and transferring the revenues to another and, in that sense, the arrangement is little different from other income transfers.

Pensions can also be partially funded, either as part of their long-run design or because they can accommodate less-than-full funding to spread risk during times of adjustment.

Multiple Objectives

When retirement provisions were introduced in the nineteenth century, someone aged 65 was typically infirm and interfered with the productivity of younger workers. The purpose of pensions was to clear out unproductive older workers, so it made sense for retirement to be mandatory and complete. Over time, people have been living longer and countries have grown richer, making it possible to give people a period of leisure at the end of their working lives. Thus the purpose of retirement has changed: it is no longer simply a device for getting rid of dead wood, but a social construct for dividing the life cycle into working life and leisure. For this latter purpose, it is right to recognise that individuals vary widely in their preferences and circumstances. Many people do not want to retire fully as soon as they are allowed, because of the extra earnings, because of extra pension and/or because they continue to enjoy working. Pension design needs to recognise these new complexities.

From the viewpoint of individuals and families, income security in old age requires two sets of instruments: a mechanism for smoothing consumption, and a means of insurance:

- **Consumption smoothing:** a central purpose of retirement pensions is to enable a person to transfer consumption from her earnings in middle years to her retired years, allowing her to choose a better time path of consumption over working and retired life.
- **Insurance:** pensions can provide at least partial insurance against a range of risks. Annuities address the longevity risk. Individuals also face risks to future earnings during working life. These risks can be insured in part through unemployment and disability insurance, but they also have consequences for retirement, which pension systems can address at least partly through a redistributive element.

Public policy has objectives additional to improving consumption smoothing and insurance.

- **Poverty relief:** pension systems target resources on people who are poor on a lifetime basis, and are thus unable to save enough. As a practical matter, poverty relief also has to address transient poverty, either through programmes specifically for the elderly or through a wider programme for poverty relief. In some ways, the design of poverty relief for older people is simpler in that transfers to a group that has partly or wholly stopped paid work are less likely to weaken work incentives.
- **Redistribution:** lifetime redistribution can be achieved by paying pensions to low earners that are a higher percentage of their previous earnings. Since lifelong earnings are uncertain from the perspective of an individual, such a system provides some insurance against low earnings. There can also be redistribution towards families: for example paying a higher pension to a married couple than to a single person.

Pension systems can also redistribute across generations. This element has been common in the startup of PAYG pension systems, because people who worked before the system was created would otherwise have had no or low retirement incomes.

Alongside these primary objectives, pensions may have secondary goals, including economic growth or, less stringently, avoiding undercutting economic growth. There is debate about the relative weights accorded to old age security and to these secondary objectives.

Multiple Risks

It is helpful to distinguish different elements.

- Individual (or idiosyncratic) risk concerns the distribution of a given average risk across individuals, for example the risk that an airline will lose a person’s bags.
- Systemic risk (or common shocks) arise when the average risk changes; such risks affect all or

many individuals. Inflation, for example, affects everyone.

Some risks have both elements: a person aged 65 faces a probability distribution of remaining life expectancy (individual risk), but average remaining life expectancy can rise over time (systemic risk).

The risks facing an individual can loosely be divided into systemic risks, market risks and risks connected with individual behaviour.

- **Systemic risks.** Macroeconomic risk affects output, prices or both. Demographic risk arises through longer life expectancy and lower fertility. Political risks can arise even in well-governed countries.
- **Market risks** arise from systemic shocks, but also have idiosyncratic elements:
  - Earnings risk: a worker's earnings profile has deterministic elements (e.g. the decision to invest in human capital) and stochastic elements, relating to labour markets and health risks.
  - Investment risk: accumulations held in the stock market are vulnerable to market fluctuations. At its extreme, if a person with a fully funded individual account is obliged to retire on her 65th birthday, there is a lottery element in the value of her pension accumulation.
  - Annuities market risk: for a given accumulation, a person's annuity at a given age will be affected by the life expectancy of his birth cohort and the discount rate used by the annuity provider. Annuity providers can also fail.
- **Risks connected with individual behaviour**
- Principal risk arises through bad decisions by participants. As discussed below, poor choices can arise from imperfect information, and also for reasons which behavioural economics explains.
- Agency risk can arise through incompetent or fraudulent fund management. More importantly, managers in private systems may have different incentives from plan participants.

Many of these elements face policy makers not only with risk (where the probability distribution of outcomes can be estimated fairly precisely), but also with uncertainty, where the probability distribution of outcomes is not well known. Actuarial insurance can address risk, but faces problems with uncertainty.

Multiple Ways of Relating Contributions and Benefits

Whether funded or PAYG, a separate question is how closely pension benefits are related to a worker's previous contributions. Three approaches are common.

- **Defined-contribution (DC) plans.** In a pure defined-contribution system (i.e. one with no redistribution across individual accumulations), a person's consumption in retirement, given life expectancy and the rate of interest, is determined by the size of his or her lifetime pension accumulation.
- **Defined-benefit plans.** In a defined-benefit (DB) plan, a worker's pension is based not on his or her accumulation, but on the worker's wage history. The sponsor's contribution is conceptually the endogenous variable ensuring the system's financial balance.

Defined-benefit systems can be structured in different ways. A key design feature is the way in which wages enter the benefit formula. In a final salary system, pensions are based on a person's wage in his or her final year or final few years. Alternatively, the pension can be based on a person's wages over an extended period, including a whole career.

A second design feature is the rules which specify how the level of benefits changes when a worker delays claiming a pension. Such adjustments may or may not be actuarial. Third, defined-benefit systems can be run by the state or by employers.

- **Notional defined-contribution (NDC) plans.** This arrangement is conceptually similar to defined-contribution plans in that contributions are notionally 'accumulated' to determine a balance which is converted into an annuity at retirement, but different in that that they are not fully funded and may be almost entirely PAYG.

NDC plans parallel defined-contribution plans:

- A workers pays a contribution of *x*% of his or her earnings, which is credited to a notional individual account, that is, the state 'pretends' that there is an accumulation of financial assets, though in reality the account balance is for record keeping only.
- The cumulative contents of the account are credited with a notional interest rate, specified by legislation.
- At retirement, a person's notional accumulation is converted into an annuity, such that the present value of benefits (given the worker's age and the remaining life expectancy of his or her birth cohort) is equal to the value of the person's notional accumulation, using the notional interest rate as the discount rate.

Multiple Ways of Adjusting Contributions and Benefits Over Time

In the face of the risks outlined above, any pension system must adapt to actual developments over the medium term. Adjustment can be on the contributions side, on the benefit side, or both.

- **Increasing the income of the pension system.** Pensions can adjust through:
  - Higher savings by current workers (fully funded individual accounts) or higher contributions by today's workers (a less-than-fully funded definedbenefit system). Thus the extra revenue comes from today's working participants.
  - Higher contributions by the plan sponsor (a defined-benefit plan provided by a firm or industry). Depending on elasticities in labour, capital and product markets, the extra revenue can come from current workers (through effects on wage rates), shareholders and the taxpayer (through effects on profits), customers (through effects on prices) and/or past or future workers, if the company uses surpluses from some periods to boost pensions in others.
  - Higher contributions by insurance companies where retirees or plan sponsors have bought annuities. In that case, again depending on the relevant elasticities, the extra revenue comes from the insurance company's workers, shareholders or customers.
  - Higher contributions by today's taxpayers (a public pension). Thus the extra income comes from today's taxpayers and hence, through government borrowing, can also come from future taxpayers, allowing intergenerational risk sharing.
- **Reducing pension spending.** Total pension spending is the product of (a) the level of the average pension and (b) the number of pensioners. A major determinant of the latter is the earliest age at which a person can begin to draw pension. Policies to reduce pension spending can operate on either or both.
  - The monthly pension at a given eligibility age can be reduced in several ways. A lower rate of accrual during working life can be implemented through (a) a lower return to financial assets (a fully funded definedcontribution pension), or (b) a less generous legislated accrual rule. Lower pensions in payment can be implemented through less generous indexation of pensions in payment, or a reduction in pension.
  - An increase in earliest eligibility age affects workers but not retirees. With less-than-actuarial adjustment, total spending on pensions declines, e.g. a defined-benefit plan. With actuarial adjustment, there is no saving in total pension spending, but a given volume of spending can maintain a desired replacement rate (fully funded defined-contribution pensions or an NDC system). In this case, the purpose of an increase in eligibility age is to address adequacy rather than sustainability. In either case, rules are needed about how benefits increase where someone chooses to start benefit later than the earliest eligibility age.

Principles of Analysis

No Single Best Pension System

Pension systems have the multiple objectives noted earlier. The pursuit of those objectives faces a series of constraints, including fiscal capacity, institutional capacity and the empirical value of behavioural parameters, such as the responsiveness of labour supply to the design of the pension system, and the effect of pensions on private saving. A further constraint is the shape of the pre-transfer income distribution: a heavier lower tail increases the need for poverty relief. Countries also face political and historical constraints.

There is no single best system for all countries, because policy makers at different times and in different places will attach different relative weights to the different objectives and the pattern of constraints will differ across countries. If objectives differ and constraints differ, the optimum will generally differ.

Though there is no single best system, there are clear principles of analysis.

- **A holistic view.** Analysis should consider the pension system as a whole. Pensions have a wide range of effects, including on the labour market, saving, economic growth, the distribution of risk and the distribution of income, including effects by gender and generation. What is relevant for analysis is the combined effect of the system as a whole. Thus it is necessary to consider together the parts of the pension system that provide poverty relief and those where the primary focus is the pursuit of other objectives.
- **Second-best analysis.** Simple theory assumes that individuals make optimal choices and that labour markets, savings institutions and insurance markets function ideally. Those assumptions do not apply to pension systems. As discussed below, workers and pensioners face information problems, behavioural problems and missing markets, as well as factors broader than pensions, such as the inescapable existence of distortionary taxation.

  Framing the argument in second-best terms starts from the multiple objectives of pension systems. Thus policy has to optimise (not minimise or maximise) across a range of objectives, which cannot all be achieved fully at the same time. Policy has to seek the best balance between consumption smoothing, poverty relief and insurance, a balance that will depend in each society on the weights given to those and other objectives and to the different constraints that societies face.
- **Not just economics.** The optimal pension design depends not only on good economics, but also on good politics. The political economy question is how to reconcile the long-run objectives of pensions with short-run economic and political pressures. Different designs give governments more or less scope for adjusting the system; greater flexibility allows wider risk sharing, but can face the risk of government failure. Thus the choice of pension design will depend in part on the weight that policy makers give to wider risk sharing and in part on an empirical view of the quality of government in the country concerned.

  Alongside discussion of what design might be optimal is the equally important question of what is feasible. The greater a country's fiscal and institutional capacity the wider the range of feasible pension designs. Many reforms have come to grief not because of conceptual flaws, but because reformers were over-optimistic about economic circumstances or the ability to administer the new system effectively.

Why Does Government Get Involved?

To address Information and Behavioural Problems

The economics of information explains why the model of the well-informed consumer does not hold in many areas of social policy. There is considerable evidence of poor information about pensions. A survey revealed that 50% of Americans did not know the difference between a stock and a bond. Most people with an individual account do not understand the need to shift from equities to bonds as they age. And few people realise the significance of administrative charges for pensions. A system which offers wide choice is administratively costly: with an individual account, over a full career an annual management charge of 1% of the individual's accumulation reduces the accumulation (and hence the pension) by 20% (Barr and Diamond 2008, Box 9.4).

Recent lessons from behavioural economics also yield powerful lessons, explaining such phenomena as procrastination (people delay saving, do not save, or do not save enough), inertia (people stay where they are) and immobilisation (where conflicts and confusion lead people to behave passively, like a rabbit in a car headlight).

These bodies of theory suggest that in the context of pensions the benefits of wide choice are limited and, for most people likely to be outweighed by the costs of choice. These considerations suggest a series of guidelines for the design of individual accounts:

- Use automatic enrolment.
- Keep choices simple: for most people, highly constrained choice is a deliberate and welfare-enhancing feature of good pension design.
- Design a good default option for people who make no choice.
- Decouple account administration from fund management, with account administration centralised and fund management organised on a wholesale, competitive basis.

The US Thrift Savings Plan for federal civil servants (www.tsp.gov) complies with these criteria. The plan offers participants a limited choice of portfolios. In 2007 workers could choose from six funds, including a life-cycle option (i.e. an option in which a person's portfolio shifts automatically from mainly equities to mainly bonds as he or she ages). A government agency keeps centralised records. Fund management is on a wholesale basis. Investment in private sector assets is handled by private financial firms, which bid for the opportunity, and which manage the same portfolios in the voluntary private market, providing some insulation from political interference.

The plan (a) simplifies choice for workers, includes (b) automatic enrolment and (c) a default option, and (d) keeps administrative costs low, thus respecting information and behavioural constraints. The system of NEST pensions (www.nestpensions.org.uk) being introduced in the UK is a similar arrangement.

To address Missing Markets

A second role of government is to address missing markets. Two areas are particularly salient.

- **Indexed government bonds.** Efficient consumption smoothing allows workers to plan their future consumption. Thus workers need an instrument to provide a given real income in retirement. To achieve that, workers need to be able to protect themselves against inflation, particularly once the pension is in payment. However, inflation is a common shock, so that the private sector has problems providing risk-free protection against inflation. An important role for government is to provide indexed bonds that pensioners or pension funds can buy.
- **Annuities.** Both public and private projections tend consistently to underestimate increases in life expectancy. As a result, annuity providers make losses and either leave the market or price future annuities cautiously, giving pensioners poor value for money. One way to address the problem is for government to sell longevity bonds, allowing annuity providers to cover the risk that the average life expectancy of a cohort will exceed that which is predicted. In this arrangement, in (say) 2020, an insurance company would sell an annuity to an individual aged (say) 70 priced on official estimates of the remaining life expectancy of a 70-year old person in 2020, and insures against the cohort living longer than the 2020 projection by buying longevity bonds. If the cohort of annuitants lives longer than the 2020 projection the taxpayer finances the resulting extra cost through the longevity bonds. Thus the insurance company takes on the risk, the

taxpayer the uncertainty. This is a sensible division of labour. The role of government is to fill the missing market.

To Provide Poverty Relief

Though consumption smoothing and some forms of insurance can be provided by the private sector (e.g. fully funded individual accounts together with annuities), a pension system also needs to provide poverty relief. That element will require government involvement even in a system which is otherwise mainly private.

To Widen Options for Risk Sharing

Different pension designs and different forms of adjustment have different implications for the pattern of risk bearing.

In a pure fully funded defined-contribution system there is no redistribution across generations. Thus a cohort is constrained by its own past savings so that, in present-value terms, a representative individual gets out of a funded system no more than she has put in. Though annuities protect the individual against the risks associated with longevity, a pure defined-contribution system leaves her facing a wide range of risks associated with varying real rates of return to pension assets, the risks of future earnings trajectories and the future pricing of annuities. Thus risk falls entirely on the individual worker's future pension. It is possible to share risks more widely by adjusting current as well as future benefits, but in a fully funded system such risk sharing is only among current participants.

In a defined-benefit state system financed entirely from contributions, the risk of adverse outcomes falls on contributions, i.e. on current workers, and none of the risk directly on pensioners.

In a defined-benefit state system in which contributions can be supplemented by taxpayer support, the risk of adverse outcomes can be shared widely. The risk can fall on pensioners (e.g. by less generous indexation); on workers, through higher contributions; on current taxpayers; or (through government drawdown of past surpluses or increased borrowing) on past, present and/or future taxpayers.

In a pure defined-benefit system provided by a firm or industry, the risk of varying rates of return to pension assets falls on the employer, and hence, as discussed, on some combination of the industry's current workers, shareholders, customers and/or its past or future workers.

A major implication of any less-than-fully funded system, is that it relaxes the constraint that the benefits received by any generation must be matched by its own contributions. Thus, in sharp contrast with fully funded arrangements, a system with a PAYG element can redistribute across generations and can share risks across generations.

Debates and Analytical Errors

Debates

There is considerable controversy over the relative merits of PAYG and funded systems. There are debates about the right economic model; empirical magnitudes; the extent of a country's institutional capacity; the political economy of reform (for example, whether citizens regard their pension as safer based on a promise by government or as the owners of accounts); and ideology (for example about the role of the state).

The World Bank was a powerful advocate of funded systems in the 1990s and early 2000s, growing out of its influential publication *Averting the Old Age Crisis* (World Bank 1994). The book's many critics argue that its strength is in its diagnosis of the problems facing many pension systems, but its central weakness is that the book's analysis did not substantiate its central prescription – mandatory individual funded accounts. Although the debate continues, it can be argued that individual funded accounts have not stood the test of time, exemplified by countries which introduced individual funded accounts in the 1990s but did not follow through (China), or liquidated them (Argentina in the early 2000s, Hungary after the financial crisis of 2007) or partially liquidated them (Poland).

Proponents of individual funded account point to Chile, which has had the system since 1981. Barr and Diamond (2008) argue that Chile is a special case. It introduced funding at a time of budgetary surplus and over the years has displayed greater institutional capacity than countries at a similar level of development. The fact that Chile sustained the system does not mean that other countries will be able to do so. In addition, Chile came to recognise that individual accounts are not a complete pension system, but only part of one (the understated element being poverty relief) and set up a Presidential Commission (the Marcel Commission) which recommended a system of non-contributory pensions (introduced in 2008) to complement individual funded accounts. A further Presidential Commission was appointed in 2014 to consider reform of the system of individual accounts.

Analytical Errors

Discussion of pensions is prone to analytical errors.

Tunnel Vision

Analysis that focuses, often implicitly, on a single objective such as consumption smoothing may be flawed because it pays inadequate attention to other objectives such as poverty relief and gender balance. Similarly, it is generally mistaken to consider one part of the pension system in isolation, ignoring the effects of other parts. There is no efficiency gain from moving redistribution from one part of the system to another, even if the change leaves one part with no deviation from full actuarial principles.

Improper Use of First-Best Analysis

It is a mistake to focus on the labour market distortions caused by a given set of pension arrangements while ignoring or downplaying the contributions of those arrangements to the various goals of pension systems – contributions that are not available without distortions. A pension system that includes poverty relief will be distorting; minimising distortions implies minimising poverty relief – the cure is worse than the disease. Of course, pensions should be designed to avoid larger distortions than are justified by their contribution to goals, but minimising distortions is not the right objective.

Improper Use of Steady State Analysis

It is mistaken to focus on the design of a reformed pension system in a steady state while ignoring or underplaying the steps that are necessary to get to that steady state. This issue becomes especially important when considering whether or not to move from PAYG toward funded pensions. For example, US Social Security is less than fully funded because earlier cohorts were paid higher benefits than their contributions could have financed. The purpose of paying higher benefits was to raise the consumption of those cohorts after retirement.

If one does not include the value to earlier generations of this extra consumption, the analysis implicitly makes a long-run comparison; that is, it compares the economic situation in the USA today with what it would have been in an alternative long run with funded pensions. Thus the underlying question is: how does welfare in long-run state B differ from that in long-run state A? For a policy choice the appropriate analysis asks a different question: what are the welfare effects of moving from state A to state B? Either question is coherent. What is not legitimate is to take the answer to one question and apply it to the other.

Incomplete Analysis of Implicit Pension Debt

Some commentators point to the present value of all future promised pensions (a large figure) as being necessarily a problem. The analytical flaw in that approach is that it looks only at future liabilities (i.e. future pension payments) while ignoring explicit assets and the implicit asset of the government's ability to levy taxes. Too narrow a focus on costs also ignores the considerable improvement in people's wellbeing from increased old-age security. Just as public debt never needs to be fully paid off so long as the debt-to-GDP ratio does not get too large, so publicly provided pensions need not be fully funded, as long as the unfunded obligations are not excessive relative to the contributions base.

Incomplete Analysis of the Effects of Funding

This error appears in a number of guises. One example is to focus analysis purely on financial assets, ignoring the fact that what matters to pensioners is consumption. With the exception of housing, a pensioner's consumption in old age will depend on the output of goods and services produced by younger workers. PAYG and funding are both ways of organising claims on that output. It is therefore mistaken to focus excessively on how pensions are financed while ignoring future national output and its division between workers and pensioners. The error in this focus is its failure to recognise that the effects of funding on future output will depend on the answers to a series of questions, many of which are often addressed incompletely or ignored:

- Will funding pensions increase saving?
- Is increased saving the right objective?
- Will the regulatory changes that may (and generally should) accompany funding strengthen the performance of capital markets?
- If so, is it necessary for this purpose that pensions are mandatory?
- Are redistributive effects across generations from a move towards funding, discussed below, desirable policy?

Ignoring Distributional Effects

Because pension systems can redistribute across cohorts, it is necessary to consider who gains and who loses. It is a major error to ignore the fact that any choice between funding and PAYG *necessarily* makes choices about redistribution across generations. The point is most obvious if policymakers are establishing a brand new pension system. If they introduce a PAYG system, the first generation of retirees receives a pension, but returns to subsequent generations are lower; if they introduce a fully funded system, later generations benefit from higher returns, but the first generation receives little or no pension. Thus it is mistaken to present the gain to pensioners in later generations as a pure welfare gain, since it comes at the expense of the first generation. The same argument applies in a country that already has a PAYG system: a policy to move toward funding through higher contributions or lower benefits redistributes from current generations to future ones.

Whatever the merits of a move towards funding, the error in ignoring distributional effects is profound: it leads to mistaken claims for the superiority of some policies, and ignores the fact that a PAYG element in a pension system is generally welfare-enhancing because of the resulting possibility of intergenerational risk sharing.

These analytical errors matter: analytical errors lead to policy errors, many of which are identified in a World Bank evaluation of its own pensions work (World Bank 2006).

Disclaimer

The article draws heavily on writing with Peter Diamond (Barr and Diamond 2008, 2009, 2010). The responsibility for the views expressed and remaining errors is entirely mine.

Pensions

Zvi Bodie

Abstract

Pensions are benefit contracts that replace a person's earnings after she reaches old age and retires from the labour force. Pension systems vary widely across countries, but everywhere the government's role is to provide a minimum through a mix of cash and medical benefits. Governments often provide tax incentives for employers and unions to sponsor occupational pension plans that complement the government-run system. The nature of the pension benefits promised and the assets that back them have profound effects on social welfare, on the development of a country's domestic asset markets, and on the global financial system.

Pensions are retirement income contracts, and their manifest function is to replace a person's earnings after she reaches old age and retires from the labour force. Prior to the Industrial Revolution, the extended family was the primary institution that performed this function. Elderly family members lived and worked with offspring on a family-owned farm, and all drew a common livelihood from it. In many of today's less developed countries, this family-based pattern for old-age support still holds true.

Over time, urbanization and other fundamental economic and social changes gave rise to new institutional structures for the care and support of the elderly in much of the industrialized world. An often-used metaphor for describing developed countries' pension systems is that of the 'three-legged stool'. The first leg consists of government-provided old-age assistance and insurance programmes; the second leg is comprised of employer or labour union-provided pensions; and the third is individual and family support. There is substantial variation in the mix of the three sources of retirement income, both across households in a given country and across different countries (Bodie and Davis 2000).

Pensions should be analysed in the context of a life-cycle model of saving. In this framework, people save during their working years so that they can consume in their non-working retirement period. Some simplifying assumptions can quickly convey the essence of the life-cycle approach. Assume for the sake of illustration that an individual enters the labour force at age 20, works until retiring at age 65, and dies at age 80. His initial wealth is zero. During the working years, he earns constant real labour earnings, a portion of which is saved for retirement. The saving includes personal saving and the accrual of benefits under social security and employer-sponsored pension plans. We assume that the individual chooses to save an amount during the working years sufficient to make his level of real consumption after retirement equal to what it was before retirement. These savings earn a zero real rate of interest. At retirement, a constant real retirement benefit is paid, and at death there is nothing left over as a bequest.

These assumptions imply that the ratio of consumption to earnings must equal the ratio of years of work to total years of work and retirement:

$$\begin{aligned}&\text{Years of work} \times (\text{earnings} - \text{consumption})\\&= \text{years of retirement}\\&\times \text{consumption Years of work} \times \text{earnings}\\&= (\text{years of work} + \text{years of retirement})\\&\times \text{consumption}\end{aligned}$$

$$\frac{\text{Consumption}}{\text{Earnings}} = \frac{\text{years of work}}{\text{years of work} + \text{years of retirement}}$$

In this example, there are 45 years of work and 15 years of retirement, so the ratio of consumption to earnings is equal to 45/60 or 75 per cent, and the individual's 'gross saving' rate during his working years is 25 per cent. The benefits received during retirement come from three sources corresponding to the components of gross saving: social security, employer-provided pensions, and personal saving.

The Government's Role in Providing Retirement Income

The government's role in providing retirement income varies considerably across countries, but despite these variations there is a common theme: in virtually every country the government provides a 'floor' of income protection for the elderly, with the aged population's needs met by some mix of national insurance and national welfare systems, in the form of cash and medical insurance. This floor (or 'safety net') is usually mandatory and cannot be transferred.

Several economic arguments justify the government's provision of a layer of retirement benefits for everyone (Merton 1983). The first deals with *informational inefficiencies*. It is costly to acquire the knowledge necessary to prepare and carry out long-run plans for income provision. Although peoples' lifetime financial plans depend on their individual preferences and opportunities, their goals may be similar enough that a standard retirement savings plan can prove suitable to many. By providing a basic plan that supplies at least a minimum level of old-age support, the government is likely to help people save more efficiently than they could on their own.

The second argument revolves around *adverse selection* problems, There is considerable 'longevity risk' that people will outlive their retirement savings because their date of death is not known with certainty, in contrast to the simplified version of the life-cycle model we described earlier. One way to insure against the risk of exhausting one's savings during retirement is to purchase a life annuity contract. But the private market for life annuities suffers from adverse selection because people with a higher-than-average life expectancy have a high demand for this kind of insurance. As a consequence, an average individual will find the equilibrium price for privately purchased life annuities too high, and will tend to self-insure against longevity risk by having an extra reserve of retirement savings. Universal and mandatory social security is one way of overcoming this adverse selection problem. Making participation in the national plan mandatory and not giving anyone a choice about the form of benefit payouts creates more complete pooling of longevity risk.

A third reason for a government-mandated universal retirement income system is to address the *free-rider* problem, which arises when the citizenry collectively feels an obligation to offer a universal 'safety net'. If this collective commitment were well understood by all, some people would avoid saving for their own retirement, intending instead to rely on benefits provided by others when they are old. Similarly, some might take on more risk in investing their retirement savings than they would in the absence of a safety net. In such an environment, mandating universal participation simply forces people to pre-pay in the form of social security taxes for benefits they ultimately will receive from the system. Therefore, the purpose of a mandatory system is to protect society against free riders.

While these three arguments explain why governments might believe it important to mandate a minimum level of universal participation in a national retirement programme, they are silent about what the particular level of government benefits should be. These arguments are also silent on whether the government might merely mandate a plan, leaving it to the private sector to manage it. For example, in several countries the other two legs of the retirement-income stool are encouraged by government regulation as an alternative to government provision. Governments often use tax policy to provide incentives for employers and unions to sponsor pension plans that, like the government-run plan, are mandatory and non-assignable. In some of those countries, tax incentives are also given to self-employed individuals and households (who are not otherwise covered) to create a retirement fund for themselves. Use of such funds for other purposes is discouraged by imposing penalties on early withdrawal of money from the fund.

The Role of Occupational Pensions

Pension plans sponsored by employers or unions – also known as occupational pensions – are often integrated with the government-run plan, either explicitly or implicitly. When combined with the government-provided retirement benefit, these plans are usually designed to replace 70–100 per cent of pre-retirement earnings of lower- and middle-income employees in developed nations. Benefits are usually lower for higher-income workers, who then must rely on direct personal savings for a larger part of their retirement income.

Why are employers and/or trade unions logical sponsors of retirement plans for their employees? There are at least four good reasons (Bodie 1990). First, they make for *efficient labour contracting*. Pension plans are an incentive device in labour contracts because they affect employee hiring and turnover patterns, work effort, and the timing of retirement.

Second, they promote *informational efficiencies*. Employment-based plan sponsors often have better access than the plan's beneficiaries to information needed for preparing long-run financial plans tailored to the needs of the employees. In particular, sponsors may have better knowledge of the probable path of future labour income for their employees. By providing a basic plan that saves enough to provide for replacement of anticipated future labour earnings, the corporate sponsor can potentially save more efficiently than each employee acting individually. In order for the sponsor to provide efficiently for future wage and salary replacement of employees, it is enough to have accurate forecasts of the earnings of the group as a whole and not the individual earnings of each member of the group. It is probably easier (although by no means simple) to forecast group earnings than it is to forecast an individual's future earnings.

Third, employment-based plans can avoid *principal–agent problems*. While plan sponsors and beneficiaries may have conflicting economic interests, in many respects their interests coincide. Employers who acquire a reputation for taking care of their employees' retirement needs may find it easier to recruit and retain higher-quality employees. If employees' trust and goodwill towards their employers develop, then motivation and labour productivity may also be enhanced. Employers therefore have some economic incentive to act in the best interests of their employees.

Other possible providers of retirement planning services may be less suitable as beneficial agents of employees. Insurance agents, stockbrokers, and others who are often engaged in providing these services to individual households may be less trustworthy than employers because they could be interested in selling individuals some product or service that those individuals might not choose were they well-informed. These other agents may be motivated to persuade individuals to save too much for retirement or to invest in inappropriate ways. Anyone who has ever tried to find competent and impartial personal financial planning or investment advice is aware of the difficulties.

Fourth, plan sponsors often have *access to capital markets* that is unavailable to their employees acting as individual savers. Employees may not be able to buy certain kinds of insurance individually, but might be able to do so as members of an employee group. In addition, sponsoring firms can take advantage of scale economies while individual employees cannot. Financial intermediaries such as insurance companies can provide a suitable vehicle for the insurance needs of employees. But often a financial intermediary will not be willing to provide enough of the insurance desired by the individual at an efficient price because of problems of adverse selection and moral hazard.

Longevity insurance is an important example of this. In principle longevity risk is diversifiable and can be largely eliminated through risk pooling and sharing. But, as explained earlier, the problem of adverse selection can make the private insurance market for life annuities inefficient. Group insurance through pension plans is often seen as a solution to this problem.

Defined Benefit and Defined Contribution Pension Plans

Pension plans are usually classified in terms of what is promised to the beneficiaries. There are two basic categories: *defined contribution* and *defined benefit* plans. In a defined contribution plan, a formula specifies the amount of money that must be contributed to the plan, but does not specify benefit payouts. Contribution rules are usually a predetermined fraction of salary (for example, the employer contributes ten per cent of the employee's annual wages to the plan), although that fraction need not be constant over an employee's career. The pension fund consists of a set of individual investment accounts, one for each covered employee. Pension benefits are not specified, other than that at retirement the employee gains access to the total accumulated value of the contributions and the earnings on those contributions. These funds can be used to purchase an annuity or can be taken in the form of a lump sum.

In a defined contribution plan, the participating employee frequently has some choice over both the level of contributions and the way the account is invested. In principle, contributions could be invested in any security, although in practice most plans limit investment choices to bond, stock, and money-market funds. The employee retirement account is, by definition, fully funded by the contributions, and the employer has no legal obligation beyond making its periodic contributions. Therefore, in a defined contribution plan much of the task of setting and achieving retirement income replacement goals falls on the employee. In some defined contribution plans, employees have the option of transferring some of the risks to an insurance company.

In a defined benefit plan, by contrast, the pension plan specifies formulae for the cash benefits to be paid after retirement. The benefit formula typically takes into account years of service for the employer and level of wages or salary (for example, the employer pays a retired worker an annuity from retirement to death, the amount of which might be equal to one per cent of his final annual earnings multiplied by years of service). Contribution amounts are not specified, and the employer (called the 'plan sponsor') or an insurance company hired by the sponsor guarantees the benefits and thus absorbs the investment risk. The obligation of the plan sponsor to pay the promised benefits is similar to a long-term debt liability of the employer.

In the United States, the United Kingdom, and many other countries the trend since the mid-1990s has been away from defined benefit towards the defined contribution form. The two plan types are not, however, mutually exclusive. Many sponsors have defined benefit plans as a 'primary' plan, in which participation is mandatory, and supplement them with voluntary defined contribution plans. Moreover, some plan designs are 'hybrids' combining features of both plan types. For example, in a 'cash-balance' plan each employee has an individual account that accumulates interest. Each year, employees are told how much they have accumulated in their account and, if they leave the firm, they can take that amount with them. If they stay until retirement age, however, they receive an annuity determined by the plan's benefit formula. A variation on this design is a 'floor' plan, which is a defined contribution plan with a guaranteed minimum retirement annuity determined by a defined benefit formula. These plan designs usually take into account the benefits provided by the government-run system.

Why Does Funding Matter?

The *pension plan* is the contractual arrangement setting out the rights and obligations of all parties; the *pension fund* is a pool of assets set aside to provide collateral for the promised benefits. In defined contribution plans, the value of the benefits equals that of the assets and so the plan is always exactly fully funded. In contrast, defined benefit plans have a continuum of possibilities. There may be no assets dedicated to the pension plan in a separate fund, in which case the plan is said to be *unfunded*. When there is a separate fund but assets are worth less than the present value of the promised benefits, the plan is *underfunded*. If the plan's assets have a market value that exceeds the present value of the plan's liabilities, it is said to be *overfunded*.

Why and how does funding matter? The assets in a pension fund provide collateral for the benefits promised to the pension-plan beneficiaries. A useful analogy is that of an equipment trust. In an equipment trust, such as one set up by an airline to finance the purchase of airplanes, the planes serve as specific collateral for the associated debt obligation. The borrowing firm's legal liability, however, is not limited to the value of the collateral. By the same token, if the value of the assets serving as collateral exceeds the amount required to settle the debt obligation, any excess reverts to the borrowing firm's shareholders. So, for instance, if the market value of the equipment were to double, this would greatly increase the security of the promised payments, but it would not increase their size. The residual increase in value would accrue to the shareholders of the borrowing firm.

The relation among the shareholders of the firm sponsoring a pension plan, the pension fund, and the plan beneficiaries is similar to the relation among the shareholders of the borrowing firm in an equipment trust, the equipment serving as collateral, and the equipment-trust lenders. In both cases, the assets serving as collateral are 'encumbered' (that is, the firm is not free to use them for any other purpose as long as that liability remains outstanding), and the liability of the firm is not limited to the specific collateral. Any residual or 'excess' of assets over promised payments belongs to the shareholders of the sponsoring firm. Thus the greater the funding, the more secure the promised benefits. However, whether the plan is underfunded, fully funded, or overfunded, the size of the *promised* benefits does not change.

Why do employers fund their defined benefit plans? Reasons appear to vary across countries. First, funding offers benefit security if there is no government insurance of pension benefits, or only partial insurance. Employees may demand that the future pension promises made to them by their employer be collateralized through a pension fund. In the United Kingdom, for example, there is no government pension insurance beyond the minimum guaranteed pension of the State Earnings Related Pension Scheme (SERPS). Pension funding in this case provides an important cushion of safety for retirement income.

Second, some countries impose minimum funding standards by law. These standards seek to insure that promised pension benefits are paid even in the event of default by the corporate sponsor and also aim to protect the government (and the taxpayer) from abuse of government-supplied pension insurance. In the United States, for example, the Pension Benefit Guaranty Corporation (PBGC) must continue pension payments offered by defined benefit pension plans if their sponsoring corporations become bankrupt with an underfunded pension plan. Recent changes in United States pension law mandate that the PBGC insurance premium must depend on the plan's extent of underfunding, and have also eliminated the possibility of voluntary termination of an underfunded pension plan.

Third, there may be tax incentives for plan sponsors to fund their defined benefit plans. Black (1980) and Tepper (1981) have shown that the tax advantage to pension funding stems from the ability of the sponsor to earn the pre-tax rate of return on pension investments. It is no accident that in Germany, where employers face a tax disadvantage if they fund their pension plans, pensions are predominantly unfunded.

Finally, funding a pension plan may provide the sponsoring firm with financial 'slack' that can be used in case of possible financial difficulties the firm may face in the future. In the United States, pension law allows plan sponsors facing financial distress to draw upon excess pension assets by reduced funding or, in the extreme case, voluntary plan termination. The pension fund therefore effectively serves as a tax-sheltered contingency fund for the firm.

Funding of Pensions in the Public Sector

In a strictly unfunded *pay-as-you-go* government-operated pension system, retirees' benefits depend entirely on the stream of revenue generated by taxes levied on currently active workers. If this were exactly true, benefits would fluctuate with changes in economic fortunes, rising when tax collections rose, and falling in recessions. In practice this does not happen because most government pensions are of the defined-benefit variety and promise to deliver retirement benefits according to a specified benefit formula. Nevertheless, without funding, benefit payouts are susceptible to cuts when the public sector experiences a rising ratio of retired to active workers and/or large government deficits. In this event benefits accrued under that formula may be altered as a way of reducing this form of government debt.

As a case in point, consider the 1983 reform of the United States Social Security system. A changing demographic structure for workers led many to become concerned that the future benefits in a pure pay-as-you-go system could be dramatically reduced. Hence, a key provision of that reform was to require substantial pre-funding of future benefits. To do this, the Social Security payroll tax rate was raised and the excess of current revenues over current benefit payments was invested in government bonds held in a trust fund.

While this reform apparently funds the plan, some are less sure about the result. In a private plan, funding is used to insure against default by the plan sponsor. Under Social Security, the promise to pay benefits seemingly has the same level of full faith and credit of the government as the bonds used to fund the plan. Yet there seems to be a belief that pre-funding will ensure that when workers reach retirement they will indeed receive benefits approximating those promised under the current benefit formula (that is, the one in effect when they were active in the labour force).

A problem with this view is that there remains a potential risk associated with benefits promised under a government-run retirement income system. Even if the current government is committed to maintaining the current schedule of promised benefits, it cannot credibly fully bind future governments to do so. Indeed, it has become evident in many countries that the benefit formula and the method of financing those benefits can be and often are changed. In the United States, for example, the Congress has changed both in the past and it can surely do so again in the future. Perhaps more strikingly, public pensions in Chile were radically restructured in the early 1980s, replacing the defined benefit public social security system with a mainly private defined-contribution plan. In the 1990s Australia followed Chile's lead, and several eastern European countries have done so too.

These examples bring out an important difference between government and private-sector obligations. A private-sector plan sponsor cannot unilaterally repudiate its legal liability to make promised payments. It can default because of inability to pay, but it cannot repudiate its legal obligations without penalty. On the other hand, a government – because it has the power to legislate changes in the law – can sometimes find ways to repudiate such obligations without immediate and obvious penalty. Indeed, an integrated system in which private plan sponsors supplement government-provided pension benefits to achieve a promised 'replacement ratio' of pre-retirement earnings can be seen as a type of private-sector insurance against the political risks of the government-run system.

In sum, a mixed public–private system of retirement income provision is a way of reducing the risks of each separate component through diversification across providers. Public-sector pension plans can change the law to reduce promised benefit levels. Private-sector pension plan sponsors are committed by law (and perhaps reputation) to pay promised benefits, but they may default. And sometimes, as an additional linkage reinforcing the first two legs of the retirement income stool, the government may insure private pension benefits against the risk of default (Bodie and Merton, 1993).

Perfect Competition

M. Ali Khan

Abstract

This article attempts a critical appraisal of the literature on perfect competition as it has evolved since the work of Debreu–Scarf and Aumann in the 1960s, following papers of Debreu–Scarf and Aumann. It focuses on mathematical techniques that have been garnered to cope with the presuppositions of the classical theory relating to *finitude, convexity* and *agent-independence.*

An allocation of resources generated under perfect competition is an allocation of resources generated by the pursuit of individual self-interest and one which is insensitive to the actions of any single agent. Self-interest is formalized as the maximization of profits over production sets by producers and the maximization of preferences over budget sets by consumers, both sets of actions being taken at a price system which cannot be manipulated by any single agent, producer or consumer. An essential ingredient then in the concept of perfect competition, that which gives the adjective *perfect* its thrust, is the idea of *economic negligibility* and, in a set of traders with *many* equally powerful economic agents, the related notion of *numerical negligibility.* Perfect competition is thus an idealized construct akin (say) to the mechanical idealization of a frictionless system or to the geometric idealization of a straight line.

Following the lead of Wald, a mathematical formalization of perfect competition in a setting with an exogenously given finite set of commodities and of agents was developed in the early 1950s in the pioneering papers of Arrow, Debreu and McKenzie. It was shown that convexity and independence assumptions on tastes and technologies guarantee that a competitive equilibrium exists, and that a Pareto- optimal allocation can be sustained as a competitive equilibrium under appropriate redistribution of resources. It was also shown, drawing on the tacit assumption that markets are universal but by avoiding any convexity assumptions, that, with local non-satiation, every competitive allocation is Pareto-optimal. Relegating precise definitions to the sequel, we refer the reader to Koopmans (1961) for a succinct statement of the theory; Debreu (1959) and McKenzie (2002) remain its standard references, Fenchel (1951) and Rockafellar (1970) its mathematical subtexts, and Weintraub (1985), Ingrao and Israel (1987) and Mirowski (2002) its sources of historical appraisal.

However, in its exclusive focus on drawing out the implications of convexity and agent-independence for a formalization of perfect competition, the theory remained silent about environments with increasing marginal rates, in production and in consumption, as well as those where private and social costs and benefits do not coincide, to phrase this silence in Pigou's (1932) vocabulary of a preceding period. In particular, the notion of perfect competition that was fashioned by the initial theoretical development had no room for economic phenomena emphasized, for example, in the papers of Hotelling (1938), Hicks (1939) and Samuelson (1954). It took around two decades to show that, at least as far as collective consumption and public goods were concerned, the theory had within it all the resources for an elegant incorporation, but of course within the confines and limitations of its purview (see Foley 1970 and his followers). Non-convexities in production and consumption were a different matter entirely; they required mathematical tools that went beyond convexity, and further development had to await the invention of non-smooth calculus of Clarke and his followers; see Rockafellar and Wets (1998) and Mordukhovich (2006) for a comprehensive treatment.

A robust formalization of the idea of perfect competition for non-convex technological environments in the specific form of marginal cost pricing equilibria, with the regulation of the increasing returns to scale producer(s) given an explicit emphasis, can be outlined under each of the three headings of the theory identified by Koopmans: existence and the two welfare theorems. Marginal cost pricing equilibria exist under suitable survival and loss assumptions, but are not globally Pareto-optimal even under the assumption of universality of markets. Finally, Pareto-optimal allocations can be sustained as marginal cost-pricing equilibria under appropriate redistribution of resources. Moreover, under the terminology of Lindahl–Hotelling equilibria, Khan and Vohra (1987) provide the existence of an equilibrium concept that incorporates both public goods and increasing returns to scale in one sweep. This work on perfect competition in the presence of individualized prices stemming from collective consumption and a regulated production sector (or sectors) merits an entry in its own right, and rather than a detailed listing of the references, we refer the reader to Vohra (1992) and Mordukhovich (2006, ch. 8) for details and references.

Three observations in connection with this recent, but already substantial, literature are worth making. First, in the attempts to generalize the second fundamental theorem of welfare, one can discern a linguistic turn whereby both the Arrow–Debreu emphasis on decentralization and the Hicks–Lange–Bergson–Samuelson–Allais equality of marginal rates are seen as special cases within a synthetic treatment emphasizing the intersection of the cones formalizing marginal rates; Khan's (1988) introduction is an emphatic articulation of this point of view. Second, a canonical formulation of the notion of marginal rates, despite fits and starts, now seems within reach, though a notion that works well for the necessary conditions may not be the one equally suited for the question of existence; see Hamano (1989) and Khan (1999). Finally, conceptual clarity requires an understanding of circumstances when this type of non-convex theory bears a strong imprint of its finite-dimensional, convex counterpart, as detailed in Khan (1993), as opposed to when its higher reaches require a functional-analytic direction totally different from that charted out in the pioneering papers of the 1950s; see Bonnisseau and Cornet (2006) for reference to recent work.

With price-taking assumed rather than endogenously deduced, there is no overriding reason why a formalization of perfect competition must limit itself to a setting with a finite, as opposed to an unbounded (infinite), number of (perfectly divisible) commodities. Indeed, another set of pioneering papers of Debreu, Hurwicz and Malinvaud, written in the 1950s with an eye to a theory of intertemporal allocation but over a time horizon that is not itself arbitrarily given, fixed and finite so to speak, did consider the decentralization of efficient production plans as profit - maximizing ones. But again, it was only two decades later that the work of Bewley, Peleg-Yaari, Gabszewicz and Mertens inaugurated sustained attempts to provide a general formalization of perfect competition over infinite-dimensional commodity spaces (see Khan and Yannelis 1991). The work can again be categorized under Koopmans's three headings of the theory, but relative to its finite-dimensional counterpart, it noted that the separation of disjoint convex sets, and the use of aggregate resources to furnish a bound on the consumption sets to ensure compactness, proved to be matters of somewhat greater subtlety. In short, even a norm-compact set of an infinite-dimensional commodity space is 'rather large' and its cone of non-negative elements 'rather small'. Indeed, as Negishi's method of proof attained dominance, the imbrication of the convexity assumption in a clear demarcation of fixed-point theorems for issues of existence and separating hyperplane theorems for those of decentralization, no longer obtained. The subject is surveyed in Mas-Colell and Zame (1991), but another survey is perhaps overdue as exploration of individual mathematical structures, ordered structures in particular, reveals hitherto unforeseen essentials, and increasing returns to scale and other nonclassical phenomena are inevitably accommodated; see the references of Aliprantis et al. (2002, 2006), on the one hand, and those of Shannon (1999) and Bonnisseau (2002) on the other.

However, the question persists as to what meaning can be given to the study of perfect competition in a setting with an exogenously given infinite-dimensional commodity space where markets open only once and there is no room for the correction of mistakes and unfulfilled plans. If the extension of the theory requires additional technical assumptions, how do they translate into *desiderata* that are of relevance for the formalization of the coherence of decentralized, self-interested decision-making of independent agents acting independently of each other? Even if, for example, the *uniform properness* assumption of Mas-Colell (1986) and his followers could be pinned down as a formalization of bounded marginal rates of substitution (see the notion of a Fatou cone in Araujo et al. 2004, and one failed attempt in Khan and Peck 1989), what does it say about the set-up of the model itself that lifts this up to be a limitation as fundamental as that of convexity or independence? If the underlying motivation for the extension to infinite-dimensional commodity spaces is time, risk, quality, information or location, how do these considerations manifest themselves in the infinite dimensionality of the commodity space, in a situation that necessities (or precludes) one commodity in an economy being numerically negligible relative to the entire set? More sharply, why ought not the resulting problems be more squarely faced in simpler partial equilibrium models, rather than studied under the limitation of a construction whose primary emphasis is the viability and desirability of static interaction? We defer these issues to turn to our principal theme, namely, the formalization of the perfectness of perfect competition.

The point is that the assumption of a finite number of agents embodied in all of this work is an explicit admission of the fact that the economic non-negligibility of each agent, at least in principle, and therefore her non-manipulation of, and corresponding submission to, the price system furnishes a somewhat muted maximization of her self-interest. In terms of the emphasis on *negligibility* as a prerequisite for a rigorous formalization of perfect competition, as is being emphasized in this article, the postulated behaviour of individual agents in the so-called Arrow–Debreu–McKenzie model of perfect competition, with or without infinite commodities, externalities and increasing returns to scale, leads to the rather natural puzzlement as to what it is precisely that guarantees an agent's passive acceptance of the price system, let alone individualized pricing rules, and that too in a construction whose primary motivation is consistency and generality. In the vernacular due to Hurwicz (1972), one that has gained increasing currency since the 1980s, what is it that makes this model of the economic system *incentive- compatible*? How is its gloss of the intuitive notions of *negligibility, large* and *many* to be made precise?

Six conceptually separate attempts to answer this question are distinguished here; these alternative but interrelated formalizations of perfect competition draw their meaning from two early conjectures: (i) Edgeworth's (1881) conjecture on the shrinking of the *core* to its set of competitive allocations (again, precise definitions to follow), and (ii) Farrell's (1959) conjecture on the existence of competitive equilibrium in a environment that is not necessarily convex. Interpreted literally, both conjectures are clearly false for a given finite economy, but the first can be distinguished from the second in not being simply a case of dispensing with an assumption in a result whose basic contours are well-established, but rather in going beyond Koopmans's categorization of perfect competition to include a solution concept other than that of Pareto optimality. It is in the reliance of the core notion as a test for the perfectness of competition, in working with a third fundamental theorem of welfare economics, so to speak, and in giving precision to the ambiguity inherent in the term *shrinking*, that allows an entry into the formalization of the negligibility of individual agents. However, at this point, the discussion demands the rigour of notation and definitions; and since the essence of the ideas can be adequately communicated in the context of an economy without producers, that is, in an *exchange economy*, we confine ourselves to this case.

An *exchange economy* consists of a commodity space L, a set of traders T, a space of trader characteristics P defined on the commodity space, and a mapping $\mathscr{E}$ from T into P with the value of $\mathscr{E}$ at a particular t in T being given by the triple $\mathscr{E}(t) = ((X(t), \succcurlyeq_t, e(t))$ specifying the characteristics of agent t in T. The space of characteristics is thus a product space constituted by consumption sets $X(t) \subseteq L$, by binary relations $\succcurlyeq_t$ over $X(t) \times X(t)$, preferences over the consumption set read 'preferred or indifferent to', and by initial endowments $e(t) \in X(t)$. An *allocation* x: $T \rightarrow L$ is an assignment of commodity bundles such that $x(t) \in X(t)$ for all t in T and such that the summation, suitably formalized, of $(x(t) - e(t))$ over T is zero, or, in the case of *free-disposal*, less than or equal to zero. In either case, the fundamental economic problem facing a particular exchange economy, as discussed above and being given symbolic formulation here, is the choice of an allocation.

An allocation x: $T \rightarrow L$ is said to be in the *core* if there does not exist any other allocation y and a coalition S $\subseteq$ T, suitably formalized, such that $y(t) \succcurlyeq_t x(t)$ and not $x(t) \succcurlyeq_t y(t)$ for all $t \in S$, and that the summation of $(y(t) - e(t))$ over S is zero, or again with free disposal, less than or equal to zero. A perfectly competitive allocation of resources is a price-based allocation where a *price system* is a non-zero, continuous linear function on the commodity space L. A *competitive equilibrium* is a pair (p, x) where p is a price system and x an allocation such that for all t in T, $x(t)$ is a maximal element for $\succcurlyeq_t$ in the budget set $\{y \in X(t)) : (y, p) \preccurlyeq (e(t), p)\}$. Here (y, p) denotes the valuation of the commodity bundle y by the function p and, in case L is the Euclidean space IR^{ℓ}, the Riesz representation theorem allows it to be given a simple accounting interpretation of an inner product $(y, p) = \Sigma_{i=1}^{\ell} p_i y_i$; see Rudin (1974) for this theorem and for other unspecified terminology. For any competitive equilibrium (p, x), x is referred to as a *competitive allocation.* In terms of the earlier discussion of infinite-dimensional commodity spaces, the commodity space L has presumed on it enough mathematical structure so as to give meaning to the ordering 'less than or equal to', to the summation operator in the notion of an allocation and of a blocking coalition, and to linearity and continuity in the notion of a price system. Conceptually, what is of consequence here is that competitive allocations can be viewed as making precise the idea of some sort of individual rationality, and core allocations as making precise the idea of some sort of group rationality.

In Aumann's (1964) formulation of perfect competition, the set of traders is the Lebesgue unit interval, the commodity space is the Euclidean non-negative orthant IR^{ℓ}_{+}, the set of admissible coalitions the Borel σ-algebra on the unit interval, and summation, Lebesgue integration. Under the assumption of Lebesgue measurability of preferences $\succcurlyeq_t$, and of Lebesgue integrability of the initial endowments $e(\cdot)$, he proved that the set of competitive allocations of such an economy coincides with its set of core allocations and, in Aumann (1966), that neither set is empty. These precise and elegant affirmations of the conjectures of Edgeworth and Farrell did not require any convexity hypotheses on preferences, and, what is perhaps of equal significance, they furnished a precise formulation of an idealized limit economy in which price-taking is rendered theoretically reputable: every agent is numerically and economically negligible in that the effect of his or her action, not only on the price system but also on the equilibrium allocation, is precisely zero. An agent has a negligible weight very much akin (say) to the probability of a particular point on a dartboard being hit by a dart.

The seminal nature of Aumann's conception was quickly realized and incorporated in to the mainstream. The metaphor of a continuum of agents is now routinely (but not incorrectly) invoked to validate the removal of idiosyncratic uncertainty by aggregation even in models of a representative agent in theoretical work in macroeconomics and other, so-called applied, fields. This work that is nothing if not an investigation of competition, perfect or otherwise. Two observations are worth making. First, whereas Aumann's assumption of a Lebesgue unit interval was only a simplifying one, and that the results hold for any arbitrary *atomless* and finite measure space, Lebesgue (rather than Riemann–Stieltjes) integration is essential to a theory based on T as the set of agent-names, and therefore free of any topological considerations; see Khan and Sun (2002, Introduction) for a detailed exposition of this point. Indeed, Shapley has even questioned the postulate of measurability, leave alone continuity, for a notion of an allocation whose very *raison d'être* is a formalization of independent individual self-interest. Second, since the theory is based on a neglect of sets of measure zero, it is a conception of an allocation as an equivalence class of functions, rather than of functions themselves, that is identified by the theory. Put more sharply, Pareto-optimal allocations in an economy with a continuum of agents do not exist if their definition is taken verbatim from that of a finite economy, and not recast in terms of coalition of positive measure. In any case, the theory of an economy E conceived as a measurable map, at least in its finite-dimensional embodiment, is a testimony to the power of the Lyapunov theorem on the range of an atomless vector measure and to a powerful mathematical theory of the integration of correspondences that emerges as its corollary; Hildenbrand (1974) is the relevant reference.

A contemporaneous formulation of Vind (1964) short-circuits some of these issues concerning sets of zero measure by ignoring agents altogether, and focusing instead on coalitions, each with its own preferences and endowments, as the primitive data of the economy. Allocations then are measures on a non-atomic measure-space, and the notions of core and competitive allocations, correspondingly defined, can be shown to be identical solution concepts. This is a formulation of perfect competition that is also measure-theoretic, but one, alternative to that of Aumann, that explicitly does away with mathematical integration as its necessary microfoundation. However, by assuming countable additivity, Vind enabled Debreu (1967) to draw on Radon–Nikodym differentiation to effect a reconciliation. It took subsequent work of Armstrong and Richter to give fuller autonomy to this alternative point of view by first eliminating countable additivity, and then in setting the discussion in the framework of nonatomic Boolean algebras; see Armstrong and Richter (1986) and their references. Whereas the technical underpinning of this approach is now clearly seen to be the Armstrong and Prikry (1981) extension of the Lyapunov theorem, it is perhaps fair to say that the conceptual ramifications of this alternative (perhaps syndicalist) vision have yet to be fully explored and understood; see Avallone and Basile (1998) and Basile and Graziano (2001) for references to current research.

The formulation of perfect competition due to Brown and Robinson (1975), the third to be discussed here, returns to the methodological individualism of Aumann, and requires the set of agent-names T to be an internal star-finite set, the commodity space to be ${}^*\mathrm{IR}^{\ell}_{+}$, the nonstandard extension of IR^{ℓ}_{+} based on manipulable infinitely large and infinitesimally small numbers, the summation in the definitions of allocations and core to be summation over internal sets, the set of admissible coalitions to be the set of all internal subsets of T and $\mathscr{E}$ to be an internal map from T to ${}^*\mathscr{P}$, the set of agent characteristics modelled on ${}^*IR^{\ell}_{+}$. Such a formulation utilizes methods of nonstandard analysis, a specialization in mathematical logic due to A. Robinson; see Loeb and Wolff (2000) for details and references. On replacing equality by equality modulo infinitesimals in the definitions of allocation and the core, Brown and Robinson (1975) and, without their ad hoc standardly bounded assumption on allocations, Brown and Khan (1980) showed the equivalence (and Brown 1976, and Khan 1975, the existence) of core and competitive allocations of a nonstandard economy without any convexity assumptions on preferences. Loeb's (1973) combinatorial analogue of Lyapunov's theorem provided the mathematical underpinning of the theory. This alternative affirmation of the conjectures of Edgeworth and Farrell is another way of making precise the concepts of *many* agents and of their individual *negligibility:* meaning can be given to an individual trader's actions having a positive, but infinitesimal, effect on the price system and on an allocation. Even though an initial motivation of this work was to explore a formulation of perfect competition and of a *large* economy in a vernacular alternative to that of measure theory, it was heavily influenced by measure-theoretic formulations, but with an added emphasis on asymptotic implementation (discussed below), something clear even in the earliest papers of Brown–Robinson and Khan; see Rashid (1987), Anderson (1991) for details and references.

Relative to the classical theory brought to a culmination by Arrow, Debreu, McKenzie, Uzawa, Gale, Nikaido and Negishi, and succinctly surveyed in Koopmans (1961), the literature discussed above can be read as an exploration of the structural analytics of the set of agents of a stylized economy. Where Aumann takes the replicated sequence of Debreu–Scarf to a countably additive atomless measure space of agents, Brown–Robinson take it to a star-finite internal set each of whose points (agents) is given the same weight, and Armstrong–Richter, following Vind's cue, to a finitely-additive atomless measure space of coalitions. A fourth direction, intriguing and not yet fully synthesized in and with the other three, is represented in the work of Kaneko and Wooders (1986, 1989) and Hammond et al. (1989); also see Hammond (1995), Kaneko and Wooders (1994, 1996), Winter and Wooders (1994) and their references. The heart of this approach is to grapple with absolute and proportional magnitudes within the same framework, to focus on finite coalitions chosen from a continuum, through the notion of a *measure-consistent* partition. It concerns an atomless countably additive measure space of agents in which a single agent (and therefore a finite set of agents) is closed and thereby measurable, and a set of measure-preserving isomorphisms. A notion of an *f*-core is formulated and shown to be equivalent to the set of competitive equilibria *even* with externalities, and to the so-called Aumann core, without externalities; Wooders (1997) focuses on public goods. This approach yields its own particular way of looking at the continuum as a idealized limit of a finite economy, one that revolves around finer and finer measure-consistent partitions of an atomless continuum. It is thereby different in spirit from the more conventional way that asymptotic implementation has been formalized. We refer the reader to the references for details, and turn to what is seen here as the fifth formulation of perfect competition.

Strange as it may seem in retrospect, the idealizations of Aumann and Brown–Robinson were criticized on grounds of realism, on the observation that there do not exist economies with uncountably many agents; see Koopmans (1974) and the Georgescu-Roegen–Rashid exchange discussed in Khan (1998). The work categorized here as an asymptotic implementation of the idealized limiting versions of perfect competition was motivated, in part, by this criticism (ironically also used by Armstrong–Richter as their stated motivation for finitely additive measures), and, in part, by a methodological curiosity as to whether the results established for nonstandard and measure-theoretic economies are artifacts of the way *negligibility* and *large* economies were being modelled. Taking its point of departure from the replicated sequences of Debreu and Scarf (1963), the response is to consider a sequence $\mathscr{G} = \{\mathscr{E}_k\}_{k=1}^{\infty}$ of finite economies based on the commodity space IR_+^l where $\mathscr{E}_k$ is an economy with a set of agents T_k of cardinality k. For each finite economy $\mathscr{E}_k$, competitive and core allocations can be defined in the conventional way without encountering any technical difficulties in the formalization of summation or of a coalition. It is clear that agents in $\mathscr{E}_k$ get increasingly numerically negligible with an increase in k, and given a uniformly bounded assumption on initial endowments, also get increasingly economically negligible. For this *perfectly competitive sequence* of economies, one can ask: for any $\varepsilon > 0$, however small, does there exist an integer k_o such that core allocations of all $\mathscr{E}_k \in \mathscr{G}, k \succcurlyeq k_0$, can be sustained as approximate competitive equilibria, and whether such equilibria exist, with ε indicating in either instance, the degree of approximation? In short, are the formulations of perfect competition in idealized limit economies capable of an asymptotic implementation, with an arbitrarily fine degree of approximation, in economies of arbitrarily large but finite cardinality?

Asymptotic equivalence and existence theorems under varying degrees of generality followed quickly once the problem was posed. We shall not touch upon the various elaborations and refinements except to note that they have been obtained under two disparate techniques, both drawing on the results for an idealized limit economy. The first, associated especially with Hildenbrand, is to conceive of an economy as a measure on the space of characteristics and to utilize Skorokhod's theorem and the theory of weak convergence of measures on a topological space (typically metrizable) of characteristics $\mathscr{P}$. Under Debreu's rather vivid terminology of 'neighboring economic agents', such topologies were formulated by Debreu, Kannai, Hildenbrand–Mertens, Grodal and others, and surely have independent interest; see Hildenbrand (1974). The second approach is based on the observation that 'any sentence which is true in the standard universe is true for internal entities in the nonstandard universe', and as such, results pertaining to a nonstandard exchange economy can be 'flipped over', as it were, to a corresponding result for a large but finite economy. The differences between the two approaches are interesting from a methodological point of view: the fact that one approach is, in principle, not inherently dependent on any topology on the space of preference relations or on their continuity (as in Khan and Rashid 1976, 1982) and applies as readily to core as to competitive allocations (as in Khan 1974), suggests a further look as to how the other may be extended; see Anderson (1992) for a comprehensive treatment. In any case, we have two mutually supporting ways of extracting information for large but finite economies from idealized limit economies, even of the mixed type with atoms that generated the scepticism about idealized limit economies in the first place; see Gabszewicz and Shitovitz (1992) and their references. This claim is further underscored by a development due to Loeb (1975), but before turning to it, we discuss what may be seen as fifth formulation of *negligibility* and thereby of perfect competition.

The asymptotic interpretation of the perfectness of perfect competition concerns sequences of economies, and a question arises as to whether, given an arbitrary economy rather than an arbitrary degree of approximation, one can find the error, independent of the number of agents, with which the equivalence and existence theorems hold. Thus, rather than ask how large is large enough, one asks how small is small enough for the assumption of price-taking behaviour to be unjustified. For the question posed in this way, initially by Starr (1969), it was the definitive result of Anderson (1978) that capped initial explorations of Arrow–Hahn, Henry, Shaked and others. With the shedding of compactness and continuity assumptions under the nonstandard approach, Anderson observed that the argument in Khan and Rashid (1976) could be based on the Shapley–Folkman theorem instead of that of Loeb (1973) (itself based on Steinitz's theorem), and carried out entirely in standard terms to obtain an elementary equivalence theorem. This yields the asymptotic results as corollaries, and also furnishes them with a rate of convergence, a consideration emphasized by Shapley (1975). The same observation applied to Khan and Rashid (1982) led to an elementary existence theorem; see Geller's (1986) extension of Anderson et al. (1982).

In the prominence that it gives to a fixed finite economy, this sixth and final fifth formulation of perfect competition connects directly to the results whose introduction began this entry; it emphasizes that the equalities in the results surveyed by Koopmans, and the counter-examples implicitly underlying them, perhaps ought to be given a probabilistic cast rather than taken completely literally. In his alternative proof of the Shapley–Folkman theorem, Cassels (1975) had already emphasized this connection. Mas-Colell deepened it further by appealing to results of especial sophistication concerning the law of large numbers and the central limit theorem, and by noting that his refinement of the equivalence theorem has 'no analogue in Aumann's continuum of traders model', and that the precise probabilistic estimates that this approach offers have no counterpart in the continuum framework (see Anderson 1992, Sections 8 and 9 for details and precise references). However, it is undeniable that it is the exact results for the idealized limit economies that generally indicate the directions of pursuit of the approximations for a finite economy: approximations and numerical algorithms come into play once the exact has been exactly identified. Thus, from a substantive point of view, modulo fine technicalities, how a particular issue pertaining to perfect competition is set, measure-theoretic or nonstandard or asymptotic, is largely a contextual matter of analytical convenience and preference.

This conclusion is further sharpened by the methodological unification offered in Loeb (1975) (see Khan and Sun 1997b, for exposition). It is the central claim of this article that Loeb probability spaces go a long way towards settling the question of how the perfectness of perfect competition is to be given a precise mathematical formulation. It is already clear in Aumann's pioneering papers that perfect competition draws from the atomlessness rather than any other particularities of the measure space of agents: the metric on the unit interval, or the topology of any topological measure space, is not, indeed cannot be, of any direct relevance. What is presumably of the essence is that the space of agents' names be hospitable to measurability as well as to independence (the latter term now being used in its precise probabilistic sense rather than as a reference to an absence of externalities), that it generates results capable of straightforward asymptotic implementation, and that, for concepts that revolve only on distributions of the allocations as in Hart–Kohlberg, it yields solutions that are insensitive to a permutation of agent names. In the context of *large* games (discussed below), Khan and Sun (1996, 1999b) make the case for Loeb spaces on the basis of these *desiderata* and emphasize their dual identity in the 'pushing down' and 'lifting up' theorems: being standard, measure spaces, any result on an abstract measure-space (Aumann) economy applies to them, and thereby to an internal non-standard (Brown–Robinson) economy and hence can be asymptotically interpreted; or alternatively, any approximate result can be translated, as indicated above, to a non-standard economy, and thereby pushed down to its standard Loeb measure-theoretic counterpart. As such, Loeb spaces go a considerable way in obliterating the sixfold categorization of perfect competition that marks this entry.

Going beyond method to mathematical substance, atomless Loeb spaces are ideally suited for operations ensuring that aggregation removes the irregularities that arise from non-convexities as well as from idiosyncratic uncertainty. In a systematic and far-reaching development, Sun established that the integrals and distributions of correspondences defined on Loeb spaces and taking values in a separable infinitedimensional Banach space, in the first instance, and into Polish spaces (separable and completely metrizable) in the second, have all the properties that the theory of perfect competition requires of them. Moreover, a perfectly satisfactory law of large numbers for a continuum of random variables is obtained, and for a such a continuum, the notions of *independence* and of *exchangeability* are dual in a very elegant sense, and yields, as in Duffie and Sun (2007), the existence of an independent random matching. Supplementing the notion of an economy as a random variable, the measurability of the map noted above, a stochastic economy can now be formalized as a stochastic process on a product space, the space of agent names T and an atomless Loeb space of states of nature, Ω, to reveal circumstances under which the distributions of core and competitive allocations of a sampled economy coincide, or approximately coincide in the case of a large economy, with those of the deterministic (population) economy; see Sun (1999). Further application of this substantial theory is noted below; here the reader is referred to Sun's chapters in Loeb and Wolff (2000, chs. 7 and 8) for exposition and full mathematical references. (For references to work on random economies that does not rely on Loeb spaces, see Radner 1982, Section 7.6, and Majumdar and Rotar 2000.)

In taking stock at this stage, we underscore the fact that even though six robust and logically related methods of studying perfect competition have been illustrated through the conjectures of Edgeworth and Farrell, the discussion could, in principle, equally well have been conducted through alternative tests based on alternative solution concepts: the value (Hart 2002 and his references), or the bargaining set (Anderson 1998 and his references), or Cournot's conjecture (Mas-Colell 1986; Novshek and Sonnenschein 1983 and their references), all now conceived in a setting where individual agents are negligible. Alternatively, we could discuss applications, particularly in mathematical finance where Arrow markets and ideas of negligibility find concrete expression in derivative financial instruments and in *well-diversified* portfolios (see Anderson and Raimondo 2006; Khan and Sun 1997a, respectively, for references). However, rather than turn to them and make this article unmanageable, we draw on the rich and diverse formulation of perfect competition at our disposal to consider the substantive issues broached earlier: public goods, externalities, increasing returns to scale and infinite commodities, all under the rubric of static interaction. Ironically, non-convexities in idealized limit economies have concerned consumptions sets and survival assumptions rather than increasing returns to scale technologies (see Trockel 1984; Hammond 1993 and their references); research efforts have been most active in the study of public goods and externalities, and here the theory dovetails, from a technical point of view, into work on infinitedimensional commodity spaces.

The formalization and defence of perfect competition has, from the very beginning, proceeded on the independence assumption: the fact that individual agents are not related other than through the price system, with a 1952 paper of McKenzie's being the sole exception. Thus Hayek (1948, pp. 96–7) quotes Stigler in emphasizing the 'explicit and complete exclusion from the theory . . . of all personal relationships existing between the parties'. Such relationships are *external* to the perfected concept, and, to the extent that positive and normative content can be cleanly distinguished, externalities, and the Pigovian private–social divergences that they entail, have strong and negative implications for its normative content. If the nonconvexities identified by Starrett (1972) are ignored (but also see Otani and Sicilian 1977), Arrow's universality requirement for the first fundamental theorem of welfare economics can always be met by the creation of markets, fictitious or otherwise, but it clearly leans on a particularly acute form of myopia. Arrow securities and Lindahl prices for public goods, and more generally, prices for contingent commodities, and personalized prices for more pervasive externalities, bring out an obvious tension between incentive compatibility and efficiency. As emphasised in Starrett (1971), if there is a commodity that reflects a particular agent's dependence on my consumption, why should she or I, let alone the others, take the price of that commodity to be given and non-manipulable? or take myself to be economically negligible?

Of course, one response to these difficulties is to face the future as a future without the fiction of a complete set of commodity markets or, equally imaginatively, existing markets for securities that span *all* contingencies. Under this alternative, one can regard the price system itself as a means of fostering a relationship between the parties, and to conceive of a rationality which explicitly incorporates the informational resources of the *others* in the economy. This is to look on a price system as an instrument of solidarity as well as an instrument of allocation, a keeping up with the Joneses, not so much in their actions as in the individualized information that undergirds their actions, a move reminiscent of Veblen in the space of information rather than that of conspicuous consumption. This is a move inaugurated by Radner (1967), and it leads to a notion of equilibrium, a *rational expectations equilibrium* so to speak, in which both aspects of the price system are taken into account while not necessarily departing from the purview of the static Arrow–Debreu–McKenzie theory. One can only wonder what mathematical form such a theory will take when it is set in the framework in which individual agents are *negligible;* we point the reader to Radner (1982) and Jordan and Radner (1982) for details and references, and revert to the idealized limit economy.

There is also a technical problem in the consideration of pervasive externalities in an idealized limit economy. Since the individualistic, as opposed to the coalitionally based, approach to perfect competition works with an equivalence class of functions from the space of agent-names to agent-actions rather than the function itself, it is difficult to give meaning to one agent's dependence on the actions of another. In a context of a Lindahl equilibrium of an idealized limit economy, even one with a finite number of commodities and a single public good, one has to reckon with the fact that public goods enjoin equality instead of aggregation, and thereby force the analysis out of a finite-dimensional Euclidean space, as in the Aumann–Brown–Robinson limit theory, to a search for a suitably tractable space of equivalence classes of functions of individualized prices. It is these attendant functional-analytic difficulties, perhaps as much as the fact that the incentive- compatibility problems are most acute in this setting, that have discouraged the initial exploratory attempts of Roberts, Emmons and Khan and Vohra from being followed up; see Khan and Vohra (1985) for references. And it is precisely difficulties of this kind that also prevent a successful theory for idealized limit economies with non-ordered preferences; see Balder's (2000) interpretive use of the argument in Khan and Papageorgiou (1987), originally due to Grodal, to turn a positive proof into a negative claim of inconsistency, a claim that apparently derails the initial exploration of Khan and Vohra (1984) and their followers. Externalities, rather than being widespread, need to be controlled and confined in an idealized limit economy. This previous sentence, as well as the tone of this entire paragraph so far, runs counter to the fourth approach to perfect competition associated with Hammond, Kaneko and Wooders, but, as emphasized above, the integration of this fourth approach with the other five has not yet been fully achieved. The theory is under active development, and it is too early to say that a formulation sufficiently robust as to be deemed canonical has been achieved (see Balder 2007b; Cornet and Topuzu 2005; Hammond 1995; Kaneko and Wooders 1994; Noguchi 2005; Noguchi and Zame 2006 and their references).

In its dissociation of the study of perfect competition from its roots in welfare theory, the inclusion of externalities makes explicit its connection to game theory. Competitive equilibria with externalities take their place next to marginal-cost pricing and Cournot–Nash equilibria in violating Pareto optimality, but do allow one to ask whether decentralized self-interested decision-making is consistent in the aggregate if it is taken with respect to certain measurable indices of societal responses rather than solely with respect to a price system. Such a formulation of perfect competition goes back to the early 1950s in the papers of McKenzie and Debreu, and to the 1970s in Chipman's formulations of Marshallian parametric externalities. Indeed, the original proof of Arrow–Debreu of the existence of competitive equilibrium revolved around viewing the economy as a game in which the only 'personal relationship' between the parties relates to that with a fictitious auctioneer, a point of view that finds fuller expression in the Shafer–Sonnenschein notion of an *abstract economy.* In more recent investigations of a *large game*, the literature takes another turn towards probability theory, and conceives of an agent's actions as resulting from maximization that takes as given the distribution, or individual moments, of the random variable summarizing societal responses. The question then reduces to the existence of such equilibrium distributions, but with social interaction, however limited, recourse has to be made to assumptions on ideal types, and on the *conditional* or *mutual independence* of these types (see the prescient remarks of Hayek 1948, p. 47). This is a theory of competition in which Loeb spaces, and the Dvoretsky–Wald–-Wolfowitz extension of the Lyapunov theorem play a dominant role; see Khan and Sun (1999b, 2002); Khan et al. (2006) Loeb and Sun (2006) and their references to the work of Schmeidler, Radner–Rosenthal, Milgrom–Weber and Mas–Colell. (Balder (2007a) offers a perspective based on Young measures.)

The technical machinery forged through the study of large games enables a broadened notion of economic negligibility, one that includes *informational negligibility* in an environment with asymmetric information. In a 1936 article on 'Economics and Knowledge', Hayek (1948, pp. 43–44) had already supplemented Adam Smith's emphasis on the *division of labour* by the principle of the *division of knowledge* and asked.

> whether, in order that we can speak of equilibrium, every single individual must be right, or whether it would not be sufficient if, in consequence of a compensation of errors in different directions, quantities of the different commodities coming on the market were the same as if every individual had been right. A fuller discussion of this problem would have to consider the whole question of the significance which some economists (including Pareto) attach to the law of great numbers in this connection.

The issue is: 'right' about what? The problem devolves on anticipations and expectations, beliefs about beliefs regarding each other and the price system, and it does not require more than a mild degree of scepticism to abandon fictional markets responding to predetermined and universally agreed upon states of nature. There is a need for viable notions of independence and aggregation to eliminate idiosyncratic risk and nullify 'combination of fragments of knowledge existing in different minds'. Sun (2006) and Sun and Yannelis (2007a, 2007b) give pride of place to the Fubini property in idealized limit economies, and consolidate earlier applications of Loeb spaces for a successful resolution of Malinvaud's work on insurance markets, and that of Gul, McLean and Postlewaite on the compatibility of efficiency and incentive compatibility; also see Jackson and Manelli (1997). Khan and Sun (1999a) and Sun (2006) also present compelling arguments why finitely additive measures and the conventional product measure cannot respond to the technical difficulties.

The problems arising from asymmetric information are, at their root, problems of agent interdependence that cannot be internalized through markets, and as such represent particularly recalcitrant externalities; the assumptions that Sun–Yannelis impose on their signal process can be seen as one successful attempt to subdue them. And in an idealized limit economy with *many* commodities, each commodity seen on its own rather than through the externalities' lens, one has to cope with the fact that Lyapunov's theorem is false for an infinite dimensional vector measure, in addition to all of the problems discussed earlier. It is the *thinness* of its target space, as proposed by Kingman–Robertson in the late 1960s, that allows an atomless probability space of agents to work its magic in the form of the existence and equivalence theorems; see Kluvanek and Knowles (1976) and Diestel and

Uhl (1977) for necessary and sufficient conditions for the validity of the Lyapunov theorem. There is a hidden assumption, to adopt the postmodern flourish of Tourky and Yannelis (2001), in the Aumann–Brown–Robinson formulations of perfect competition, and the equivalence theorem can fail when the qualitative relationship between the cardinalities of agents and commodities fails; in addition to Muench's example, see Forges et al. (2001) and Serrano et al. (2001). More generally, if the intricacies of reaching binding agreements in coalition formation cannot be bracketed away, how can a concept embodying group rationality coincide with one hinging on individual rationality? An option, but one that goes against the very grain of this article, is to dissociate competition from price-taking entirely and derive it as a consequence, as in the no-surplus characterizations of Makowski and Ostroy (2001, Section 9) and Serrano and Volij (2000). The field is under active development; in addition to the papers of Sun, Tourky and Yannelis, see Forges et al. (2002), Herves-Beloso et al. (2005), Martins-da-Rocha (2003, 2004), and Podczeck (1997, 2001, 2004) and their references.

In his classic 1936 tour de force, Hayek deconstructed the Arrow–Debreu–McKenzie construction before it was constructed, so to speak, by distinguishing between an a priori 'pure logic of choice' and an empirical science. In so far as this article, in its focus on existence and core equivalence, has concentrated on the adjective *perfect,* and avoided questions of cardinality, computability, learning and stability of a perfectly competitive allocation of resources, it has neglected the noun *competition* as being outside its scope. For this, the reader could perhaps begin with Morgan (1993), and move from there to Arrow (1986), Buchanan (1987) and Radner (1991), and from there, if she is still so inclined, to the entire gamut of economic theory.

Perfect foresight is an occasionally convenient theoretical assumption whose total lack of realism is undisputed, and perhaps unrivalled. There are two elements to perfect foresight; firstly that people have definite point expectations, allowing no uncertainty, of future variables, and secondly that these expectations are correct. In practice, as these fortunate perfectly foresightful individuals generally inhabit models with instantaneously clearing perfectly competitive markets, they only need to forecast prices. The pioneering work by Hicks (1939) on intertemporal general equilibrium theory provides a framework in which the issues associated with perfect foresight can be explored. Writing prior to the development of the expected utility theory of choice under uncertainty (von Neumann and Morgenstern 1944), Hicks had no alternative to a deterministic model in his discussion. He acknowledges the existence and importance of uncertainty in expectation formation, but argues in a somewhat unsatisfactory fashion that point predictions can be interpreted as risk-adjusted summaries of underlying probability distributions. Hicks divides time into weeks. Trade takes place weekly. Supply and demand in each week depend upon decisions made in the past, expectations of spot prices in future weeks, and current spot prices. In temporary equilibrium these spot prices adjust to clear markets, but expectations may be wrong. In the situation which Hicks terms ‘Equilibrium over Time’, markets clear at each date, and, crucially, everyone has perfect foresight; price expectations are fulfilled.

Hicks’s insight that perfect foresight is an equilibrium concept is important. If people have non-equilibrium expectations, the temporary equilibrium prices in the current spot markets differ from the prices in full equilibrium over time, and the effects of current investment and production decisions based on mistaken expectations reverberate through the future. This can be illustrated in the simplest model of supply and demand in which expectations play a part: the cobweb model, used by Kaldor (1934) in discussing disequilibrium adjustments, and by Muth (1961) in the paper which gave us the phrase ‘rational expectations’. In the cobweb model, demand at t D_t, depends upon the price at t p_t, $D_t = a - bp_t$. Supply depends upon point expectations p_t^e formed before t about $p_t; S_t = cp_t^e$. In temporary equilibrium supply equals demand, $a - bp_t = cp_t^e$, so $p_t = \left(a - cp_t^e\right)/b$. In the perfect foresight equilibrium expectations are correct $p_t^e = p_t = a/(b + c)$. If the price is and has been at the perfect foresight equilibrium level for a long time people will, quite reasonably, expect this price to persist. In an economy in a long-run stationary state with unchanging prices perfect foresight is plausible. Difficulties arise when a shift in an exogeneous variable changes the perfect foresight equilibrium price. Suppose that in the cobweb model an increase in costs causes the supply curve to shift to $S_t = c'p^e$. If people are aware of the change, and understand fully the working of their economy, they may at once calculate and expect the new equilibrium price; alternatively they may all believe the forecast generated by the brilliant economist who knows it all. Less well-informed people may be forced to use past prices in forming their expectations. If these expectations are not at the new equilibrium value $a/(b + c')$ actual prices also differ from equilibrium prices; the economy will take some time to adjust to its new equilibrium and may, as Kaldor shows, fail to get there at all. The dynamic adjustment process, as people try to learn from their mistakes, depends very much upon how they learn, and is not understood in any generality (Bray 1983).

As Hicks argued, equilibrium over time with perfect foresight is most plausible when people expect prices to remain steady, and they do remain steady at the expected level. In the long-run stationary state with no uncertainty there is no need to distinguish between current prices and price expectations. Supply and demand can be thought of as relating to either. In this context the atemporal textbook theory of production and consumption can be reinterpreted to describe a world where production takes time, and is determined by price expectations as well as prices.

In the long-run stationary state tastes and technology must be unchanging and the size of the population and supplies of natural resources static, or possibly in a semi-stationary state growing steadily. These conditions are demanding and implausible. Further, they are not always sufficient for steady prices. As Grandmont (1985) shows, a very simple overlapping generations model has a constant price equilibrium, but may have other perfect foresight equilibria in which the price follows a very complicated, possibly chaotic, path. Unless people know precisely the underlying nonlinear difference equation generating prices they may have great difficulty in inferring prices from past prices.

Postulating perfect foresight allows another reinterpretation of an atemporal general equilibrium model to allow for time (Debreu 1959). In the atemporal model there is a list of different commodities, and a market and price for each commodity. These markets all operate simultaneously; in general equilibrium they all clear. The same mathematical formalism can be used to describe an intertemporal model, by distinguishing commodities by their date of delivery as well as by their characteristics. Commodities may be produced or consumed at a number of different dates, but all trade takes place at the initial date, in a complete set of spot and contingent futures markets. This of course strains credibility; only a very limited number of futures markets exist. However, as Bliss (1975) shows, the same trades, production and consumption can take place if there is a futures market for one good at each date and spot markets for all other goods, provided everyone foresees the full equilibrium over time prices perfectly. There is little to be gained in realism by exchanging the myth of complete markets for the fantasy of perfect foresight. The value of this approach lies in the handle which the well-understood atemporal general equilibrium theory gives in seeking to understand those aspects of intertemporal economics where mistakes in expectation formation appear unimportant.

The most obvious limitation of perfect foresight models is the absence of uncertainty; but the concept has been extended to allow for uncertainty, in the form of the 'rational expectations hypothesis'. This allows expectations to take the form of a probability distribution rather than a point, and requires the distribution to be correct. This begs the question of what is meant by a correct probability distribution. In a theoretical model this is conceptually straightforward. Writing down a theoretical model quite naturally generates a probability distribution describing people's beliefs about certain variables, and another describing the actual probability distribution of these variables. In a rational expectations equilibrium these are the same. In simple cases it may be easy to show that a rational expectations equilibrium exists, by solving the equations equating the distributions.

Consider, for an example, a slight generalization of the cobweb model discussed earlier, in which demand $D_t = a - bp_t + \varepsilon_t$ where ε_t is a normal random variable with mean 0 and variance 1. The price $p_{t.}$ is now a random variable; suppliers believe that it is normal with mean $\widehat{p}_t^e$ and variance $\widehat{\sigma}_t^2$ and want to supply $S = c\widehat{p}_t^e - \widehat{\sigma}_t^2$. In temporary equilibrium supply equals demand, $a - bp_t + \varepsilon_t = c\widehat{p}_t^e - \widehat{\sigma}_t^2$ so $p_t = \left(a - c\widehat{p}_t^e - \widehat{\sigma}_t^2 + \varepsilon_t\right)/b$. Given the $N(0,\ 1)$ distribution of ε_t the price p_t is indeed normally distributed with mean $Ep_t = \left(a - c\widehat{p}_t^e - \widehat{\sigma}_t^2\right)/b$ and variance $1/b^2$. The suppliers have rational expectations if $Ep_t = \widehat{p}_t^e$ and $\widehat{\sigma}_t^2 = 1/b^2$ in which case $Ep_t = \widehat{p}_t^e = \left(a + 1/b^2\right)/(b + c)$.

In more complex theoretical models the mathematics is more difficult, but the concept is clear enough. But is it plausible? The very name 'rational expectations equilibrium' is based on the presumption that this is how rational, optimizing economic agents form expectations. This requires, minimally, that they should, at some point, be able to tell whether their beliefs are correct or not. Apart from examples of the card-choosing or coin-tossing type which have little economic relevance, empirical knowledge of the probability distribution of, for example, a price, depends upon repeated observations of that price. If the probability distribution is stationary, given enough observations of the price, the statistical frequency distribution of past prices reveals the underlying probability distribution. But stationarity is a very strong condition to require. Even if the exogenous random variable (ε_t in the example) is stationary, the distribution of p_t will change as beliefs change. As noted above, we know very little about dynamic adjustment processes outside perfect foresight or rational expectations equilibria.

Knight (1921) uses the term ‘risk’ to describe situations where probabilities can be inferred from data giving the results of repeated observations of similar events, or symmetry arguments (for example coin-tossing). He reserves ‘uncertainty’ for situations concerning unique events where there is no such basis for numerical probability assessments. It is a matter of some philosophical debate whether it is in fact possible to interpret probability numerically in situations which Knight calls uncertainty; subjectivists claim that it is possible, but make no claim that different people will make the same probability assessments. Whatever the outcome of this debate the rational expectations hypothesis is in trouble in situations of Knightian ‘uncertainty’ because there is no single ‘correct’ probability distribution.

Knight argues that economies with risk, but no uncertainty, are essentially identical to economies with perfect foresight, whereas uncertainty (which he claims is all pervasive in business decisions) has a very great effect on the workings of the economy, accounting for imperfect competition and the existence of profit. Risk is unimportant because its effects are nullified by the ability to hedge, to diversify through stock markets, and most importantly because all risks can be perfectly insured. In the light of more recent theory, Knight is clearly wrong, but his argument anticipates recent developments in a fascinating way.

The formalism of the Arrow–Debreu model can be extended to allow for risk and uncertainty, as well as time, by assuming a complete set of contingent futures markets. Commodities are distinguished by the contingencies in which they are available as well as the date. This provides complete insurance. This model has all the properties of the Arrow–Debreu model without risk (existence of equilibrium and Pareto efficiency); thus far Knight’s intuition is correct. Knight is also correct in his observation that in practice complete insurance is not available for many contingencies; we do not live in a world of complete markets. His grand theme is that the presence of uncertainty as opposed to risk renders complete insurance impossible; but in his detailed discussion ‘moral hazard’ plays a key role. Moral hazard is due to the incentive insurance gives to take less care to avoid accidents, and explains why complete insurance is rarely available. As Knight points out, it is a very widespread phenomenon; any implicit or explicit contract which allows one of the parties discretion whose exercise cannot be observed by the other is subject to moral hazard. It is, as Knight argues, all-pervasive in business. But it does not require uncertainty in Knight’s sense; if there is risk and imperfect information there is moral hazard. The economics of information has been an enormously active area of theoretical research in recent years; considerable progress has been made by formal modelling of situations with imperfect information, giving us a much clearer view of its considerable importance and implication. We know that these make for an economics which is qualitatively quite different from that of the Arrow–Debreu model. We would not have learnt this if theorists had not been willing to make assumptions which cannot be taken literally or completely defended, in order to pursue questions. Quantitative probability, perfect foresight and rational expectations have been crucial tools in developing our understanding of economics.

Perfect information is usually thought of as complete knowledge of a person's economic environment. It is clear that nobody in a real economy has perfect knowledge about every aspect of the economy. However it has been argued that perfect knowledge is unnecessary since the price system summarizes all necessary information. Under this line of reasoning the only information that economic agents need are their own tastes and prices. This seems like a very naive argument. However, the real world is more complicated than this argument suggests. Even the prices system itself is not so simple: there are nonlinear prices, for example quantity discounts, as well as different prices for exactly the same commodity. Moreover the economy would function quite differently if the information structure was different, for example if all agents had more knowledge about economic variables. Hence the question arises: how are prices and information used in ideal models of the economy where many very complicated real world relationships have been simplified? In the following discussion the effect of information and the value of prices in conveying and summarizing this information in economic models is described. It appears that in economic models of the economy the 'information content' of prices is not as valuable as it appears on the surface. A well-functioning economy needs much more information than is contained in the price system.

In the quest for the effect of information on the economic environment two basic models come to mind. These are the general equilibrium and partial equilibrium models. The remarks in this article will be aimed basically at the Walrasian general equilibrium model without production. However, many of the points dealing with equilibrating prices – and information – can be made about partial equilibrium models as well as general equilibrium models with production.

The Walrasian paradigm envisioned an economy consisting of a large number of agents trading many goods. Each person, at each point in time, knowing their own tastes and stock of resources (or endowments) decides how much of each good to buy or sell at each possible price, that is, excess demands can be calculated on the basis of each person's environment (tastes and endowments) and the market price. Walras envisioned a steady state or stationary economy. Prices were thought to be generally in equilibrium, known to the consumers or economic agents but with perhaps slight, insignificant fluctuations. In this stable environment the price system regulates the supply to the market and dictates market clearing. In fact each individual agent reacts to the price system which summarizes all necessary information for this agent. Hence if any agent found himself confronted with an equilibrium price vector, then knowledge of only his own tastes and endowments would be sufficient to find the demands which equilibrate the market. However, to actually find the equilibrium price vector requires considerably more information. This difficulty also occurs in a partial equilibrium environment in which the price regulates the market clearing quantity and even the long-run number of producers.

This perception of the Walrasian economy translates into the well-known modern general equilibrium model. In this model there are generally assumed to be a finite number of commodities and a finite number of agents. Each agent is assumed to be a price taker. Equilibrium is found from the market clearing condition on the basis of the aggregate excess demand functions. The price taking behaviour is somewhat unnatural with a finite number of agents since each agent has some market power and therefore would naturally be expected to use strategic behaviour rather than passively taking prices as given. However, there is a very important extension of this model in which there is a continuum of agents. In this extension price taking behaviour is natural since no agent has any market power.

In this economy agents, in deriving their excess demands, need only information about their own tastes and endowments as well as prices. This model is analogous to the Walrasian paradigm described above. However, the analogy does not hold exactly since in the mathematical model there is no historical equilibrium price vector. Hence it is necessary to use an agent outside of the model, for example an auctioneer, to set equilibrium prices. In order to do this, aggregate excess demands must be known to the auctioneer. As a result, although each agent needs to know prices only, any equilibrating mechanism can work only if it has information about all the agents. If no auctioneer is used then it is necessary to design some sort of tâtonnement or groping mechanism to find equilibrating prices. However for such a mechanism to work and to converge to equilibrium prices, it must take account of all agents, In particular, information about excess demands must be available to make the mechanism work.

In order to make clear exactly how information is used in an economic environment, consider a simple economy consisting of two goods and two individuals. Each agent is assumed to take prices as given. For each of these agents only the price is required to describe excess demands while knowledge of both consumers is needed for an equilibrium. Suppose now that agent 2 can have two possible endowments. The first possibility corresponds to a good year while the second corresponds to a lean year. The good year results in high endowments and the lean year results in low endowments. The process of determining the excess demand function for agent 1 remains the same as before; no knowledge of agent 2 is necessary. Agent 2 on the other hand has two possible excess demand functions – one corresponding to the good year, the other to the lean year. These two excess demand functions will in general be quite different, leading to two quite different equilibria. Since he is a price taker no knowledge of agent 1 is needed by agent 2. To find equilibrium prices and allocations, however, the exact characteristics of each agent must be known, no matter what means is chosen to find an equilibrium.

The ideas discussed above can be illuminated by studying various equilibrium concepts and their informational requirements from the theory of games. In particular the information requirements in the general equilibrium model can be highlighted using the core concept of a cooperative game.

First consider the various notions of information in the game context. A distinction is made between games with perfect information and games with complete information. Perfect information in the game theoretic sense pertains to knowledge of the previous history of the game; that is, for perfect information all previous actions of the agents and equilibrium outcomes of the game are known. The notion of complete information in a game theoretic setting pertains to knowledge about the environment. In the general equilibrium context, complete information means that each agent knows his own taste and endowments as well as the tastes and endowments of all other agents. An even sharper notion of information is used in game theoretic models. This is the notion of common knowledge. Common knowledge implies not only that each agent knows his own environment – complete information – but each agent knows that the other agents know that the first agent has complete information and so on ad infinitum.

To see the importance of the common knowledge requirement in a noncooperative game consider a duopolistic market structure using the Cournot–Nash equilibrium concept. In this model each firm maximizes profits given the behaviour of the other firm. An equilibrium is a pair of outputs which is optimal for each firm given that the other firm is playing its equilibrium strategy (or output). In this model, each firm must know its own and its opponents' payoff function but each firm must also know that the opponent knows this information. This is clearly the case since the opponent's strategy will depend upon whom he thinks he is playing against. Moreover the opponent should know that the first firm knows that the opponent has this information. This chain must be continued indefinitely in order to achieve a Cournot–Nash equilibrium. Clearly for a Cournot–Nash equilibrium to obtain, that is, for the common knowledge requirement to be valid, a great deal of information is required.

Another game theoretic equilibrium concept is the core of an economy. The general equilibrium model is a very natural setting for the cooperative notion of the core. The relationship between the purely game-theoretic idea of the core and the general equilibrium concept using prices again illustrates the importance and role of information in a Walrasian general equilibrium model. The core of a general equilibrium economy is defined as the set of outcomes or allocations which cannot be improved upon by any coalition or group of agents. This means that, for any allocation in the core, no subset of agents can band together, trade among themselves using their own endowments and make each agent as well off and at least one agent better off than with the allocation in the core. The core is a cooperative game with complete information. Since the idea of a core involves coalitional or cooperative behaviour the core and competitive equilibrium are quite different. In particular the price taking assumption is incompatible with cooperative behaviour. Hence it is not surprising that more information seems to be needed to find the set of core allocations. The surprising result is that for economies with a continuum of players the set of core allocations coincide with the set of competitive allocations. The use of a continuum of agents is a natural way to model price taking behaviour since no individual agent has power to affect prices. The notion of a core for large economies involves the use, by each agent, of considerably more information than the competitive economy, and yet for large economies the informational content of both notions is exactly the same. Moreover even for finite economies a similar, although not identical, statement can be made. This result is surprising since the core does not contain any explicit reference to prices. However, the relationship between competitive equilibrium and the core does show that prices are implicitly contained in the idea of a core. The relationship also underlines the fact that more information than contained in prices is needed to find a general competitive equilibrium.

The discussion thus far has centred on perfect information in a general equilibrium model without uncertainty. Putting uncertainty into the model involves changing the specification of the market structure and the informational flow of the model. It is now necessary to know when the uncertainty is resolved to specify how the market reacts. Moreover, it is also necessary to specify the agent's subjective beliefs about the likelihood of the various states of nature. Although the advent of uncertainty raises many interesting questions about imperfect or incomplete information – for example, moral hazard problems when actions are unobservable or adverse selection problems when information is unobservable – questions remain about perfect information in models with uncertainty. In particular, consider an Arrow–Debreu world under uncertainty. In this model the information requirements are analogous to the requirements in a general equilibrium model under certainty with perfect information. In this economy trading takes place for contingent claims or Arrow–Debreu commodities. More precisely, since each state of the world can be distinguished, trading for commodities occurs for each commodity for each state of the world. This increases considerably the number of markets and the number of trades. However, except for information about which state of the world has occurred there are no extra informational requirements in this model. Each agent, knowing his own tastes and endowments in each state of the world, must know only prices. To actually find equilibrium prices, however, excess demands must be known in each possible state of the world.

Perhaps a more reasonable economy under uncertainty is to allow trading to take place on the basis of expectations or beliefs about the likelihood of the states of the world and not to assume that the state of the world is known after trading occurs, that is, not to allow contingent trades. The informational requirement in this model is quite different than in the Arrow–Debreu model. In this model there is only one market clearing price for each commodity, rather, as in the Arrow–Debreu world, than a price for each commodity in each state of the world. The agents (or auctioneer) need not know which state of the world actually occurred. However, they must know which states are possible. Finally, the equilibrium in this model depends crucially on the subjective beliefs of the agents, whereas in the Arrow–Debreu model subjective beliefs do not affect the equilibrium outcomes.

This difference in market structure and information requirement in these two models leads to a loss in efficiency. In the Arrow–Debreu model equilibrium is always Pareto optimal but in the non-contingent claims model it will, in general, not be Pareto optimal. Non-contingent claims equilibrium will in general be *ex ante* but not ex *post* Pareto optimal. In fact, if the market were to reopen after the realization of the state of the world and trading were allowed to take place, a Pareto optimal Arrow–Debreu equilibrium would result.

Perfectly and Imperfectly Competitive Markets

John Roberts

In the competition between economic models, the theory of perfect competition holds a dominant market share: no set of ideas is so widely and successfully used by economists as is the logic of perfectly competitive markets. Correspondingly, all other market models (collectively labelled ‘imperfectly competitive’ and including monopoly, monopolistic competition, dominant-firm price leadership, bilateral monopoly and other situations of bargaining, and all the varieties of oligopoly theory) are little more than fringe competitors.

Although it is not surprising that perfect competition should play a central role as a benchmark for normative purposes, the dominance of perfectly competitive forms of analysis in descriptive and predictive work is remarkable. First, economic theorists seem to be increasingly of the view that something like imperfect competition is the fundamental idea, in that perfect competition should be justified by deriving it from models where imperfectly competitive behaviour is allowed and, in particular, agents recognize the full strategic options open to them and any monopoly power they have. This view has led to a large volume of work over the last twenty-five years that, for the most part, suggests that perfect competition corresponds to an extremely special, limiting case of a more general theory of markets. Second, as the idea of perfect competition has been made more precise and the conditions supporting it have become better understood, it has become completely evident that no important market fully satisfies the conditions of perfect competition and that most would not appear even to come close. This is not to say that models should be descriptively accurate; the only way a map could approach descriptive accuracy would be for it to have a scale of 1:1, but such a map is useless. Still, it is striking that economists so consistently opt for a mode with so little apparent descriptive value. Third, the received theory of perfect competition is a theory of price competition that contains no coherent explanation of price formation. That such a fundamental incompleteness does not severely limit the value of the theory is striking.

Given all this, the dominance of perfectly competitive methods should probably be viewed as a reflection of the weakness of imperfectly competitive analysis. There is in fact no powerful general theory of imperfect competition. Instead, there is a myriad of competing partial equilibrium models of imperfectly competitive markets, and the only general equilibrium theories either rely on questionable assumptions or embody institutional specifications that are no more satisfactory than those associated with perfectly competitive analysis.

Despite the unsatisfactory state of both perfectly and imperfectly competitive market theory, recent work based on game-theoretic methodology holds promise of providing a more satisfactory theory of imperfectly competitive markets, of yielding better insight into why perfectly competitive analysis seems to work so well, and of unifying these theories.

Perfect Competition

The idea of perfect competition has many aspects: absence of monopoly power; demand and supply curves that, to the individual, appear horizontal; negligibility of an individual's quantities relative to aggregates; price-taking behaviour (with respect to publicly quoted prices); zero profits and equality of returns across all activities; prices equalling marginal costs and factor returns equalling the values of marginal products; and Pareto-efficiency of market allocations and the efficacy of the Invisible Hand. Stigler (1957) has traced the historical development of the idea of perfect competition essentially through the 'imperfect competition revolution' of the 1930s, noting the appearance of many of these features and documenting the increasing recognition of the stringency of the conditions that appeared to be necessary and/or sufficient for perfect competition. Together these include: large numbers; free entry and exit; full information and negligible search costs; product homogeneity and divisibility; lack of collusion; and absence of externalities and of increasing returns to scale.

The theory about which Stigler wrote still largely corresponds to what is presented in intermediate textbooks and probably to the way most economists think about perfect competition when doing applied work. Firms and consumers are treated as making quantity choices at given prices, because with large numbers, it is suggested, individual quantities are) 'negligible' relative to the aggregate, upon which prices are assumed to depend. (These arguments derive from Cournot 1838.) But how prices are determined is not modelled. This approach is justified by informal arguments that prices are actually set by individual agents, but that, with many agents on each side of the market, any individual would be unable to deviate significantly from the prices charged by others without losing all demand or being overwhelmed by buyers. This idea is connected to the work of Bertrand (1883), but is not supported by formal arguments showing that the outcome of such price setting would be perfectly competitive under the assumed structural conditions (large numbers, homogeneity, free entry, etc.).

When Stigler wrote, Arrow, Debreu and MacKenzie had already provided their path-breaking formal analyses of Walrasian general equilibrium, and within two years Debreu published *Theory of Value* (1959), which is still the standard treatment of this subject. In this theory, competition is given a behavioural definition. There is a given list of consumers and of firms and a given list of commodities. A single price for each good is introduced, and perfectly competitive behaviour is then defined. It involves each consumer selecting the net transactions that maximize utility, subject to a budget constraint defined under the assumptions that the consumer can buy or sell unlimited quantities at the specified prices and that the consumer's purchases do not influence the profits he/she receives. As well, each firm selects the inputs and outputs that maximize its net receipts, again given that the firm can buy and sell any quantities it might consider without influencing prices. Finally, equilibrium is a price vector and perfectly competitive choices for each agent at these prices aggregate to a feasible allocation, that is, such that markets clear.

Three fundamental results are proved for this model. These give conditions on tastes, endowments, and technology under which competitive equilibria exist (existence), equilibrium allocations are Pareto-optimal (efficiency), and, with an initial reallocation of resources, any Pareto optimum can be supported as a competitive equilibrium (unbiasedness). The efficiency and existence theorems together formalize Adam Smith's argument of the invisible hand leading self-interested behaviour to serve the common good, while the unbiasedness result indicates that the competitive price system does not inherently favour any group (capitalists, workers, resource owners, consumers, etc.). The non-wastefulness result requires few assumptions beyond those built into the structure of the model: it is enough that not all consumers are satiated. The existence theorem, however, involves much stricter conditions, including especially the absence of any increasing returns to scale. (This is also needed for the unbiasedness result.)

Many of the conditions arising in less formal treatments of perfect competition are embodied in Debreu's formulation. For example, the very definition of a commodity involves homogeneity, and divisibility is explicitly assumed. Strikingly, however, free entry and large numbers play no explicit role in this theory: all the theorems would hold if there were but a single potential buyer and seller of any commodity.

This numbers-independence property relies crucially on the theory being only an *equilibrium theory*, that is, one which specifies what happens only if behaviour is exactly as stipulated and prices are set at equilibrium, market-clearing values. No examination is offered of what would happen if prices were not at their Walrasian levels, nor indeed, of how prices are determined. Further, not even the famous story of a disinterested Walrasian auctioneer and *tâtonnement* (no trade at nonequilibrium prices) supports this equilibrium by giving a consistent model of price formation with rational actors. Instead there would be incentives to misrepresent demands, responding consistently to each price announcement by the auctioneer as if one had different preferences than actually obtain, with the object of effecting monopolistic prices and outcomes (Hurwicz 1972).

The ability of an individual to manipulate price formation by an auctioneer does disappear once one moves to a model where individuals truly are negligible. Such a model was first introduced by Aumann (1964), where the set of agents is indexed by a continuum endowed with a non-atomic measure. This measure is interpreted as giving the size of a group of agents in comparison with the whole economy. The absence of mass points implies that no individual's excess demands represent a positive fraction of the totals. Thus, any individual's withholding of supply affects neither the magnitude of excess demand (as measured on a per capita basis) nor, correspondingly, whether particular prices clear markets. Thus price-taking is fully rational if prices can be considered to be set by a disinterested auctioneer.

The infinite economy framework captures the large numbers, negligibility, and (with an auctioneer) price-taking aspects of perfect competition. Infinite models also provide a setting where numerous other models of production and exchange agree with the Walrasian in their outcomes. However, infinite models clearly are an extreme abstraction, and the real issue is the extent to which they approximate finite economies. This question leads to consideration of sequences of increasingly large finite economies in which each individual becomes relatively small, perhaps with many others like him or her being present. The identification of perfect competition with such sequences of economies and the asymptotic properties of their allocations dates back to Cournot (1838) and Edgeworth (1881) and has become the basis of several major lines of research.

The most complete of these shows that the core converges to the Walrasian allocations (see Hildenbrand 1974). However, recently attention has focused on the programme initiated by

Cournot of obtaining perfect competition as the limit of imperfectly competitive behaviour and outcomes (see Mas-Colell 1982).

There are three approaches to this problem. One, represented by Roberts and Postlewaite (1976), effectively takes some version of the auctioneer story as given and examines the incentives to respond to price announcements using one's true demands. Here it is shown that if the economy grows through replication or if the sequence of economies under consideration converges to one at which the Walrasian price is locally a continuous function of the data of the economy, then correct revelation of preferences and price-taking is asymptotically a dominant strategy. The second line of work builds more directly on Cournot's model. Agents select quantities and prices somehow arise to clear markets, with some agents (usually the firms) recognizing the impact of their choices on prices and others (consumers) taking prices as given. The central results here are due to Novshek and Sonnenschein (1978), who showed that the freeentry Cournot equilibria converge to the Walrasian allocations as the minimum efficient scale becomes small, provided that a condition of downward sloping demand is met. Finally, the game-theoretic models of noncooperative exchange initiated by Shubik (1973) also lead asymptotically to Walrasian equilibria (see Postlewaite and Schmeidler 1978). A significant feature of these game-theoretic models is that they explicitly treat out-of-equilibrium behaviour: the outcome of *any* pattern of behaviour is specified, not just what happens in equilibrium. This is an important advance. However, in these models, prices appear only as the ratio of the amount of money bid for a good to the amount of the good offered, and are not directly chosen by agents.

A complementary approach to perfect competition (Ostroy 1980) relates to marginal productivity theory and to horizontal demands. Central to this approach is a non-surplus condition that, agent by agent, the rest of the economy would be no worse off if the agent's resources and productive capability were removed from the economy. No-surplus allocations correspond to the economy's having Walrasian equilibria at the same prices with or without any single agent (so demands are horizontal). An economy is defined as perfectly competitive if the no-surplus condition is met. This can happen with a finite number of agents, but typically it requires an infinity.

Thus, various pieces of formal theory capture most of the aspects of the intuitive notion of perfect competition, but this theory points to perfect competition being a limiting case associated many agents in each market or existence of close substitutes for each firm's output, as well as with properties of continuity of the Walras correspondence and downward sloping demand. Also, this theory lacks models in which prices are explicitly chosen by economic agents. None of these results gives much reason for the success that economists have using perfectly competitive analysis.

Imperfect Competition

Formal modelling of markets begins with Cournot's (1838) treatment of quantity-setting, noncollusive oligopoly. Cournot's model yields prices in excess of marginal cost, with this divergence decreasing asymptotically to zero as the number of firms increases. The nineteenth century saw two other important contributions to imperfect competition theory: Bertrand's (1883) pricesetting model which, with constant costs, yields perfectly competitive outcomes from duopoly, and Edgeworth's (1897) demonstration that introducing capacity constraints into this model could prevent existence of (pure strategy) equilibrium.

Thus, even before the important competition revolution, the theory of imperfectly competitive markets was subject to one of the standard complaints still made against it: that it consists of too many models that yield conflicting predictions. This complaint intensified with the proliferation in the 1930s and later of models of firms facing downward-sloping demands. These models usually capture some element of actual competition (or at least appear more realistic than the perfectly competitive alternative). However, it sometimes seems that one can concoct an imperfect competition model that predicts any particular outcome one might wish.

A second complaint against imperfectly competitive analysis is its lack of a satisfactory multiple market formulation.

The first significant contribution to a general equilibrium theory of imperfect competition was Negishi's (1961) model, with later contributions from numerous authors during the 1970s. Although these models differ on important dimensions, the basic pattern in this work involves supplementing the Arrow–Debreu multi-market model of an economy by allowing that some exogeneously specified set of firms perceive an ability to influence prices. (These firms may or may not perceive the actual demand relations correctly.) Equilibrium is then a set of choices (prices or quantities) for each imperfect competitor that maximizes its perceived profits, given the behaviour of the other imperfect competitors and the pattern of adjustment of the competitive sectors (under Walrasian, price-taking behaviour) to the choices of the imperfect competitors.

This theory, as it stood in the mid–1970s, was obviously incomplete on several grounds. Most fundamentally, there was no explanation of why some agents should take prices as given while other agents, who formally might be identical to the price-takers, behave as imperfect competitors. Moreover, it then emerged that there were serious flaws in the crucial existence theorems that purported to show that the models were not vacuous.

These theorems obtained profit maximizing choices for the imperfect competitors that were mutually consistent by use of fixed-point arguments based on Brouwer's theorem. To use these methods, the optimal choices of any one agent must depend continuously on the conjectured choices of the others. This role of continuity of reaction functions is analogous to that of continuity of demand functions in the Arrow–Debreu model. However, unlike the continuity of demand, continuity of reaction functions was not derived from conditions on the fundamental data of the economy. Rather, it was either directly assumed or obtained by supposing that the imperfect competitors' perceptions of demand yielded concave profit functions.

Roberts and Sonnenschein (1977) showed that this approach was problematic by displaying extremely simple, nonpathological examples in which reaction functions are discontinuous and no imperfectly competitive equilibrium exists. The source of these failures is nonconcavity of the profit functions, and no standard conditions on preferences ensure the needed concavity: it can fail with only a single consumer or when all consumers have homothetic preferences. (Note, however, that existence ceases to be a problem in general equilibrium Cournot models if the economy, including the number of imperfect competitors, is made large enough through replication.)

These problems with imperfect competition theory perhaps explain some of the popularity of perfect competition models. However, they also suggest two important, positive points. First, the multiplicity of models and the divergence in their predictions indicates that, at least in small numbers situations, institutional details are important. Economists, habituated to the use of perfectly competitive methods, typically are imprecise about such factors as how prices are actually determined, whether decisions are made simultaneously or sequentially, whether individuals select prices, quantities, or both, and what happens when agents' plans are inconsistent. These factors cannot be treated so cavalierly in dealing with imperfectly competitive models and probably ought not to be when actual markets are being analysed. Second, both the failure of existence in models of imperfectly competitive general equilibrium and the unexplained asymmetry of assumed behaviour in these models suggest that a simple grafting of imperfect competitors onto the standard Arrow–Debreu model will not yield a satisfactory theory. Rather, one ought to start afresh from the foundations with a more careful modelling.

Strategic Models of Competition

An approach to both of these points is provided by the methods of the theory of noncooperative games and especially games in extensive form. Recent work using this approach has resulted in significant improvements in the partial equilibrium theory of imperfect competition, and there is reason to hope that these same methods can provide a satisfactory general equilibrium theory. Moreover, this approach also offers hope of ultimately yielding a unified theory of competition that would encompass both perfect and imperfect competition.

To model a market as a game in extensive form, one must specify the set of participants, the beliefs each has about the characteristics of the other agents, the order in which each acts, the information available to each whenever it makes a decision, the possible actions available at each decision point, the physical outcomes resulting from each possible combination of choices, and the valuations of these outcomes by the agents. Thus, such a model involves a complete specification of a particular set of institutions. This aspect might be viewed as a drawback, but it is in fact a potential strength of these methods.

(Note that adopting this approach does not require that price formation be modelled by having prices be chosen by agents in the model. Indeed, Cournot's original model is a well-specified game, but price formation is not explicitly modelled. However, this framework does facilitate and encourage such a specification.)

Given a game, one next specifies a solution concept. In principle, there is great freedom in making this specification, but most researchers opt for the Nash equilibrium or some refinement thereof. Note that adopting the Nash equilibrium does not rule out collusion if opportunities to coordinate and to enforce agreements are modelled as part of the game. Nor does it mean that the agents are acting simultaneously: the order of moves is part of the specification of the game, and the Nash equilibrium applies equally to simultaneous or sequential moves. To illustrate, the von Stackelberg solution corresponds to subgame-perfect Nash equilibrium in a game where the designated leader moves first and the follower observes the leader's choice before making its own. Finally, the Nash criterion does not restrict analysis to one-shot situations; it is equally applicable to models of repeated play.

When von Neumann and Morgenstern's (1944) treatise on game theory first appeared, there was hope among economists that these methods would unify and advance the analysis of imperfect competition. When these hopes were not quickly realized, many economists wrote off game theory as a failure. This position is still reflected in many intermediate textbooks. However, in the last decade these hopes have been revitalized by actual accomplishments of these methods.

The first contribution of this work has been to begin unifying the existing theory of imperfect competition. This has been done on one level by providing a common language and analytical framework in terms of which earlier work can be cast and understood. In this line, game theoretic treatments have made formal sense out of such ideas as reaction curves and kinked demand curves by obtaining equilibria of well-specified, dynamic games that have these features. As well, various of the older theories that appeared to be in conflict have been shown to be consistent in that they arise from a common, more basic model. For example, the Cournot and the von Stackelberg solutions can both be attained as Nash equilibria in a single model where the timing of moves is endogenous. In a similar vein, the Cournot, Bertrand and Edgeworth models have been integrated by showing that equilibrium in a two-stage game where duopolists first select capacities and then compete on price yields the Cournot quantities.

A second contribution has been to provide models embodying aspects of imperfect competition that had been widely discussed in the industrial organization literature but previously lacked formal expression. The best example here is work showing how limit pricing, predatory pricing, and price wars can arise as rational behaviour in the presence of informational asymmetries between competitors (see Roberts 1986). Further examples include explanations of sales and other discriminatory pricing policies, the determination and maintenance of product quality, the use of capacity and other investments in commitment to deter entry, and the opportunities for and limitations on implicit collusion. This work is revolutionizing the field of industrial organization.

The third contribution has been to permit the analysis of realistic models of institutions for exchange actually present in the economy. The best-developed example of such work is that on auctions to sell a single object to one of many potential buyers (see Milgrom 1986), but important work has also been done on multi-object auctions and other monopoly pricing institutions (including posted prices, priority pricing, and nonlinear pricing), bilateral monopoly and bargaining, and bid-ask markets or oral double auctions. In this work, the rules of the institution being modelled, the distribution of information about tastes, costs, etc., held by the various participants, and the preferences of these agents together induce a game in extensive form. This game captures the full strategic options open to all the participants, specifying completely the prices and allocations resulting from any choice of actions. Thus, the Nash equilibrium of this game yields explicit predictions of the choices of prices and of the volume, timing, and pattern of trade. Often these predictions are both remarkably tight and in agreement with observed behaviour.

This work is providing a more complete description and a clearer theoretical understanding of the operation of actual markets. Moreover, by providing detailed predictions of the outcomes of equilibrium behaviour under different institutions, it gives the basis for a theory of the choice among market institutions (see, for example, Harris and Raviv 1981). Finally, it provides an approach to unifying the theories of perfect and imperfect markets and market behaviour. In this work, agents' behaviour is rationally strategic relative to the given economic situation. However, in particular environments this imperfectly competitive behaviour may be very close to perfectly competitive or may yield outcomes that are essentially competitive (see Wilson 1986). By determining the situations in which this is true, we may finally understand when and why perfectly competitive analyses succeed.

Performing Arts

William J. Baumol

In the past two decades a substantial international literature on the economics of the arts has accumulated. Aside from the importance of the cultural contribution made by the arts, interest in the subject among economists has been elicited by some special attributes of the economics of the arts which have proved interesting analytically and whose analysis has had significant applications outside the field. Notable is the 'cost disease of the performing arts' which has been proposed as an explanation for the fact that, except in periods of rapid inflation, the costs of artistic activities almost universally rise (cumulatively) faster than any index of the general price level. Another major theoretical issue with which the literature has concerned itself is the grounds on which public sector funding of the arts can be justified.

Organization and Funding

The structure of the performance industry is similar in many of the industrialized countries. The largest enterprise in terms of budget and personnel is the opera, followed, in rank order, by the orchestra, theatre and dance. The theatres are the only group that contains a substantial profit seeking sector. All of the others, and many of the theatres as well, receive a substantial share of their incomes from government support and private philanthropy. The US, with its policy of tax exemptions, is probably the only country in which the share of private philanthropy is large, and there it exceeds the amount of government funding by a large margin. In many countries the bulk of such financing is provided by only a single agency, while in the US an arts organization whose application has been rejected by one funding source can usually turn to others for reconsideration.

The available statistical evidence suggests that demand for attendance is fairly income elastic but quite price inelastic, at least in the long run. This suggests that the widely espoused goal of diversity in audiences prevents ticket prices from rising more than they have, although fear that such rises will cause temporary but substantial declines in revenues and will reduce philanthropic or government support no doubt also plays a part.

In every country in which systematic audience studies have been carried out, the audience has been shown to be drawn from a very narrow range. It is far better educated than the average of the population, it has a far higher average income, it is somewhat older, and it includes a remarkably small proportion of blue-collar workers. Even free or highly subsidized performances affect this only marginally.

While total expenditures on ticket purchases have, of course, risen over the years, the pattern is modified substantially when corrected for changes in population, the price level and real incomes. Thus, in the US, the share of per capita disposable income devoted to admissions to artistic performances declined from about $0.15 out of every $100 in 1929 to about $0.05 in 1982. The latter figure has been virtually unchanged throughout the period since World War II.

The Cost Disease of the Performing Arts

One of the special features of the economics of the performing arts that seems to colour their cost structure is their 'cost disease'. This condemns the cost of live performance to rise at a rate persistently faster than that of a typical manufactured good. An illustration comparing the costs of watchmaking and of musical performance over the centuries shows the reason. There has been vast and continuing technical progress in watchmaking, but live performance benefits from no labour-saving innovations – it is still done the old-fashioned way. Toward the end of the 17th century a Swiss craftsman could produce about 12 watches per year. Three centuries later that same amount of labour produces over 1200 (non-quartz) watches. But a piece of music written three centuries ago by Purcell or Scarlatti takes exactly as many person hours to perform today as it did in 1685 and uses as much equipment.

These figures mean that while one has to work just about as many hours to pay for a ticket to an opera today as one would have in similar jobs 300 years ago, the cost of a watch or of any other manufactured good has plummeted, in terms of the labour time we must pay for it. In other words, because manufactured goods have benefited from technological advance year after year while live performances have not, almost every year theatre and concert tickets have become more and more expensive in comparison with the price of watches. This phenomenon has been called 'the cost disease of live performance'.

To facilitate comparison with the discussion of the cost structure of the mass media that follows, it is helpful to describe the cost disease formally. Let

y_{it} = output of product *i* in period *t*
x_{kit} = quantity of input *k* used in producing *i*
AC_{it} = average cost of *i* in period *t*
w_{kt} = (real) price of *k* in period *t*
$\pi_{it} = y_i / \sum w_{kt}\, x_{kit}$ = total factor productivity in output *i*
* = rate of growth, i.e. for any function, $f(t)$
$f^* = \cdot f/f.$

Then we have:

Proposition 1 Let y_{1t} and y_{2t} be two outputs produced by single product firms. Then, if $\pi^*_{1t} \leq r_1 < r_2 \leq \pi^*_{2t}$, so that output 1 may be called relatively 'stagnant' (and output 2 is relatively) 'progressive'), the ratio of the average cost of output 1 to that of output 2, AC_{1t}/AC_{2t} will rise without limit.

Proof By definition

$$AC_{1t}/AC_{2t} = \pi_{2t}/\pi_{1t}$$

so that

$$(AC_{1t}/AC_{2t})^* = \pi^*_{2t} - \pi^*_{1t} \geqslant r_2 - r_1.\ \text{Q.E.D.}$$

Here, of course, y_1 may be interpreted as the output of live performance and y_2 as the output of manufactured goods. It follows that the prices of manufactured goods can be expected to rise less quickly than those of concerts, dance or theatrical performances. Ticket prices must therefore rise faster than the economy's overall rate of inflation, since the latter is an average of the increases in the prices of all the economy's goods.

It is sometimes suggested that the mass media – film, radio, television and recording – can provide the cure for the cost disease, but recent analysis suggests that despite their sophisticated technology many of the mass media are in the long run vulnerable to essentially the same problem. As a matter of fact, the data indicate that the cost of cinema tickets and the cost per prime-time television hour have been rising at least as fast as the price of tickets to the commercial theatre. The explanation apparently lies in the structure of mass media production, which is made up of two basic components that are very different technologically. The first comprises preparation of material and the actual performance in front of the cameras, while the second is the transmission or filming.

Television broadcasting of new material requires these two elements in relatively fixed physical proportions – one hour of programming (with some flexibility in rehearsal time) must be accompanied by one hour of transmission for every one hour broadcast. However, since the first component of television is virtually identical with live performance on a theatre stage, there is just as little scope for technical change in the one as in the other, while the second component, on the other hand, is electronic and 'high tech' in character and constantly benefits from innovation.

Industries with this cost structure have been referred to as) ‘asymptotically stagnant’. The evolution of such an industry over time is characterized by an initial period of decline in total cost (in constant dollars) which *must* be followed by a period in which its costs begin to behave in a manner more and more similar to the live performing arts. The reason is that the cost of the highly technological component (transmission cost) will decline, or at least not rise as fast as the economy’s inflation rate. At the same time, the cost of programming increases at a rate surpassing the rate of inflation.

If each year transmission costs decrease and programming expenses increase because of the cost disease that besets all live performance, eventually programming cost must begin to dominate the overall budget. Thereafter, total cost and programming cost must move closer and closer together until virtually the entire budget becomes a victim of the disease, with the stable technological costs too small a fragment of the whole to make a discernible difference.

These results are encompassed in the following propositions:

Proposition 2 Suppose an activity, A, uses stagnant input x_1 and progressive input x_2 in fixed proportion v, so that $x_{2t} = vx_{1t}$. If w_{1t}, the unit price of x_{1t}, increases at a nonnegative rate no less than r_1 and w_{2t} increases at a rate no greater than r_2, where $r_2 < r_1$, then the share of total expenditure by A that is devoted to x_{1t} will approach the limit unity. Moreover, for any g such that $0 < g < 1$, there exists T such that for all $t > T$

$$1 \geqslant w_{1t}x_{1t}/(w_{1t}x_{1t} + w_{2t}x_{2t}) \geqslant 1 - g.$$

Proof We are given

$$\begin{aligned} &w_{1t} \geqslant a_1 \mathrm{e}^{r_1 t} \\ &w_{2t} \leqslant a_2 \mathrm{e}^{r_2 t}, x_{2t} = vx_{1t}. \end{aligned}$$

Then,

$$1 \leqslant \frac{w_{1t}x_{1t} + w_{2t}x_{2t}}{w_{1t}x_{1t}} = 1 + \frac{\upsilon w_{2t}}{w_{1t}} \leqslant 1 + (a_2/a_1)\upsilon\,\mathrm{e}^{(r_2 - r_1)^t}\cdot \text{ Q.E.D}$$

Along similar lines one can prove:

Proposition 3 Let A in Proposition 2 be supplied under conditions of perfect competition, and let its output, y_t satisfy $y_1 = ux_{1t}$ (u constant) and let its price be p_t. The p^* will approach that of the price of its stagnant input.

Corollary The smaller the value of w_{2t}, i.e. the more progressive is the progressive input of A, the more rapidly will the behaviour of A’s price approximate to that of its stagnant input.

Grounds for Public Support

Several economists have explored the grounds, if any, on which public support for the performing arts can be justified. They have examined all the usual criteria and found most of them weak. For example, income distribution concerns surely do not explain public financing of activities consumed largely by persons with incomes above the average. The beneficial externalities of attendance of the arts are not only difficult to document but are even hard to describe in the abstract. The same is true of the public good properties of performance. The best that has been done is to argue (1) that they have an ‘option value’ – even those who do not care to attend, themselves, may want to keep the arts alive for their grandchildren; and (2) that they constitute a partially public good through their part in the educational process and the (national) pride they engender even in those who do not attend themselves (or the embarrassment they avoid among those who do not want to belong to a nation of philistines). In the last analysis, it is simply argued that the arts deserve support because they are) ‘merit goods’ (to use Musgrave’s term). But that amounts to substitution of nomenclature for analysis. What the discussion comes down to is that the evidence suggests strongly that the public considers the arts worth supporting, and that in a democracy the public has the right to support what it wants to. Welfare theory has little to contribute here.

The cost disease analysis has been used by administrators throughout the world as justification for support but, of course, the fact that an activity is under financial pressure is, by itself, no valid reason for public subvention, as economic theory shows so clearly. However, if support is decided upon on other grounds, the cost disease analysis does legitimately help to give guidance on the amounts it will be appropriate to provide. It also warns us of the dangers of underfinancing as a result of what W.E. Oates has called 'fiscal illusion'. The cost disease implies that the cost of performance will rise faster than the general price level. If so, when government support for the arts increases only marginally faster than the general price level, politicians are likely to conclude that, though they have increased the real level of support, the quantity and quality of activity the public is getting for its money is declining. Mismanagement and waste are then likely to be blamed and budgets may be trimmed, on those grounds, below the level that is called for by the public's actual preferences.

The period of production is, or purports to be, a measure of aggregate capital per head. More specifically, it is a theoretical concept which tries to measure an economy's (heterogeneous) capital stock per head in (homogeneous) units of time.

Necessarily the concept of the period of production is based on an Austrian, or temporal, view of production. In this view production is conceptualized as a sequence of primary inputs on the one hand and a corresponding sequence of consumption outputs on the other. Produced means of production (capital goods) are reduced to dated primary inputs and consumption outputs. This implies that the approach is suited best to the analysis of steady states, where specific properties of capital goods are irrelevant, whereas it will be misleading, in general, if applied to problems of transition or disequilibrium. In particular, this approach is inadequate for business cycle analysis.

Although the temporal view can be traced back to Thünen, Senior, Rae and Jevons, it was Böhm-Bawerk (1889) who made it a cornerstone of his theory. This theory was directed at a fundamental problem of political economy: why is the (net) rate of profit positive? A related problem concerns the measurement of heterogeneous capital goods in homogeneous units which are independent of distribution.

A sketch of Böhm-Bawerk's theory is as follows. According to Böhm-Bawerk the fundamental feature of an economy using capital is that there is a temporal distance, called *period of production* (or *period of investment*), between primary inputs and corresponding consumption outputs. Capital is, in its essence, a fund of means of subsistence which allows for consumption during this period. In a steady state this subsistence fund consists of different 'layers' of goods which are distinguished by their respective degree of maturity, such that each period's consumption can be provided by the layer which has just become ready for consumption. A longer period of production is equivalent, in this view, to more capital per head. Hence the per capita stock of heterogeneous capital goods can be measured in homogeneous units of time. Adding to this (*a*) the technological hypothesis that consumption output per head increases with the period of production, and (*b*) the psychological hypothesis of a positive time preference gives, in a nutshell, Böhm-Bawerk's explanation of the positivity of the rate of profit.

From the beginning, Böhm-Bawerk's theory, and in particular the concept of the period of production, has caused heated debates (involving, among others, J.B. Clark, Irving Fisher, Schumpeter, Wicksell, Hayek, Kaldor and Knight). The contributions to these debates, not all of them to the point, are not reviewed here (see, however, Kaldor 1937; Weston 1951). Instead, we will analyse the period of production from a *fundamentalist* and from a pragmatic point of view. In a fundamentalist view the period of production is seen as an important component of the theory sketched above and, therefore, must have properties which make it consistent with this theory. In particular, it must be a technological parameter. In a *pragmatic* view the period of production is just a conventionally measured distance between primary inputs and consumption outputs and need not have any definite properties.

In order to give a more rigorous presentation of the period of production and the problems associated with it, we make the following assumptions. Unless stated otherwise time is measured continuously and it is assumed that primary inputs and consumption outputs can each be measured in homogeneous units. A technique is assumed to be representable by a pair (*a, b*) of non-negative, continuous functions a: $R \rightarrow R_+$ and b: $R \rightarrow R_+$ where $a(t)$ is the amount of primary inputs expended at *t* and b(*t*) is the amount of consumption outputs delivered at *t* (note that such a representation where (*a, b*) is independent of the rate of growth may not be possible for technologies with joint production; cf. the non-substitution theorem). The primary input will be called 'labour'; 'per head' (or 'per capita') will mean per unit of labour. It is assumed that

$$\lim_{t\to-\infty} a(t) = \lim_{t\to-\infty} a(t) = \lim_{t\to-\infty} b(t) = \lim_{t\to-\infty} b(t) = 0$$

that *a* and *b* are not identically zero, that there are constant returns to scale (that is, for any feasible technique (*a, b*) and any $\lambda > 0$ the technique (λa, λb) is also feasible) and that there exist some real numbers $H < 0,\ G > 0$ such that the improper Riemann-integrals

$$\int_{-\infty}^{\infty} \mathrm{e}^{-\gamma t} a(t)\mathrm{d}t$$

and

$$\int_{-\infty}^{\infty} \mathrm{e}^{-\gamma t} b(t)\mathrm{d}t$$

converge for $\gamma \in (H,G)$. The analysis is restricted to steady states with technique (*a, b*), a rate of growth g $\in$ *(H,G)* and a rate of interest $r \in (H,G)$ and to conditions of zero excess profits, implying

$$w\int_{-\infty}^{\infty} \mathrm{e}^{-rt} a(t)\mathrm{d}t = \int_{-\infty}^{\infty} \mathrm{e}^{-rt} \mathrm{b}(t)\mathrm{d}t \qquad (1)$$

where w is the steady state price of the primary input, henceforth called (real) wage, and the price of the consumption good is set equal to 1. Given a technique (*a, b*) and any point of time s, let λ (*s, t*) denote the activity level, at s, of the techniques which are in 'stage' *t*. For a steady state λ (*s, t*) = $\mathrm{e}^{-\mathrm{gt}}$ λ (*s*, 0) and total labour inputs at s are

$$A(s) = \int_{-\infty}^{\infty} \lambda(s,t)a(t)\mathrm{d}t = \lambda(s,0)\int_{-\infty}^{\infty} \mathrm{e}^{-gt} a(t)\mathrm{d}t.$$

Similarly, total consumption outputs at *s* are

$$B(s) = \lambda(s,0)\int_{-\infty}^{\infty} \mathrm{e}^{-gt} b(t)\mathrm{d}t.$$

This implies for per capita consumption *c*: = *B*(*s*)/*A*(*s*)

$$c\int_{-\infty}^{\infty} \mathrm{e}^{-gt}a(t)\mathrm{d}t = \int_{-\infty}^{\infty} \mathrm{e}^{-gt}b(t)\mathrm{d}t \qquad (2)$$

which is dual to (1). For the value of capital k per head the steady state identity.

$c + gk = w + rk$ implies

$$k = \begin{cases} \dfrac{c-w}{r-g} & \text{for } r \neq g \\ -\dfrac{\mathrm{d}c}{\mathrm{d}g} = -\dfrac{\mathrm{d}w}{\mathrm{d}r} & \text{for } r = g \end{cases}. \qquad (3)$$

The Fundamentalist View

In a fundamentalist view the period of production *T* must have two properties: first, it must be a technological parameter, that is, for each technique (*a, b*) and rate of growth g it must be uniquely determined by the associated flows of labour inputs and consumption outputs (which are proportional to $\mathrm{e}^{-gt}a(t)$ and $\mathrm{e}^{-gt}b(t)$ respectively); second, as a subsistence fund for *T* periods with per period consumption c the steady state value of capital per head k must be given by $k = cT$. But this leads to an inconsistency: since it implies $T = k/c$ and since in general *k/c* varies with the rate of interest, *T* cannot be a technological parameter. Hence the period of production in the fundamentalist sense does not exist. An analogous inconsistency occurs, if one follows Böhm-Bawerk in (wrongly) identifying consumption with wages and therefore postulates $k = wT$ rather than $k = cT$.

Part of the fundamentalist perspective can be rescued if one gives up the idea that the period of production is one-dimensional. This has been shown by Orosel (1979) within the context of a flow input–point output model where time is measured discretely.

The basic idea can be sketched for a stationary state. With time measured discretely a (flow input–point output) technique can be described by oness consumption output $\beta(0) > 0$ and corresponding labour inputs $\alpha(t) \geq t = 0, -1, -2, \ldots$, where, for some $G>0$,

$$0 < \sum_{t=-\infty}^{0} (1+\gamma)^{-t}\alpha(t) < \infty$$

for $\gamma \in (-1,G)$. To the sequence of labour inputs $\{\alpha(t)\}_{-\infty}^{0}$ is associated a sequence of wage payments $\{z_1(t) = w\alpha(t)\}_{-\infty}^{0}$; a sequence of simple interest payments on these, that is

$$\left\{z_2(\mathrm{t}) = r\sum_{\tau=-\infty}^{t-1} z_1(\tau)\right\}_{-\infty}^{0};$$

a sequence of simple interest payments on z_2(t), that is

$$\left\{z_3(\mathrm{t}) = r\sum_{\tau=-\infty}^{t-1} z_2(\tau)\right\}_{-\infty}^{0},$$

and so on, that is

$$z_{i+1}(t) = r\sum_{\tau=-\infty}^{t-1} z_i(t),$$

i=1,2,... To each sequence $\{z_i(t)\}_{-\infty}^{0}$ we can define a ‘period of production’ *Ti* as the ‘average distance’ of $\{z_i(t)\}_{-\infty}^{0}$ from output $\beta(0)$, that is, from $t = 0$, by

$$T_i := \frac{\sum_{t=-\infty}^{0} (-t)z_i(t)}{\sum_{t=-\infty}^{0} z_i(t)}.$$

Further, with each period of production Ti we can associate a (per capita) subsistence fund s_i which makes it possible to consume the incomes $\{z_i(t)\}_{-\infty}^{0}$ generated by the technique before the technique generates a consumption output. These funds are given by $s_1 = wT_1$ for wages, by $s_2 = (rs_1)T2$ for simple interest on wages, and so on, that is, $s_{i+1} = (rs_i)T_{i+1}$, $i = 1, 2, \ldots$, for simple interest on s_i during the period of production T_{i+1}, associated with these interest incomes. The total per capita subsistence fund is given by

$$s = \sum_{i=1}^{\infty} s_i = wT_1 + \sum_{i=1}^{\infty} (rs_i)\mathrm{T}_{i+1},$$

which is a sum of consumption terms (*w* and *rsi* respectively) each of which is multiplied by the associated period of production. It can be shown that for $r \in [0,G)$ all series converge and (i) all *Ti* are technological parameters; (ii) $k = s$, that is, the value of capital (per head) equals the subsistence fund (per head); (iii)

$$c = w + \sum_{i=1}^{\infty} rs_i,$$

that is, the consumption terms in s add up to per capita consumption. These results can be generalized to steady states with a positive rate of growth (Orosel 1979).

The periods of production *Ti* are fundamentalist in the sense that they are technological parameters and that the subsistence fund corresponding to them equals the value of the capital stock. They lead to a consistent reformulation of some of Böhm-Bawerk's main ideas, but they do not give a measure of aggregate capital. In fact, in the 1960s the debates in the theory of capital have made clear that such a measure does not exist.

The Pragmatic View

There are three prominent proposals as to how to measure the time interval between primary inputs and consumption outputs. They are associated with the names of (i) Böhm-Bawerk (1889), (ii) Hicks (1939) and von Weizsäcker (1971), and (iii) Dorfman (1959). Although only von Weizsäcker's analysis is directly applicable to steady states with a given (flow input–flow output) technique (*a, b*), all three proposals can be generalized accordingly. These three (generalized) concepts of the period of production, denoted by T^B, T^H and T^D respectively, are defined as follows (all integrals being improper Riemann-integrals):

$$T^B(g) := \frac{\int_{-\infty}^{\infty} t\mathrm{e}^{-gt}b(t)\mathrm{d}t}{\int_{-\infty}^{\infty} \mathrm{e}^{-gt}b(t)\mathrm{d}t} - \frac{\int_{-\infty}^{\infty} t\mathrm{e}^{-gt}a(t)\mathrm{d}t}{\int_{-\infty}^{\infty} \mathrm{e}^{-gt}a(t)\mathrm{d}t}, \quad g \in (H,G) \tag{4}$$

$$T^{\mathrm{H}}(r) := \frac{\int_{-\infty}^{\infty} t\mathrm{e}^{-rt}b(t)\mathrm{d}t}{\int_{-\infty}^{\infty} \mathrm{e}^{-rt}b(t)\mathrm{d}t} - \frac{\int_{-\infty}^{\infty} t\mathrm{e}^{-rt}wa(t)\mathrm{d}t}{\int_{-\infty}^{\infty} \mathrm{e}^{-rt}wa(t)\mathrm{d}t}, \quad r \in (H,G) \tag{5}$$

$$T^{\mathrm{D}}(g,r) := \frac{k(g,r)}{c(g)}, g \in (H,G), \ r \in (H,G) \tag{6}$$

where *k*(*g*, *r*)/*c*(*g*) is, in value terms, the capital–consumption ratio (if, as in Dorfman's analysis, a stationary state is considered, it is also the capital–output ratio). Given our assumptions all integrals are convergent. Definitions (4) and (5) measure the difference between two points of gravity, or mean values of time, associated with outputs and inputs respectively (the densities being

$$\mathrm{e}^{-gt}b(t) / \int_{-\infty}^{\infty} \mathrm{e}^{-gt}b(\mathrm{t})$$

and so on). In (4) the densities applied are given by the respective steady state *quantities*, in (5) they are given by the steady state *values*. The justification of (6) is less obvious. Dorfman's argument is that, given g and *r, k* is a constant stock (of value) with a constant outflow *c*; therefore, the average time a unit of *c* remains in *k* is *k*/*c* ('bathtub theorem'). Alternatively, (6) can be derived from the postulate that the (per capita) subsistence fund associated with T^{D}, that is, cT^{D}, equals k.

What are the properties of T^{B}, T^{H} and T^{D}, and how are the three concepts related to each other? First, it is interesting, though not shown in the literature, that T^{D} can also be represented as a difference between points of gravity. Without loss of generality, let the level of activity associated with *t* be $\mathrm{e}^{-\mathrm{gt}}$. Then to a point of time *t* there corresponds a technique ($\mathrm{e}^{-\mathrm{gt}}$ *a*, $\mathrm{e}^{-\mathrm{gt}}$ *b*) and therefore wages $w\mathrm{e}^{-\mathrm{gt}}$ *a*(*t*), profits $r\kappa(t)$ and investments $g\kappa(t)$ where

$$\kappa(t) := \int_{-\infty}^{t} \mathrm{e}^{r(t-\tau)}[w\mathrm{e}^{-gt}a(\tau) - e^{-gt}b(\tau)]\, d\tau$$

is the accumulated value of capital, at t, associated with process ($\mathrm{e}^{-\mathrm{gt}}$ *a*, $\mathrm{e}^{-\mathrm{gt}}$ *b*). Therefore, in a steady state with technique (*a*, *b*), growth rate g and interest rate r there is associated to each t an amount $q(t)$ of consumption claims (wages plus profits minus investments)

$$q(t) := \mathrm{e}^{-gt} wa(t) + (r - g)\kappa(t) \qquad (7)$$

It is possible to prove that these claims sum up to total consumption, that is,

$$\int_{-\infty}^{\infty} q(t)\mathrm{d}t = \int_{-\infty}^{\infty} \mathrm{e}^{-gt} b(t)\mathrm{d}t \qquad (8)$$

and that T^{D} is the 'temporal distance' between consumption outputs and consumption claims, that is

$$T^{\mathrm{D}} = \frac{\int_{-\infty}^{\infty} t\mathrm{e}^{-gt} b(t)\mathrm{d}t}{\int_{-\infty}^{\infty} \mathrm{e}^{-gt} b(t)\mathrm{d}t} - \frac{\int_{-\infty}^{\infty} tq(t)\mathrm{d}t}{\int_{-\infty}^{\infty} q(t)\mathrm{d}t} \qquad (9)$$

In (9) T^{D} has a structure analogous to T^{B} and T^{H}. Because of (4), (5), (7) and (9)

$$T^{\mathrm{B}} = T^{\mathrm{B}} = T^{\mathrm{D}}, \text{for } r = \mathrm{g}. \qquad (10)$$

Differentiation of (2) gives

$$T^{B} = -\frac{1}{c}\frac{\mathrm{d}c}{\mathrm{d}g};$$

of (1)

$$T^{H} = -\frac{1}{w}\frac{\mathrm{d}w}{\mathrm{d}r}.$$

Therefore, using (3), $k = cT^{\mathrm{B}} = wT^{\mathrm{H}} = cT^{\mathrm{D}}$ for $r = g$. For $r \neq g$ we have

$$\frac{1}{r-g}\int_g^r c(\gamma)T^{\mathrm{B}}(\gamma)d\gamma = -\frac{1}{r-g}\int_g^r \frac{\mathrm{d}c(\gamma)}{d\gamma}d\gamma$$
$$= \frac{c(g) - w(r)}{r-g} = k(g, r)$$

since $c(r) = w(r)$ Similarly

$$\frac{1}{r-g}\int_g^r w(\rho)T^{\mathrm{H}}(\rho)\mathrm{d}\rho = k(g, r).$$

Hence k can be interpreted as an average of subsistence funds of the form cT^{B} and wT^{H} respectively. Finally, if for two techniques (a^1, b^1) and (a^2, b^2) one of the three periods of production, $T^{\mathrm{B}}(g)$, $T^{\mathrm{H}}(r)$ or $T^{\mathrm{D}}(g, r)$, is for all feasible g and r greater for (a^1, b^1) than for (a^2, b^2), then for these techniques no reswitching or other paradoxa can occur and (a^1, b^1) can be regarded as unambiguously more capital intensive than (a^2, b^2). However, in general the ranking of techniques according to their period(s) of production will depend on the chosen g and r. Therefore, none of the pragmatic concepts of the period of production gives an unambiguous and generally applicable measure of capital intensity. In the light of the so-called reswitching debate this result is to be expected.

Conclusions

The period of production purports to be a measure of capital intensity. Although it is a useful concept for clarifying the relation between capital and time, it is not, and cannot be, a rigorous measure of aggregate capital per head because even in a restricted model with only one primary input and one consumption output such a measure does not exist. As a *fundamentalist* concept the period of production fails because it cannot simultaneously be a technological concept and explain capital as a subsistence fund; as a *pragmatic* concept it fails because it is not possible to rank techniques according to their period of production independently of the rate of growth and the rate of interest. Hence the period of production cannot avoid the inconsistencies (pointed out in the capital controversies of the 1960s) which are associated with the concept of aggregate capital.

Periphery

Immanuel Wallerstein

The term ‘periphery’ makes sense only as part of the paired antinomy ‘core(centre)–periphery’. It refers to an economic relationship that has spatial implications. This pair of terms has long been used in the social sciences, but until recently it has been used metaphorically rather than spatially, and to refer to social and political rather than to economic phenomena. Palgrave’s original *Dictionary of Political Economy* (1894–9) did not know the concept.

Nor is it merely an issue of semantics. It is not the case that some other reasonably similar concept had previously been used instead. The issue is more fundamental. Mainstream nineteenth-century economic thought – both classical and neoclassical economics, but to a very large extent Marxism as well – had no place in its theorizing for space, except as location that might affect the cost of a factor of production. Transport costs obviously affected total costs. And location might give a natural rent advantage. Geological deposits were where they were. Water sources that could be dammed for power were located in one place but not another. Space thereupon became one more theoretically accidental, exogenous variable which had to be taken into account in concrete economic practice but was in no sense intrinsic to the functioning of the economic system.

The classic formulation of this view is to be found in the theory of comparative costs. England and Portugal each had certain natural advantages, such that it followed that it was rational, to use Ricardo’s example, for Portugal to exchange her wine for English cloth even though she was able to produce cloth more cheaply than England. In this example the Methuen Treaty never entered the discussion.

It is not that no one ever raised the issue as to whether the natural advantages were not the result of political and social decisions which themselves were integral to the processes of economic behaviour. There had long been, for example, a current of theorizing which justified protectionism. Friedrich List stands out as a leading spokesman of this view in the nineteenth century. The protectionists did argue in effect that comparative advantage was socially structured and that therefore state policy could and should endeavour to transform inequalities. But there are two things to note about this current of protectionist thought. Firstly, it was always marginal to the leading centres of academic economics, and to the extent that its views were incorporated, state policy was once again relegated to the status of an exogenous variable. Secondly, the protectionist current did not challenge, indeed on the contrary it reinforced, a basic pillar of mainstream thought, the parallel and theoretically independent trajectories of a series of states (societies, economies), each of which was separately governed by the same economic laws.

In the interwar period, the worldwide depression in agricultural prices which dates from the early 1920s led to a revival of protectionist theorizing, particularly in those parts of the world which combined three features: a predominance of agricultural production; a small industrial sector; a reasonably large scholarly sector. The three areas which best matched this profile were eastern Europe, Latin America, and India and in all three zones such economic writings appeared. They had in fact, however, rather little impact on local policy and even less on world scholarship.

The situation changed in the post-1945 period. Although the general expansion of the world-economy was no doubt conducive to free trade ideology, the political emergence of the Third World led to some questioning of what in the 1970s would come to be known as 'the international economic order'. It is in this context that the concept of 'periphery' took shape, first of all in the work of Raúl Prebisch and his associates in the UN Economic Commission for Latin America (ECLA).

The original Prebisch thesis laid emphasis on the 'structural' factors which underlay what by the 1950s was being called) 'underdevelopment'. Prebisch argued that peripheral countries were basically exporters of raw materials to industrialized core countries. He argued that there was a long-term decline of the terms of trade against raw materials exporters. Prebisch concluded that this relationship had two basic effects. It maintained the peripheral countries in a vicious cycle of lower productivity and a lower rate of savings than the core countries. And it made it impossible for them to retain the benefits of such increases in productivity as they might experience.

The explanation was 'structural', that is, that there were socio-political 'structures' that affected, even shaped the market, and thereby in (large) part determined advantage in the market. The industrialized countries had 'self-sustained' economies whereas the underdeveloped countries did not, since they functioned as peripheries to centres. The world market forces operated to maintain this undesirable 'equilibrium'. The policy implications were clear. Since the 'normal' operations of the market would only continue the same pattern, state action was required to alter it. The basic immediate recommendation was industrialization via import substitution. The long-run implication was, however, more fundamental. Unlike Ricardo's analysis, the Prebisch argument suggested that the pattern of international trade was established importantly, perhaps primarily, by political decisions and therefore could be changed by political will. Or more generally, the determining framework for the 'world market' was more the overarching world political structure than vice versa.

This basic thesis was picked up and developed by a large number of economists and other social scientists, in Latin America to be sure, but in the Caribbean, in India and Africa as well. It also became the basic argument of a group of social scientists located in Europe and North America, although it should be noted that many of these were persons whose areas of research were in what was now being called the Third World. One of the first of this latter group was H.W. Singer, whose principal contribution was published in 1950, the same year as Prebisch's famous report. For this reason, this viewpoint is sometimes called the Prebisch–Singer thesis.

In time, the Prebisch thesis developed in the 1960s into a doctrine which was called *dependista*, because it emphasized the fact that peripheral areas were in a larger system within which they were 'dependent' as contrasted with more autonomous zones. The primary focus of criticism of the *dependistas* was a dominant mainstream model which was coming to be called 'modernization theory' or 'developmentalism'.

Developmentalism centred around the issue of how those *countries* which were 'underdeveloped' might 'develop'. Developmentalism made several assumptions. Some combination of traits of a country – there was much debate about what they were – led to development. All countries could develop in similar ways, were they to ensure the proper combination of traits – in this sense, the doctrine was melioristic. Development was a patterned process. The last assumption was often expressed as a stage theory. The single most influential expression of this last argument was W.W. Rostow's *Stages of Economic Growth* (1960). Developmentalism originated as an economic doctrine, but others soon began to suggest parallel processes of political development and social development. There was much discussion of the linkages among the various) 'aspects' of development and hence much encouragement of so-called interdisciplinary analysis.

By the 1960s developmentalism had become a dominant and self-conscious mode of analysis in world scholarship, particularly in any discussion of the 'Third World' or the) 'underdeveloped' countries. Prebisch had argued against classical free trade ideology. The main thrust of the 'second generation' of theorizers about the periphery – that of the *dependistas* of the 1960s – was directed against these) 'developmentalists' even though many of them had already accepted the legitimacy of some state intervention in the economy. This second generation was still very largely Latin American – F.H. Cardoso, T. Dos Santos, Celso Furtado, Ruy Mauro Marini, O. Sunkel, R. Stavenhagen were major figures – but there were also Lloyd Best (Trinidad), Samir Amin (Egypt) and Walter Rodney (Guyana). All of these scholars attacked in one way or another the theory of modernization and in particular the assumption that Third World countries could 'repeat' European–North American patterns of development by copying in one way or another the policies, past or present, of the presumably 'successful' states.

The contribution of André Gunder Frank to this second-generation theorizing was that he spelled out two arguments which, while present in the work of his colleagues, had not been as clearly underlined, or as widely disseminated. The first argument is to be found in the slogan he coined, 'the development of underdevelopment'. This is the argument that underdevelopment is not undevelopment, a primordial pre-capitalist or pre-modern state of being, but rather the consequence of the historic process of worldwide development through the linked formation of core and periphery. It followed from this perspective that the further extension and deepening of the division of labour on a world scale led not to national development (as the developmentalists argued) but to the further underdevelopment of the periphery. The policy implications of the two perspectives therefore were directly opposed one to the other.

The second argument involved a critique not of modernization theorists but of so-called orthodox Marxists. To understand this critique we have to look at the history of Marxist theory. From about 1875 on there arose a version of Marxist theory which became predominant in the two major world organizational structures, the Second and Third Internationals, and which very largely reflected the theoretical input of the German Social-Democratic Party (*c*1875–1920) and the Bolsheviks, later Communist Party of the Soviet Union (*c*1900–50). Whether this version was or was not faithful to Marx's own theorizing is not under discussion here, and is irrelevant to the issue at hand.

Since both Internationals were oriented to the issue of obtaining state power, the de facto unit of economic analysis became the state, and, in this respect, there was no real difference with neoclassical models of economic development. Furthermore, under Stalin, a very strong stage model of) 'modes of production' was delineated which paralleled structurally the Rostowian model, although the details were quite different.

In the period 1875–1950, the worldwide structure of capitalist development disappeared or became secondary in) 'orthodox' Marxist theorizing except for a brief interval around World War I where momentarily such figures as Otto Bauer, Nikolai Bukharin, Rosa Luxemburg, and in part Lenin discussed these issues. By the 1920s all such discussion ceased, and by the 1950s Communist parties in Latin America (and elsewhere) were deriving very specific policy implications from the state-centred 'orthodox' theorizing. The reasoning went as follows. Feudalism as a stage comes before capitalism which comes before socialism. Latin America was still in the feudal stage. What was on the politico-economic agenda, and implicitly 'progressive', was national capitalist development. Ergo, Communist parties should enter into political alliances with the national bourgeoisie in order to further national development, postponing to a later date 'socialist revolution'.

The *dependistas* saw this analysis as leading to virtually the same policy results as the analysis of the modernization theory developmentalists. Since the late 1960s was also a period of increasing US–USSR political detente, they saw the theoretical) 'convergence' as tied to a world-level political convergence which in turn was facilitated by the hitherto unremarked common underpinnings of analysis.

The *dependista* popularization of the concept 'periphery' was abetted by two theoretical works which claimed to be Marxist in economic theory yet challenged in each case a major strand in 'orthodox' Marxist economic theorizing. The first was Paul Baran's *Political Economy of Growth*, published in 1957, and which directly inspired many *dependista* authors. Baran modified the concept of *surplus* by introducing a distinction between 'actual' and 'potential' economic surplus, suggesting that the consequence of capitalism was not merely a particular allocation of actual surplus but even more importantly the non-creation of a potential surplus. This non-created potential surplus existed throughout the system but one major component was located in the 'backwardness' of underdeveloped countries.

The second challenge was in Arghiri Emmanuel's *Unequal Exchange*, published in 1969. Emmanuel's book launched a direct attack on the Ricardian theory of comparative advantage, noting that its assumption, the immobility of the factors of production, had never been seriously challenged even by Marxists. Asserting that while capital is internationally mobile, labour has not been, Emmanuel argued that wages determine prices, and not vice versa. Given unequal wages (and immobile labour) internationally, international trade involves unequal exchange, since items priced identically and ensuring parity in rate of profit in fact encompass different amounts of labour. This theory thus challenges the idea that surplus is transferred only in the work process, and that space is irrelevant. The fact that frontiers are crossed is crucial to the theoretical explanation of unequal exchange.

Two other, initially separate intellectual debates entered the scene to complicate the issue further. In the late 1950s, Maurice Dobb and Paul Sweezy had a public debate (in which others then joined) about the so-called transition from feudalism to capitalism in western Europe in early modern times. They disagreed about many things: the time of the change, the motor of change, the geographical context of analysis, the very definition of feudalism and capitalism. What the debate accomplished was that it forced a reconsideration of the definition of feudalism, which was important, since many peripheral zones were being characterized as having) 'feudal' characteristics. When in the late 1950s and 1960s a new debate arose on the nature of, indeed the existence of, an) 'Asiatic mode of production', the debate widened. The more the debate widened, the more the distinction between what is internal and what is external (to the nation/state/society) so fundamental to 'orthodox' Marxist thought, but also to neoclassical thought, came under challenge.

There was a second debate, purely political and far outside world academic circles. It was the obscure, seemingly esoteric debate between the Soviet and Chinese state apparatuses over the process of the hypothetical transition from socialism to communism. This too occurred in the 1950s. The issue was whether states would go forward in this hypothetical transition singly or collectively. This too implied a difference concerning the unit of analysis. The Chinese position had far-reaching implications which by the late 1960s were being called) 'Mao-Zedong thought'.

It was in the 1970s that these strands of thinking about the) 'periphery' and related topics came together. The term) '*dependista*' disappeared. Some began to speak of 'world-systems analysis'. The core–periphery relationship was now being defined as the description of the axial division of labour of the capitalist world-economy. Core and periphery were now less linked locations than linked processes which tended to be reflected in geographical concentrations. These processes had as one major consequence the formation of states within the framework of an interstate system. One could think of the interstate system as the political superstructure of the capitalist world-economy. This world-economy was an historical social system, a socially created whole which developed in specific ways over its history. The overall structure was seen as defining the parameters within which the capitalist market processes occurred. As new geographical zones had been incorporated historically into this system, they had been for the most part ‘peripheralized’. This meant that various worldwide mechanisms (political, financial, and cultural) tended to make it profitable for individual entrepreneurs to segregate production processes spatially such that some zones had disproportionately high concentrations of peripheral processes – that is, processes with a high labour component and relatively low-cost labour – ensured by the involvement of wage-workers in these zones in usually reorganized household structures in which lifetime income returns from wage labour comprised a minority percentage of total real revenue.

While state policies could affect these relationships, the ability of any single state to transform the situation was constrained by its location in the interstate system and therefore depended significantly upon the changing condition of the balance of power. The interstate system varied in patterned ways between periods in which there was one hegemonic power and periods in which there was acute rivalry among several strong powers.

In addition, the ability of states to affect the processes of peripheralization was said to be a function of the cyclical rhythms of the world-economy, believed to alternate, once again in patterned ways, between periods of expansion and stagnation.

The regular cyclical rhythms and the alterations of the conditions of the interstate system led to some continuous but limited shifting in the economic roles of particular geographical zones within the system without necessarily changing the basic structuring of core–periphery relations.

Finally, it has been argued that the geographical concentration of different economic processes has been trimodal rather than bimodal, there having been at all times semiperipheral zones, defined as regions having a fairly even mix of core-like and periphery-like economic processes.

The concept ‘periphery’ thus has involved a basic theoretical criticism of nineteenth-century economic paradigms. It has not been spared counterattack from three main quarters: of course from the modernization/developmentalists under attack, most of whom have been basically Keynesians in their economic theorizing; but even more from so-called neo-liberals (the critique of P.T. Bauer has been the most trenchant), and from) ‘orthodox’ Marxists.

The concept ‘periphery’ has served a polemical purpose in the last 20 years. To advance its utility, its proponents must now come to clearer terms about the functioning interrelations of the three antinomies of the capitalist world-economy; core–periphery relations in the division of labour; A and B phases in the cyclical long waves; and periods of hegemony versus periods of rivalry in the interstate system.

Selig Perlman was born in 1888 at Bialystok, Poland, then a part of Tsarist Russia. His father was a yarn spinner. Perlman grew up in an atmosphere shaped at once by the labour movement, socialism and Zionism. He emigrated to the United States in 1908, and took up studies with John R. Commons at the University of Wisconsin. He received his Ph.D. there in 1915, joined the teaching faculty and became professor of economics in 1927. He collaborated on the four-volume *History of Labor in the United States* compiled by Commons (1918–35), and published *A History of Trade Unionism in the United States* (1922). His most important work, the influential *A Theory of the Labor Movement,* appeared in 1928. Perlman died in 1959.

Perlman's early sympathies were Marxist, but his views were shaken considerably upon his going to America and coming under the influence of Commons. He came to regard the ideas of socialism as essentially the creation of intellectuals, fundamentally at odds with manual workers' own aspirations and experience. Where the labour movement is weak, Perlman argued, it is more susceptible to control by intellectuals; where, on the other hand, political conditions allow it to become strong, the labour movement is better able to outgrow its early ideological trappings and advance to maturity. Late 19th- and early 20th-century America seemed to Perlman the clearest case of a labour movement 'emancipated from the hegemony of intellectual revolutionists' and expressing its own 'philosophy of organic labor'. The key to successful trade unionism, in Perlman's view, was a limited, practical 'job-consciousness', struggling toward collective control of employment opportunities but not otherwise challenging the prerogatives of capitalists.

Permanent-Income Hypothesis

Mark Aguiar and Erik Hurst

Abstract
The permanent income hypothesis (PIH) is a theory that links an individual's consumption at any point in time to that individual's total income earned over his or her lifetime. The hypothesis is based on two simple premises: (1) that individuals wish to equate their expected marginal utility of consumption across time and (2) that individuals are able to respond to income changes by saving and dis-saving. In this article we present the intuition and empirical implications of the PIH in several standard contexts.

The permanent income hypothesis (PIH) is a theory that links an individual's consumption at any point in time to that individual's total income earned over their lifetime.

The PIH is based on two simple premises: (1) that individuals wish to equate their expected marginal utility of consumption across time and (2) that individuals are able to respond to income changes by saving and dis-saving. Because consumers are making their consumption decisions based on lifetime resources, the PIH implies that today's consumption will respond differently to changes in today's income depending on whether the income changes are expected as opposed to unexpected, or temporary as opposed to permanent. The PIH provides a sharp contrast to Keynesian consumption rules, which assume consumers make their consumption decisions based only upon current income.

The major insights of the PIH originated in Friedman (1957). They are closely related to the ideas expressed in Modigliani and Brumberg's (1954) life-cycle hypothesis (see Carroll 2001, for a summary of Friedman's original work). Since the 1950s there have been many additional theoretical and empirical contributions. This article presents the intuition and empirical implications of the PIH that have evolved since the 1950s in several standard contexts.

The Canonical Model

Consider the canonical model in which an individual lives $T+1$ periods and earns y_t in period $t = 0,\ldots,T$. For now, we assume that the income stream is known at time zero. The canonical model assumes that the individual can borrow and lend freely at an interest rate r. The standard model also assumes that the future is discounted at the rate $\beta < 1$ and utility is additively separable across time and additively separable across consumption and leisure. For simplicity, we treat leisure as fixed and treat income as exogenous to the consumer. We revisit these assumptions below. Let $u(c)$ represent the period utility enjoyed from consumption, where $u' > 0$; $u'' < 0$. The consumer's problem is therefore:

$$\max_{\{c_t\}_{t=0}^{T}} \sum_{t=0}^{T} \beta^t u(c_t) \tag{1}$$

subject to $\sum_{t=0}^{T}(1+r)^{-t}c_t \leq \sum_{t=0}^{T}(1+r)^{-t}y_t + A_0$, where A_0 represents initial assets.

A necessary condition for an interior optimal consumption plan is $u'(c_t) = \beta(1+r)u'(c_{t+1})$, for all $0 \leq t \leq T-1$. Therefore, the relationship between consumption in two periods is independent of the relationship between income in those two periods. For example, suppose that individual's discount the future at the rate of interest such that $\beta(1+r) = 1$. With such a restriction on preferences, the individual will consume the same amount each period. Also for simplicity, let $T \to \infty$ and $A_0 = 0$ (and impose the 'no-Ponzi-game' condition $lim_{t\to\infty}A_t/(1+r)^t \geq 0$). The budget constraint then implies that consumption in each period equals the annuity value of the present discounted value of income, or 'permanent income,' such that:

$$c = r\sum_{t=0}^{\infty}(1+r)^{-t}y_t. \tag{2}$$

Note that consumption is a function only of permanent income, and not how that income is allocated across periods. The ability to borrow and lend is key to the permanent income hypothesis. This allows the individual to transfer income across periods at the rate $(1+r)$. Access to such an asset makes the present discounted value of income the only relevant constraint on consumption.

The result has a natural implication in a life-cycle model. Suppose individuals work for $S < T$ periods and then retire. Aside from a potential trend due to time discounting, the PIH implies that consumption should not respond to the drop in income at a known period of retirement. Rather, assets built up over the working years are used to finance retirement consumption. Similar examples are plentiful. For example, a teacher on a 9-month salary consumes steadily over 12 months, or a yearend bonus is used for purchases throughout the year. The fact that income is expected to change tomorrow should already be incorporated into today's consumption plan.

In the above model, there was no uncertainty about future income. This is reasonable for predictable changes to income such as retirement or seasonal work, but less useful in understanding consumption's response to unexpected 'shocks' such as an unemployment spell or changes in business cycle conditions. We extend the model to the case of uncertainty by assuming that income follows a stochastic process. In particular, let *yt* denote the random variable of income at time $t = 0,\ldots,T$.

We continue our assumption that individual's have access to a risk-free bond. Let *Et* denote expectations conditional on information as of time *t*. At any point in time, *t*, the consumer's problem can be expressed as the following:

$$\max_{\{c_\tau\}_{\tau=t}^{T}} E_t \sum_{\tau=t}^{T} \beta^{\tau-t} u(c_\tau) \qquad (3)$$

subject to the period-by-period budget constraint: $A_{t+1} = (1 + r)(A_t + y_t - c_t)$. Notice that Eq. (3) differs from Eq. (1) in that individuals in Eq. (3) are maximizing expected utility. The first-order conditions imply the following 'Euler equation':

$$u'(c_t) = \beta(1 + r)E_t u'(c_{t+1}). \qquad (4)$$

The marginal utility of consumption varies in a predictable way due only to the interest rate and the subjective discount rate. All other movements are unpredictable (with respect to information available prior to time *t*). Jensen's inequality implies that consumption will be a martingale when $\beta = 1 + r$ only if marginal utility is linear in consumption (that is, quadratic utility). In many standard utility functions, marginal utility is convex, implying that consumption trends upward in expectation when marginal utility is a martingale. Moreover, all else equal, consumption will respond more to unanticipated permanent innovations to income than to transitory innovations.

Empirical Tests of the Canonical Model

Equation (4) states that, aside from r and β, information known at time *t* should not affect the change in the marginal utility of consumption between *t* and $t + 1$. Estimating Eq. (4) has been the focus of numerous empirical studies, beginning with seminal paper of Hall (1978). Using aggregate data, Hall finds that lagged consumption and lagged income have minimal predictive power for changes in current consumption growth between *t* and $t + 1$. This, by itself, may be interpreted as a victory for the PIH. However, Hall also finds that a lagged index of stock prices does have predictive power for future consumption changes, an apparent violation of Eq. (4). Hall's study was followed by a large empirical literature exploiting aggregate consumption data to test whether innovations to consumption are predictable using information available in prior periods. However, a consensus has emerged that aggregation issues undermine the validity of tests using aggregate data.

A large literature has emerged testing Eq. (4) using micro data. For example, Attanasio and Weber (1995) and Attanasio and Browning (1995) find support for the PIH using data from the US Consumer Expenditure Survey and the UK Family Expenditure Survey, respectively. Additionally, Shea (1995), Parker (1999), Souleles (1999), Browning and Collado (2001), and Hsieh (2003), among others, have used micro data to examine how consumption responds to anticipated changes in income. These results, however, have been mixed. The conclusion of this literature is that, at least in some instances, consumption responds to predictable changes in income. This excess sensitivity of consumption to predictable income changes has been seen as a violation of the canonical model of the PIH outlined above.

Moving Beyond the Canonical Model

Depending on the context, the ability to freely borrow and lend may be considered too restrictive or not restrictive enough. On the one hand, it rules out state-contingent insurance contracts between consumers. On the other hand, the ability to borrow against future income is often limited in practice due to lack of enforcement. We now briefly describe how the canonical PIH differs from optimal consumption patterns in models with complete insurance markets or models with borrowing constraints.

Perfect insurance in an economy inhabited by agents that enjoy utility as given by Eq. (3) implies that individual consumption depends only on aggregate income rather than how that income is distributed across individuals. That is, consumption depends only on aggregate shocks and not on idiosyncratic shocks. This contrasts with the PIH's statement that consumption responds to idiosyncratic permanent income shocks. The difference reflects the limits of the insurance provided by a risk-free bond. However, there is a parallel as noted by Cochrane (1991). The implication that consumption should not respond to idiosyncratic income shocks was formalized and tested by Townsend (1994) using data from Indian villages and Cochrane (1991) using US data. While Townsend rejects perfect risk sharing, he presents evidence that there is significant insurance of idiosyncratic shocks within villages in India. Cochrane rejects perfect insurance in the case of long illness and involuntary job loss, but fails to reject in the case of several other idiosyncratic shocks.

Another alternative to the standard PIH asset market structure is limiting the amount one can borrow against future income. The inability to borrow implies that Eq. (4) may not hold. When constrained, a consumer may be forced to adjust consumption in response to a transitory or predictable shock to income. For example, if an individual receives a temporary income decline, the inability to borrow against future income may necessitate that consumption moves with contemporaneous income. Zeldes (1989) argues that liquidity constraints do bind for a significant fraction of consumers. Moreover, the inability to borrow presents consumers with the risk that a series of negative income shocks may force consumption down to extremely low levels. To mitigate this risk, potentially constrained consumers build up a 'buffer stock' of savings. See precautionary saving and precautionary wealth for a discussion of the accumulation of wealth for precautionary reasons.

Life-Cycle Consumption

While liquidity constraints can explain the empirical fact that consumption is excessively sensitive to changes in predictable income, empirical critiques remain about the ability of individuals to rationally make consumption decisions today based on their expectations of future income realizations. Two of the strongest critiques are that consumption expenditures are hump-shaped over the life cycle (peaking when households are in their mid-forties) and that there is a significant decline in consumption expenditures at the time of retirement. The latter fact has been referred to as the 'retirement consumption puzzle' and has been documented and discussed by, among others, Bernheim, Skinner and Weinberg (2001).

The two empirical critiques are related. According to the standard permanent income hypothesis outlined above, individuals should be smoothing their marginal utility of consumption over their lifetimes. Researchers have been trying to modify the PIH so that it matches these two additional empirical facts. For example, Attanasio et al. (1999) find that, if preferences are a function of demographics, the life-cycle profile can be matched. Alternatively, Gourinchas and Parker (2002) find that a model with a properly calibrated income process can match the hump-shaped consumption profile if households are liquidity constrained and sufficiently impatient.

Aguiar and Hurst (2005, 2007) adopt a different approach from those above by appealing to the intuition of Becker (1965). They argue that the PIH theory concerns consumption while the data reports expenditure. The distinction is important because consumption requires time as well as market goods. In particular, households may substitute time for expenditure and maintain a constant level of consumption as expenditures fall. This margin of substitution is suppressed in the canonical form of the model, but Aguiar and Hurst (2005, 2007) document that it is empirically important and reconciles the PIH with both the life-cycle profile of expenditure and the changes in expenditure associated with retirement.

In summary, the current state of literature has expanded on the insights of Friedman's original discussion of the PIH by building in additional features to the canonical model to match a wide variety of empirical regularities. However, this discussion highlights the broader point that any empirical test of the PIH is always a joint test of the hypothesis itself as well as the specific restrictions the researcher places on preferences (for example, whether utility is non-separable between consumption and leisure, the curvature of marginal utility, or the extent to which individuals are impatient), information (for example, assumptions about the income process), or technologies (for example, the existence of liquidity constraints, a home production sector, or complete markets) used to construct the hypothesis' empirical counterpart.

A linear transformation mapping $(x_1,x_2, \ldots, x_n)$ to $(y_1, y_2, \ldots, y_n)$ by

$$y_i = \sum_{j=1}^{n} a_{ij}x_j(i = 1, 2, \ldots, n)$$

all of whose coefficients a_{ij} are non-negative has special properties not shared by the general linear transformation. In a matrix form the transformation takes the form

$$x \to y = Ax,$$

where A is the n-dimensional square matrix with elements a_{ij} in the ith row and the jth column, x is the vector having x_j in the jth component and y is the vector y_i in the ith component. The non-negativity of elements of the coefficients matrix A obviously implies that a vector x with all its components non-negative is mapped to a vector y with all its components non-negative in the transformation. This peculiar nature gives rise to special properties of the eigenvalues and associated eigenvectors of the matrix A. Among them, those found and proved by Frobenius (1908, 1909, 1912), also already noticed for a special case by Perron (1907), are the most relevant to linear economic models in which variables are non-negative. The Perron–Frobenius theorem states them in several propositions

(1) A has real non-negatives eigenvalues. With the largest $\lambda = \lambda(A)$ of the non-negative eigenvalues is associated an eigenvalues x having non-negative components fulfilling

$$\lambda x = Ax.$$

(2) The absolute value $|\omega|$ of any eigen value ω of A, either real or complex, is bounded by $\lambda(A)$ so that $|\omega| \leq \lambda(A)$.

(3) The matrix $\rho I - A$ where I is the identity matrix and ρ is a real number, has an inverse matrix with all its elements non-negative if and only if ρ is larger than $\lambda(A)$.

Alternative methods of proving the propositions (1), (2) and (3) are available. Some of them are given below.

Proof of (1). The proof is straightforward for A with all its elements positive. Among all the pairs (θ, y) of a real number θ and a nonzero vector y having all its components non-negative that fulfil the n inequalities, the ith component of A$y \geq$ the ith component of $6y$ ($i = 1, 2, n$) there is one (λ, x) with λ being the largest of all such θ. Then $Ax = \lambda x$. For otherwise, some components are larger than the corresponding components of λx while the other components of Ax are not less than the corresponding ones of λx. Whence all the components of $A(Ax)$ are larger than the corresponding ones of λ (Ax) so that λ can be further increased to get another pair (θ, Ax), $\theta > \lambda$ fulfilling the inequalities, contrary to the maximum property of λ. Generally A can be approximated from above by $A_\varepsilon = A + \varepsilon T$ where ε is a small positive number and T is the matrix all of whose elements are one. A_ε with all its elements positive has a special pair $(\lambda_\varepsilon, x_\varepsilon)$ satisfying $A_\varepsilon x_\varepsilon = \lambda_\varepsilon x_\varepsilon$ and maximizing θ at λ_ε over all pairs (θ, y) fulfilling the inequalities, the ith component of $A_\varepsilon y \geq$ the ith component of θy ($i = 1, 2, ...,$ n). Then, for $\varepsilon' \geq \varepsilon$ the ith component of $A_{\varepsilon'} x_\varepsilon \geq$ the ith component of

$$A_\varepsilon x_\varepsilon = \lambda_\varepsilon x_\varepsilon (i = 1, 2, \ \ldots, \ n),$$

implying $\lambda_{\varepsilon'} \geq \lambda_\varepsilon$, Whence, λ_ε converges monotonically to a non-negative λ as ε decreases toward zero. The corresponding eigenvector x_ε if so normalized that its components sum up to 1, converges to a nonzero vector having all its components non-negative for a subsequence $\varepsilon(s)$ of positive numbers tending monotonically to zero when s $\to \infty$. Hence $A_{\varepsilon\ (s)} x_{\varepsilon(s)} = \lambda_{\varepsilon(s)} x_{\varepsilon(s)}$ becomes $Ax = \lambda x$ in the limit when $s \to \infty$.λ is the largest of θ of all pairs (θ, y) fulfilling the inequalities, the ith component of $Ay \geq$ the ith component of θy ($i =$ 1, 2, ..., n). For $\lambda_\varepsilon \geq \theta$ by construction, which becomes $\lambda \geq \theta$ in the limit.

Alternatively, this proposition can be proved by virtue of Brouwer's fixed point theorem as a fixed point of the mapping that transforms each vector x with non-negative components $x_i (i = 1, 2, \ \ldots, n)$ adding up to unity to a vector y with components

$$y_i = \left(x_i + \sum_{j=1}^{n} a_{ij} x_j \right) \Big/ \left(1 + \sum_{k,j=1}^{n} a_{kj}, x_j \right),$$
$$(i = 1, 2 \ldots . n)$$

At a fixed point x^* that is transformed to itself these equations can be rearranged to

$$\lambda x^* = Ax^*,\ \lambda = \sum_{k,j=1}^{n} a_{kj}x_j^*.$$

Then λ (A) is obtained as the largest of λ's of all such fixed points.

Proof of (2). For an eigenvalue ω of A and an associated eigenvector z with components z_j, the equations

$$\omega z_i = \sum_{j=1}^{n} a_{ij}, z_j, (i = 1, 2, ..., \quad n)$$

hold by definition. Then the absolute values of ω, z_i satisfy

$$\sum_{j=1}^{n} a_{ij}|z_j| \geq |\omega||z_i|, \quad (i = 1, 2, \quad ..., \quad n)$$

Whence λ (A) ≥ |ω| by the maximum property of λ (A). In particular, λ (A) is the largest of all non-negative eigenvalues of A.

Proof of (3). Necessity. If $\rho I - A$ has an inverse matrix having all its elements non-negative, $p'(\rho I - A)$ has all its elements positive for some vector ρ having all its components positive, where the prime stands for transposition. Then, $Ax = \lambda x$, $\lambda = \lambda(A)$ with x an associated eigenvector having all its components non-negative, becomes, when pre-multiplied by p' , $\rho p'x$, $\lambda p'$ x , p' $x > 0$, which implies $\rho > \lambda$.

Sufficiency. First note that $\lambda(A) \geq \lambda(C)$ for any principal minor matrix C of A. For, if $\lambda(C)\,y = Cy$ for an eigenvector y with all its components non-negative associated with λ(C) the inequalities, the ith component of $Az \geq$ the ith component of $\lambda(C)$ $z(i = 1, ,2, ..., n)$ hold for the vector z augmented from y by putting zero in the missing components, so that λ (A) ≥ $\lambda(C)$ by the maximum property of λ (A). *If* $\rho > \lambda = \lambda(A)$, the determinant of $\rho I - A$ must not be zero, for otherwise ρ would be a positive eigenvalue of A larger than λ (A). Hence ρI–A is nonsingular and invertible. For any vector c with non-negative components $x_i = (\rho I - A)^{-1}c$ must have all its components non-negative. Otherwise x would have some components negative, and an identical, simultaneous renumbering of equations and variables would bring the relation between x and c to the form

$$\begin{aligned} \rho x_i - \sum_{j=k+1}^{n} a_{ij}x_j &= \sum_{j=1}^{k} a_{ij}x_j + C_j, & (i = k+1, \ldots, n) \\ x_j &\geqq 0, & (j = 1, 2, \ldots, k) \\ x_j &< 0, & (j = k+1, \ldots, n) \end{aligned}$$

which are non-negative on the right side. Whence

$$\begin{aligned} &\sum_{j=k+1}^{n} a_{ij}y_i \geqq \rho y_i, (i = k+1, \ldots, n) \\ &y_i = -x_j > 0, \quad (j = k+1, \ldots, n) \end{aligned}$$

so that $\rho > \lambda(A) \geq \lambda(C)$ contrary to the maximum property of λ(C) for the principal minor matrix C of A obtained by deleting the first k rows and columns of A. This shows that the components of x are non-negative, which ensures the non-negativity of all the elements of $(\rho I - A)^{-1}$.

The condition in (3) that ρI –A has an inverse matrix with all its elements non-negative can be paraphrased as the positivity of all the principal minor determinants of ρI –A the so-called *Hawkins–Simon conditions.*

The Perron–Frobenius theorem pertains to the possibility of special solutions of linear economic models and to the 'good behaviour' of those solutions. The most typical instance of such models is the Leontief system. In a Leontief system consisting of n sectors, each of which produces a single good, without joint products, under constant returns to scale, using n goods as current input and as capital, let a_{ij} and b_{ij} be the amounts of the ith good consumed as input and used as capital, respectively, which are necessary to produce one unit of the jth good in the jth sector (i, j = 1,2, ..., n).

Let the levels of sectoral output $x_j(t)$ at time t (j =1,2, ..., n) be so determined that net outputs are invested to increase capital. Then

$$x(t) = Ax(t) + B(x(t+1) - x(t)),$$

where A and B are the input coefficients matrix and the capital coefficients matrix having elements a_{ij}

and b_{ij} in the *i*th row and the *j*th column, respectively. A special time path of output $x_i(t) = (1 + g)^t x_i$ ($i = 1,2, ..., n$), called a balanced growth path, on which the levels of sectoral output grow at the equal positive rate g is generated by an eigenvector x with non-negative components x_i associated with the Perron–Frobenius eigenvalue λ (=1/g) of the matrix $(I - A)^{-1}B$ having all elements non-negative, provided the system is *productive* enough for A to have its Perron–Frobenius eigenvalue less than 1. On the dual side a row eigenvector p' with non-negative components $p_j (j = 1, 2, \ldots, n)$ associated with the Perron–Frobenius eigenvalue $\lambda(= 1/r)$ of $B(I - A)^{-1}$, equal to that of $(I - A)^{-1}B$, gives a special set of prices determined by

$$p' = p'A + rp'B$$

at which the sectoral rates of profit are equalized to the common rate $r = 1/\lambda$.

In the system of Sraffa (1960) in which input–output correspondences are

$$\begin{aligned}&(A_a,\ B_a,\ \ldots, K_a) \to A(A_b,\ B_b,\ldots, K_b)\\&\times \to B(A_k,\ B_k,\ldots, K_k) \to K\end{aligned}$$

the standard commodity is constructed by non-negative multipliers $q_a, q_b,\ldots, q_k$ that fulfil

$$\begin{aligned}&(A_a q_a + A_b q_b\ \ldots\ + A_k q_k)(1 + R)\\&= A q_a (B_a q_a + B_b q_b +\ \ \ldots\ \ + B_k q_k)(1 + R)\\&= B q_b (K_a q_a + K_b q_b +\ \ \ldots + K_k q_k)(1 + R) = K q_k.\end{aligned}$$

These multipliers are obtained as components of an eigenvector associated with the Perron–Frobenius eigenvalue λ[=1/(1 + R)] of the matrix

$$\begin{pmatrix} A_a/A & A_b/A & \ldots A_k/A \\ B_a/B & B_b/B & \ldots B_k/B \\ K_a/K & K_b/K & \ldots K_k/K \end{pmatrix}.$$

More specific information is available about the Perron–Frobenius eigenvalue of those matrices having all their elements non-negative in such a way as to be *indecomposable,* in the sense that no identical, simultaneous renumbering of its rows and columns can be put into the form

$$\begin{pmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{pmatrix},$$

where A_{11} and A_{22} are square submatrices while A_{12} is a rectangular submatrix and 0 is a rectangular submatrix having zero in all its elements.

(4) If A is indecomposable, the Perron–Frobenius eigenvalue $\lambda(A)$ is positive, and with it is associated an eigenvector x having all its components positive. Any eigenvector associated with $\lambda(A)$ is a scalar multiple of x.

(5) $\lambda(A)$ is a simple root of the characteristic equation. If A has s eigenvalues of moduli equal to $\lambda(A)$, they give all the roots of the equation

$$\omega^s = \lambda(A).$$

(6) By an identical, simultaneous renumbering of the rows and columns A can be put in a form

$$\begin{bmatrix} 0 & . & . & . & 0 & A_{15} \\ A_{21} & 0 & & & & 0 \\ 0 & A_{32} & 0 & & & \\ . & & & & & \\ . & & & & & \\ 0 & . & . & 0 & A_{35-1} & 0 \end{bmatrix},$$

where s is the number of eigenvalues of moduli equal to $\lambda(A)$ and $A_{1s}, A_{21}, \ldots, A_{ss-1}$ are rectangular submatrices, while all the other elements are zero.

A standard reference compiling the main results centring around the Perron–Frobenius theorem is Debreu and Herstein (1953).

French economist, best known for his construction of a theoretical system of economic power. He was born in Lyon and his academic career led him to the Sorbonne and from 1955 to 1975 to the Collège de France. A critic of neoclassical economics, Perroux shared some of the concerns of the American institutionalists, but went beyond them by constructing a system of economic analysis – the only one at his time – that rivals conventional equilibrium economics. This system, comprehensive and consistent, is grounded in an all-pervasive 'domination effect' that reflects the inequality of economic agents with respect to their economic power. In equilibrium economics the actions of the economic agents are considered coordinated by an adequate amount of equality, leading to mutual concessions that in turn bring about adjustments and the removal of disturbances. Such an approach, according to Perroux, is contradicted by the facts of economic life and fails to reveal the role of economic power in the market. Where conventional economics stresses coordination among equals and their functional interdependence, Perroux sees a relationship of subordination among economic agents, with the latter either dominating or dominated. Just as Schumpeter, who influenced Perroux and about whom he wrote a book, had revealed the dynamics of innovation, so Perroux disclosed the dynamics of inequality. He acknowledged that there were other theories of monopolistic market situations that shared features of his own ideas, and himself introduced Chamberlin's work to French readers, but pointed out that these theories covered only special cases that would be more adequately handled by a general theory such as that developed by him.

Perroux described his domination effect as asymmetrical and irreversible and as not presuming any intention on the part of the dominating agent. Unlike conventional economics, the domination effect does not produce equilibrium but protracted and cumulative changes. It operates at the level of the firm, of the industry and of the national economy. A dominant firm, for example, can integrate its operations and earn a surplus from increasing sales to and declining purchases from the outside, and from a market position that yields it favourable prices. The surplus adds to the power of the dominant firm by providing it with means for internal financing, for mergers and acquisitions, and for financing or manipulating the demand for its products. At the international level Perroux's domination effect yields new insight into the position of the dominant economy. His theory differs from the theories of imperialism by not requiring an intention on the part of the dominating power.

Perroux's general theory of economic power was developed during the 1940s and 1950s, not long after the new theories of Keynes, input–output analysis, mathematical programming and game theory had been absorbed into mainstream economics. The economics profession was not ready for still another profound change. Thus, Perroux's general theory of economic domination did not upset conventional analysis. However, from his general theory Perroux derived theories of 'economic space' and 'poles of development', which in turn yielded theories of structural change, unbalanced economic growth and regional development that continue to be widely discussed and applied in regional planning.

Personal Debt and Psychological Health

John Gathergood

Abstract

Problematic personal debts and associated outcomes, such as bankruptcy and foreclosure, lead to significant declines in psychological health. This article summarises the recent literature and discusses the key issues in measurement and causality. Medical studies show that problem debts are associated with depression, self-harm and even suicide. Recent studies using econometric techniques show that some of the association in self-reported data is due to perception bias. Quasi-experimental studies using data from the housing crises show the onset of problem debt causes deterioration in psychological health, including effects upon physical health and health behaviours.

Introduction

Problematic personal debts and associated outcomes, such as bankruptcy and foreclosure, lead to significant declines in psychological health. High levels of consumer debt are associated with anxiety, depression and poor general health. Personal bankruptcy or foreclosure events are associated with large declines in psychological health and increased likelihood of adverse health outcomes, including stress-related medical conditions, self-harm and suicide.

Economists are interested in the potential negative effects of personal debt because in standard economic models access to debt is welfare-improving. In dynamic consumption theory access to debt allows consumers to smooth their (marginal utility of) consumption over time and hence increase overall utility. However, inability to repay debt can result in consumer bankruptcy or foreclosure on property, which incurs large welfare losses to individual consumers through loss of goods and services, and the experience of these may impact upon psychological health.

The causality between problem debt and psychological health is difficult to establish. The positive relationship between the two might be explained by perception bias or unobserved factors not captured in cross-section analysis. There is also the possibility of a two-way causality between debt and depression: the anxiety and worry caused by the onset of problem debt might lead to declines in individual psychological health, or alternately an individual's psychological health might lead them to incur problem debts through suboptimal financial choices.

This short article summarises empirical findings from the economics literature on the psychological health effects of personal debt, as well as findings from clinical psychology, psychiatry and epidemiology. The article first summarises findings from the medical literature, then discusses the measurement of psychological health in survey data typically used in economic research on the topic and reviews recent studies which aim to understand the direction of causality between personal debt and psychological health.

Evidence from the Medical Literature

Numerous studies in the medical literature show that high levels of personal debt are associated with poor psychological health and related adverse health behaviours. These studies typically use data from the United States of America (USA) or United Kingdom (UK). For recent published literature reviews in medical journals see Fitch et al. (2011) and Richardson et al. (2013). Medical studies are typically based on samples from health service user populations, i.e. patients (Hatcher 1994; Battersby et al. 2006; Abbo et al. 2008), statistical analysis of cross-section survey data (Clark et al. 2012; Jenkins et al. 2009; Meltzer et al. 2011) or psychological autopsy studies following suicides (Chan et al. 2009; Wong et al. 2008, 2010). In general the literature does not attempt to ascertain the direction of causality between personal debt and psychological health.

Stress is the main mechanism through which problem debt impacts upon psychological health. The experience of stress is related to reduced functioning of the immune system and the direct release of stress-related hormones, which impact upon blood pressure and cardiovascular function. Findings from a large literature are consistent with the idea that life experiences which induce stress are causes of physical and mental illness (Goldberger and Breznitz 1993; McEwen 1998a, b; Cooper 2005; Schneiderman et al. 2005).

Measures of psychological health used in studies on personal debt in the medical literature differ according to the research design. Studies based on data from health service user populations (i.e. patients) typically measure psychological health using practitioner evaluations of patient symptoms, attitudes and behaviours using scaling instruments such as the Clinical Interview Schedule Revised, Beck Depression Inventory or Beck Suicide Intent Scale. Psychological autopsy studies use data from interviews with relatives of suicide completers and information from coroner reports. Studies using cross-sections of survey data make use of self-completion survey modules such as the 12-point General Health Questionnaire (or GHQ-12, see below), also used by economists.

Evidence from a meta-analysis in Richardson et al. (2013) reveals that the majority of studies (78.5%) find that high levels of personal debt are positively associated with poor mental health and also suicide completion, drug and alcohol abuse. Among recent psychological autopsy studies, which typically use only small samples with few controls, Chan et al. (2009) found that 23% of suicides are attributable to personal debt problems. However, Richardson et al. (2013) conclude 'The main problem with the current research is that the vast majority of studies are cross-sectional, meaning that causality cannot be established'.

Measurement of Debt and Psychological Health in the Economics Literature

The economics literature emphasises the causality between personal debt and psychological health, but also focuses on the measurement of debt and health in household survey data, which is the typical form of data used in the literature. Large-scale cross-section or panel surveys used for analysis include the British Household Panel Survey (BHPS) for the UK or Panel Study of Income Dynamics (PSID) for the USA. Panel surveys include self-reported data on individual indebtedness, often at the product level which over formal and informal debts, plus self-reported evaluations of whether the individual or household faces repayment problems or is behind on scheduled payments. Some surveys, such as the UK Wealth and Assets survey, also contain data on non-payment, delinquency, arrears and personal insolvency.

Panel surveys contain self-reported measures of psychological health. These include self-reported medical conditions (e.g. ‘anxiety’, ‘depression’) based on the respondent reporting their own medical history or medical conditions for which they have sought help from a medical professional. Surveys also contain psychological health data constructed from self-completion modules such as the GHQ12 in the BHPS or K-6 screening scale in the PSID. As an example, the GHQ-12 comprises 12 questions which ask respondents about their recent experience of poor psychological health, such as feeling anxious, lack of ability of concentrate on everyday activities, sleep behaviours and evaluations of their own self-worth. Responses to these questions form a 0–12 scale rating an individual’s psychological health state. The advantage of these survey instruments is that they are commonly used by public health professionals to diagnose low-level psychiatric disorders in the general population. There is strong evidence that clinical assessments of the severity of psychiatric illness closely correlate with the number of symptoms reported by the GHQ-12 scale (Goldberg 1985).

To illustrate these data, Table 1 (adapted from Gathergood 2012) provides summary data on individual problem debt status and psychological health from the BHPS. The summary data is based on two samples of BHPS respondents. The first is a 1991–2008 sample spanning the whole survey period which covers the head of each household from which summary statistics on housing payments are calculated. The second is a 1995–2008 sample, also covering the head of each household, from which summary statistics on consumer credit are calculated; this later sample is due to the introduction of questions on consumer credit payments from 1995 onwards only.

Among the whole (Column 1) 8% of respondents reported suffering from ‘anxiety, depression or bad nerves’ the average GHQ-12 score was 2.03, indicating that respondents on average reported suffering two of the 12 indicators of poor psychological health. In contrast, 16% of individuals who reported that meeting payments on their housing rent of mortgage schedule had been a problem over the past 12 months (Column 2) were currently suffering anxiety, and the average GHQ among this group was 3.50.

Among those currently two or more months late on housing payments (Column 3), 21% reported suffering anxiety and the average GHQ-12 score was 4.04. These differences in means for the groups in Columns 2 and 3 compared with the whole sample in Column 1 are in both cases statistically significantly different from zero at the 1% level. For consumer credit (Column 4 and 5), those reporting their payments as a ‘heavy burden’ on their finances also showed, on average, higher GHQ-12 scores and higher rates of reporting suffering from anxiety. The

Personal Debt and Psychological Health, Table 1 Debt problems and psychological health, BHPS sample

	1991–2008			1995–2008	
	1. Whole sample	2. Housing payment problems	3. 2+ months late on housing payments	4. Whole sample	5. Consumer credit payments a heavy burden
N	66,664	6499	1541	54,731	8864
Percentage of sample	100 %	9.7 %	2.3 %	100 %	16.2 %
Psychological health					
GHQ-12 Score (0–12)	2.03	3.50	4.04	2.04	2.87
Suffers anxiety = 1	0.08	0.16	0.21	0.09	0.14

difference in means between the two groups is again statistically significant at the 1% level.

By way of comparison, the size of the differences in psychological health among groups shown in Table 1 (with those late on housing payments 13% points more likely to suffering anxiety and showing GHQ-12 score on average 2.1 points higher) are large compared with comparisons between those in employment and unemployment. In the whole data sample unemployed workers are 4% points more likely to suffer anxiety and have GHQ-12 scores on average 1.6 points higher; hence the relationship between debt problems and psychological health is two to three times stronger than the relationship between unemployment and psychological health in these unconditional comparisons. The relationship between unemployment and health has been researched extensively in the economics literature (on which see Ruhm 2000, 2003).

Data Reliability and Perception Bias

Most studies in the economics literature make use of self-reported survey data on debt and psychological health described in the previous section (Bartel and Taubman 1986; Lea et al. 1995; Hamilton et al. 1997; Drentea 2000; Brown et al. 2005; Lenton and Mosley 2008). However, the reliability of self-reported survey debt data may be compromised if an individual's psychological health state influences their reporting of their debts or answers to debt-related questions.

This may be a particular problem for questions which ask about whether an individual's debts are a 'problem' or 'burden' for them. An individual's perception of the severity of their debt problems may be affected by their psychological health state. An individual with poor psychological health might be more, or less, inclined to subjectively report they are struggling with debts compared to an individual with good psychological health in the same financial situation. This 'perception bias' would lead to biased estimates of the impact of debt upon psychological health.

This potential measurement problem is examined by Bridges and Disney (2010). They use a short-panel of UK household survey data (The Family and Children Survey) to model the relationship between debt and psychological health. They find that objective measures of debt problems (such as self-reported values for arrears or late payment on credit) correlate more weakly with subjective evaluations of poor health than subjective measures of debt problems (such as those from questions which ask individuals about their ability to cope with their financial burdens). Their results indicate that an individual's psychological health state impacts on their subjective evaluation of their debt position.

Furthermore, they model the simultaneous relationship between debt and psychological health in a bivariate probit model and find that the relationship between both objective and subjective measures of problem debt and psychological health weakens further. They conclude that poor psychological health affects an individual's perception of their financial situation and that unobserved heterogeneity in the tendency of individuals to report problems with both their health and their finances explains most of the observed correlation between measures of problem debt and measures of psychological health. They state: 'In conclusion, it appears that much of the observed correlation between self-reported psychological well-being on the one hand and financial circumstances on the other, is a person-specific effect, associated with the individual' psychological make-up about which, as economists, we can offer little expertise'.

An alternative empirical approach which avoids potential perception bias is to use health and debt data that is not self-reported but derived from external, verifiable sources. Verifiable sources of individual-level health data include patient medical records and information collected form nurse visits conducted as part of the survey process (nurse visits are used in, for example, the English Longitudinal Survey of Ageing). Verifiable sources of credit and debt records include data from credit reference agencies or lenders. However, it is unlikely that a researcher would be able to combine individual health and debt data from different sources due to data availability and restrictions. An alternative empirical approach using administrative data is to combine local-level credit and debt data with local-level health information, an approach used by Currie and Tekin (2011) discussed below.

Evidence from Panel Data and Instrumental Variable Approaches to Measurement

Descriptive studies based on cross-sections of data provide evidence for an association between problem debt and poor psychological health. The evidence from descriptive studies is strongly suggestive that there is a causal link between problem debt and poor psychological health, but in itself it is not conclusive. Ascertaining the direction of causality between the two involves identifying the direction of causality in a way that rules out the possibility of reverse causality or the existence of omitted factors which co-determine both problem debt and psychological health.

A recent study by Gathergood (2012) exploits the panel dimension of BHPS survey data and uses exogenous instruments for problem debt. Exploiting the panel dimension, Gathergood (2012) shows that a simple analysis of the dynamics of problem debt, GHQ-12 scores and reported rates of anxiety shows that the onset of problem debt is associated with worse existing psychological health. This analysis suggests that poor psychological health is a precursor to problem debt.

Evidence for this is shown in Table 2, reproduced from Gathergood (2012). Table 2 provides summary data on GHQ-12 scores and reported rates of anxiety for different groups in the BHPS sample defined by their problem debt status over two waves of the survey for individuals present in at least two consecutive waves of the BHPS panel. The first two rows of data provide average values for two groups of individuals: those who do not have housing payment problems in the first wave (T) but report housing payment problems in the second wave (T + 1); and those who do not have housing payment problems in either wave.

As can be seen from the table, at the time of the second wave (T + 1) the difference in GHQ-12 scores and rates of anxiety among these groups is large at 1.60 points on the GHQ-12 score and 9% points difference in rates of anxiety. However,

(*N* = 648)	(3.88)	(4.16)	(0.39)	(0.43)
Not 2+ months late at T, Not 2 + months late at T + 1	1.93	1.94	0.08	0.08
(*N* = 43899)	(3.03)	(3.07)	(0.27)	(0.27)
Consumer credit repayments				
Not a heavy burden at T, Heavy burden at T + 1	2.42	2.64	0.12	0.12
(*N* = 3561)	(3.37)	(3.53)	(0.32)	(0.33)
Not a heavy burden at T, Not a heavy burden at T + 1	1.78	1.78	0.08	0.08
(*N* = 31,949)	(2.94)	(2.96)	(0.27)	(0.27)

those who reported housing payment problems at the time of the second wave had, on average, much higher GHQ-12 scores and rates of anxiety at the time of the first wave (T), at which they did not report housing payment problems. The increase in GHQ-12 score between waves for this group is only 0.43 points and the increase in the rate of suffering of anxiety among this group is only 2% points.

This evidence suggests that most of the difference in psychological health between those with and without housing payment problems is due to the pre-existing level of psychological health. This pattern is repeated for the other debt problem categories shown in Table 2, with in each case the existing levels of psychological health being much worse among those experiencing the onset of being at least 2 months behind on housing payments or facing a ‘heavy burden’ of their consumer credit debts, compared with existing levels of psychological health among those not experiencing the onset of payment problems. These results show that selection into debt problems on the basis of poor psychological health explains most of the observed association between problem debt and psychological health in the cross-section comparison.

To test whether perception bias compromises the reliability of the self-reported data, Gathergood (2012) uses two instruments for the self-reported problem debt responses in the BHPS questionnaire. Firstly, self-reported debt problems are instrumented using lender-provided measures of local-level delinquency rates on consumer credit and mortgage debt. These local-level measures correlate with geographic variation in reported rates of problem debt, but would not correlate with the variation in purely perceived debt problems induced by psychological health status.

Secondly, Gathergood (2012) examines the relationship between the self-reported data provided by the respondent in the survey (which in all cases is the head of household) and the psychological health of his or her partner or spouse. If the head of household’s perception of a payment difficulty arises due to his or her mental health state and not due to an actual difficulty, we would not expect to find a positive relationship between the head of household’s answers to the payment difficulty questions and the psychological health of the household head’s spouse or partner.

Results from both approaches yield estimates of the impact on problem debt on psychological health which are very similar in magnitude and statistical significance to those returned from estimates not using these instrumental variables strategies. As a result, Gathergood (2012) concludes that perception bias is not a driver of the observed variation in psychological health in the BHPS survey data.

Identification of Causal Effects

This final section reviews existing evidence on the causal relationship between problem debt and mental health. Studies based on household panel data have shown that the relationship is not explained by unobserved individual specific drivers of both debt and mental health or short-term changes in economic circumstance such as income reductions, job loss or other adverse events. Brown et al. (2005) conducted a panel data analysis using the BHPS and an individual fixed effects modelling approach, estimating the impact of changes in personal debt on mental health using within-individual variation over time. They controlled for a broad range of covariates, including income, employment, respondent physical health status, and physical and mental health status of other family members, plus additional socio-economic controls. Controlling for these they found a statistically significant and positive association between problem consumer credit debt and poor mental health. However, their results do not identify the direction of causality.

Two recent approaches to estimating the causal relationship between personal debt and mental health are those adopted by Gathergood (2012) and Currie and Tekin (2011). Both are based on sources of exogenous variation in financial circumstances derived from the housing market and have arisen in light of house price booms and busts in the USA and the UK. The key requirement of an instrument for problem debt is that an instrument is correlated with individual-level experience of problem debt, but is exogenous to individual changes in psychological health.

The first approach, used in Gathergood (2012), exploits movement in house prices as exogenous changes in the financial situation of individual households. Gathergood (2012) argues that local-level shocks to house prices are a source of exogenous variation in home equity and that these shocks impact upon the severity of payment problems. The reasoning behind this approach is that if a household defaults on its housing debts, it is unambiguously better for a household to face default with more rather than less housing equity. Defaulting with negative housing equity implies foreclosure, sale of the property and a resulting unsecured consumer debt which may be pursued by the credit through bankruptcy. Defaulting with positive housing equity at least allows the household to sell the home and pay down outstanding debts, or potentially renegotiate the mortgage contract and extract equity if the reason for default is temporary, such as a short-term income shock.

Using local-level house price movements as an exogenous source of home equity shock, Gathergood (2012) showed that a negative home equity shock for an individual with mortgage payment problems leads to a worsening in psychological health, whereas a positive home equity shock leads to an improvement in psychological health. Estimates also show that home equity changes in and of themselves do not impact upon psychological health directly. These results are shown for both the GHQ-12 measure of psychological health and the self-reported anxiety measure of psychological health.

Finally, Gathergood (2012) also showed that there is a social norm dimension to the relationship between problem debt and psychological health. Results show that individuals experiencing the onset of problem debt (either mortgage debt or consumer credit debt) in localities in which the bankruptcy of repossession (foreclosure) rate is higher suffer less deterioration in psychological health compared with individuals who experience the onset of problem debt in localities in which the bankruptcy or repossession rate is lower. This result also holds for both measures of psychological health.

An alternative approach to identifying the causal effect of problem debt is that adopted by Currie and Tekin (2011). They exploited the national wide-scale nature of the housing foreclosure crisis in the USA from 2005 as an unanticipated shock to household debt problems not caused by individual health. While some foreclosures are due to individual health deterioration and related job loss or medical expenses, the nature of the US housing crises was of such a scale that it was not conceivably caused by a widespread outbreak of ill health.

They used data on foreclosures at the zip code level in four US states (Arizona, California, Florida and New Jersey), combining this administrative data with data on Emergency Room (ER) visits and hospitalisations. The four states used in the analysis saw 50% of foreclosures in 2008. They investigate whether increases in foreclosures at the zip code level are linked to higher rates of ER admissions and hospitalisations.

As there is much geographic variation between neighbourhoods which might be linked both with foreclosure and psychological health (such as rates of poverty, unemployment and other socio-economic characteristics), the authors identify causal effects using within-zip code variation over time. The econometric model estimated to determine causal effects includes controls for variation in healthcare quality across localities and over time which might impact upon the decision to seek medical treatment when suffering adverse medical effects related to foreclosure.

Results show that an additional 20 foreclosures in a locality lead to a 2.8% increase in non-elective hospital visits to local hospital facilities, either as ER visits or as hospital admissions. Results also show a lag from foreclosure events to hospital visits, with estimates implying that an additional 80 foreclosures over the course of the prior four quarters lead to a 0.94% increase in the number of hospital visits. Currie and Tekin (2011) show that the adverse health effects of foreclosure are not evenly distributed across household types. Foreclosures are particularly associated with increases in non-elective visits involving young children, potentially reflecting young working households with children as a group particularly susceptible to foreclosure. They also show that house price movements not associated with foreclosure have no statistically significant impact upon hospital admissions, suggesting no severe health effects arise from movements in house prices alone (a result which mirrors the finding in Gathergood (2012) that house prices movements only impact upon psychological health for mortgage holders with existing mortgage payment problems).

Directions for Further Research

Directions of for further research include using alternative instruments for problem debt to identify the impact of exogenous problem debt events on individual health. It is possible that the nature and extent of the health impact is dependent upon the type of problem debt, in particular whether the problem debt relates to short-term debts without lasting impacts or long-term debt problems (for example those associated with poverty). It may be the case that individuals with perpetual debt problems due to poverty and low income adapt to the psychological experience of problem debt such that the impacts are less severe.

An alternative direction for future research is also to investigate the impact of poor psychological health on debt decisions. The approaches to causality used in studies in economics to date have focused on estimating the causal impact of problem debt on health while ruling out reverse causality. It may be the case that there are causal links from poor psychological health to problem debt and studies of decision making among those with poor psychological health might also consider other aspects of financial management such as budgeting and retirement saving.

Personnel economics is the application of economic and mathematical approaches and econometric and statistical methods to traditional questions in human resources management. Many of the issues studied by personnel economists can be found in traditional textbooks written by organizational behaviour scholars and other human resources specialists. Economists have something new to say about these issues, however, primarily because economics provides a rigorous, and in many cases more straightforward, way to think about these human resources questions than do the more sociological and psychological approaches. Certain questions, especially those dealing with compensation, turnover and incentives, are inherently economic. Others, like those associated with non-monetary aspects of the job, norms, teamwork, worker empowerment and peer relationships, while seemingly non-economic, are capable of being informed by economic reasoning. Economists have the advantage of knowing how to strip away extraneous detail and focus on the essentials. This allows them to provide precise and reasoned answers that are testable and refutable and thereby follow the scientific method used by the physical sciences. One drawback of the economic approach, when applied to human resources (and other) issues, is that sometimes its simplifications miss some of the descriptive detail that gives depth and understanding to a situation.

What are the main goals of personnel economics? The primary goal is to provide positive analysis of human resources practices and methods. When do firms choose to use one form of compensation over another? When are teams important? When is job rotation effective? When are certain benefits or stock grants given to workers? The list extends. But in addition to being able to describe what is, personnel economics is more normative than most fields of economics. Perhaps because the subject was taken up by business school economists whose job is to teach managers what to do, personnel economics has not shied away from being somewhat prescriptive. In part, personnel economics is an attempt to look inside the black box. It is an imperialistic attempt by economists to do what Alfred Marshall (1890) said that 'economists do not do': Marshall's famous statement that it is not the economist's business to tell the brewer how to brew beer has not been adhered to when it comes to personnel economics. Personnel economists often attempt to do precisely that; namely, to use the tools of economics to understand and sometimes even to guide practitioners and consultants in their trade.

From a practical point of view, personnel economics is important. Labour accounts for approximately 70 per cent of costs and this number has been reasonably stable over time. Changes that affect labour productivity, turnover, or aspects of compensation can have quite dramatic effects on company profits. In one recent example (see Lazear 2000b), a company altered its method of pay and consequently experienced a 44 per cent increase in productivity in a period of about six months. Such large shifts in productivity are extremely rare and come about mostly with major innovations in technology. Although changes of this magnitude are likely to be unusual even in the realm of personnel economics, the point remains that action on the cost front is likely to involve labour issues because labour is the primary component of cost for most firms.

Personnel, which has become more fashionably known as human resources management, has been around as an academic and practical subject for at least the last 50 years. But personnel economics takes a different view of many of the same questions and issues that are part of standard human resources management. How does personnel economics differ from 'old-style' personnel analyses? Primarily, the difference lies in the rigour associated with the economic approach, which is absent from traditional analyses. Personnel economics is, above all, economics. As such, it follows the approach used by economists. This approach is described in Lazear (2000a) and again in Lazear (2000c). Much of the material in the next few paragraphs is taken directly from Lazear (2000c).

First, personnel economics assumes that the worker and firms are rational maximizing agents. Constrained maximization is the basic building block of all theories in personnel economics. Empirical analyses focus on tests of rational, maximizing models. When evidence contradicts a model, the approach of personnel economists is to think more carefully about the nature of the model set-up, rather than to drop the assumption of rationality. The assumption of maximizing rational behaviour in personnel economics is in large part done in order to allow the analyst to express complicated concepts in relatively simple, albeit abstract, terms.

In many respects, this is the main virtue of personnel economics. The typical human resources text eschews generalization, arguing that each situation is different. The economist's approach is the opposite, following the scientific method that places a premium on discovering the underlying general principle.

A second distinguishing feature is that personnel economists focus on equilibrium. Like the physical sciences, almost all theories in personnel economics are consistent with some notion of equilibrium. This differs dramatically from the approaches used in other social sciences, primarily psychology and sociology. Psychologists are interested in individual behaviour and so equilibrium at the market level is not central. But when discussing issues at the level of the firm, especially those that are imbedded in a market context, equilibrium is essential. Personnel economics differs from other approaches to studying personnel in that, as in all branches of economics, there is no free lunch. Firms hire workers in a competitive labour market and cannot simply take advantage of them. Workers cannot be induced to do things that they do not want to do without appropriate compensation, either in the form of money or some other non-monetary reward.

Consider, for example, the provision of incentives. A psychologist might argue that a particular compensation structure offers stronger incentives than another – the best known is Kahneman and Tversky's (1979) prospect theory, which argues that losses impose more disutility than an equivalent gain produces utility. This implies that penalties are more powerful incentive providers than are bonuses – and might suggest that, as a result, firms should adopt the more powerful form of compensation. This ignores the fact that effort is costly and in equilibrium firms that induce more effort must pay higher wages. It is possible that too much effort results because the additional output from the effort may be smaller than the additional amount necessary to compensate the worker for the increased effort.

Third, efficiency is a central concept of personnel economics. Adam Smith's early notion of the invisible hand makes its way into personnel economics. Individuals who maximize their own utility and interact with firms that maximize profits generate behaviour that usually makes both parties better off. When efficiency suffers, say as a result of moral hazard problems that arise in the agency literature, the economist pushes the analysis to another level, asking what actions might firms and/or workers take to alleviate such inefficiency. Taking this further step assists in making better positive predictions and also normative prescriptions for the business student.

In an analogous vein, personnel economists think in terms of substitution, where other human resources specialists do not. For example, most firms have a benefits department that is distinct from the compensation department and compensation is defined specifically to include monetary remuneration only. There is no explicit recognition of trade-offs, and non-economists frequently think in terms of providing some market level of each job attribute rather than thinking in terms of a total package that guarantees some reservation utility.

Some Basic Theory

Much of the early work in personnel economics was on the theory of compensation. This was a natural outgrowth of the agency literature that dates back to 1950 (see Johnson 1950, and later Cheung 1969). The early modern treatments of the agency problem are found in Ross (1973), who lays out the fundamental agency analysis and later Stiglitz (1975) and Bergson (1978). The basic idea in this early work is that the owner and the worker are not the same individual, and so their interests may not be aligned. In particular, the worker wants money, but does not like to put forth effort. The owner wants output, but would rather not pay for it.

The standard agency problem is solved by a piece-rate compensation scheme. In the simple, risk-neutral worker case, the optimal scheme pays the worker the full value of his output on the margin, setting the piece rate equal to the (net) value of output. Generally coupled with this is a rent-sharing parameter so that

$$\text{Wage} = a + b\,q, \tag{1}$$

where q is output, $b = 1$ and a is set so that the worker is just indifferent between taking the job and taking his next best alternative.

The analysis becomes more complicated, but not fundamentally different, when noise in production and risk aversion are introduced. The most complete early analysis of this is contained in Hölmstrom (1979). The primary result is that there is now a trade-off. Because workers do not like risk, the firm must dampen the relation of wages to q. There is a trade-off between insurance and incentives. In the context of (1), full insurance can be provided by setting $b = 0$, but as a result, the worker has no incentive to put forth. Were $b = 1$, incentives are provided but the worker bears the full risk. The solution, which generally uses a nonlinear compensation scheme, forces the worker to bear some risk and sacrifices effort relative to the risk-neutral case. Another variant on this scheme is presented by Gibbons (1987). Gibbons considers the case where only the worker knows the difficulty of the job and only the worker knows his true action. Under these circumstances, Gibbons shows that workers will restrict output.

Although piece-rate incentive pay characterizes part of the labour market, especially those jobs where output is easily measured, other jobs, perhaps most, do not lend themselves to piece-rate pay. In such cases firms pay salaries, defined as pay based on an input measure, like hours of work, rather than an output measure, like sales. Lazear (1986) describes the factors that lead firms to choose between paying on output or paying on input. But salaries are not fixed and motivation is provided to workers by altering salaries over time based on performance. When absolute output is difficult to observe, workers are ranked, one relative to another, and promotions that are awarded to the better workers serve as motivation. This logic forms the basis of tournament theory, which shows that a well-designed promotion scheme based on rank alone is a perfect substitute for a piece-rate scheme. See Lazear and Rosen (1981).

There are three basic principles of tournament theory. First, prizes are fixed in advance and depend on relative rather than absolute performance. Second, larger spreads in wages at different levels of the hierarchy motivate those at lower levels to put forth more effort. Third, there is an optimal spread. Although a greater spread increases effort, at some point the additional wages necessary to compensate workers for the increased effort is larger than the additional output generated. The formal analysis sets up a problem in which workers maximize

$$\underset{\mu_j}{\text{Max}} \quad W_1 P + W_2(1-P) - C\left(\mu_j\right) \tag{2}$$

where W_1 is the wage to the winner who gets the promotion, W_2 is the wage to the loser who is not promoted, P is the probability that a worker gets promoted to the high paying job by out-performing his rival, and μ_j is effort, having cost $C(\mu_j)$. The first-order condition to the worker's problem is

$$(W_1 - W_2)\frac{\partial P}{\partial \mu_j} - C'\left(\mu_j\right) = 0 \tag{3}$$

A firm takes (3) into account and sets wages, W_1 and W_2, so as to maximize profits subject to paying enough on average to attract workers to the job.

Some implications follow from (3). First, an increase in $W_1 - W_2$ implies a higher equilibrium level of effort, since $C'(\mu_\mathrm{j})$ is increasing in μ. Larger rises associated with promotion increase the equilibrium level of effort. If promotion is valuable, workers work hard to obtain a promotion.

Second, a decrease in $\partial P/\partial \mu_j$ lowers effort. It is straightforward to show that an increase in noise or luck lowers $\partial P/\partial \mu_j$. Volatile industrial environments generally have highly skewed earnings, which serve to offset the tendency for workers to give up when there is too much randomness associated with the promotion decision.

Additional implications follow. Because nepotism reduces the effect of effort on changing the probability of winning, nepotism kills off effort in an organization. Additionally, if too many workers are competing for a given promotion, incentives are weak because effort does not alter the probability of winning very much. This provides a rationale for limiting the competition in a promotion race.

Some workers will never be promoted again and know it, but it may nevertheless be important to keep them motivated. Upward-sloping experience-earnings profiles that result in back-loaded compensation provide incentives. Workers are paid less than they are worth in the early years of their job, but more than they are worth when senior. The higher-than-alternative wage that they receive in the latter years keeps them performing on the job because they do not want to lose the (*ex post*) rents associated with satisfactory performance on the current job. To clear the market, they accept lower wages when young so that over their working life, wages add up to their productivity. Unlike the efficiency wage literature (see Shapiro and Stiglitz 1984; and Akerlof 1984 for the classic reference) that focuses on how unemployment can emerge, the thrust in personnel economics has been to ask whether less constrained compensation schemes can remove the excess supply of labour.

The theoretical literature in personnel economics is now quite rich. Topics of hiring and firing, the trade-off between money and benefits, evaluation and worker empowerment and delegation of authority are only a few of the topics analysed.

Empirical Literature

Theory is most valuable when it provides predictions that can be verified or refuted by real-world experiences. Personnel economics has an array of implications and some have been analysed in the context of data from businesses that try different aspects of personnel and compensation policy.

There are many examples, but only a few are listed here. Most obvious are tests of incentive theory. Compensation variations provide fertile ground on which to examine worker responses to incentives. A number of recent papers have examined piece-rate pay and its implications for worker behaviour, both in terms of incentives and sorting (see Lazear 2000; Paarsch and Shearer 1999; Fernie and Metcalf 1999; Eriksson and Villeval 2004). The finding is that a move from hourly pay to piece-rate pay generally increases output and attracts a more productive workforce. The incentive models of the theoretical personnel economics literature are excellent predictors of real behaviour. They do not imply that piece-rate pay is superior to hourly wages. Higher output comes at a cost (higher wages, sometimes lower quality) and the choice of compensation scheme depends on the factors described in the theory, such as measurement costs and quality–quantity trade-offs. Other examples that tie pay to output involve evidence on the nature of executive compensation and formulae that link pay to measures of output. In most cases, earnings of top executives are tied to a measure of team performance instead of, or in addition to, individual performance. The metric is stock or bonuses that are based on earnings (the best known is Jensen and Murphy 1990).

Stock and stock options have become an important part of compensation for high-level managers and for knowledge workers in general. Stock may provide incentives, but for most workers the incentive effects of stock ownership must be quite small because they own only a small part of the firm and capture a trivial part of the returns to their effort. Some argued that stock ownership, because of its gradual vesting structure, provides incentives to stay on the job (Oyer 2004; Oyer and Shaefer 2005). Recently, evidence has become available that demonstrates the significant effect of non-vested stock options and certain types of bonus payments in employee retention (Russell 2005). It is important to point out that the fact that non-vested compensation provides incentive effects does not imply that they should be used. Again, this is part of thinking about equilibrium. Inefficient retention provides benefits to the firm that fall short of worker costs and in equilibrium vanish as firms find that they must pay workers too much when they create excessive retention incentives.

There is also empirical support for the tournament view of labour markets. Larger prize spreads induce more effort; wage structures seem consistent with tournament structures, and workers behave selfishly and fail to cooperate when relative performance pay is too strong (see for example Ehrenberg and Bognanno 1990; Drago and Garvey 1998; Eriksson 1999; Falk and Fehr 2006; Knoeber 1989).

Related to tournaments, other empirical evidence provides support that upward-sloping experience-earnings profiles are used to motivate workers. These studies use the implications of the theory with respect to variations in use of the method across demographic groups and job complexity. More complex jobs with harder-to-measure output must seek forms of incentive pay other than pure piece rates. The evidence suggests that steeper profiles are used in jobs where measurement is less straightforward (Hutchens 1986, 1987, 1989). Others have pointed out that long-term employment incentives can only be used for workers who are permanently attached to the labour market. Those who have shorter expected employment duration should be more likely to be paid piece rates; those with permanent attachments should be relatively more likely to see upward-sloping experience-earnings profiles. The evidence supports this claim (see Goldin 1986).

Another kind of evidence relates to how human resource practices affect productivity. (The best known are a series of papers by Ichniowski and Shaw, for example, Ichniowski et al. 1997, 2001, 2007). Compensation is only one way that worker productivity can be altered. The actual organization of work can matter. Working in teams, using job rotation, providing training, sharing information and a number of other practices have been shown to have significant effects on worker productivity. Interestingly, the more modern human resource practices are always coupled with some kind of (team) incentive pay (Jensen and Kevin 1990). Apparently, the practices themselves, without the incentives to use and implement them, do not produce the desired effects on output.

Conclusion

Personnel economics has been among the most active fields in labour economics since the 1980s. There are three reasons. First, the questions it raises are fundamentally important. Labour is the key factor of production and understanding the ways by which labour productivity can be altered is central to the economics of business. Second, there has been an abundance of theoretical insights that are satisfying not only at the intellectual level, but that seem inherently sensible and able to explain the real world. Third, the theories provide specific implications that can be tested: when the analyses are brought into contact with real data, the theories are confirmed.

Persons was born on 12 March 1878 in West De Pere, Wisconsin; he died on 11 October 1937 in Cambridge, Massachusetts. After studying mathematics and economics at the University of Wisconsin, he taught at several universities, including Harvard where he became, in 1919, the first editor of the *Review of Economics and Statistics.*

Persons' primary contribution was in the application of statistical methods to the analysis and measurement of economic fluctuations. Early on in his career, he was involved in the debate regarding the empirical validity of the quantity theory of money. He introduced the use of the correlation coefficient into the quantity theory literature as a means of testing the relationships among the variables in the equation of exchange (Persons 1908) and was the first to employ first-differencing in the quantity-theory debate to remove trend from his data (Persons 1910).

At Harvard, Persons set out to put differing numerical series into a form which comparisons could be made both among the various series and between different points of time in a given series. In this regard, he devised the 'Harvard Barometer' technique of eliminating seasonal and trend influences from time series. Comparisons of the timing of the adjusted series showed systematic differences among them, and led Persons to emphasize the short-run, periodic, nature of business fluctuations. Consequently, in *Forecasting Business Cycles* (1931), he predicted an end to the business downturn then under way by March 1931. His prediction of an early end to the Great Depression, combined with his advocacy of fiscal retrenchment to combat the depression, may have served to deflect the profession from his substantial contribution to the literature on business-cycle measurement.

Pesch, Heinrich (1854–1926)

H. C. Recktenwald

Abstract
After studies in economics and law at the university of Bonn (1872–5) Pesch became a member of the Society of Jesus in 1876 and took holy orders in 1888. At the University of Berlin (1901–3) he deepened his economic knowledge, which was strongly influenced by the triumvirate Schmoller, Sering and particularly Wagner, who greatly appreciated Pesch's theoretical ability. In the stillness and seclusion of a Berlin cloister his scientific and literary works grew to maturity, among them the five volumes of his *opus magnum Lehrbuch der Nationalökonomie* (1905–23), a treatise of excellent scholarship yet not too proficient in economic analytics. Pesch died in 1926 in Valkenburg, Holland.

After studies in economics and law at the university of Bonn (1872–5) Pesch became a member of the Society of Jesus in 1876 and took holy orders in 1888. At the University of Berlin (1901–3) he deepened his economic knowledge, which was strongly influenced by the triumvirate Schmoller, Sering and particularly Wagner, who greatly appreciated Pesch's theoretical ability. In the stillness and seclusion of a Berlin cloister his scientific and literary works grew to maturity, among them the five volumes of his *opus magnum Lehrbuch der Nationalökonomie* (1905–23), a treatise of excellent scholarship yet not too proficient in economic analytics. Pesch died in 1926 in Valkenburg, Holland.

For his original doctrine of a community, namely the conception of a 'corporative' state which is roughly embodied in the normative programme of the encyclical *Quadragesimo Anno* (*1931*), Pesch is trying to establish norms for a reasonable order and adequate means to realize them. The guiding principle is that man is the origin, bearer and aim of all social life. Like Smith's natural axiom of controlled self-interest (never selfishness), this supreme principle can be rationally determined and empirically tested. Both principles have their roots (and no more) in Aristotle's and Aquinas' ideas. And both are in the final analysis traceable to the Creator or Nature. From this leading idea (*Leitidee*) Pesch derives a social order which stands on three pillars: the subsidiary principle (i.e. the human being and his family rank first, all other groups have to follow and to serve him); the principle of solidarity (the corollary of the *homo socialis*, who is embodied in a community which, however, can never be considered a goal in itself but has to serve man's evolution and unfolding (*Selbstentfaltung*); and the principle of unit (*Ganzheit*) (man is to consider the welfare of his brethren; that is, Smith's fellow-feeling).

On these ethical foundations Pesch explains the economic, social and political order. His eminent ability to arrive at a creative synthesis and his productive intuition in this field are widely underrated in the literature. His concept of order comes close to Smith's 'obvious and simple system of natural liberty'.

Pesch did not postulate absolute free trade and radical social policy (*Sozialpolitik*). He neglected to base his concept on a thorough analysis which would lead him to provable or falsifiable hypotheses. However, he did not argue on the level of most ethical discussions, which up to now have taken place in an illusory world of speculative possibilities and moral rigour rather than in a world constrained by fact and of explanatory hypotheses. Furthermore, Pesch avoided postulating the *absolute* observance of ethical norms by the imperfect man in his natural and imperfect surroundings.

Pesch's theory of order is still more clearly presented in his *Liberalismus, Sozialismus und christliche Gesellschaftsordnung* (1896–9). His intellectual disciple O. von Nell-Breuning, S.J., further developed and refined this theory in his *The Reorganization of the Social Economy* (English trans., 1936).

Indeed, Pesch's concept may substantially contribute (1) to modern discussion on further development of the classical order theory to solve the central problem of how to reconcile both self-interest and group-interest with the *bonum commune* of the society in a world of scarcity (as the theories of public choice or of bureaucracy are trying to do); and (2) to an understanding of the order concept behind the 'theology of liberation'.

Peso Problem

Karen K. Lewis

Abstract

If market participants expect a future discrete change in asset fundamentals, then rational forecast errors may be correlated with current information and have a mean different from zero in finite samples. This statement may seem inconsistent with the standard assumption that forecast errors are orthogonal to current information and have a mean of zero. By contrast, this article describes how this phenomenon may be rational using the example of the Mexican peso market in which it was first noted. It then illustrates how the peso problem applies more generally to a wide range of asset prices.

Asset prices are determined by expectations about the paths of future economic variables. Therefore, anticipated discrete changes in the distribution of these variables directly affect asset price behaviour. The 'peso problem' focuses upon how asset prices behave when market traders have expectations about infrequent discrete shifts in economic determinants. With these expectations, the discrete switches can induce behaviour in asset prices that apparently contradicts conventional rational expectations assumptions. The fundamental shifts are rare events and typically occur infrequently, even in relatively large samples. As such, the term ‘peso problem’ is interchangeably with the small-sample inference problems arising from these expected events.

The specific currency reference used in the term ‘peso problem’ may seem at odds with its general potential effects on asset prices. The origins of the term therefore deserve further explanation. The phenomenon is called the ‘peso problem’ because it was first noted in the Mexican peso market. The original source of the term is unknown, though some economists have attributed it to Milton Friedman.

The empirical phenomenon was originally mentioned in writing in the dissertation by Rogoff (1977, 1980) and in publication form by Krasker (1980). Based upon evidence from the Mexican peso futures market from June 1974 to June 1976, Rogoff used the relationship between futures contracts and spot contracts to test market efficiency under rational expectations and risk neutrality. He found that the implications of market efficiency were rejected, but that the behaviour of futures contracts could be explained by the market’s persistent belief that the Mexican peso might be devalued. Consistent with this explanation, the peso was devalued in August 1976.

The Peso Problem in the Mexican Currency Crisis

To illustrate the effects upon asset prices during this period, consider the relationship between the spot and forward rate of a contract for future delivery. If we define S_{t+1} as the logarithm of the future spot rate (dollars per peso) at date $t+1$ and F_t as the logarithm of the forward rate contracted at date t for delivery at date $t+1$, the relationship between the two variables may be written

$$S_{t+1} - F_t = r_t + u_{t+1} \qquad (1)$$

where r_t is the risk premium, the forecast error on the spot rate is $u_{t+1} \equiv S_{t+1} - E_t S_{t+1}$, and E_t is the expectations operator conditional on information available at time t. Through covered interest parity, the difference between the spot and forward rate also equals the return on holding peso deposits over the same period and converting the proceeds back into dollars at date $t+1$. In order to focus on the effect of expectations, the analysis below will ignore the risk premium effect. This assumption is not necessary, however, and much of the literature described below includes models of the risk premium term, r_t.

From April 1954 to August 1976, the spot peso exchange rate was fixed at 0.08 dollars per peso. During this period, which covered over 20 years, the exchange rate was constant. If we use the notation above, therefore, S_{t+1} was equal to a constant, call it S^0. Nevertheless, futures and forward contracts sold at a discount for much of the early 1970s. For example, the year ahead contract on June 1975 and June 1976 futures contracts sold at a discount of 2.6 and 2.7 per cent respectively. Similarly, Mexican peso deposit rates traded higher than dollar deposit rates over this period, implying a forward rate in (1) that was less than the *ex post* spot rate. Therefore, the *ex post* rate of return on holding Mexican peso accounts, $S^0 - F_t$, was systematically positive. Under risk neutrality, this behaviour contradicts the assumption of rational expectations since it implies that the market’s forecast errors, $S_{t+1} - E_t S_{t+1}$, were biased and serially correlated.

At the end of this period, on 31 August 1976, the authorities allowed the Mexican peso to float. Subsequently, the peso fell to 0.05 dollars per peso, implying a devaluation of about 46 per cent. If we define the logarithm of the spot rate associated with this level as S^1, the implied forecast error over this event was $S^1 - F_t \cong -46$ per cent. If one takes account of this large negative observation together with the many small positive observations over the early 1970s the implication is an average forecast error close to zero, which explains the apparent Mexican peso paradox.

Examining how traders with rational expectations would have formed their forecasts helps to define the peso market phenomenon further. Lizondo (1983) postulated that the expected future peso exchange rate could be written as:

$$E_t S_{t+1} = (1 - p_t) S^0 + p_t S^1 \qquad (2)$$

where p_t is the market's assessed probability that the authorities will devalue the peso to S^1 during the next period. Therefore, as long as the peso remains fixed at S^0, the forecast error is

$$u_{t+1} = S^0 - E_t S_{t+1} = p_t\left(S^0 - S^1\right) \qquad (3)$$

Since the Mexican spot rate over the early period was greater than the devalued August 1976 rate, the initial spot rate S^0 was greater than the anticipated rate if devaluation were to occur, S^1. As such, *ex post* forecast errors were systematically positive. The ex *post* bias observed in forecast errors depended upon both the probability of the devaluation, p_t, and the expected size of the fall in the exchange rate, $S^0 - S^1$. On the other hand, for the period when the devaluation occurred, the forecast error was a large negative number, $(1 - p_t)(S^1 - S^0)$.

In a sample with many observations of similar devaluations, forecast errors would be persistently positive with infrequent large negative observations. The frequent small positive forecast errors and the infrequent large negative forecast errors will tend to cancel each other out. Over a sufficiently large sample with enough of the rare events, the forecast errors would roughly sum to zero, as implied by rational expectations. However, the market would appear to make systematic forecast errors between the episodes of discrete changes, even though the forecasts will be unbiased in sufficiently large samples. Even in large samples, therefore, rational forecast errors with a 'peso problem' may be serially correlated.

The Peso Problem in General Asset Prices

Although first noted in the period of the fixed Mexican peso rate, this phenomenon can be found in any forward-looking asset price when market traders anticipate a discrete change in the distribution of its economic determinants. A simple example serves to illustrate the peso problem in general. Suppose that agents rationally anticipate a switch in the process of an economic variable from its current process, R^0, to an alternative, R^1. In this case, rational forecasts of asset prices that depend upon this variable include forecasts of the price conditional upon each regime process. Denote the general asset price as S_t to preserve the same notation as above. Then the expected future value of the asset price is:

$$E_t S_{t+1} = (1 - p_t) E_t\left(S_{t+1} \middle| R^0\right) + p_t E_t\left(S_{t+1} \middle| R^1\right) \qquad (2')$$

where p_t is the market's assessed probability conditional upon time t information that the process will switch to process 1; and where $E_t(S_{t+1}\,|R^i)$ for $i = 0, 1$ is the expected value conditioned upon time t information and upon process i generating the asset's determining variables.

A few examples of peso problem studies serve to illustrate the breadth of its application in diverse settings. Salant and Henderson (1978) considered the effects upon the price of gold from the market's assessed probability that governments might sell their gold holdings in large discrete amounts. In this case, the spot rate S_t represents the price of gold, $E_t\,(S_{t+1}\,|R^i)$ are the expected future gold prices conditional upon $i = 0, 1$, no government sales or government sales, respectively, and p_t is the market's assessed probability that the government will sell gold. Flood and Garber (1980) examined the price level effects resulting from anticipated monetary reforms in hyperinflation-era Germany. In this case, the spot rate represents the price level, $E_t(S_{t+1}\,|R^i)$ are the expected future price levels conditional upon no reform and reform, alternatively, and p_t is the market's assessed probability that the reform will take place. Lewis (1991) evaluated the term structure of US interest rates following the 1979 change in Federal Reserve operating procedures to determine whether the market believed a shift in policy to lower interest rates was possible. In this case, S_t represents the interest rate, $E_t(S_{t+1}\,|R^1)$ is the expected future interest rates conditional upon on shift to lower rates, and p_t is the marker's assessed probability that this shift will take place. Bates (1991) used option prices to estimate the market's beliefs that the US stock market might crash before October 1987. In this case, S_t represents the stock price, $E_t(S_{t+1}\,|R^i)$ is the expected future stock prices conditional upon no crash or crash, respectively, and p_t is the market's assessed probability that the crash will occur. Bekaert et al. (2001) analysed international term structure returns using expectations of discrete shifts in short-term interest rate regimes. In this case, S_t is the excess return of long bonds over shortterm bonds, and R^i refer to different short-term interest rate regimes. Ang et al. (2007) examine the effects upon long-horizon initial public offering (IPO) returns based upon uncertainty about which performance regime determines a given initial listing. In this case, S_t refers to the abnormal returns and R^i dictate whether they follow under- or over-performance.

In general, when traders believe a future shift may occur in determinants of asset prices, expectations will have the form given in (2′), as the above examples demonstrate. Now suppose that no change in regime occurs in the sample. Define $(S_{t+1}\,|R^0)$ as observations drawn from the current regime process. Then, the forecast errors become:

$$\begin{aligned} u_{t+1} &= \left(S_{t+1}|R^0\right) - E_t S_{t+1} \\ &= \left[\left(S_{t+1}|R^0\right) - E_t\left(S_{t+1}|R^0\right)\right] \\ &\quad + p_t\left[E_t\left(S_{t+1}|R^0\right) - E_t\left(S_{t+1}|R^1\right)\right] \end{aligned} \tag{3′}$$

As long as the process does not change, the first term represents the forecast error conditioned on the current regime and therefore has mean zero. By contrast, the second term captures the effect of an expected switch to process R^1 that does not materialize in the sample. If the expected price conditioned on process R^0 is on average greater, say, than the price conditioned on regime R^1, the mean of the forecast errors within the sample will tend to be positive. Note that, for the Mexican peso example, the conditional expectations are simply constants where $E_t(S_{t+1}\,|R^i) = S^i$, for $i = 0, 1$, so that Eqs (2′) and (3′) are equivalent to (2′) and (3′) in this case. In general, however, the expectation conditional upon each regime varies over time as new information arrives to the market.

The example in (3′) illustrates the peso problem effects upon realized returns when no switches occur in the sample. Of course, the forecast error will include this event when the switch occurs. If the switches do not occur with sufficient frequency in the sample, however, forecast errors may continue to appear to be biased. Moreover, even with sufficient occurrences of these shifts, the forecast errors may be serially correlated since they weight the difference between the two expected processes, given by the second term on the right-hand side of Eq. (3′). When the probabilities or the differences in expectations under the two regimes are serially correlated, these components of the forecast errors are serially correlated as well. In this case, the difference between the spot rate and the forward rate as in (1) will be serially correlated even in the absence of risk premia. This explanation is consistent with the observation in Rogoff (1977) that Mexican peso futures prices before the devaluation did not follow a martingale as they should have by the efficient markets hypothesis.

The Peso Problem and Bayesian Learning

The simple intuition of the Mexican foreign exchange devaluation example casts the peso problem as a problem arising from anticipated *future* shifts in fundamentals. More generally, the peso problem phenomenon has also come to encompass the asset price implications due to uncertainty about *past* discrete changes. To see why the asset price behaviour is similar, consider a simple example. Suppose that market participants believe that the regime may have shifted in some past time period, $\tau < t$. Given priors about the probability of a change, they will then update their assessed probabilities of living in a new regime as new information arrives. If they learn through Bayesian inference, the forecast errors will depend upon expectations conditioned on each regime process and upon the updated probabilities of being in each regime.

The form of these forecast errors is isomorphic to Eq. (3′). To illustrate, suppose that in fact the process changed at time τ. In this case, the current regime R^0 is the new regime, and the alternative regime R^1 is the old regime. The probability p_t represents the market's assessed probability that no change took place. Over time, as the market learns the truth, the probability of no change goes to zero and the second component in the forecast error (3′) vanishes. Clearly, these forecast errors converge to mean-zero, white-noise levels even though they may appear biased during the learning process. Similar results hold when the market does not know the parameters of the new distribution but learns them over time. For example, Lewis (1989) relates the US dollar foreign exchange rate behaviour in the early 1980s to the market's uncertainty about whether a past shift to tighter monetary policy took place. Similarly, Timmermann (1993) shows how the learning can help explain the excess volatility in stock markets.

Despite the similarity of expectations based on learning about past discrete changes and on anticipating future discrete changes, their implications for forecast error behaviour in sufficiently large samples can be somewhat different. A once-and-for-all shift in the asset process with subsequent learning will induce forecast errors that are biased and serially correlated over the learning period. However, as the market learns, the probability of the old regime continuing will go to zero and the effect from the second term on the right-hand side of (3) will vanish. Thus, with sufficient observations, forecast errors following learning will behave according to the standard rational expectations assumptions; that is, they will be mean zero and serially uncorrelated. By contrast, with sufficient observations of the discrete shifts in processes, forecast errors arising from anticipated future discrete events will remain serially correlated in general but will be unbiased.

Empirical Approaches to the Peso Problem in Asset Prices

As this description makes clear, the peso problem is inherently a problem of identifying a low probability event in a given sample. Many researchers simply acknowledge that this small sample problem may be an issue in their results. Other researchers examine the potential for peso problems to explain anomalous asset price behaviour by using different approaches to identify the peso problem in sample.

These approaches can be divided into three main groups. The first group uses a calibrated asset pricing model to consider whether a peso problem explanation can explain a given empirical regularity. For example, Rietz (1988) uses this approach to consider whether the equity premium can be explained by rare adverse events. More recently, Barro (2006) examines the plausibility of this explanation using data over the 20th century.

The second group identifies the peso problem by using dates of known discrete changes in fundamentals to empirically back out expectations from asset prices. This group of studies focuses upon easily observable shifts in fundamentals. Examples include exchange rate realignments (Bertola and Svensson 1993; Campa and Chiang 1996; Campa et al. 2002; Mundaca 2004) and announced shifts in monetary policy targeting (Lewis 1991; Hallwood et al. 2000).

The third group analyses the peso problem by directly estimating regimeswitching models of fundamentals to explain anomalous behaviour in their asset prices. This approach has the advantage that the fundamentals process can be estimated from the available data and does not require the researcher to take a stand on the timing of the events. As a result, the analysis can be conducted in a wide range of applications where the dating of events is not known a priori. Many different asset prices have been studied using this approach, including floating spot exchange rates (Engel and Hamilton 1990; Kaminsky 1993), the equity premium (Cecchetti et al. 1993), the real interest rate (Evans and Lewis 1995a), the foreign exchange risk premium (Evans and Lewis 1995b), the term premium (Bekaert et al. 2001), and IPO abnormal returns (Ang et al. 2006).

Summary

In summary, as long as agents anticipate occasional discrete changes in the process of economic variables that affect asset prices, and these changes occur infrequently, asset prices contain the potential for the peso problem. If so, then forecast errors will be serially correlated. Furthermore, unless the sample contains many observations of the discrete shifts, forecast errors will appear biased when observed ex *post* even though traders may have rational expectations. Despite this problem, empirical financial studies frequently measure the risk premium as the predictable component of the realized spot rate less the forward rate, described in (1). Therefore, if the 'peso problem' is present in the sample, researchers may incorrectly attribute asset price behaviour to anomalies rather than to the market's rational forecasts of discrete events.

Peter, Hans (1898–1959)

H. C. Recktenwald

After initial studies at Tübingen in theology, mathematics and philosophy, and later on in economics, Peter became Lectúrer (*Privatdozent*) in economics and statistics at the University of Tübingen. The Nazi regime denied him a chair because his thorough but critical analysis of Marx's and Ricardo's theories was considered to show dependence on Jewish thinking. Peter courageously defended his intellectual and ethical position as a scientist in an open letter to the *Finanz-Archiv*, a valuable document of this dark period of German history. It was not until 1947 that he obtained a full professorship in Tübingen, where he died in 1959.

Peter had a sharp and independent mind. His scientific interests and deep knowledge ranged from abstract philosophy, logic and ethics to economic analysis and social policy. He applied relatively complicated mathematical models to explain the circular flow of the economy and was one of the first economists in Germany to use econometric methods and game theory. He also made an essential contribution to modern growth theory. He postulated the application of a variety of methods (a *Methodenpluralismus*). It seems justified to classify Peter as a liberal socialist, whatever this contradictory notion may mean.

Sir William Petty was born on 26 May 1623 in the village of Romsey, Hampshire, and died on 26 December 1687 in London. His life was hectic: son of a clothier, he was a cabin boy on a merchant ship at 13, admitted to the Jesuit college in Caen (France) at 14; after serving in the Royal Navy he sought refuge in the Netherlands (1643) and Paris (1645), where he studied medicine and (with Hobbes) anatomy. He returned to Romsey in 1646 to revive his father's business; became a doctor of medicine in Oxford University in 1648, and, after an impressive academic career, Professor of Anatomy in 1650, but moved immediately – in 1651 – to the Chair of Music at Gresham College, London. He was also appointed chief medical officer to the English army in Ireland in 1651, and was responsible in 1655–8 for the topographical survey of Irish lands destined for English soldiers, from which he himself emerged with a large landed estate. From then until his death, he was engaged in the management of his estate and in endless litigation over titles of property and taxes, constantly travelling between England and Ireland. Petty also managed to participate, in 1660–2, in the founding of the Royal

Society (in full: the Royal Society for the Improving of Natural Knowledge) and in furthering its activities. He married Elizabeth Waller in 1667, and had five children by her and at least one illegitimate child.

Only a small part of Petty's written work was published under his own name during his lifetime. The main essays concerned with economic issues were published after his death, soon after the Glorious Revolution of 1688 made the political climate more favourable to the reception of Petty's ideas. The *Verbum Sapienti* and the *Political Arithmetick* were published in 1690, The *Political Anatomy of Ireland* in 1691, and the *Quantulumcumque concerning Money* in 1695, though they were written respectively in 1664, 1676, 1672 and 1682. Among the writings published during Petty's lifetime, the *Natural and Political Observations upon the Bills of Mortality* appeared in 1662 under the name of John Graunt, a good friend, although it seems certain that Petty authored at least part of it.

This work is generally considered as marking the birth of the science of demography. A collection of Petty's economic writings, containing some unpublished material, appeared in 1899 as *The Economic Writings of Sir William Petty*, edited by Charles Hull. In 1927 and 1928 other unpublished material appeared (*The Petty Papers*, in two volumes; and *The Petty–Southwell Correspondence*), edited by the sixth Marquis of Lansdowne, a descendant of Petty. Unpublished material (known as 'the Bowood Papers') is still extant at the Bodleian Library in Oxford. An important item – *A Dialogue on Political Arithmetic* – edited by S. Matsukawa was published in 1977 (Matsukawa 1977). (For Petty's complete bibliography, see Keynes 1971; for a bibliography on Petty, see Roncaglia 1985.)

Petty's contribution to the origins of classical political economy is threefold, involving method, conceptual framework, and analysis. These aspects are interconnected and often implicit in Petty's writings, which specifically refer to policy issues of his time. We will consider the three aspects separately for the sake of clarity, summarizing Petty's ideas on each of them from his several writings.

Petty refers to his method as 'political arithmetick', which comprises the following principles:

> To express my self in Terms of Number, Weight or Measure; to use only Arguments of Sense, and to consider only such Causes, as have visible Foundations in Nature; leaving those that depend upon the mutable Minds, Opinions, Appetites and Passions of particular Men, to the Consideration of others. (Petty 1899, p. 244)

This method recalls Hobbes's *logica sive computatio*, and Bacon's inductive method (to which Petty explicitly refers). It points to a rejection of the then prevailing qualitative approach to science, based on the description of the quality of the sensations associated with physical objects and human events, in favour of the newly rising quantitative–objectivistic approach. The physical sciences were experiencing this shift during the 17th century; the foundation of the Royal Society marked a decisive step in the transition from the old to the new methodology.

In this respect, the commonly held idea that Petty's 'political arithmetick' simply marks the origin of modern economic statistics should be rejected. Petty aims at something more than *recording and describing reality* 'in terms of number, weight or measure'. He aims at *expressing reality* in such terms, since this allows him to identify 'such causes, as have visible foundations in nature', that is, to identify the laws intrinsic in reality. Petty thus adopts a point of view which was embedded in the new quantitative approach to science. As Galileo expresses it: 'This great book which is open in front of our eyes – I mean the Universe – . . . is written in mathematical characters' (Galilei 1623, p. 232). According to this point of view reality *contains* natural laws, so that the task of the scientist is to *discover* these natural laws lying beneath the surface of the apparently erratic phenomena experienced by our senses. Petty himself recognizes that as a description of reality political arithmetick is necessarily imperfect; however, his aim is to locate reality's *inner structure*, not the descriptive details.

Petty's methodological contribution to the development of political economy consists precisely in this: he brings the new quantitative method into the political science dealing with the nature and causes of social wealth. As already stressed, this method means more than an intention to *measure* social phenomena: it means a systematic search for the main characteristics of human societies – a fact well expressed by Petty's other favourite term for the object of his enquiries, 'political anatomy'.

In the Preface to *The Political Anatomy of Ireland* (1691) Petty recalls Francis Bacon's parallel between the 'body natural' and the 'body politick'. (This parallel has a long tradition indeed, going back to Menenio Agrippa's apology in Ancient Rome; but in Petty's writings it loses its old moral connotation, no longer suggesting the need for diverse social groups to cooperate.) Petty then goes on: 'as Anatomy is the best foundation of the one [the body natural], so also of the other [the body politick]', and points to the need of 'knowing the Symmetry, Fabrick, and Proportion' of the 'Body Politick' (Petty, 1899, p. 129).

There is a clear parallel between the triad 'Symmetry, Fabrick and Proportion' of Political Anatomy, and the triad) 'Number, Weight or Measure' of Political Arithmetick. The new science, of which Petty claims to be the founder, is thus characterized both by its quantitative nature and by its objectivistic approach. Also, Petty's reference to the Political Body points to the 'systemic nature' of the new approach (or, in other terms, to the 'holistic nature' which from Petty onwards characterizes classical political economy).

The vision of society as a political body, comparable to the human body, was probably influenced by Petty's medical career, which earned him the Oxford chair in Anatomy (another illustrious example of a doctor–economist is provided by the founder of the Physiocratic school, François Quesnay). Thus the human body–political body comparison constitutes the background to the specification of the conceptual framework of the new science, to which Petty makes an important contribution.

Petty's notion of money, for instance, is specified through a human-body metaphor:

> Money is but the Fat of the Body-politick, whereof too much doth as often hinder its Agility, as too little makes it sick . . . As Fat lubricates the motion of the Muscles, feeds in want of Victuals, fills up uneven Cavities, and beautifies the Body, so doth Money in the State quicken its Action, feeds from abroad in the time of Dearth at Home; evens accounts by reason of its divisibility. (Petty 1899, p. 112)

This metaphor shows that Petty perceived the three functions of money: unit of measure, means of exchange, and store of value. It also shows that Petty did not consider money as constituting the wealth of nations. In fact, Petty's notion of wealth is well expressed through another body-politick metaphor (in all likelihood influenced by William Harvey's then recent discovery of the circulation of the blood: 'the blood and nutritive juices of the Body Politick' are 'the product of Husbandry and Manufacture' (Petty 1899, p. 28).

In relation to money, we can also recall that Petty clearly perceived the notion of the velocity of circulation (which is measured through reference to the customary payment intervals for taxes, rents, wages; and which is used for estimating the optimal quantity of money required to finance a given volume of income and trade).

Furthermore, Petty stresses that banks, in creating paper money, allow society to save on the cost of acquiring the precious metals necessary for ensuring the required monetary circulation.

The idea of the 'body-politick' is also relevant for Petty's analysis of the fiscal system, which mainly concerns its impact on the economic development of society.

Petty confronts his ideas on the optimal conditions for a system of taxation, considered as a coherent whole, with the chaotic situation then prevailing, and spells out the preconditions for modern fiscal institutions. He also introduces the notion now known as fiscal pressure, frequently referring in his works to the ratio between the amount of taxation and the level of national income (or of national expenditure: in fact, Petty favoured an expenditure tax over an income tax system). Interestingly, but not uncommonly, the devaluation of the currency (that is, inflation) is considered as a particular kind of tax.

The idea of the 'body-politick' implies a connection between the concept of the economic system and the concept of the nation-state. Machiavelli's work most probably influenced Petty in this respect, as well as in the shift from the moral judgement of human actions to the objective analysis of social events. Machiavelli and Petty also share common limits in their notions of the nation-state and the economic system, since they seem not to perceive the productive interrelationships connecting city and countryside, industry and agriculture: productive interrelationships on which Richard Cantillon was to focus attention, and which would constitute the main analytical contribution of Quesnay's *Tableau économique* in the 18th century.

The notion of the surplus is generally regarded as one of Petty's most relevant contributions. Petty expresses the surplus in physical terms, as the amount of product (corn) exceeding the required means of production, and identifies it with rent. In this way Petty avoids the problem of the determination of the profit rate, which in turn involves the problem of relative prices, since relative prices are required for evaluating both capital advances and the net product. (Such problems were to be taken up later by classical economists like Ricardo and Marx, and then, more recently, by Piero Sraffa.) Interestingly, Petty also expresses the surplus in terms of the number of unemployed persons who can be maintained by a group of labourers who are producing the strict necessaries for both groups, workers and non-workers alike: shades of Marx's surplus labour notion? Like the production of services and luxury goods, unemployment thus appears as a particular way of utilizing the surplus. Wages are not included in the surplus, since they correspond to the necessary subsistence of the workers (and Petty, who considers the workers as nothing else but a produced means of production, considered the subsistence wage not as the result of some automatic mechanism, but as an objective to be reached through laws regulating maximum wages).

Petty's strictly analytical contributions to the origins of classical political economy are more limited than his methodological and conceptual contributions, but are nonetheless relevant.

Petty was credited, by Marx and others, with a labour-embodied theory of value. However, the passages usually quoted to support this interpretation are in fact simplifications of a more complex (and less useful) labour-cum-land theory, based on the idea that the price of each commodity depends on the quantities of the various means of production required to obtain it. In particular, the absence of any consideration of profits and the profit rate suggests that Petty's theory of prices must be considered as very primitive. However, it provided a starting point for subsequent developments. Richard Cantillon's posthumously published *Essay* (1755), for example, dwells on the problem of the 'par' between labour and land, and this is derived from Petty's attempt to find a way of expressing one of the two 'originary' means of production in terms of other, in order to obtain a single magnitude expressing the difficulty of production of any commodity.

But what is especially relevant for all subsequent analyses of price is Petty's distinction between 'actual' and 'natural' prices or, in other terms, between exchange relationships actually taking place, and theoretical prices which express the most relevant factors influencing current prices. Petty clearly identifies (in the *Dialogue of Diamonds*, first published in 1899) the factual preconditions – the existence of a regular market, namely, of repeated acts of exchange following regular patterns – necessary for the notion of 'natural price' to be meaningful. This is an *objective* notion of natural price, distinct from the notion of the 'just price', the determination of which, as a moral rule of behaviour for sellers and buyers, was one of the main purposes of the writers dealing with economic issues for centuries before Petty's time (for example, Pufendorf). Thus, once again, Petty's contribution to the development of classical political economy relates more to concepts and method than to specific analytic propositions. Nevertheless, it is difficult to overestimate his contribution to classical value theory, for which the notion of natural price (as well as the surplus) represents a necessary prerequisite.

Petty's importance for 17th-century culture is undeniable. His search for an 'objective' science contributes to the paradigm shift that was taking place at the time. In this regard his part in the creation of the Royal Society went hand in hand with his development of the new science of 'political arithmetick'. The 'human body–political body' comparison provides a much-needed 'systemic' background to the emerging objective analysis of economic events. On both levels ('political arithmetick' and 'political anatomy'), his influence on subsequent developments was decisive: his immediate followers (for example, Gregory King and Charles Davenant) definitively established the sciences of demography and economic statistics, while Petty's conceptual framework, adopted by Cantillon, exerted a decisive influence on the development of Quesnay's economic thinking. In this way (as well as through other less direct channels) Petty influenced both Smith and Ricardo, even if they do not refer directly to his writings. Petty's relevance for the development of classical political economy is emphasized by Karl Marx, who considers Petty to be the 'founder of Classical political economy'. Later economists limit reference to some specific aspect of Petty's ideas: for instance Keynes (1936, pp. 359, 362) quotes with approbation his ideas on the use of public works as a tool of employment policy; and Luigi Einaudi (1941) refers with enthusiasm to Petty's preference for expenditure taxes. However, these aspects, while testifying to Petty's brilliant intelligence, should not obscure what are in fact his main contributions to economic science: the emphasis on the 'objective' method, and the establishment of certain key concepts which later became so basic to economic science as to be unconsciously but consistently accepted as part of our scientific background.

The pharmaceutical industry comprises firms which manufacture medicines, including vaccines. Many of these firms also perform some or all of the following functions: conducting basic scientific research to identify (patentable) chemical compounds with medicinal properties, developing those chemical compounds into safe, effective, and commercially viable medicines, gaining government approval to sell those medicines, and marketing those medicines to potential consumers and prescribers. This industry has been widely studied by those interested in the analysis of health care systems. However, I focus here on industrial organization research which seeks to explain general economic phenomena by using the pharmaceutical industry as a setting.

Certain salient features of the pharmaceutical industry have made it a popular focus of research in industrial organization. First, asymmetric information and agency problems are present. Second, innovation plays a central role. Third, entry of new products is common. Fourth, data are unusually available. Finally, the industry is regulated along many dimensions.

Economists have used the pharmaceutical industry to study how asymmetric information and agency problems can affect demand for products in a differentiated product setting. Properties of medicines are not always easily verified or understood by consumers. Furthermore, some medicines are available only through a physician's prescription, and consumers may not be the ones making purchase decisions or paying for the medicine once the decision is made. Hellerstein (1998) and Stern and Trajtenberg (1998) study the role of the prescribing physician in the type of medicine dispensed. Ellison et al. (1997) measure price sensitivity of various agents involved in prescribing and dispensing medicines. Berndt et al. (2003) study the impact of incomplete product information on the diffusion of medicines after initial release.

Researchers have used the industry to study determinants of innovation, including incentives provided to firms by various patent systems, incentives faced by researchers within a firm, the size of the firm's research effort, the diversity of its research portfolio, and the geographic proximity of other research centres. Work in this area includes Henderson and Cockburn (1996) and Azoulay (2004).

Most pharmaceutical products are initially patent-protected because they are based on the discovery or synthesis of some new chemical compound. When patents expire, then, the potential exists for entry by chemically identical products, or 'generics'. The large number of similar markets with observable dates of potential entry has proven a boon to researchers studying entry. Caves et al. (1991) and Scott Morton (1999) identify factors important in generic manufacturers' decisions to enter a market, and Ellison and Ellison (2000) look for empirical evidence of strategic entry deterrence by incumbent producers. Pervasive entry has also made the industry a natural setting for critiquing how government price indices handle product introductions. Griliches and Cockburn (1995) and Berndt et al. (1993) influenced the Boskin Commission report (Boskin et al., 1996), which suggested alternative ways of computing those indices.

Study of vertical relationships is often hampered by the proprietary nature of the transactions between firms. But pharmaceutical wholesale transactions data are often available, enabling studies such as Ellison and Snyder (2001), which tests various theories of buyer size effects.

Past regulation has shaped the industry, and significant effort is expended by the industry to shape future regulation in turn. Ellison and Mullin (2001) demonstrate the effect on the industry of proposed regulatory reform in the early 1990s, while Ellison and Wolfram (2000) provide evidence of actions the industry took to forestall reform. Also, Scott Morton (1997) studies the distortionary effect of government procurement regulations on firms' pricing decisions. Much of the research on the pharmaceutical industry has focused on the United States, but interesting questions involving international comparisons of regulatory regimes have been addressed by Danzon and Chao (2000), focusing mainly on price differences, and Kyle (2005), focusing on firms' entry, or 'launch' decisions.

Born in Calne, Wiltshire, on 10 February 1906, Phelps Brown was educated at Taunton School and then at Wadham College, Oxford, where he was a Scholar and gained First Class Honours in Modern History (1927) and in Philosophy, Politics and Economics (1929). He was a Fellow of New College from 1930 to 1947. In 1936 he published *The Framework of the Pricing System*, an orthodox exposition of marginal theory notable for its clarity.

After distinguished war service with the Royal Artillery (which provided material for *The Balloon*, a novel published in 1953), he became the first Professor of the Economics of Labour at the University of London, teaching at the London School of Economics from 1947 until 1968, when he retired as Emeritus Professor. His lecture courses, 'Applied Economics' and 'The Economics of Labour', were well attended and valued for their incisiveness and lucidity. *A Course in Applied Economics* was published in 1951, frequently reprinted and issued in a second edition, with J. Wiseman, in 1964. The reader was invited to apply economic analysis to practical problems 'seen in the many-sidedness that calls for more insights than those of the economist alone'. *The Economics of Labor* appeared in 1962 as the first of the Yale University Studies in Comparative Economics. At the LSE, Phelps Brown carried out a series of studies in the tradition of the great British sociologist-statisticians. These were republished in Henry Phelps Brown and Sheila V. Hopkin, *A Perspective of Wages and Prices* (1981). They are characterized by a scrupulous assembly of data from various countries and, in the case of building wages and the price of consumables, extended over seven centuries. A remarkable stability was found in building wage rates, with no sustained change in 500 out of 690 years, and in differentials between craftsmen and labourers, with a failure by supply and demand to overcome 'the inertia of convention' (p. 8). An ability to combine history, sociology and statistics to illuminate economics is demonstrated in *The Growth of British Industrial* Relations: *A Study from the Standpoint of 1906–14* (1959), in *A Century of Pay* (1968) and in *The Inequality of Pay* (1977). In this last, a mass of data from many countries is marshalled and analysed to assess the relative significance of market and sociological factors in determining inequalities of pay. The conclusion is that these differences are 'better explained by the play of market forces than by that of custom, convention, status, or power' (p. 325). In *The Origins of Trade Union Power* (1983), however, the emphasis is on socio-psychological forces: 'because attitudes govern responses, they are among the basic determinants of the course of history . . . . At the last we are left with the paradox of historical understanding, that we can trace past happenings to their causes without thereby gaining the power to predict' (pp. 300 and 302). Phelps Brown pursued his work on inequality in the wide ranging *Egalitarianism and the Generation of Inequality* (1988).

Phelps Brown served on a number of public bodies: as one of the 'Three Wise Men' (the Council on Prices, Productivity and Income) in 1959; on the National Economic Development Council, 1962; on the OECD Working Party on Wages and Labour Mobility, 1963–4; and on the Royal Commission on the Distribution of Income and Wealth, 1974–8. He was awarded a knighthood in 1976, and became a Fellow of the British Academy in 1960. He was President of the Royal Economic Society, 1970–2, and in his presidential address (published in the *Economic Journal*, 1972) presented his credo on the nature and methods of economics, joining other critics who had independently arrived at similar conclusions: training in advanced economics might be actively unhelpful to those concerned with the application of policy, for 'it is impaired from the first by being built upon assumptions about human behaviour that are plucked from the air' (p. 3). His remedies were the removal of the traditional boundary between economics and the other social sciences; a clinical commitment to diagnose and prescribe for particular economic ailments, beginning with practice and working back to theory; the study of history as an essential part of economic training; more observation of actual behaviour, ingenuity in devising methods, accumulating facts, seeking connections and significant detail (p. 9). This analysis was further developed in 'The Radical Reflections of an Applied Economist' (1980), reinforcing and extending the arguments of 1972.

A detailed obituary is Hancock and Isaac (1998); see as well his own 'Autobiographical Notes' (1996).

Phelps, Edmund (Born 1933)

Gylfi Zoega

Abstract

Edmund Phelps is a Nobel Prize winner in economics who has contributed to our understanding of the supply side of the macroeconomy. He showed that there is no stable trade-off between inflation and unemployment. He derived the socially optimal level of saving and the socially optimal level of research into new technologies and showed how technological progress depended on the size of the population and its level of education. In recent years, Phelps has developed models of the equilibrium unemployment rate, what he calls structural unemployment, that can explain the long swings of unemployment as well as differences across countries.

Edmund S. Phelps was born in Evanston, Illinois, on 26 July 1933 and grew up in Hasting-on-Hudson, New York. He attended Amherst College as an undergraduate, where he took a second-year economics course, at his father’s suggestion, which sparked an interest in economics. After receiving his BA degree in 1955, Phelps started graduate studies at Yale, where he was influenced by, among others, James Tobin, William Fellner, Henry Wallich and Thomas Schelling. He received his Ph.D. from Yale in 1959. After a short spell at the Rand Corporation, Phelps accepted a research post at the Cowles Foundation in 1960. In 1966 he left Yale for the University of Pennsylvania where he stayed until 1969. There followed a year visiting Stanford University and then in 1971 a move to Columbia University, where he was later made McVickar Professor of Political Economy. At Columbia he met his wife, Viviana Montdor Phelps.

Phelps was elected to the National Academy of Sciences (USA) in 1981 and was made a Distinguished Fellow of the American Economic Association in 2000. He is also a former vice-president of the Association, a fellow of the Econometric Society, the American Academy of Arts and Sciences and the New York Academy of Sciences. A Festschrift conference in his honour was held at Columbia University in October 2001 and the volume published by Princeton University Press in 2003 (Aghion et al. 2003). Phelps received the Nobel Prize in economics in 2006 for his work on intertemporal trade-offs in macroeconomics.

The Economics of Phelps – A Brief Outline

During a telephone conversation with journalists in Stockholm, after being told that he had been awarded the Nobel Prize in economics, Phelps described his contribution as that of introducing people to macroeconomics. This was indeed the tenet of the 'Phelps volume' of 1970, which contained a selection of path-breaking papers, all providing microeconomic foundations for macroeconomics (Phelps et al. 1970c). By convincing others to follow suit in explaining macroeconomic relationships with models that describe the behaviour of firms, workers and consumers, Phelps began to transform macroeconomics. Moreover, he also contributed to bringing economic theory closer in line with 20th-century economic life by emphasizing imperfect information and imperfect knowledge with its accompanied market failures into macroeconomics. This heralded another transformation of the field.

Since the publication of his well-known paper on the golden rule of accumulation (Phelps 1961), Phelps has introduced new ways of thinking about such diverse issues as the effect of monetary policy on output and employment; equilibrium unemployment and efficiency wages; the sources of economic growth in the long run; imperfect competition; discrimination in the workplace; and optimal inflation targeting. His work can be divided chronologically into four distinctive phases. In the early to mid-1960s he wrote extensively on growth theory and produced the golden rules of growth and models of technological progress that were genuine precursors to what we now call endogenous growth theory. In the late 1960s and early 1970s his attention turned to the unemployment–inflation trade-off. Phelps showed how an increase in the supply of money would make firms raise output in the short run while in the long run only wages and prices were affected. The rejection of the notion of a stable Phillips curve – providing policymakers with a menu of unemployment/inflation pairs – was one of the most significant achievements in the history of macroeconomic thought, which changed the practice of monetary policy profoundly. It also opened the avenue to research on the optimal design of monetary policy, which essentially became an intertemporal optimization problem (see Phelps 1967, 1972b), as well as towards studying the determinants of the steady-state equilibrium unemployment rate, which Friedman dubbed the natural rate of unemployment (Friedman 1968). A third phase in Phelps's research consisted of a reaction to the rational expectations revolution and its challenge to the effectiveness of monetary policy. In the 1970s Phelps and colleagues – mainly at Columbia University – constructed models with rational expectations but also having wage and price contracts, wages and prices set for longer periods than it takes to change the course of monetary policy (see Phelps and Taylor 1977; Taylor 1980; Calvo 1983). These papers showed that systematic monetary policy was possible in spite of agents having rational expectations. This was followed by a direct attack on rational expectations, when Phelps and Roman Frydman challenged the idea by demonstrating the implications of each agent having a distinct model of the world in mind (Frydman and Phelps 1983). During the fourth phase, Phelps responded to another challenge, this one that to his natural rate theory presented by the persistent elevation of unemployment in much of the Organisation for Economic Co-operation and Development (OECD) countries in the 1970s, 1980s, and 1990s. He proposed a set of generating general-equilibrium models of equilibrium unemployment (Phelps 1994) that can explain the long swings in the unemployment rate for a given country as well as differences in average unemployment across countries.

Capital Accumulation and Endogenous Growth

One of Phelps's first influential papers was his 'The Golden Rule of Accumulation: A Fable for

Growthmen', which was published in the *American Economic Review* in 1961. In the paper he follows in the footsteps of Ramsey (1928) in deriving the golden rule of capital accumulation that maximizes the long-run level of consumption per capita. According to his golden rule, the savings rate should be set equal to the share of capital in national income. Shortly after writing this paper Phelps went on to introduce the notion of dynamic inefficiency, which is characterized by a state where lowering the rate of saving would raise the utility of all generations, both current and future (Phelps 1965). In contrast, Phelps and Pollack (1968) showed how inefficiently low levels of saving might arise if each generation discounted its own future utility at a lower discount rate than the utility of future generations. This idea later became know as 'hyperbolic preferences' and has been applied to the study of diverse phenomena.

Phelps also introduced many of the ideas that later became a part of what is now known as endogenous growth theory. He went beyond the neoclassical framework and gave people an explicit role in the generation and adoption of ideas. In his 2006 Nobel Prize Lecture he describes the neoclassical growth model in the following words:

> Neoclassical growth theory was conspicuous in having no people in it. It explained the accumulation and investment of physical capital yet the driving force in that story – increases in knowledge, called 'technology' – rains down exogenously, like manna from heaven – and the selection among new technologies is instantaneous, costless and error-free. Nowhere were people required except in the production functions. It would have been better to suppose that machines do all the producing and that people are deployed over the vast range of activities involving management, judgment, insight, intuition and creativity. (Phelps 2006)

Phelps, knowing that technological progress requires people doing research, explicitly modelled technological progress as a function of the number of workers doing research. For constant exponential growth his model calls for an exponential growth of labour inputs into research, which makes the long-run rate of growth of technology ultimately determined by the growth rate of the population. Two implications followed. First, there is a golden rule level of research effort that maximizes the level of consumption per capita, similar to the golden rule of investment. In other words, a society can have excessive research in that consumption per capita is lower than it would be if more people were producing and fewer engaged in research – the gains in technology cannot compensate for lost consumption. The other implication is that a larger population provides a larger number of people doing research and hence makes it possible to climb to a higher technology path. The following quotation is revealing:

> One can hardly imagine, I think, how poor we would be today were it not for the rapid population growth of the past to which we owe the enormous number of technological advances enjoyed today. . . Another instance of external economies is parallel. Our artistic heritage is much like our technology; it is a part of our 'public capital'. If I could re-do the history of the world, halving population size each year from the beginning of time on some random basis, I would not do it for fear of losing Mozart in the process. No improvement of our dirty air and our traffic congestion could compensate me for that! (Phelps 1968b, pp. 511–2)

The adoption of new technology also requires people. Nelson and Phelps (1966) study the implications of managers needing to have an idea about the expected value (net of costs) of a technological innovation and the probability of a successful adoption. They propose the idea that education helps managers in this regard; education enhances the ability to learn, understand and adopt what others have discovered. Accordingly, economic growth in the long run depends on the level of education, not its change, as confirmed by recent empirical work. The Nelson and Phelps paper also introduces the concept of a technology gap between each country and a technology leader, an idea that has become important in recent work on endogenous growth. The steady-state technology gap is shown by Phelps to be a decreasing function of the level of education and a positive function of the rate of change of leading technology.

Inflation and Unemployment

The rejection of a stable inflation–unemployment trade-off is perhaps Phelps's greatest achievement. He did this essentially by bringing expectations into macroeconomic models of inflation and unemployment. By turning expectations into a state variable, reflecting past unemployment/inflation choices, Phelps showed how monetary policy had an intertemporal dimension. By increasing the supply of money and lowering unemployment today inflation is increased, which eventually raises expectations about future inflation and makes the inflation–unemployment trade-off worse – there is no long-run trade-off between unemployment and inflation, contrary to what the economics profession had believed.

In Phelps's 1968 paper in the JPE he sets himself the task of explaining why an increase in the supply of money has a positive effect on output in the short run, instead of just raising prices and wages (Phelps 1968a). The paper provides microeconomic foundations for wage setting, introduces the notion of efficiency wages and equilibrium unemployment, and provides a model of the labour market with job search. Each of these contributions opened up paths for others to research.

In that 1968 paper Phelps models the labour market using a search framework where heterogeneous firms and workers are searching for a suitable match and they meet randomly at a rate determined by the number of unemployed workers searching and the number of vacancies that need to be filled. The frequency of matches is described by a matching function, which makes the paper a forerunner of the matching theory of Diamond, Mortensen and Pissarides. However, as Phelps pointed out later, the existence of unemployment in equilibrium was essentially not dependent on the heterogeneity of workers and labour market search; all that was needed was rising marginal training costs and job heterogeneity that made workers quit their jobs occasionally (see Phelps 1995). In the model, firms and employees have to make their decisions before learning about the decisions made by others. An expectational disequilibrium is created when a positive monetary shock drives unemployment below its equilibrium level and firms experiencing higher quit rates respond by raising their money wages, thinking that this will raise their relative wages. Here Phelps spearheaded the work on efficiency wages, an idea later developed by Steven Salop, Guillermo Calvo, Carl Shapiro and Joseph Stiglitz. But, to continue the present story, observed wage inflation rises when every firm raises its wages and this is soon reflected in expectations of higher wage inflation which makes each firm raise wages even more, hence further increasing actual wage inflation. The only non-inflationary point is at the equilibrium rate of unemployment where expected wage inflation equal actual wage inflation. The paper has the seeds of a model of an endogenous natural rate because the rate of equilibrium unemployment is shown to be a function of the rate of growth of the labour force – an increase in the rate of growth of the labour force raises the level of the equilibrium unemployment rate due to rising marginal costs of hiring.

In a separate paper, Phelps proposed a parable of an economy in which output is produced on separate islands, each having its own labour market. When wages and prices are set on one island, this is done without the knowledge of what is happening on the other islands. When demand goes up, due to a loose monetary policy, individual producers do not realize that this is happening; instead they think this is at least partly caused by the changed preferences of consumers and hence do not raise wages and prices fully to neutralize any output effects. Only gradually do their expectations about prices and wages adjust, making them raise wages further, thus eliminating the output effects (Phelps 1970b).

Phelps treats expectations of wages and prices as a state variable affecting output and employment. What matters for output and unemployment is the deviation of actual wages and prices from their expected values. The implication is that a monetary stimulus has only a short-run effect on employment and output; in the long run both are determined by the structure of the economy (that is, non-monetary factors). This is the *natural-rate hypothesis.* The policy implication that follows is that central banks must be concerned about the effects of their actions on inflationary expectations. If they reduce interest rates today, they may stimulate output and employment but at the cost of higher expected inflation – an upward shift of the short-run Phillips curve – which requires higher interest rates in the future, hence lower employment and output. Monetary policy becomes an intertemporal planning problem (see Phelps 1967, 1972b). This intertemporal dimension of monetary policy is taken quite seriously by independent central banks that target inflation. The intertemporal dimension of policymaking was emphasized by the Nobel committee when explaining its decision to choose Phelps for the prize.

Phelps's treatment of the labour market as plagued by various imperfections and market failures was mirrored in his description of goods markets. Phelps proposed an early model of imperfectly competitive goods markets in a joint paper with Sidney Winter in the Phelps volume of 1970. The basic idea is that consumers have imperfect information about prices and therefore become customers where they believe prices to be lower. However, information about prices gradually spreads between consumers and when a consumer learns about lower prices elsewhere he leaves his present supplier. In this set-up firms treat their market share as an asset, comparable to their stock of capital and trained employees. The markup decision becomes an intertemporal investment decision; a price increase, while raising current profits, gradually causes customers to drift elsewhere, hence reducing future profits. The implication is that the markups decision is affected by macroeconomic variables such as the rate of interest and the expected rate of growth of sales to each customer. A fall in the rate of interest, as well as a rise in expected sales per customer, would make firms cut markups in order to invest in an expanded market share. Similarly, when firms expect an imminent recession they have an incentive to raise prices so that price inflation precedes recessions. The customer market model later played an important role in the general equilibrium models of the natural rate developed in the 1994 book, *Structural Slumps.*

New Keynesian Economics

In the early 1970s Robert Lucas combined Phelps's island parable and the assumption of rational expectations to generate what became known as new classical economics (Lucas 1972). In these models only unexpected demand shocks affect output and employment and, more controversially, the deviations of these variables from their equilibrium values only persist as long as expectations remain incorrect; hence anticipated stabilization policy is ineffective. Phelps responded – often in collaboration with his colleagues at Columbia, John Taylor and Guillermo Calvo – by showing that a firm's expectational errors could have real effects even in models having rational expectations, where there is no lack of understanding or perception of what other firms were up to, because of staggered wage and price contracts. The objective was to establish microfoundations for the Keynesian prediction that a permanent demand shock causes a persistent slump and that monetary stabilization policy can be effective. The proposed models are based on the simple observation that wages and prices are never adjusted continuously, but by convention they are set periodically and the timing of wage and price changes is staggered across firms. However, money is neutral in the long run in the staggering models and output tends towards an equilibrium level, unemployment towards its equilibrium level. Phelps was the first to express the view that a model combining rational expectations and wages and prices being set at regular intervals could give Keynesian results (Phelps 1974). This work later became known as New Keynesian economics (see Phelps and Taylor 1977; Fischer 1977; Taylor 1980; Calvo 1983).

Phelps continued his attacks on new classical economics in the 1980s when, in collaboration with Roman Frydman, he challenged the very notion of rational expectations by expressing scepticism about their relevance when agents' actions depended not only on their beliefs about aggregate variables but also about other agents' beliefs. Individual agents, when acting on their understanding of an economic model, may not converge to a rational-expectations equilibrium because they need to continuously re-estimate while other agents are doing exactly the same. Frydman and Phelps (1983) claim that individual rationality does not guarantee the coordination of beliefs that is assumed in a rational expectations equilibrium, and emphasize the need for a model of learning as an integral part of a model of macroeconomic dynamics.

The Changing Natural Rate

In the late 1980s and early 1990s, Phelps's attention turned to explaining the persistent rise of unemployment in most OECD countries in the previous two decades. While unemployment had been lower in Europe than in the United States in the 1950s and 1960s, European unemployment started its ascent in the 1970s and moved to a higher plateau, where the big continental economies still find themselves. This experience turned out to be a challenge to Phelps's important work on equilibrium unemployment. How come, asked the critics, that unemployment does not revert back to its pre-shock levels? What happened to the natural rate? In spite of Phelps's 1968 *JPE* paper having the seeds of a model of an endogenous natural rate, this model was inadequate when it came to explaining the persistent rise of unemployment from the early 1970s on.

It is a testimony of Phelps's pervasive influence on the theory of unemployment and inflation that initial attempts by others to explain the persistently high unemployment in the 1980s were to a large extent based on ideas taken from his 1972 book, *Inflation Policy and Unemployment Theory.* Here he introduced the concept of 'hysteresis' to economics: there is hysteresis when an equilibrium point depends on the path taken by prices and quantities towards the equilibrium. In the labour market context, the level of equilibrium unemployment may depend on the path taken toward it, that is, a temporary recession may have a permanent effect. In the same book, Phelps went on to consider some possible hysteresis channels. He suggested that unemployment might adversely affect the human capital and work habits of those affected and also that hysteresis could arise due to the dynamics of union membership: a recession reduces the number of union members and this makes those remaining push for higher wages, thus preventing employment from recovering. The hysteresis effects of long-term unemployment working through human capital depreciation were emphasized and developed further by, amongst others, Layard et al. (1991), while Lindbeck and Snower (1988) extended and developed the idea of hysteresis arising from insider–outsider dynamics.

Phelps disagreed with those who believed that hysteresis could explain the failure of unemployment to fall in the 1980s following the steep recessions at the beginning of the decade. He responded with a series of papers that gradually built a general equilibrium model of the determination of equilibrium unemployment – in steady state the natural rate of unemployment. This work culminated in the publication of *Structural Slumps* in 1994. This book has three prototype models that are non-monetary and emphasize the role of various market imperfections in goods and labour markets. The key imperfection in the labour market is asymmetric information, which leads firms to use wages to reduce quitting and shirking. There arises an upward-sloping wage curve in the wage-employment plane that reflects efficiency-wage considerations. Three models described labour demand. The first uses the customer market set-up of Phelps and Winter (1970a) where firms set markups so as to maximize the present discounted value of future profits and customers have imperfect information about prices charged by different suppliers. In this model, a rise in the real rate of interest – or a fall in the expected rate of growth of sales per customer – makes firms disinvest in market share by raising the markup of price over marginal cost, which effectively lowers the real demand wage and raises the natural rate of unemployment. In the second model, firms are concerned about quitting because of the cost of training replacements. Managers use wages to deter quits and the hiring decision also becomes an intertemporal investment decision. Higher interest rates and lower expected productivity growth both make firms reduce hiring as well as lowering wages, which raises the quit rate. The third and final set of models has two sectors: a labour-intensive capital goods sector and a capital-intensive consumer goods sector. A rise in real interest rates makes the relative price of the labour intensive capital good fall, which then lowers the price of labour, raising the natural rate of unemployment. Fitoussi and Phelps (1988) – a precursor to *Structural Slumps* – provide a monetary exposition of some of these effects.

In *Structural Slumps*, as well as in the papers that followed, the elevation of unemployment in the OECD countries in recent decades – particularly on the Continent of Europe – is explained by the simultaneous fall in the rate of productivity growth and the rise of world real interest rates in the early 1980s (see Hoon and Phelps 1997; Phelps and Zoega 1998; Fitoussi et al. 2000). Europe did well in the first two decades following the Second World War because of a combination of low world interest rates and higher productivity growth. Productivity grew at a brisk pace because Europe could imitate the United States – adopt technology that had been developed there in the pre-war years – and meanwhile enjoy high productivity growth in spite of the economic models of the large Continental economies, which otherwise stifled entrepreneurship, initiative and innovation. The closing of the gap and a simultaneous rise in world real interest rates caused a structural slump that monetary policy could not remedy. Analogously, the non-inflationary boom in the United States at the end of the century can be explained by the effect of an anticipated productivity increase in the labour demand wage.

With the passing of time the view that long swings of unemployment require a theory of a changing natural rate of unemployment has gained acceptance. The current debate is focused on the importance of labour market institutions per se and macroeconomic shocks in determining the natural rate of unemployment. Recent work by Phelps has described the adverse effects of Europe's economic model on entrepreneurship, innovation and growth, stemming from its culture as well as the institutions of financial and labour markets, which foster rent seeking and protect vested interests instead of promoting initiative, risk taking and innovation.

Phelps has been interested not only in the macroeconomic causes of unemployment; his interests also extend to the fate of the disadvantaged in modern societies. In the 1990s he wrote a book titled *Rewarding Work* (Phelps 1997) on the problems facing low-skilled workers. This book emphasizes the importance of having a stable job for self-realization, mental stimulation, lending a rhythm to daily life and participation in society as well as income to support one's family and to share in the consumption and leisure activities of others. He describes the worsening of job prospects for the lowest-skilled American workers and proposes a scheme of general subsidies for the lowest paid. The book demonstrates a genuine commitment to help improve society, as do his frequent articles in the *Financial Times* and the *Wall Street Journal*.

Other Contributions

The literature on statistical discrimination originates with Phelps (1972a) and Arrow (1972, 1973). Again we start with asymmetric information, in this case about an individual worker's productivity. Given a statistical correlation between a worker's group attributes and average productivity in the group, an employer may wish to discriminate on the basis of which group the worker belongs to. Unequal treatment of identically productive workers may give a result that does not depend in any way on the employer's preferences or prejudice.

In the field of public finance, Phelps (1973a) found that inflation, being a source of tax revenue, should be chosen optimally along with other forms of taxation. A positive rate of inflation is required to minimize the distortions from different forms of taxation. Finally, there is the 'Phelps–Sadka result', namely, that the marginal tax rate should approach zero at the top of the income distribution because policymakers can observe only wage incomes, not wage rates per hour (Phelps 1973b).

Last but not least, one should mention his *Seven Schools of Macroeconomic Thought* that offers a very personal description of the genesis and distinctive characteristics of the macroeconomics of Keynes, monetarism, the New Classical School, the New Keynesian School, supply-side economics, real business cycle theory, and what he called the Structuralist School, which includes the work done on endogenizing the natural rate of unemployment using nonmonetary models in the 1980s and 1990s.

Concluding Thoughts

This overview of Phelps's work is a testimony to his impact on the history of macroeconomic thought. From the microfoundations of macroeconomics, the attack on the Phillips curve trade-off and equilibrium unemployment, to efficiency wages, optimal monetary policy, staggered contracts and a theory of moving equilibrium rate, Phelps has helped shape our view of the macroeconomy. Moreover, as a person he has clearly inspired and motivated a host of other well-known economists in their work. A surprising number of important contributions trace their origins to his influence. One can say that this particular contribution of his is more subtle yet no less real. For almost half a century Edmund Phelps has contributed to economics, driven by the excitement of discovery and the joys of creativity.

Philippovich von Philippsberg, Eugen (1858–1917)

H. C. Recktenwald

Abstract

A Viennese by birth, Philippovich began his academic career as a Lecturer (*Privatdozent*) in Vienna (1884), after studies in economics in Graz, Vienna and Berlin. He obtained a chair in Freiburg (Breisgau) and returned to Vienna (1893), where he worked until his death. Deeply interested in the economic problems of his time and passionately engaged in social reforms, he took an active part in Austrian and German political life. As a member of the upper house of parliament and the leading spirit of the 'Austrian Fabians', Philippovich had a significant influence on social legislation in Austria. Like the German academic socialists (*Kathedersozialisten*) Schmoller and Wagner, members of the Verein für Socialpolitik (of a New Deal type) with whom he cooperated closely, he was a regulationist of the market process, who attributed to the state a moral and economic competence which seems to be wishful thinking rather than based on reason and experience. He strongly believed that a 'middle course' between socialism and a competitive economy would help to ease economic and social tensions which were largely caused by overpopulation along with the overcrowded labour market during Germany's transition from an agrarian into an industrial nation. On the other hand he realized better than most of the German reformers that a sound analytical foundation was necessary for any policy of reasonable reforms.

A Viennese by birth, Philippovich began his academic career as a Lecturer (*Privatdozent*) in Vienna (1884), after studies in economics in Graz, Vienna and Berlin. He obtained a chair in Freiburg (Breisgau) and returned to Vienna (1893), where he worked until his death. Deeply interested in the economic problems of his time and passionately engaged in social reforms, he took an active part in Austrian and German political life. Like the German academic socialists (*Kathedersozialisten*) Schmoller and Wagner, members of the Verein für Socialpolitik (of a New Deal type) with whom he cooperated closely, he was a regulationist of the market process, who attributed to the state a moral and economic competence which seems to be wishful thinking rather than based on reason and experience. He strongly believed that a 'middle course' between socialism and a competitive economy would help to ease economic and social tensions which were largely caused by overpopulation along with the overcrowded labour market during Germany's transition from an agrarian into an industrial nation. On the other hand he realized better than most of the German reformers that a sound analytical foundation was necessary for any policy of reasonable reforms.

Evidently his interest in theory increased (*Die Entwicklung,* 1910) and was influenced by the Austrian school of Menger, Wieser and Böhm-Bawerk. Indeed, in his *Grundriss* (1893–1907), a leading German textbook on economics for a whole generation, he successfully attempted to bridge the gap between the two opposing schools: it was mainly through this channel that Austrian theories and marginal utility analysis reached German students and not via Gossen's or even von Thünen's pioneering works.

Like many of his contemporaries, Philippovich was a careful thinker and a great teacher of intellectual stature who sometimes liked to mistake the chair for the pulpit in order to preach instead of explain and reason.

Phillips Curve

Edmund S. Phelps

Abstract

In 1957 A.W. Phillips argued that, other things equal, the rate at which the nominal wage level was changing was a decreasing function of the level of the unemployment rate. Further, the rate of unemployment required to keep the rate of wage inflation down to the normal level was certainly positive in the United Kingdom, the domain of Phillips's data, had remained stable for nearly a century. Milton Friedman and Edmund Phelps criticized the concept of a stable Phillips curve for having treated wage-setters' behaviour, which presumably involved their expectations of the general wage movement, as a mechanical toy.

By the 1950s there was achieved a working synthesis, despite some unsolved problems, of the contributions of Keynes to monetary theory with the older truths of his several predecessors Marshall, Pigou, Wicksell and Fisher. Given the supply of money, there is a nominal price level that is in some suitable sense the equilibrium price level; more generally, there is an equilibrium path of the price level. The equilibrium price level in the current period, given next period's price level, is just high enough to reduce the real value of this period's cash balances down to the quantity demanded – figured at the corresponding nominal rate of interest (which is a decreasing function of this period's price level) and output level (which was taken to be independent of the price level if nominal wages were also taken as finding their equilibrium level). If people expect that the general level of prices and nominal wages is higher, and we assume that the actual price level at first equals this expected level, the result will be disappointment – an unexpected weakening of sales. Presumably, the price and wage levels will then tend to adjust, and perhaps employment will detour from its equilibrium level in the process.

The disequilibrium dynamics of the adjustment process, however, remained *terra incognita*. Suppose that is a sudden and unexpected disturbance that displaces upwards or downwards the path of the equilibrium price level. Keynes had declared in his 1936 book that the money wages set by producers would not generally take the downward jumps occasionally necessary for continued maintenance of equilibrium, hence the need for a more general theory of interest and employment in which the nominal wage level was not on the equilibrium track. (He further opined that lessened wage inflexibility would be destabilizing.) By the 1950s it was agreed that wages would *gradually* move from the former equilibrium path, if we assume they were originally in equilibrium, toward the new and lower equilibrium path, whether or not there would be later overshooting, and further that, if there is such gradualness, the result will be a bulge of unemployment during the process of wage adjustment. Similarly, an upward displacement of the equilibrium path would likewise engender only a gradual adjustment of money wages, accompanied in this case by a dip of the unemployment rate below its equilibrium, or normal, level. Increasingly, economists spoke of buying a spell of abnormally low unemployment by generating a round of inflation. (Yet, some economists of Austro-Hungarian or German schooling, notably William Fellner, argued that successive doses of (equal) inflation would lose their effectiveness, so that the same effect on unemployment would require ever increasing doses, as anticipations of higher demand came to be built into wage contract increases.) The term cost inflation arose to refer to the sort of inflation the avoidance of which needed the discipline, and social waste, of unemployment above what could be achieved through high demand.

It was against this background that A.W. Phillips's extraordinary article, scholarly yet accessible, appeared in the academic journal *Economica* in 1957. Phillips changed the terms of discourse of the subject from the qualitative and discontinuous to ordinary quantitative terms. Other things equal, such as the rate of change of unemployment, the rate at which the nominal wage level is changing – the (algebraic) rate of wage inflation – is a decreasing function of the level of the unemployment rate. Further, the rate of unemployment required to hold down the rate of wage inflation to the level of normal experience – the average, and accustomed, rate – is certainly positive, perhaps 2 to 3 per cent in the United Kingdom, the domain of Phillips's data, and has not shifted notably over nearly a century of observation. Almost overnight the Phillips curve (so named in a discussion by Samuelson and Solow) invaded the language of macroeconomics.

Phillips uncovered another fact about past wage inflation. Among years with the same (annual) level of the unemployment rate there tended to be a higher rate of wage inflation when the annual unemployment rate was falling, as in a cyclical recovery or developing boom, than when the annual unemployment rate was rising. Phillips drew a counterclockwise loop around the downward-sloping Phillips curve, to indicate the typical motion of the wage inflation rate in relation to the unemployment rate over the typical historical cycle. (See the lower Phillips curve and the loop around it in Fig. 1.) It remained for R.G. Lipsey, also of the London School of Economics at that time, to express this historical phenomenon in quantitative terms too. Lipsey in 1960 published estimates obtained by regression analysis of the coefficients of a linear rate-of-wage-change equation in which the explanatory righthand-side variables were the level of the unemployment rate and its rate of change. The negative sign of Lipsey's estimate of the latter coefficient reflected the above loop. The statistical estimation of such Phillips–Lipsey equations rapidly developed from a cottage activity using electric calculators to a booming computerized industry.

In a way, the new and developing fact book seemed to contain information that was entirely reasonable and surely in keeping with existing theoretical (or pretheoretical) notions. (Indeed, a remarkably early anticipation of the Phillips curve was later unearthed in an obscurely placed paper in 1926 by Irving Fisher.) It seemed to say, essentially, that if there was an aggregate excess supply then nominal wages would be found falling and employment would be depressed – as long as wages remained too high to eliminate the excess supply – and both effects of the excess supply would be larger the greater was the size of the excess supply. More exactly, the sudden appearance of an excess supply that is maintained at a given level for a while would first generate a positive rate of change of unemployment alongside falling wages and only later, in a sort of disequilibrium steady state, a higher level of the unemployment rate without a positive rate of change. This part of the Phillips curve story seemed unsurprising and unpuzzling.

Yet some theoretical problems that had long lain submerged and unnoticed when the subject of disequilibrium adjustment was still muddy and relatively quiet came to surface once the Phillips–Lipsey formulation had stirred things up. Among these was the problem of explaining why nominal wages did not jump down to their new equilibrium level (with prices jumping after them) and, beyond that, the problem of determining the pace with which wages fell. The same theoretical void had been created more than a decade before Phillips's article when Samuelson in his *Foundations*, addressing Walrasian stability, simply postulated that the rate at which the price of a commodity falls is an increasing function of the excess supply of it. This was a macroeconomic hypothesis, perhaps a kind of theory by the behavioural standards of the day, but not a microeconomic theory running in terms of the motives and perceptions of the individual actors operating in the economy.

If the first problem was explaining that the Phillips curve was sloping, the second problem was explaining its remarkably rightward position: Money wage rates tended to be rising over a range of positive unemployment rates, including rates exceeding the lower bound obtainable by high-pressure aggregate demand levels. If nominal wages tend to be rising as long as the unemployment rate stays above nondepression levels, then the Samuelsonian hypothesis explains that markets have normally operated in a state of considerable excess demand. But is that likely? Is a state of zero excess demand (and excess supply) really marked by a zero rate of wage change, or is something missing here? Somehow, it was evident, the factors of productivity growth and inflation needed to be brought into the analysis, but not just as incantations to make the problem go away.

For many economists there was the further problem of reconciling the empirical regularity depicted by the Phillips curve, which seemed to possess an extraordinary stability, with the older Continental, or Austro-Hungarian, doctrine, propounded by Fellner and others, that below-normal unemployment constantly fuelled by a permissive monetary–fiscal policy will soon cause wages (and hence prices) to rise in ever-accelerating fashion until the hyperinflation finally brings collapse or structural change. This was the further problem of understanding in microeconomic terms the shiftability of the Phillips curve.

The solution of the first problem, that of explaining the gradualness of the wage adjustment and the attendant slump of employment, led theorists in the 1960s in the same direction in which Keynes had been led in his search for an explanation of slumps. A key element of the solution was the fact that there is no coordination, to use Keynes's term, among the managers deciding upon wages and employment (inter alia) at the various production sites. If there is a weakening of aggregate demand – here, a curve in the output–price level plane – in a previously normal and equilibrium situation, the resulting fall in the demand curve facing the individual manager, or producer, even if seen by him as permanent, would not induce the workers employed there (or unemployed there) to accept the job-preserving money wage cut unless they were expecting workers elsewhere at the same moment to be facing and accepting the very same percentage wage cut; and they would have not reason to have that expectation unless there was news bearing on the scale of the decline in demand and such news was observed to have produced job-preserving wage cuts. Pending such news, then, there would be only an insufficient wage cut, so the supply price of output would fall by less than the demand price, and hence output and employment would decline. These impact effects would show a negative correlation between wage change and unemployment level (though here the true correlation is with the change of employment).

In the 1960s, however, a number of theorists pointed out the theoretical existence of a deeper Phillips curve relation. The higher unemployment level comes about because 'expected wages' in the economy as a whole exceed 'actual wages', and as information comes in that actual wages elsewhere are lower than expected the ensuing downward revision of expectations will induce workers to accept still lower actual wages. This latter wage fall grows out of the disequilibrium situation, like the higher unemployment. If one were to go so far as to posit static expectations, so that each observed wage decline is thought to be the last, there would exist a disequilibrium steady-state relationship between the size of the (swelling of the) unemployment rate and the magnitude of the rate of wage change. A 1969 Pennsylvania conference developed these points in a variety of models, and the conference volume published a year later served to popularize these expectational microeconomic foundations of unemployment and wage-price behaviour (Phelps et al. 1970).

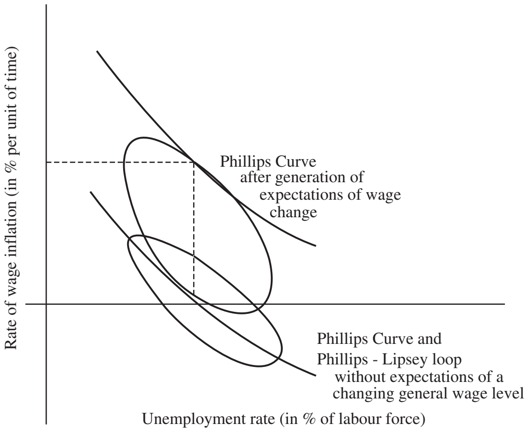
In the 1970s theorists moved toward rational expectations in the sense of Muth. In this case, the news of the initial fall of wages (together with any news on the unemployment front) is enough for workers to expect that the general wage level will now fall to exactly the job-preserving level, so that the unemployment rate will return to the equilibrium level; otherwise workers are implied to be repeatedly misforecasting the wage level, contrary to rational expectations. Here, too, the high unemployment precedes a wage fall (though large enough to eliminate the high unemployment), so that there is again a negative correlation between unemployment level and wage change. A microtheoretic model along these lines, involving known stationary stochastic processes, was developed by R.E. Lucas (1972, 1973) and an intertemporal model with which to show, as a corollary, the ineffectiveness of preannounced monetary policy in stabilizing output or employment was analysed by T.J. Sargent (1973).

The rational expectations postulate seemed at first to point to the conclusion that, following an unexpected drop of aggregate demand, nominal wages would indeed jump – though too late to prevent a recession – once the news of the economic indicators signalling a slump was out, and that with that jump the unemployment rate would jump back to its steady-state equilibrium (and normal) level. But that would have been jumping to conclusions, and fortunately so for the rational expectations hypothesis since there is convincing econometric evidence that the unemployment rate displays statistical persistence. It was soon remembered, however, that the antecedent literature on the costs of recruitment or training provided the basis for an equilibrium path of recovery from a downturn along which both the unemployment rate and the nominal wage level decline continuously, or gradually in discrete-time terms, rather than with a jump. There was also a development of the point made in the earlier literature that firms' wage commitments are apt to be durable and non-synchronous, so that the respective firms in the economy take turns over the wage-setting cycle, or 'year', in resetting their 'annual' wage scales. In such a nonsynchronous wage-setting context, the average level of nominal wages cannot jump and hence employment will not recover from a recession with a jump. Further, a model of wage staggering, though quite different from the preceding types, likewise produces an explanation of the negative correlation between wage change and the unemployment rate, as shown by Taylor (1980).

The second Phillipsian problem, that of explaining the coexistence of rising nominal wages with above-minimum unemployment, had two answers, independent and additive. One answer lay in divorcing ourselves from thinking of the unemployment rate – or even the excess of the unemployment rate over the minimum rate achievable by stimulating aggregate demand – as a satisfactory measure of downward pressure on nominal wages. If the unemployment rate (or, more accurately, the aforementioned excess rate) were driven to zero, quitting would presumably be rampant and so the representative firm would endeavour to pay a wage premium – a positive differential over the wages paid elsewhere. If this average wage level is expected to be unchanged, the firm will therefore raise its wage to a level in excess of that average, with the consequence that the average wage will actually rise – resulting in an excess of 'actual' over 'expected', thus a disequilibrium. It is only when the unemployment rate (or the excess rate) is positive and high enough that the quit rate will be damped sufficiently to encourage the representative firm to content itself with paying the representative wage, that the average wage will remain flat as expected. (The argument is implicit in Phelps 1968, and the explicit focus of Stiglitz 1974, and Salop 1979.) In this equilibrium there is involuntary unemployment in a natural sense of the term, since wages exceed the market-clearing level, and this unemployment may very well exceed job vacancies (if any), so there may be considerable excess supply. (See also Calvo 1979, for another model.)

The other answer to the problem lay in realizing that wages do not rise only when firms (or at least the representative firms) want to be more competitive than the others. Wages may also rise because the firms believe they must raise their wages just to avoid losing any of their present competitiveness. The same point can be made in terms of the excess-demand framework of Samuelson: the error in Samuelson's formulation was in excluding the possibility that wages will be increased in an anticipatory move that serves to prevent the emergence of an excess demand, not just in response to excess demands that are not previously expected and forestalled by intervening wage increases. Hence, nominal wages may be rising not because the labour market is in disequilibrium, marked by mutually inconsistent desires among the firms for superior competitiveness in the labour market, but rather because the prospect of productivity growth or of inflation or of both generates expectations that the general level of wages is going to increase (Phelps 1968).

With the latter insight our third problem, that of explaining the possible shift of the Phillips curve, is also solved. When governments seek to exploit the Phillips curve by trading off price stability in hopes



Phillips Curve, Fig. 1 Wage and unemployment dynamics

of obtaining reduced unemployment in return, they ultimately engender expectations of regularly increasing wages. Such an increase in the expected rate of wage inflation (at each level of the unemployment rate) shifts up the Phillips curve; a new one arises corresponding to the new expected rate of wage inflation. In Fig. 1 see the upper Phillips curve, which has been driven higher by expectations of a rising general wage level. It is now evident that a political business cycle, by alternately lifting and depressing the Phillips curve, would generate the clockwise loop shown in the figure.

If we posit, as a plausible approximation, that the expected wage inflation variable takes its place among the explanatory right-hand variables (alongside the. Phillips–Lipsey terms) with a unitary coefficient, the implication is that the steadystate equilibrium unemployment rate – at which expectations are borne out – is the same number independently of the inflation rate. Then, maintaining a steady unemployment rate below that constant equilibrium rate would entail rising inflation without bound (Phelps 1968; see also Friedman 1968, discussed below). With this coefficient value of one (or any larger value) the model gives algebraic expression to the abiding accelerationist fears of the Austro-Hungarian school.

The notion that the equilibrium unemployment rate was a constant, as above, also emerged from a quite different formulation by Friedman (1968), where the constant was dubbed the natural rate of unemployment. There the rate of wage change is postulated to be a function of the unemployment rate plus the expected rate of *price* inflation. The implicit rationale was that the amount of labour supplied as an increasing function of the expected real value of the nominal wage. A way to synthesize the above wage–wage model (in which expected real-wage changes are captured in the Phillips–Lipsey terms) with the wage–price model is to add to a quasi-Phillips *employment* term a weighted average of the expected rates of wage inflation and price inflation where the latter weight is positive, zero, or negative as the labour supply curve is forward rising, vertical, or backward sloped (Phelps 1979).

Phillips Curve (New Views)

Jonas D. M. Fisher

Abstract

A *Phillips curve* is an equation which relates the unemployment rate, or some other measure of aggregate economic activity, to a measure of the inflation rate. Since there is a significant correlation between inflation and unemployment over some horizons, understanding this correlation should yield insight into the impulses the economy faces and the mechanisms that propagate their effects. Since the 1990s, research has focused on making progress in three main areas: forecasting, microeconomic foundations and empirical tests of the microfoundations.

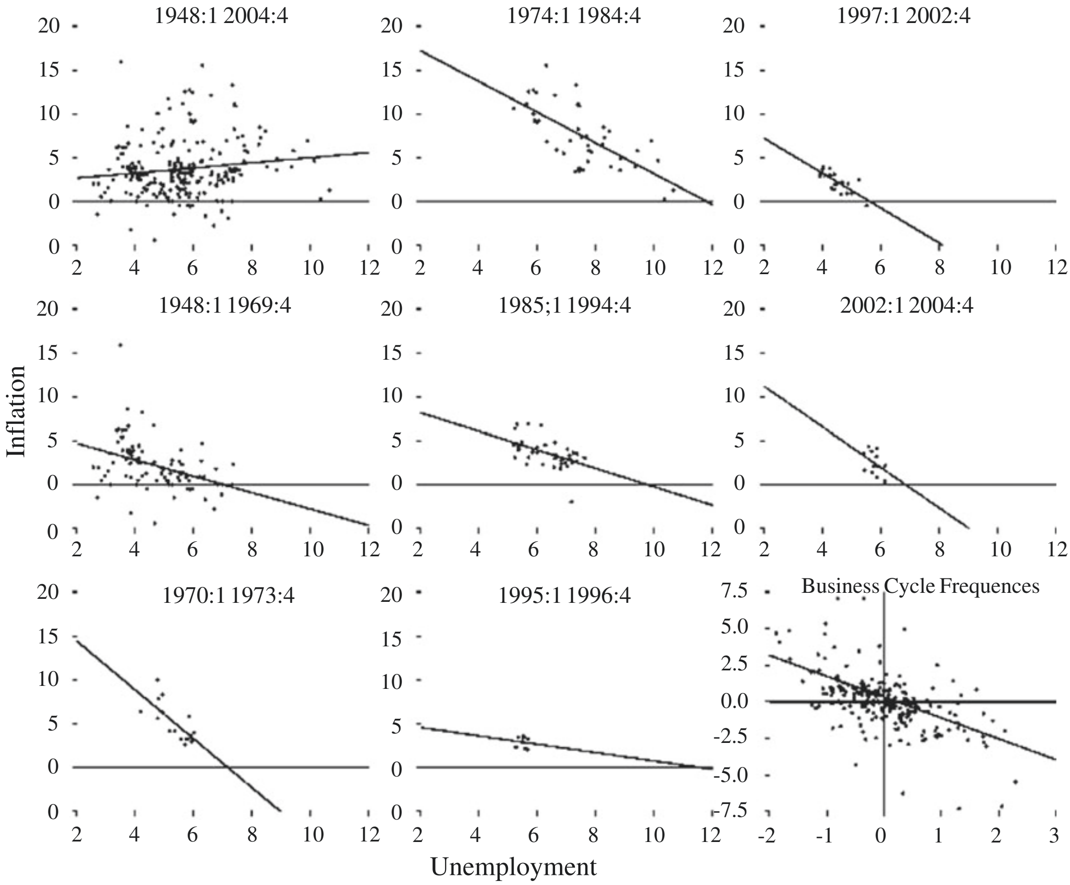
A *Phillips curve* is an equation which relates the unemployment rate, or some other measure of aggregate economic activity, to a measure of the inflation rate. This equation continues to prompt a lot of research in macroeconomics, as it has for most of the years since the influential Phillips (1958) and Samuelson and Solow (1960) articles. The early work documents a negative relationship between the unemployment rate and either nominal wage growth or inflation. Equations relating the unemployment rate to inflation were the first to be called Phillips curves. Samuelson and Solow (1960) were bold enough to posit a stable and exploitable structural relationship between unemployment and inflation. The viability of a policy of using inflation to combat unemployment was debunked theoretically in Friedman's (1968) classic presidential address and empirically in the subsequent decade.

The rise of inflation over the 1970s came along with a breakdown in the inflation unemployment relationship and gave birth to the 'expectations-augmented' Phillips curve. This formulation allows the relationship between unemployment to shift due to changes in inflation expectations. Figure 1 shows how such a formulation can be used to fit the data. This shows scatter plots of unemployment and NIPA personal consumption deflator inflation for different sub-periods over the years 1948–2004 along with regression lines. Table 1 reports the regression coefficients, R^2 for the regressions and the means of inflation and unemployment. For the whole sample there is a significant *positive* relationship. However there is always a sequence of consecutive dates where the regression line is negative. The slope coefficient is also highly significant in all cases but one. The movements in the regression line occur as changes in the mean inflation and unemployment rates. Another way to verify that there is a strong association between inflation and unemployment is to focus on business cycle frequencies, in the bottom right hand corner of Fig. 1 and the second row of Table 1. Clearly inflation and unemployment are highly correlated at business cycle frequencies.

Since there is a significant correlation between inflation and unemployment over some horizons, understanding this correlation should yield insight



Phillips Curve (New Views), Fig. 1 The US Phillips curve, 1948:1–2004:4 (*Sources*: authors' calculations; unemployment rate: US Bureau of Labor Statistics; personal consumption expenditure deflator: US Department of Commerce)

Phillips Curve (New Views), Table 1 The US Phillips curve, 1948:1–2004: 4

Sample	Intercept	Slope	R^2	Mean inflation	Mean unemployment
Full sample	2.06***	0.29**	0.02	3.70	5.64
Business cycle frequencies	0.32****	****	0.39	0.00	0.00
1948:1–1969:4	6.55****	****	0.16	2.20	4.67

Note: The number of asterisks from one to four denotes significance at the 10, 5, 1, and 0.1 per cent levels of the constant and slope terms of a regression of inflation on unemployment. Business cycle frequencies means the data have been subjected to Christiano and Fitzgerald's (2003) band pass focusing on a 2–8 year horizon. *Sources*: authors' calculations; unemployment rate: US Bureau of Labor Statistics; personal consumption expenditure deflator: US Department of Commerce into the impulses the economy faces and the mechanisms that propagate their effects. Since the 1990s, research has focused on making progress in three main areas: forecasting, microeconomic foundations and empirical tests of the microfoundations. This article reviews the recent research in each of these areas.

Forecasting with the Phillips Curve

Inflation forecasting models rely heavily on the Phillips curve. For many years, even as the traditional Phillips curve relationship evaporated, variables such as the unemployment rate have continued to be very useful predictors of future inflation. Stock and Watson (1999) argued they could do better. They proposed using principal components of large numbers of data series to aid in forecasting macroeconomic variables. The idea was that this approach uses the information in a large number of variables, which is impossible with traditional regression-based forecasting. One of their most interesting findings involves the first principal component of roughly 80 macroeconomic variables, including measures of production and income, employment, unemployment and hours, personal consumption and housing, and sales, orders and inventories. They argued that this 'activity index' variable is more useful than even unemployment for predicting inflation. Such a finding strongly suggests a connection between current activity and future inflation, essentially the Phillips curve relationship.

Atkeson and Ohanian (2001) argued that the success of the Phillips curve in forecasting is just as illusory as a stable Phillips curve. They argued that, for forecasting one year ahead, a simple random walk suffices – the best predictor of one-year-ahead inflation is current inflation. Atkeson and Ohanian's (2001) finding has proven to be remarkably robust (see Brave and Fisher 2004; Fisher et al. 2002). However, the random walk result does depend on the sample period considered by Atkeson and Ohanian (2001), which is 1984–99. Beginning the sample in 1984 is justified by evidence of a major structural change around that time (see Fisher 2006). However, as the sample is extended, the random walk loses some of its lustre. The poor performance of Phillips curve-based forecasting models is mainly confined to the period 1984–93. Since the mid-1990s the traditional variables such as unemployment have been useful forecasters. These findings are easily explained by noting that inflation was generally falling from 1984 to the mid-1990s as the economy adjusted to the Federal Reserve's stronger willingness to fight inflation. It is natural for old models to fail after a major structural change. Moreover, in an environment where output is growing strongly while inflation is falling, it is not surprising the random walk model does well between 1984 and 1993.

Microfoundations of the Phillips Curve

Since Lucas (1972) economists have known how to formulate models in which inflation and activity are correlated but there is not a policy-exploitable Phillips curve. The focus of much of the recent literature has been on the Calvo–Yun Phillips curve, which arises from one particular model. The Phillips curve in this model is named after Calvo (1983) and Yun (1996). Most of the literature uses the hopelessly ambiguous term 'New Keynesian' to describe this model of the Phillips curve.

Phillips curves arise naturally in models where firms set prices and at least some of those prices do not respond to every shock to the economy. Calvo's contribution is a very simple model of sticky prices. He assumed monopolistically competitive firms could re-optimize their price with a fixed probability, θ, each period so that firms re-optimize prices on average every $1/(1 - \theta)$ periods (usually quarters of a year). This formulation can be taken literally, in which case prices are fixed until the next opportunity to re-optimize. Alternatively, firms might follow simple pricing rules at high frequencies and occasionally adjust these rules overtime. Under this interpretation firms can index their prices to inflation.

Yun derived a Phillips curve by introducing the Calvo model of price adjustment into an otherwise standard monetary model with monopolistic competition and constant markups. The result is the Calvo–Yun Phillips curve:

$$\hat{\pi}_t = \beta E_t \hat{\pi}_{t+1} + \frac{(1-\beta\theta)(1-\theta)}{\theta} AD\hat{s}_t. \quad (1)$$

The variable $\hat{\pi}_t$ is the deviation of the log of the gross inflation rate from its steady state value, $\hat{s}_t$ is the log deviation of real marginal cost for the representative firm, and β is the time discount factor of the representative household. The A and D terms are equal to unity in the Yun paper. This equation is derived from the log-linearized necessary conditions of the equilibrium. To linearize around a steady state with positive inflation, firms must index their prices to inflation.

Eichenbaum and Fisher (2007) describe how Kimball's (1995) extension to variable markups implies that $0 < A \leq 1$, where A depends on the shape of the firm's demand curve and equals unity in the constant markup case. Eichenbaum and Fisher also study Woodford's (2003, 2005) model of capital adjustment and describe how this yields.

$0 < D \leq 1$ where D depends on the firm's supply curve. Generally, marginal cost is increasing in output. Since β and θ also lie between zero and unity, the coefficient in front of marginal cost is positive and (1) is an equilibrium relationship where output and inflation are positively related. In most of the literature assumptions are such that $A = D = 1$. This literature generally predicts reasonably large effects of monetary shocks if firms adjust their prices once a year.

The Calvo model is called a *time-dependent* model because the opportunity to change prices depends only on the passage of time. Taylor's (1980) model where firms rotate changing their prices is also a time-dependent model. The main alternative is *state-dependent* models, where changing the price is a choice of the firm which depends on both firm-level variables such as productivity and aggregate variables like the interest rate. The dominant state-dependent model involves menu costs. Studying state-dependent models is more difficult than time-dependent models because the price distribution is endogenous.

Five papers make major progress toward understanding menu cost models. Dotsey et al. (1999) study a model with random menu costs and Taylor-style staggering. A key advantage of their model is that it can be linearized like a simple real business cycle model. Klenow and Krsystov (Klenow and Krystov 2005) calibrate this model to US consumer price index (CPI) micro data for the years 1988–2003. They find that matching the micro data yields a model which behaves very much like the Calvo–Yun model. Golosov and Lucas (2003) study a menu cost model with a constant menu cost but where firms face exogenous technology and/or preference shocks. Under the assumption that the shocks are Gaussian, Golosov and Lucas find that firms choose to adjust their prices a lot when there is a monetary shock, and this makes prices flexible enough that monetary shocks have small affects. Midrigan (2005) uses scanner data to determine the distribution of technology or preference shocks in the Golosov–Lucas model. He estimates this distribution to be non-Gaussian with fat tails. With the estimated distribution monetary shocks have affects similar to models with a Calvo–Yun Phillips curve. Gertler and Leahy (2005) develop an analytically tractable state-dependent model which also behaves like the Calvo–Yun model.

Another key area of research involves building fully specified dynamic general equilibrium models with Phillips curves which fit the data well. This work has focused on the Calvo–Yun Phillips curve instead of more deeply motivated models because of its simplicity. The key contribution is Christiano et al. (2005). Their model also includes portfolio rigidities, adjustment costs in capital, and a Calvo-style version of nominal wage setting. They find their model does a good job matching the evidence on how the economy responds to a monetary shock, with a small amount of price stickiness, but wages must be more rigid. There is a growing amount of research which reaches the same basic conclusion that the wage–activity relationship is more important for understanding macroeconomic dynamics than the traditional Phillips curve (cf. Galí et al. 2007).

Empirical Evaluation of the Microfoundations

Equation (1) is to the empirical macro literature as the Lucas (1978) asset pricing relationship is to empirical finance. In recent years it has come under considerable empirical scrutiny. Galí and Gertler (1999) were the first to use Hansen's (1982) generalized method of moments (GMM) to estimate θ and test (1). They measured marginal cost using labour's share of GDP, which is true if firms use a Cobb–Douglas production technology. Gagnon and Kahn (2005) consider other production structures where marginal cost is not measured with labour's share and conclude that the Galí and Gertler (1999) findings hold up. Galí and Gertler estimate of θ implies more than a year between price changes, but they cannot reject the equation. Micro price data might be useful to identify θ, but, under the frequency of *re-optimization* interpretation of the Calvo model, estimates of θ over a year for the United States seem too high (cf. Blinder et al. 1998). Galí and Gertler consider an alternative model with 'rule-of-thumb' firms who use lagged inflation to update their prices when they have the opportunity to re-optimize. This model is motivated by the fact that lagged inflation enters significantly in the empirical version of (1). The model with rule-of-thumb firms is not rejected and the estimates of θ imply prices are re-optimized every two or three quarters. The latter estimates are within the range of plausibility. Galí and Gertler also estimate the number of rule-of-thumb firms to be small and emphasize that (1) holds approximately. Bakhshi et al. (2005) argue that the Galí–Gertler 'hybrid' model is a good approximation to Dotsey et al.'s (1999) menu cost model.

It is clear that θ is not identified separately from A and D in (1). However, A and D can be identified with auxiliary information. Sbordone (2002) identifies D by assuming the stock of capital is fixed exogenously at each firm for all time. Under the usual assumption of a Cobb–Douglas production function, auxiliary information on the share of labour income in GDP can be used to identify D. Sbordone considers the forward looking solution to (1) as well as the solution to a similar equation for the labour market. The expected present-value calculations needed to implement this estimation are implemented with a vector autoregression. This empirical strategy is analogous to Abel and Blanchard's (1986) approach to estimating investment adjustment costs. Sbordone estimates prices are re-optimized every one to two quarters. Galí et al. (2001) apply Sbordone's fixed capital assumption to their rule-of-thumb model and estimate the frequency of re-optimization to be a little higher than in Galí and Gertler (1999), and significant small positive numbers of rule-of-thumb firms continue to be estimated.

Eichenbaum and Fisher (2007) explore Woodford's (2003, 2005) dynamic version of Sbordone's (2002) model in an environment which also includes Kimball's (1995) variable markup. As in Galí and Gertler (1999) and Galí, Gertler and López-Salido. (Galí et al. 2001), they adopt a GMM estimation and testing strategy. To improve the power of their tests, Eichenbaum and Fisher (2004) impose the restrictions Eq. (1) place on the moving average structure of the Euler equation errors and reduce the number of instruments compared to the previous papers. They easily reject (1) assuming the Euler error is an MA(0). This motivates them to include the auxiliary assumption that firms make decisions based on lagged information. With one such *implementation* lag, this yields an MA(1) structure which is not rejected and which the re-optimization frequency is about two years, if $A = D = 1$. With empirically motivated values for the curvature of the demand curve and the size of capital adjustment costs, re-optimization every two quarters cannot be ruled out at conventional significance levels. Eichenbaum and Fisher include dynamic indexation (prices indexed to the most recent inflation rate) of the prices of firms that do not re-optimize in a given period. This is an alternative to rule-of-thumb firms as away of introducing a lagged inflation term into (1). Eichenbaum and Fisher (2004) find they cannot reject the possibility that there are no rule-of-thumb firms under dynamic indexation.

Recently much work has been done to document prices at the microlevel. Blinder et al. (1998) survey actual price setters and find that, among firms reporting regular price reviews, annual reviews are by far the most common. Other key contributions include Bils and Klenow (2004), Klenow and Krystov (2005) and work done with European data for example by Stahl (2005). Much of this literature emphasizes the frequency of price changes. For example, Blinder et al. (1998) report that the median time between price changes among the firms that they survey is roughly three quarters. Comparing the Calvo–Yun Phillips curve with these findings is delicate. With price indexation the model implies that prices change *too* frequently relative to the micro data because all prices are changing all the time. Also, just because firms are changing prices does not mean that they have re-optimized those prices: a subset of the price changes being recorded could reflect various forms of time-dependent pricing rules.

Integrating over all the micro evidence, with a low inflation economy like the United States, versions of the Calvo–Yun Phillips curve with an implementation lag, dynamic indexation, capital adjustment costs and time-varying markups can be reconciled with the macro data without requiring implausible degrees of rigidities in price-setting behaviour at the micro level. Of course this model is not literally ‘true’. For instance, the model also has the implausible implication that any CPI observation for which $P_{i,t}/P_{i,t-1}$ is not equal to π_{t-1} involves re-optimization. Developing tractable models that are fully consistent with the salient macro facts and the emerging literature on the behaviour of individual good prices is a key challenge going forward.

Bill Phillips was born on 18 November 1914 into a farming family in Te Rehunga, near Dannevirke, in southern Hawkes Bay in the North Island of New Zealand, and died at Auckland, New Zealand on 4 March 1975. He came to economics after a career as an electrical engineer and following military service and imprisonment by the Japanese in the Second World War; in 1946 he became a Member of the Order of the British Empire for his military services. His rise in the profession was rapid. He was appointed an Assistant Lecturer at the London School of Economics in 1950 and to a Readership in 1954. In 1958 he became Tooke Professor, resigning in 1967 to take a Chair at the Institute of Advanced Studies, Australian National University in Canberra. A crippling stroke in 1969 forced his retirement and he lived in Auckland until his death. In his short career in economics he made major contributions to problems of dynamic stabilization, estimation and, most notoriously, empirical economics, where he gave his name to the ‘Phillips curve’.

Phillips’s Ph.D. at LSE was on the problems of stabilizing or controlling an economy. Before this he had built a hydraulic model in perspex of a dynamic Keynesian-type economy and sold commercial versions of the model to academic and other institutions in Britain and the United States. (Some machines had a bottle of water named the Bank of England, used for ‘topping up’. Richard

Goodwin is credited with introducing an accelerator in Cambridge's machine, but leakages were always a problem.) In a seminal paper in 1954 Phillips dealt with response lags and the problems they presented for stabilization policy. He distinguished between proportional, integral and derivative policies, depending on whether policy changes responded to current errors, cumulated deviations or rates of change of objectives. Optimal policy depends on the lag properties of the economy, and would consist of a mixture of proportional, integral and derivative components. Subsequent analysis of stabilization policy has used this scheme (for example, Meade 1971).

This early work convinced Phillips that proper econometric modelling was a precondition for dynamic stabilization. He turned to the problem of empirical description of the lag structures and their statistical estimation. All his later papers are concerned with the problems and difficulties of describing and estimating the dynamic relationships embodied in time forms of economic responses. His retreat to Canberra and Chinese economic studies has been seen by Lancaster (1979) as an acknowledgement that he found the problems, as he posed them, of estimating the relationships required for dynamic control beyond his capacity to solve. In Canberra, however, he continued to work on problems of identification (for example, 1968). In this later work he foreshadowed subsequent thinking (for example, that of Lucas) by explaining how the application of stabilization policy through a model results in the model becoming underidentified or, more generally, how policy changes relationships. The 'Phillips dilemma' remains: in the absence of adequate econometric modelling, stabilization policy is an empty box.

But before he left macroeconomics Phillips made in 1958 his epochal contribution of the Phillips curve, which mesmerized economists for the next decade and continues to attract attention. Responding to Dennis Robertson's criticism of the Keynesian mathematical model of his Ph.D. thesis, Phillips later used a relation between the rate of price change and capacity utilization, but without being able to give it any satisfactory empirical foundation. The lengthy time series of British wages produced by Henry Phelps Brown and Sheila Hopkins gave him the opportunity to experiment with the long series of British unemployment statistics from 1861 to 1957. What began as an attempt to derive a simple relationship between rate of change of wage rates and unemployment emerged as a nonlinear long term relationship with a complex short period lagged response. The famous paper is striking for the informal estimation method and the ad hoc theorizing and Phillips admitted an excessive haste to publish while also acknowledging that A.J. Brown had almost got the results earlier but without the lags (Blyth 1975). Apart from an enquiry into Australian statistics, Phillips did not enter into the subsequent international controversy over the theoretical and empirical foundations of the 'Phillips curve'. It is necessary to read Phillips's original paper to understand its intentional exploratory character, and the deliberate absence of theoretical generalization. For an enquiry which in the eyes of, for example, Samuelson and Solow 'closed' the Keynesian system, it is remarkably but typically modest and tentative. Furthermore, on the controversial issue of the high cost of the trade-off between inflation and unemployment, Phillips refers briefly to the 5 per cent unemployment level necessary to maintain stable wage rates without expanding on it. If there were close intellectual connections with the Joan Robinson–Kalecki–Beveridge approach to the full employment–trade union problem, they are not disclosed.

Scientific problems with stabilization theory, family reasons and reaction to student revolt at LSE all may have contributed to Phillips's move to Australia, where he energetically began to develop Chinese economic studies. His interest in China had begun in the 1930s and he began to learn Chinese while a prisoner-of-war in Java. In the short period before he retired he saw the firm establishment of a Centre for Contemporary Chinese Studies in Canberra, while his final academic activity in Auckland was appropriately enough to start a lecture course in Chinese economic history. In 1974, on his 60th birthday, his colleagues and friends presented him with a subsequently published Festschrift (Bergstrom et al. 1978).

In a profession which accepts many strays from other disciplines, Phillips was outstanding. His formal education ended in New Zealand at the age of 15, and after apprenticeship as an electrician he qualified as an electrical engineer in London in 1938 after working in Australia and travelling to Britain via Japan and Siberia. An authentic hero of the Second World War, his introduction to economics was as he said through a poor degree in sociology. James Meade sponsored his hydraulic model, and Phillips's 'launching' is by tradition associated with a famous Robbins seminar in which he successfully explained his machine. A New Zealand influence and connection is not intellectually evident, but may have contributed to the willingness to 'do it himself'. Who else but a New Zealander would have learnt his differential equations at a Queensland goldmine?

Philosophy and Economics

D. Wade Hands

Abstract

The literature on philosophy and economics has traditionally been divided into two areas: economic methodology, which connects economics and epistemology/philosophy of science, and the literature on economics and moral philosophy/ethics. Recent developments in both of these areas are discussed in detail.

The essential interdependency of philosophical and economic ideas was a prominent feature of classical economics. Adam Smith was the author of *The Theory of Moral Sentiments* as well as *Wealth of Nations.* John Stuart Mill was an extremely wide-ranging scholar, as well known as the author of *A System of Logic* as of *The Principles of Political Economy.* And of course Karl Marx's *Capital* also drew on intellectual resources from economics, philosophy and a number of other fields. Classical political economy was deeply influenced by philosophy – different philosophies for different economists, but influenced nonetheless – and ideas also flowed freely in the opposite direction, from political economy to various areas of philosophical inquiry.

This changed significantly in the first third of the 20th century. The abandonment of 'political economy' and the self-conscious development of 'scientific economics' coincided with a major change in the relationship between the two disciplines. Although philosophy never completely disappeared from economic theorizing, it systematically came to play a less and less obvious role. There are undoubtedly many reasons for this. Two of the more important include the overall professionalization of disciplinary economics and the general acceptance of a more narrow, positivist-inspired notion of legitimate 'scientific' inquiry. John Stuart Mill directed his arguments at the general educated public and wrote confidently about the 'moral sciences'; by the first half of the 20th century fewer economists were doing the former and almost no professional economist would be comfortable doing the latter.

Although there were different versions of positivism, one common theme was that 'meaningful' discourse comes in only two forms: the synthetic knowledge of empirical science and the analytic knowledge of logic and mathematics. During the period of positivist dominance (roughly from the early 1930s through the 1950s), many, perhaps most, of the lines of inquiry that had previously travelled under the label of 'philosophy' – including, ethics, ontology, metaphysics, and aesthetics – were dismissed from the realm of meaningful discourse. Science ceased to be a generic category that included any rational, non-faith-based inquiry, and instead came to designate only the natural sciences (or modes of inquiry that follow the same scientific method). Economics clearly had scientific aspirations, and in such a regime fulfilling those aspirations required jettisoning the profession's old philosophical ways. Many of the significant developments in economic theory during the first half of the 20th century can be understood in precisely these terms: as an attempt to systematically discard the old metaphysical and utilitarian baggage, and replace it with more appropriate scientific concepts. Moral philosophy, for example, might still make an appearance in discussions about economic theory, but it almost always played a disparaging role: either to indict another theory for retaining some ethical residuum, or to emphasize that one's own theory was entirely free of such normative influences. Such an environment was certainly not conducive to forging new links between philosophy and economics, and for much of the 20th century very few were.

A particularly good example of the rejection of philosophy is the development of welfare economics during the second quarter of the 20th century. From the hedonism of many early neoclassicals to the so-called 'material welfare school' (Cooter and Rappoport 1984) of Alfred Marshall and Arthur Pigou, welfare economics (and applied microeconomics in general) had traditionally been associated with utilitarianism: policy A was better than policy B if A increased total utility by more than B. During the 1930s, as a result of the work of Lionel Robbins (1952) and others, most economists came to view this type of 'interpersonal' utility comparison as unscientific and thus inappropriate for economic analysis. Moral values were simply raw, subjective or 'emotive' preferences that were not amenable to scientific analysis, and must therefore be kept out of economic science.

As economists moved away from the earlier utilitarian notions of 'good' economic policy, they increasingly turned to the Pareto criterion as an alternative evaluative standard. It was argued (and still is) that Pareto efficiency – an allocation of resources such that no one person can be made better off without making someone else worse off – does not require making interpersonal utility comparisons and is therefore an entirely appropriate standard for scientific economics. The most important theoretical results of modern welfare economics – the first and second fundamental theorems – are based on a direct application of the Pareto criterion to questions about the welfare implications of competitive equilibrium. Although the norm-free credentials of Pareto efficiency have repeatedly been challenged (Blaug 1980; Hausman and McPherson 2006; Robertson 1952), the standard interpretation among practising economists remains that such judgements, and thus any policy recommendations based on them, are fundamentally value free. But it is not necessary to take sides in the debate over whether Pareto efficiency is or is not an ethical criterion in order to recognize that the entire discussion is couched in terms of whether moral concepts are properly kept out of economic science, and to note that such a discussion does not provide a very fertile environment for the cultivation of new relationships between economics and moral philosophy.

Economic methodology has traditionally been the one exception to economists' general rejection of philosophy. Although ethics and metaphysics were shunned by economists, epistemology and philosophy of science were often consulted for guidance regarding the proper scientific method. This said, even within methodology the use of philosophical resources varied greatly from economist to economist. Some of the classical works in economic methodology (Milton Friedman 1953, for example) hardly mentioned philosophy at all; others (Robbins 1952, and Hutchison 1938, for example) drew on selected aspects of the philosophy of science, while still others (Blaug 1980; Samuelson 1963) tried to apply the arguments of particular philosophers of natural science directly to economics. Thus, even in methodology economists focused on only a relatively small portion of the philosophical literature and employed even those resources in a less than systematic way.

Although the traditional methodological literature is both extensive and ongoing, it is not the focus of the following discussion. There are at least two reasons for this. First, this literature has been effectively surveyed in a number of contemporary works (Blaug 1980; Caldwell 1994; Hands 2001; Hausman 1992) and second, things have again changed. Since the mid-1980s there has been a renaissance in the interaction between economics and philosophy. The traditional approach to economic methodology continues to produce viable research, but economics and philosophy are also interacting in many other, new and important ways. Philosophy of natural science is no longer the only relevant set of philosophical ideas – ethics and ontology have both returned to the scene – and the intellectual dynamic is now one of bilateral exchange rather than economists simply borrowing ideas from one corner of the philosophical shelf.

In addition to the revival of the interplay between economics and philosophy there has been an increase in the traffic between economics and a number of other fields that compete for some of the same intellectual space that philosophy has traditionally occupied. For example, resources from the sociology of science and science studies (Mirowski 2002; Sent 1998; Weintraub 2002; Yonay 1998), the rhetoric of science (McCloskey 1998), postmodernism (Ruccio and Amariglio 2003), feminism (Ferber and Nelson 2003; Nelson 1996), and variety of other fields have provided new tools for the examination of (and often confrontation with) modern economic theory. Although these works frequently overlap with the literature on philosophy and economics, they also involve ideas sufficiently removed from disciplinary philosophy that they fall outside of the work considered here.

The discussion is divided into two parts; the first examines recent developments in the relationship between economics and scientific philosophy. Some of this work has much in common with traditional economic methodology, while other contributions approach the relationship in entirely new ways. In the interest of brevity, only five of the many possible areas of significant research are examined. The second section examines the recent literature that combines economics and moral philosophy. Ethical questions are again back on the table, and an extensive literature has grown up relating various issues in moral philosophy to developments within economic theory. Some of this research challenges the received view of the relationship between economics and ethics established during the first half of the 20th century, while other parts of the literature develop totally new connections. Again, as with the methodological literature, only a few examples are discussed. The final section briefly considers some points of convergence between contemporary work on economics and epistemology and that on economics and ethics. Throughout the discussion, the emphasis is on microeconomics and rational choice theory (rather than, say, macroeconomics or econometrics).

Economics, Epistemology, and Philosophy of Science

The first area of research to be examined goes back to Terence Hutchison (1938); it is the literature relating the philosophical ideas of *Karl Popper* (1965, 1968) to economics. Popper is best known as an advocate of falsificationism, a philosophy that has two main theses: one demarcating science from non-science and the other characterizing the growth of scientific knowledge. For a theory to be scientific it must be at least potentially falsifiable by empirical evidence (in Popperian language, be falsifiable by at least one empirical basic statement). Scientific knowledge grows as the scientific community rejects falsified theories and retains those that have survived attempted falsifications (that is, by 'bold conjecture and severe test'). The body of accepted science at any point in time consists of all scientific theories that have survived such severe empirical tests. Elements of such a methodology were present in Hutchison (1938), and elaborated in more detail in his later work. The position has been most articulately defended in the methodological writings of Mark Blaug (1980). Although many economists continue to endorse a falsificationist approach to methodological questions, there is also an extensive critical literature on the subject (Caldwell 1991, 1994; Hands 1993; Hausman 1988, 1992).

If the only research connecting the Popperian tradition to economics was the literature on falsificationism, then the subject would probably not be included in this discussion of recent developments. But that is not the case. During the last few decades the Popperian tradition has engaged economics on a number of different fronts, and currently consists of much more than just the literature defending (or criticizing) falsificationism (Caldwell 1991). At least three other developments should be noted. The first involves Popper's own brief discussion of economic methodology (Popper 1994). This work is controversial because Popper's statements about economics – and social science more generally – differ from what he said about the (falsificationist) methodology of natural science. The second concerns the so-called 'critical rationalist' interpretation of Popper's overall philosophical programme: an interpretation that goes back in the economics literature to Kurt Klappholz and Joseph Agassi (1959), but has its best contemporary representation in the work of Lawrence Boland (1997). Supporters of critical rationalism argue that Popper's main philosophical contribution was not (empirical) falsificationism but rather a more general view of the growth of knowledge through open debate and rational criticism – of which falsification by empirical evidence is simply one, albeit a very important, special case. Although the discussion of critical rationalism has remained primarily an in-house debate among Popperians, it has much broader implications because it opens the door to characterizing the growth of knowledge as a product of particular social institutions rather than as the result of following fixed methodological rules, a view that has become increasingly important in general philosophy of science. Finally, there has been an extensive discussion of the work of Popper's student Imre Lakatos (1970) and his 'methodology of scientific research programs' (Backhouse 1997; Blaug and De Marchi 1991; Latsis 1976). Economists have focused on two different aspects of Lakatos's work: his historical framework for understanding the evolution of economic research programmes (his concepts of hard core, protective belt, and so on) and his specific methodological framework for appraising scientific research programmes as progressive or degenerating. Even though there exists a critical literature on both of these issues, the Lakatosian framework has produced important case studies and also encouraged a re-examination of the general relationship between economic methodology and the history of economic thought.

The second area to consider involves the revival of interest in *ontology* and *metaphysics* in the philosophy of economics. There now exists a burgeoning literature on 'economics and ontology' (Mäki 2001), something that would have been next-to-impossible only a few decades ago. During the heyday of positivism any mention of such (occult) notions as essential natures, underlying causal powers, or ontological necessity all but disappeared from academic discussions about economics. Ontological discussion continued to some extent within certain heterodox, particularly Marxist, research programmes, but among mainstream economists, even philosophically informed ones, such concepts had no place in professional discourse. Although many things have contributed to this revival, three issues seem to be particularly important.

One factor contributing to this ontological renewal has clearly been the development of the 'critical realist' research programme, an anti-empiricist approach to the philosophy of social science that focuses on uncovering the hidden underlying causal mechanisms at work in social life. The most prolific defender of critical realism within economics has been Tony Lawson (2003), and his writings have generated an extensive secondary literature. A second factor involves changes that have taken place within the philosophy of natural science. Although there were many reasons for the decline of positivist-inspired philosophy of science, one of the most important was the perception that serious problems had developed within the Humean-inspired 'empiricist' component of the programme. Although debate continues about whether the founders of positivism were actually as empiricist as the standard view suggests (Michael Friedman 1999), it is certainly clear that the programme was perceived that way by both critics and supporters, and that it was this aspect of the programme that was most effectively targeted by the criticism that descended upon it in the last quarter of the 20th century. Some of the efforts to reconfigure our reigning philosophical conceptions in light of these developments – particularly about scientific laws (Cartwright 1989) and causality (Hoover 2001) – draw directly on insights from economics. Finally, the literature on economics and ontology has benefited from recent changes that have taken place within the discipline of economics itself. A discipline that is more willing to entertain theoretical pluralism is more likely to be willing to entertain philosophical, even ontological, pluralism as well. The bottom line is that ontology and metaphysics are back and they are opening up a number of new (and renewed) lines of inquiry relevant to the philosophy of economics.

The third set of changes to consider involves border crossings between economics and certain other scientific fields – *cognitive science, neuroscience,* and related disciplines – that have influenced the recent literature on the philosophy of mind. This literature is relatively new and rapidly growing, so much so that no appellative convention has emerged. Until such a consensus has been reached it is perhaps best to be inclusive and simply call it the literature on 'the mind, the brain, rationality, agency and economics'. Examples would include such disparate works as Davis (2003), Glimcher (2003), Mirowski (2002), and Ross (2005). Although the arguments of the various contributors are quite different, there is some agreement about the main issues, as well as about the requirements for any adequate approach to these issues. These requirements concern consistency with recent developments in fields such as cognitive science, neurophysiology and artificial intelligence. The common concern is the core rational choice framework of modern economics: explaining economic behaviour as the outcome of rational constrained optimization of well-ordered preferences. Consumer choice theory is the paradigm case of such an explanatory strategy, but it is standard throughout economics (traditionally microeconomics, but increasingly macroeconomics as well).

Such rational choice explanations have recently been subject to a variety of criticisms. Some of these relate to the abundance of contrary empirical evidence that has appeared in the experimental literature – in both economics and psychology (Kahneman and Tversky 2000) – and some of it has to do with the well-known philosophical problems associated with 'intentional' or 'folk psychological' (belief-desire-action) explanations (Rosenberg 1992). Although much of the impetus comes from critiques of rational choice theory, this does not mean that all of the resulting literature advocates doing away with it. Some authors clearly do, but others interpret these recent theoretical developments as a way of defending standard practice. In either case, whether its authors defend or attack rational choice theory, the literature embodies a fundamental change in the rules of engagement. It is too early to know how it will develop, or the various turns it might take along the way, but it is clear that both in its use of resources from other disciplines and in its overall mode of argumentation it has moved economics and philosophy in a substantially different direction.

The fourth area to consider overlaps substantially with previous section on minds, brains, cognitive science, and such. It concerns the tendency towards *'naturalism'* in epistemology and philosophy of science. The standard interpretation of both positivist and falsificationist philosophy of science puts 'philosophy before science' in the sense that philosophers first decide what scientists must do to produce theories that are cognitively significant – constitute legitimate scientific 'knowledge' – and then evaluate specific scientific practices on the basis of this philosophical analysis. Naturalism – and there are many specific versions, but here we consider its most generic form – reverses this relationship. Instead of starting with a priori philosophical analysis about what scientific knowledge must be, naturalism starts with science, that is, the best current scientific practice, and uses this best practice to inform our epistemological inquiries about knowledge in general. Much of the philosophical literature discussed in the previous section – the literature that employs contemporary cognitive science and neuroscience in the investigation of knowledge in general – is naturalist in this sense. Such naturalism raises a host of questions, particularly questions about how it is possible to have a 'normative' philosophy of science, one that explains what ought to be done in science, when the 'philosophy' in question is based on descriptions of scientific practice. Such questions are the subject of much current debate and do not have easy or simple answers. Fortunately, such answers are not required for a discussion of how naturalism has affected research in the philosophy of economics.

Much of the recent research in the history and philosophy of economics is broadly naturalist in spirit. Naturalism informs some of the work on traditional methodological questions (Hausman 1992) as well as research in general philosophy of science that draws heavily on economics (Cartwright 1989). It also provides the backdrop for a number of recent studies on specific research programmes within economics, including the role of models (Morgan 1999, 2001), the practice of empirical macroeconomics (Hoover 2001), and the development of experimental economics (Guala 2005). Although the boundary that separates such naturalist-inspired research from similar work informed by science studies is somewhat blurred, it is often possible to categorize a particular piece of work as primarily one or the other. If the main question is the philosophical justification of the particular economic tool or theory – even if the standards for such justification are naturalistically or historically grounded – then the research is in the spirit of naturalistic philosophy; but if the explanation of the acceptance or rejection of particular economic tools or theories is based primarily on the influence of social, political, or individual (non-epistemic) interests, then it falls more into science studies.

The final category of literature to be considered, the *economics of scientific knowledge,* reverses the standard relationship between a particular social science like economics and the philosophy of natural science. As discussed above, the traditional relationship between philosophy of science and economics has been that philosophy comes first (laying the foundations for knowledge), economic methodology then translates those philosophical ideas into the context of economic science, and finally particular economic theories are appraised on the basis of the methodological rules so acquired. In the economics of scientific knowledge this process is reversed. Certain areas of economic theory – for example, industrial organization (IO) economics – examine how the institutional organization of a particular industry contributes to economic efficiency. Shifting this type of reasoning from the production of goods and services to the production of scientific knowledge is the basis for one way of thinking about the economics of scientific knowledge. The scientific community has a particular institutional structure; if the goal of this scientific 'industry' is the production of (reliable, justified, . . .) scientific knowledge, then an obvious question is the degree to which the industrial organization contributes to the growth of knowledge (that is, epistemic efficiency). Since the goal is the growth of knowledge within the community, it might be the case that all of the individual scientists following the same methodological rule may not be the optimal way to arrange the available epistemic resources; perhaps the greatest production of scientific knowledge comes about as the result of a 'cognitive division of labor' (Kitcher 1993) rather than methodological homogeneity. It is easy to see how such an approach opens up new ways of thinking about the growth of scientific knowledge, and does so by employing economic theory as a resource (in the spirit of naturalism) to address general questions about the growth of knowledge and the optimal design of scientific institutions.

It can be argued that such research on the economics of scientific knowledge goes back to Charles Sanders Peirce in 1879 (Wible 1998), but regardless of its origins it has expanded rapidly during the last few years, with contributions coming from both economists and philosophers (Dasgupta and David 1994; Goldman and Shaked 1991; Kitcher 1993; Wible 1998). As one might expect, the literature has also generated a variety of critical responses (Hands 1997; Mirowski 2004). In addition, many other contributions to the economics of scientific knowledge are quite different from the version of epistemic IO discussed above (Mirowski and Sent 2002). But in all of its various forms this work clearly represents a significant change in the interaction between economics and philosophy of science.

Economics and Moral Philosophy

One of the many changes that have taken place in the relationship between economics and moral philosophy has been a re-examination of economists' traditional stance on the 'positive-normative dichotomy'. This change is sufficiently complex that it is examined in two parts. First, there has been a substantive reconsideration of the general place of 'the normative' within the science of economics (where 'normative' does not necessarily concern ethics), and second, ethical norms are increasingly being considered in the causal explanation of economic phenomena.

Enforcing the prohibition against value judgements in economics requires maintaining a strict dichotomy between positive statements about what 'is' and normative statements about what 'ought to be'. These two issues – dichotomization and prohibition – are certainly related, but they can also be separated. The first asserts that a dichotomy should be maintained – 'ought' should be kept separate (and cannot be derived) from 'is' – while the second asserts that separate is not equal – things on the normative/'ought' side of the dichotomy have no place within scientific economics. Although the first (dichotomy) is necessary for the second (prohibition), it is clearly not sufficient; one could argue, as, say, Mill and Marshall did, that there is a difference between positive and normative economics, and yet also leave room for a version of normative economic science.

Debate over the strict dichotomy and the prohibition against deriving 'ought' from 'is' has a long history. It was popularized by David Hume in the 18th century, labelled the 'naturalistic fallacy' by G.E. Moore early in the 20th century, and is the subject of a long and contentious debate within philosophy (Putnam 2002). Although many economists have been concerned with these issues, the one who probably played the most important role in the profession's ultimate establishment of the principle of strict separation was Lionel Robbins. Robbins (1952, p. 149) endorsed a strict dichotomy – 'Propositions involving the verb "ought" are different in kind from propositions involving the verb "is"' – but he went beyond mere separation to prohibition, advocating complete exclusion of normative analysis from scientific economics. In particular, he criticized the normative welfare economics of the Marshallian school because it relied on 'interpersonal' utility comparisons. For Robbins, the normative economics resulting from such analysis was 'illegitimate' and 'lacking in scientific foundation' (1952, p. 141).

By and large Robbins's position on these matters has become the conventional wisdom among practising economists as well as among most contributors to the methodological literature. Where methodological commentators often differ is not over whether normative concerns should be kept out of scientific economics but rather on the factual question of whether most practising economists have actually done so. For example, two well-known contributors to economic methodology, Mark Blaug (1980) and Milton Friedman (1953), both endorse the dichotomy and prohibition, but differ on the question of whether the economics profession has in fact been successful at keeping normative propositions out of its scientific practice.

The core of standard microeconomics continues to be rational choice theory; economic agents are assumed to have well-ordered preferences and make optimal choices given those preferences and the various constraints they face. Such rational choice explanations involve two parts: preferences (goals/ends) are assumed to be rational (that is, well-ordered, satisfying conditions such as transitivity and completeness) and the agent is presumed to act in the most efficient way to achieve those given ends (that is, to act in an instrumentally rational way). Philosophers have traditionally called such rationality 'practical rationality' to distinguish it from 'theoretical' or 'epistemic' rationality. In general practical rationality involves what it is rational to do, or at least intend to do, while theoretical or epistemic rationality involves what it is rational to believe.

The literature on practical rationality leads to a very different characterization of the positive–normative dichotomy than the one standard in economics. Although most practising economists continue to view rational choice theory as a positive theory about the behaviour of economic agents (at least under ideal conditions), most philosophers writing on the subject consider it a normative theory in the sense that it involves norms and obligations. Practical rationality, and thus rational choice theory as a particular instantiation of it, is a normative theory because it tells agents what they 'ought' to do in order to act rationally. In the contemporary philosophical literature this view is often associated with the work of Donald Davidson (2001), but it has a long history and continues to be debated (Searle 2001). Philosophers have certainly not closed the book on the question of how a theory of practical rationality could be a descriptive theory, or how, if it is normative, it might relate to associated descriptive theories. The point is simply that it is increasingly the case, in both philosophy and economics, that the discussion of rational choice theory starts from the presumption that it is a particular instantiation of the theory of normative rationality, and as a result, the description of actual economic agents – whether in the laboratory or in 'the wild' – is coming to be seen as something to be compared with, or reconciled with, this theory of normative rationality. It is still possible to discuss the ways in which rational choice theory is or is not an adequate scientific theory, but the starting point of the discussion has changed substantially (Hausman and McPherson 2006; Mongin 2006; Ross 2005).

The second change to be examined requires us to step back from the previous discussion of normative rationality. Suppose we use 'normative' to mean 'ethically normative', and view rational choice theory as a strictly positive, not a normative, theory, then *there are still a number of arguments for increasing the normative content of* *positive economic science*. Although these arguments are less of a challenge to the conventional wisdom, they still constitute a potentially significant change in the relationship between economics and moral philosophy.

Many of the arguments for increasing the (ethically) normative content of economic science come from the experimental literature, either experimental economics or experimental psychology. Researchers in these fields often reaches similar conclusions about the behaviour of the agents they study, although they differ regarding experimental protocols (particularly the role of cash payments) and how such results are to be interpreted (as a critique of rational choice theory or as a critique of the standard assumptions of rational choice theory). One of the systematic results of the literature has been that moral beliefs matter to decision making in experimental environments, and are sufficiently important that such morality often provides better empirical predictions than self-interested rational choice. For example, one of the earliest counter-intuitive experimental results was the tendency for individuals to over-contribute to (that is, not free ride on) public goods (Isaac et al. 1984). One explanation for this over-contribution is an ethical 'taste for fairness'. Another example involves the 'ultimatum game', a game where a self-interested rational agent should offer the smallest possible amount to the other player. The experimental evidence indicates that individuals do not generally behave as rational choice theory suggests, but rather give the other player a more 'fair' distribution. Since rational choice theory allows for the possibility of 'moral' (or otherwise non-self-interested) preferences, these results do not constitute a direct falsification of the core theory of rational choice (Guala 2005), but they certainly do challenge profession's traditional view of the positive and the normative. Instead of ethical norms interfering with the scientific investigation, these are cases where including ethical beliefs in the analysis improves the theory's descriptive accuracy.

The next two developments shift attention away from the positive–normative dichotomy but still challenge key features of the view passed down from Robbins and the ordinal revolution. According to the standard history of demand/choice theory, three (good) things happened as the theory of consumer choice progressed from the hedonistic cardinalism of the late 19th century, through the ordinal revolution of the 1930s, and on to the revealed preference/consistency interpretation in contemporary textbooks. First, all vestiges of hedonistic psychology were finally abandoned; second, all interpersonal comparisons of utility were eliminated; and finally, these changes brought about a steady improvement in the scientific foundations of the theory.

In recent years there has been serious reconsideration of at least two of these aspects of choice theory: hedonism and the impossibility of interpersonal utility comparisons. There have, of course, always been critics of the move away from hedonism and interpersonal utility comparisons (Harsanyi 1955; Robertson 1952), but the goal of such criticism has traditionally been to defend utilitarian ethics as the normative basis for economic policy. Appeals on such grounds certainly continue, but in recent years support for a return to hedonism and interpersonal utility comparisons has come from a number of new directions. Although these two topics are closely related, it is useful to discuss them separately.

Hedonism in rational choice theory is the idea that an agent's preference for a particular bundle of goods is based on the psychological feeling of satisfaction the agent receives when the bundle is purchased or consumed. This is clearly the notion of utility present in 19th century utilitarianism, and, even though it has been replaced by a non-hedonistic notion of preference in modern economics, it is still heard in casual conversation and in the classroom. One criticism of the move away from such psychological hedonism – a criticism from an earlier generation as well (Little 1957; Robertson 1952) – is that the move enervated the theory's ability to provide any real explanation of observed behaviour. Although this criticism has been a theme in a number of important recent studies (Davis 2003; Giocoli 2003; Mandler 1999), these authors do not generally recommend returning to a version of the earlier hedonist doctrine. On the other hand, some recent research does reach such neo-hedonist conclusions.

One research programme that endorses a return to hedonism is the work of the 2002 Nobel Prize winner in economics, the experimental psychologist Daniel Kahneman (Kahneman and Tversky 2000). Although the research of Kahneman and his associates is wide-ranging, and perhaps not every participant would support this particular aspect of the programme, the argument for a return to hedonism – what is called 'experienced utility' – has been a key aspect of Kahneman's approach (Kahneman 1994, 1999; Kahneman et al. 1997). There are two main parts to the argument for experienced utility, one philosophical and the other based on recent changes in our scientific tools. The philosophical argument is simply that weakening the positivist grip on experimental practice has opened the door to a number of new and fruitful possibilities; the more practical argument is that new tools for measuring experienced utility are becoming, and will continue to become, more available over time.

> The methodological strictures against a hedonistic notion of utility are a relic of an earlier period in which a behavioristic philosophy of science held sway. Subjective states are now legitimate topic of study, and hedonic experiences such as pleasure, pain, satisfaction or discomfort are considered open to useful forms of measurement. (Kahneman 1994, p. 20)

Paralleling such neo-hedonist arguments from experimental psychology are similar arguments from economics, particularly the literature endorsing 'happiness research' as a source of useful, and measurable, data for applied economic theory (Frey and Stutzer 2002). Economists appear to be more willing than psychologists to accept measures of happiness based on survey data, but the hedonistic themes are very much the same. Finally, there is a literature on the relationship between economic rationality and evolutionary biology that also suggests a hedonistic characterization of utility is scientifically appropriate (Robson 2001). It does not seem, as yet, that these newer interdisciplinary arguments defending hedonism have been integrated into the more traditional defence of utilitarian-based ethics as the basis for economic policy, but it is an obvious next step and is therefore extremely important for the relationship between economics and moral philosophy.

To turn from hedonism to a fourth change in the recent economics and ethics literature, there are similar (and often overlapping) arguments endorsing the revival of *interpersonal utility comparisons* in economics. Although the two issues – hedonism and interpersonal comparisons – are closely related, it is important to keep them separate. Hedonism is about feelings of pleasure and pain, and interpersonal comparisons are about having a common unit of comparison between the preferences of different agents (Mandler 1999). One can compare the current running through two different electrical appliances, but it is reasonable to conclude that such appliances do not 'feel' anything; similarly, two individuals could possess subjective, even cardinal, feelings about various goods and yet there would exist no way for a third party to measure or compare those feelings.

As in the case of hedonism, there have been consistent defenders of the legitimacy of interpersonal comparisons within economics, even when it was out of favour with most of the profession; many of these defenders came from the Marshallian tradition (Pigou 1920), but that is not exclusively the case (Harsanyi 1955, 1982). Often the argument was simply that economists should start with the observable facts of everyday life, and the fact is that humans make interpersonal comparisons all the time (Little 1957). Such defences continue, but in addition – again, as in the hedonism case – a number of new arguments are being made that draw on a range of interdisciplinary resources.

One source of evidence for interpersonal utility comparisons comes from recent research on neuroeconomics, part of the literature on 'the mind, the brain, rationality, agency and economics' discussed above. Neuroeconomics is a research programme that combines contemporary neuroscience and economics in the investigation of the microfoundations of decision making

(Glimcher 2003). Imaging studies from neuroeconomic research suggest that humans have the capacity to both represent the mental states of others and to empathize, that is, share the feelings of others. These abilities, it is argued, were selected for in human evolution because they 'enable people to predict others' behavior and, therefore, help them meet their individual goals' (Singer and Fehr 2005, p. 343). Neuroeconomics is not the only source of such arguments for the reliability, and survivability, of interpersonal utility comparisons. Similar arguments have also been made in the literature on the philosophy of mind. For example Alvin Goldman (1995) combines a reliabilist approach to the philosophy of science with various arguments from cognitive psychology to make the case for individuals having the ability to mirror, or simulate, the mental states of others in a reliable way, including interpersonal utility comparisons. In addition to the obvious support such research provides for moral theorizing within the utilitarian tradition, it also seems to provide a naturalistic explanation for the sympathy that played such an important role in Adam Smith's moral theory. At the very least, moral, economic and cognitive theorizing are simply different parts of a single intellectual exercise – as they were for Smith and Mill – rather than being hermetically isolated, as they were for most of the 20th century.

The fifth and final research to examine carries us outside the boundaries of the previous topics. Whether one is considering rational choice theory as normative theory, using moral preferences to explain observed behaviour in experimental economics, or defending hedonistic psychology and interpersonal utility comparisons, the discussion continues to be broadly within the research programme that identifies welfare with the satisfaction (or feelings received from the satisfaction) of individual preferences. In all of these cases, regardless of how much the recent literature conflicts with the mainstream view on such matters, the bottom line is still that individuals have preferences (hedonistic or not) and the individual 'good' is to have those preferences satisfied. But not all moral and political philosophy, even all that involves economics, follows this tradition.

John Rawls's *A Theory of Justice* (1971) is arguably one of the most important books on moral philosophy of the 20th century; it, and the philosophical discussion surrounding it, set the stage for many of the changes discussed above. Although Rawls's theory of justice falls squarely within the contractarian tradition – defining 'justice' as a property of the social contract that would emerge from the interaction of rational self-interested agents – he imposed strong restrictions on the context in which such contractual bargaining takes place; the decisions must be made in 'the original position' behind a 'veil of ignorance'. The principles of justice are those that would emerge from the bargaining of rational agents if those agents did not have any information about the position they would ultimately occupy (professional, class, gender, level of health, . . .) within the society governed by the contract, or even about what their preferences would be. Rawls goes on to argue for specific rules of justice that would emerge from such a context – including the much-debated 'difference principle' – but it is possible to separate his general approach to the question of justice from his specific distributional answers.

Although it is impossible to discuss the extensive literature surrounding Rawls's work in the space available here, it is important to consider the related contribution of one economist. The economist is Amartya Sen, the 1998 winner of the Nobel Prize in Economics. Sen has long been a critic of standard rational choice theory (Sen 1977), but his critical writings have come to be overshadowed by his own *capabilities* approach to social welfare and related issues (Sen 1985, 2002). The core idea of the capabilities approach to social welfare is to focus on the capabilities that people have, that is, on the things that people are effectively able to do or be – the functionings they are free to achieve – rather than on the satisfaction of individual preferences. Such capabilities are obviously multifaceted; they depend on the person's mental and physical characteristics as well as his or her social context and opportunities. One may have the capability to ride a bike, to find meaningful work, to express oneself artistically, or to participate in the governance of one's society; alternatively, one may have none, or only a few, of these capabilities. For Sen, such capabilities should be the proper focus for both the analysis of social welfare and the theory of economic development. The point of both welfare and development is to increase the capabilities of the population – to give them the freedom and opportunity to be better able to live the kind of life they find valuable. This, of course, does not rule out increasing the quantity of goods and services they have available, but it is at best only part of the story. In this sense Sen's approach actually moves us farther away from the traditional preference-based notion of social welfare than Rawls. Rawls's concept of justice is still based on the notion of a distribution of preference-satisfying goods (albeit primary social goods), while Sen shifts the focus away from individual preferences towards freedom and functioning.

Needless to say, Sen's approach has many critics, but his work has also generated an extensive supporting, extending and implementing literature. An important example of support and extension is Martha Nussbaum's (2000) research on women and development, which provides a specific list of the most important 'central human capabilities'; an example of implementation is the United Nations Development Program's Human Development Index, which builds on Sen's capabilities approach. Undoubtedly the capabilities literature will continue to evolve, but, regardless of the eventual shape it takes, it is an important contribution that has substantially changed the discourse on economics and moral philosophy.

Convergences

In closing, it is important to note the change that has taken place in the general way that various questions in philosophy and economics are approached in the recent literature compared with the way they were approached, at least by economists, for most of the 20th century. The traditional view considered 'the philosophical', whether it be epistemology or ethics, as something 'out there' with respect to economics. In the case of epistemology it was appropriate to seek methodological advice from philosophers about the character and practice of science, but the border crossing remained sporadic and one-way. In the case of ethics, the traditional view was simply to be aware of such ideas in order to prevent them from influencing the discipline's scientific practice.

Things have indeed changed. This is not to say that there is any consensus about specifics in the contemporary literature on either economics–epistemology or economics–ethics – in fact there has been an explosion of diversity and debate, and as such there is far less consensus on such matters than among economists in the past – but rather that the style of discussion has changed in both fields, and in a sense converged. Although a much longer list could be constructed, there seem to be three features of the debates in philosophy and economics discussed above that were effectively absent from the previous discussions: the interdisciplinarity, the naturalism, and the two–way relationship involved. The literatures discussed above all draw on a wide range of resources: economics and disciplinary philosophy certainly, but also cognitive psychology, neuroscience, the history and sociology of science, ideas from evolutionary biology, and a host of others. They are also broadly naturalist in focus in the sense that the relevant philosophical questions – whether epistemological or ethical – are on equal footing with the science, social or natural, that is employed in, and constrains, the philosophical discussion. Finally, and perhaps most obviously, work in philosophy and economics is much more of a two-way street. It is not simply that a shelf of scientific philosophy is 'applied' to economic methodology, or that a shelf of moral philosophy is used to cull normative concepts from economic science, but rather that economic notions of agency, choice, efficiency and equilibrium now condition the discussions in philosophy in the same way that alternative philosophical ideas, and 'normativity' more broadly, are increasingly involved in discussions within economic theory. On the one hand, these are substantive changes; on the other hand, such interconnections were present in the work of Smith, Mill and others. Perhaps these changes in the relationship between philosophy and economics are not so new after all; perhaps what needs explanation is not recent developments but the aberration of the 20th century.

The Physiocrats lived and worked in France in the middle of the 18th century. The name derives from the title of a collection of some of the most important writings of their master François Quesnay, *Physiocratie, ou constitution naturelle du gouvernement le plus avantageux au genre humain* published in 1767 by P.S. Du Pont de Nemours. The term Physiocracy indicates the importance ascribed by these authors to natural forces, and derives from the Greek: *phýsis,* nature, and *kràtos,* power. The Physiocrats can be regarded as the first school of economists. They acted as an organized group of thinkers who intended to influence the French government's economic policy. They were accused of being sectarian because of their strict allegiance to the economic theories and opinions of their master, Quesnay. He provided the most important and original ideas, Victor Riqueti, Marquis de Mirabeau, was his first disciple, and included among the best known Physiocrats were Du Pont de Nemours, l'Abbé Nicolas Baudeau, Le Mercier de La Riviére and François Guillaume Le Trosne. One should also mention Henry Pattullo, an Irishman, who was deeply influenced by Quesnay's early articles (see Hecht 1958, vol. 1, p. 257). These French authors can be regarded as the 'inner circle' of the Physiocrats.

Another group of writers, sometimes confused with the Physiocrats, was Vincent de Gournay and his followers, the most famous of whom is Turgot. Gournay was appointed *Intendant* of commerce in 1751, and, like Quesnay, favoured laissez-faire. However, Gournay and his school never followed the Physiocratic programme and, in particular, disagreed on such important points as the idea that agriculture was the only productive sector of the economy.

Physiocracy covers a period of 20 years, from 1756 when Quesnay published his first economic articles in the *Encyclopédie* of Diderot and D'Alembert, until 1777 when Le Trosne's book appeared.

After a period of relative prosperity at the end of the 17th century and the beginning of the 18th century France experienced many bad years, mainly due to the backwardness of her agriculture. Often the Physiocrats recalled the age of Sully, Prime Minister to Henry IV, as the golden period of French agriculture and of the whole country. But now farmers were poor and could not implement the best methods of cultivation; the fiscal system was inefficient and unjust; and there were many different taxes and duties, both on the peasants themselves and on their products (Loménie 1879, vol. 2, p. 218). For instance, one had to pay an excise in order to take products from one province to another. Trade in agricultural products was greatly hindered by these impediments to the free circulation of commodities. There were also taxes that were levied on the number of people in the family – the various forms of *capitation*.

On top of these duties there were taxes which had to be paid to the Church and to the King, the *dîme* for the Church and the *taille* for the government. These taxes were levied on the revenue of lands, but their collection was extremely inefficient. The government used to sell the right to collect the *taille* in one province to some wealthy people who became tax collectors. This was the system of the *ferme général*, and was opposed by the Physiocrats because the peasants were oppressed by the *fermiers généraux*, who, having paid the government in advance, tried to make as much money as possible. They were allowed to keep all the taxes for themselves, and thus the King received much less money than that paid by the peasants.

There was a huge public deficit, and at the same time the peasants and the farmers were deprived of the fruits of agriculture.

The fiscal systems and the various barriers to the domestic and foreign trade of agricultural products discouraged the farmers from improving farming and agricultural productivity. During the first half of the 18th century there were many years of misery and famine (see Meek 1962, p. 46). According to Quesnay, during that period the population of France decreased from 24 million to 16 million (INED 1958, vol. 2, p. 506). He was too pessimistic (Eltis 1984, p. 39), but certainly French agriculture was unable to sustain a growing population. The Physiocrats compared the farming conditions in France with those in England, where farmers were rich and productivity was very high (INED 1958, vol. 2, pp. 440–41). The backward economic situation in France was made worse by the almost continuous wars, which absorbed human and financial resources. The Physiocratic movement must be examined in the light of this situation of recurring economic crises. The purpose of Physiocracy was to bring changes to certain characteristics in the French economy and in the political system of the *ancien régime*. They were a group of reformers, who tried to convince the rulers and the sovereign that some changes were needed to make the country more wealthy and politically stronger.

The history of the school can be divided into three periods: the years in which the main ideas appeared from 1756 to 1760, mostly in the works of Mirabeau and Quesnay; from 1760 there was a period of almost three years silence; the third period, from 1764 to 1777, saw a flourishing of writings and enterprises, thanks to the younger Physiocrats. Quesnay published his first economic articles in the *Encyclopédie,* to which he had been asked to collaborate on matters of agrarian economics. In 1756 *Evidence* and *Fermiers* appeared and in 1757 he published *Grains.* These works present most of the new ideas of the school and in particular they stress the view that agriculture is the most important sector in the economy. This is the corner stone of the Physiocratic theory of the nature and causes of national wealth. Quesnay identified the entire social product with the annual output of agriculture, and maintained that neither industry nor trade could increase the country's wealth, a doctrine which won him many enemies. In 1757 Quesnay met his first disciple: the Marquis de Mirabeau. This member of the French aristocracy had become famous because of his book *L'ami des hommes, ou traité de la population,* in which he stated that the wealth of a country depended upon the size of her population; like the title of his book he was called 'the friend of mankind', because of his liberal and reformist views. On July 1757 Quesnay and Mirabeau met at Versailles, where Quesnay was one of the King's physicians. Quesnay convinced Mirabeau that the products of land were more important than people because they secured the survival of the peasants and their families, who had to be regarded as the most important element in the economy (Weulersse 1910, vol. 1, pp. 55–6). Mirabeau was won over to the cause of Physiocracy, and in a couple of years he wrote many important works. In 1758 Quesnay wrote his famous *Tableau économique,* which was printed in three different editions between the end of 1758 and the first months of 1759. The analytical structure of Physiocratic economics was an enormous step forward. French society was divided into three main classes: the landlords – including the King and the Church – the farmers, and finally the artisans; the last two groups were respectively in charge of agricultural and industrial production. The *Tableau* outlines the main features of the process of circulation of commodities, at the end of the productive process, and gives a precise definition of the means of production and the net product. To illustrate his main economic ideas Quesnay used some rather obscure diagrams, which nevertheless greatly impressed the Versailles aristocrats. To make the *Tableau* more understandable to the public Mirabeau wrote some explanation in three further books of his *L'ami des hommes,* which were published between 1758 and 1760, and in which Quesnay's influence is very strong. Always in strict collaboration with the master, Mirabeau wrote a treatise on one of the major economic problems of the time: the reform of the fiscal system. The *Théorie de l'impôt* appeared in 1760 and presented one of the Physiocrats' most famous proposals: the single tax on rent. Fiscal reform must abolish all taxes and duties which are levied either on the peasants or on their products. This tax burden is one of the main reasons why cultivation cannot become profitable. The financial needs of the Kingdom must be met by a single general tax, which has to be paid in proportion to the net product of agriculture. This recommendation was the logical consequence of Quesnay's division of the social product into two parts: capital and surplus. The capital consists in the *avances* for farming, and must be preserved to maintain the same level of agricultural output. Any form of taxation falling on farmers' advances, *les avances*, would reduce the amount of capital employed in agriculture, and this would have disastrous effects on the whole country. Thus, only the surplus is really disposable for taxation, because it does not affect reproduction of output.

The largest part of agricultural net product accrued to the landlords in the form of rent. Quesnay and Mirabeau's single tax on the net revenue meant the abolition of all the fiscal privileges of the ruling classes, the Church, and the aristocracy.

Mirabeau and Quesnay tried to convince the nobles that in the following years their rents, net of taxes, would be much higher than before. In fact, the farmers, freed from the previous fiscal burden, would invest more money in the cultivation of land. The productivity of agriculture would rise, as would the surplus. But these arguments did not impress the nobility. Moreover, Mirabeau also violently attacked the tax collectors. The state must collect its taxes without the intermediation of these merchants and businessmen. But for many members of the aristocracy and the merchant bourgeoisie the role of tax collector meant power and wealth. Their reaction to Mirabeau's book was so strong that he was imprisoned for a few days, and then exiled to his countryside estate for some months (Loménie 1879, vol. 2, p. 226).

Here ended the formative period of Physiocratic school. Quesnay and Mirabeau did not publish anything for two and a half years. Du Pont wrote that Mirabeau's misfortune delayed the development of enlightenment (Du Pont, 1769, *Ephémérides*, vol. 2). Quesnay and Mirabeau spent this period of silence working towards a new book which was to be a fundamental text for Physiocratic doctrine. It appeared at the end of 1763 in three volumes, with the title *Philosophie rurale ou économie générale et politique de l'agriculture.* 1763 saw renewed interest in Physiocratic ideas; the government accepted the principle of free trade for corn inside France, which was one of the main reforms advocated by the Physiocrats. New followers joined Quesnay and Mirabeau; Du Pont de Nemours became an enthusiastic propagator of Physiocracy and in 1764 published a pamphlet in favour of free foreign trade for French corn. The mid-1760s were the period when Physiocracy had most influence on French economic policy.

In 1764 Du Pont became chief editor of a famous periodical, the *Journal de l'agriculture, du commerce et des finances*, which became an important vehicle for Physiocratic propaganda for some years. In the same year two new followers joined the school: Le Trosne and the less famous Saint Péravy. In 1765 Mercier de La Rivière was converted to Physiocracy. The school was now powerful enough to try to gain more influence on political and economic matters. After six years during which he mostly collaborated with Mirabeau's work Quesnay wrote again on his own, and from 1765 to 1768 he published many important articles intended to explain the principles of Physiocracy further, and to defend them from growing attack. At least three articles must be mentioned: ‘Le droit naturel’, which was written in 1765, the ‘Analyse de la formule arithmétique du Tableau économique’, which was written in 1766, both of which appeared in the *Journal de l’agriculture.* The latter is particularly important because it provides an easy explanation of the *Tableau économique* and in fact became its best-known version. The third work is the ‘Dialogue sur les travaux des artisans’, published in 1767 in the *Ephémérides.* Here Quesnay defended his view that only agriculture was capable of yielding a net product, while industrial activity was sterile because it only replaced the value of the raw materials and necessaries which had been used up in production.

During this period other Physiocrats contributed to the development of the school. In 1767 Mercier de La Rivière published his book *L’ordre naturel et essentiel des sociétés politiques*, in which he elaborated the political doctrines of Physiocracy. In the same year Du Pont published a collection of some of Quesnay’s work, entitled *Physiocratie,* where this term appears for the first time. The Physiocrats met every Tuesday in Mirabeau’s palace, and became a political group (Weulersse 1910, vol. 1, p. 132).

The abbé Baudeau too became a Physiocrat. In 1767 Baudeau founded an influential periodical, the *Ephémérides du citoyen* in which several Physiocrats collaborated. In the same year Du Pont started losing power in the *Journal de l’agriculture.* Since it was important for the Physiocrats to publish in a friendly periodical, they tried to win over Baudeau. After a few months of discussion the *Ephémérides* became the official periodical of Physiocracy. Many powerful people looked favourably on this group of intellectuals. Among them were Traudaine de Montigny and, above all, Turgot.

Physiocracy was also exerting some influence abroad. Catherine II invited Mercier de La Rivière to St. Petersburg to spread the new ideas. The Margrave of Baden also became a Physiocrat and exchanged letters with Du Pont. At home the Physiocrats had good relationships with the *encyclopédistes*; Diderot personally admired Mercier, but never shared the Physiocratic opinion that the wealth of a country derives from agriculture. The school also received support from the *Sociétés d’agriculture*, coalitions of wealthy farmers who tried to defend their interests and gain power over landlords. For these bourgeois farmers the doctrines of the Physiocrats were a powerful instrument of propaganda and political influence on the government.

The growing prestige and power of the Physiocrats also gained them new enemies including many of the aristocrats, and all those merchants who had exclusive trading privileges granted by the government.

In 1767 and 1768 many authors wrote against the Physiocrats. Grimm, Forbonnais and Mably, a disciple of Rousseau, attacked different aspects of Physiocracy. In his pamphlet *L’homme à 40 écus,* Voltaire ridiculed the Physiocrats’ fixation with numerical examples. The *encyclopédistes* became less friendly towards the Physiocrats. Some critics accused Quesnay and his disciplines of trying to mitigate the most unjust aspects of the *ancien régime* and to improve its inefficiencies only to prevent any major change in the French political system.

One particular point of Physiocratic theory came under attack at the end of the 1760s: the doctrine of the exclusive productivity of agriculture and the sterility of industry. (Notice that the Physiocrats regarded as productive not only the cultivation of soil but all the activities directly connected with agriculture, such as ‘grasslands, pastures, forests, mines, fishing’ (Kuczynski and Meek 1972, p. i).) Nobody questioned the importance of agriculture, but the attacks focused on the view that trade and above all industry were regarded as sterile occupations. This was the crucial point of the Physiocrats’ definition of wealth, and all their policy measures depended upon this doctrine. The liberalization of the corn trade, the reform of the fiscal system, and the attack on expenditures on luxury goods all depended upon the Physiocrats’ identification of national wealth with agricultural production. Many contemporary authors rejected the idea that national wealth could only be increased through land.

Veron de Forbonnais, a former pupil of Gournay, defended the productive role of commerce and industry (see Weulersse 1910, vol. 1, pp. 121–2). The strongest attack on the doctrine of the exclusive productivity of agriculture came from a Neapolitan priest, the abbé Ferdinando Galiani. With the help of Diderot, at the end of 1769, he published the *Dialogues sur le commerce des bléds,* in which he used brilliant prose to ridicule the supposed superiority of agriculture over industry. Galiani gave very simple and straightforward examples to show that increases in productivity were much more likely to take place in industrial production than in agriculture. Good and bad weather does not influence the output of manufacturing, and the advantages of the division of labour which derive from increases in capital stock are not limited by the existence of a fixed amount of soil (see Galiani 1770, p. 142). The decisive element which undermined the influence of Physiocratic views on government policy was growing opposition to the deregulation of the corn trade. From 1763 the commercial policy for the products of land, and in particular corn, had become one of the main economic issues in French society. We have already seen that the Physiocrats had some success with the 1763 declaration of the free circulation of corn inside France. In July 1764 an edict authorized the exportation of corn under certain circumstances. According to Quesnay laissez-faire in domestic and foreign trade was designed to favour the circulation of corn and increase its demand. A free trade policy implied the abolition of all the rights and the rules which hampered the corn market (Mirabeau 1764, vol. 2, p. 343). The merchants and all the people who had been granted some ‘exclusive privileges’ in corn trade were damaged, because they lost the position as middlemen between consumers and producers (INED 1958, vol. 2, p. 532). The Physiocrats wanted to favour direct contact between consumers and cultivators. The final outcome of a laissez-faire policy would have been an increase in the price received by farmers without damaging consumers, thanks to the squeeze, or the abolition, of the earnings of all intermediate agents. Free corn exportation would have further contributed to sustaining its demand and its price on the French market. The establishment of a *bon prix* for primary commodities was meant to raise farming’s profitability (INED 1958, vol. 2, p. 529). Farmers would have been able to make new investments, the productivity of French agriculture would have risen and the gross and net output of the primary sector would have been larger than before. This was the Physiocratic road to welfare and prosperity for the French Kingdom (Mirabeau 1760, vol. 2, p. 143).

In the second half of the 1760s the price of corn rose, but unfortunately this happened both in the wholesale and in the retail markets. It is difficult to ascribe this rise to free corn exports: most likely the price increases were due to a series of bad harvests. But the Physiocrats were accused of having contributed to the worsening of the living conditions of the French people, for whom corn was the most important consumption good. In 1768 there were popular uprisings against the high price of corn both in Paris and in the countryside.

Part of public opinion began to consider Physiocratic theory as a dangerous attack on poor people, and some parliaments, in particular those of Paris and Rouen, called for the reintroduction of the restrictions on the corn trade. Between 1768 and 1770 there were many discussions for and against laissez-faire for primary commodities; the public and the government itself came gradually to oppose the Physiocratic views. At the end of 1769 the abbé Terray, one of the fiercest opponents of Physiocracy, was appointed *contrôleur général*, a sort of minister in charge of all economic matters. There were more uprisings and more declarations by provincial parliaments against the free exportation of corn.

During this period relationships between the Physiocrats and the *encyclopédistes* deteriorated notably. Grimm made fun of the *secte* of the *philosophes économistes,* who were accused of presenting a reactionary doctrine, designed to favour the landlords and the rural classes against the people in the cities (Weulersse 1910, vol. 1, pp. 230–1). In this hostile climate Turgot and Morellet rejected the invitation to join the Physiocrats. After a period of irregular publication the *Ephémérides* were put under censorship. At the end of 1770 corn trade legislation was completely changed and strict regulations were introduced both in foreign and domestic trade. The period of political influence of Physiocracy was almost over, and Physiocratic doctrines rapidly disappeared from public debate and the political arena. A final glimpse of the Physiocrats' impact on French economic policy was due to Turgot. On becoming *contrôleur général* in 1774 he restored internal free trade in corn, with the exception of Paris (Groenewegen 1977, p. xxxii). But this policy had many powerful opponents, and caused Turgot's fall after two years.

At the end of the 1760s Physiocracy was on the wane. After 1768 Quesnay wrote nothing on economic matters, lost interest in economic problems, and spent the last years of his life studying geometry; he died in 1774. In the 1770s there were only two works by Physiocrats. In 1772 Du Pont published an *Abrégé des principes de l'économie politique.* In 1777 Le Trosne published his book *De l'intérêt social, par rapport à la valeur, à la circulation, à l'industrie et au commerce intérieur et extérieur*. These attempts to renew interest in Physiocracy failed to influence either the policies of the government or discussions in French society.

Quesnay and his followers must be regarded as part of that cultural phenomenon which was the French Enlightenment. Many authors had already pointed out France's disastrous economic circumstances in the first half of the 18th century. Moreover, most of these writers did not limit their denunciations to the unjust and inefficient aspects of French society, but extended their investigations to the problem of the origin and nature of civil societies and the analysis of the best rules and laws which should regulate the relationships between individuals.

Quesnay and his disciples contributed to the French enlightenment. They concentrated their efforts on the economic and social reforms which were needed to make France more efficient. But they were not very much interested in the analysis of the fundamental principles of the civil societies and the role of subjects and the state; such issues have no prominence in their works. The only exception is the book by Mercier de La Rivière, which is mainly dedicated to the analysis of the political system. In general the Physiocrats never questioned the existence of the absolute monarchy and the political organization of the *ancien régime.* This is one of the main reasons why they were accused of being too hesitant in the defence of individual rights against state power. Montesquieu's *L'Esprit des lois* was one of the philosophical works which most influenced the Physiocrats; this book appeared in 1748. A year later Rousseau published his *Discours,* with which the Physiocrats were much less in agreement.

In the first half of the century, several authors had already analysed the economic and social conditions in France, paying particular attention to the agricultural sector. In different ways these writers can be considered as the forerunners of Physiocracy. We have already seen that at the beginning of the 17th century, French agriculture was prosperous thanks to Sully, Henry IV's Prime Minister. The years of Louis XIV were marked by Colbert's attempt to favour industrial activities by keeping the prices of subsistence goods low. At the end of the 17th century there was a reaction to Colbert's policy and the role of agricultural production was again emphasized. Among the authors who influenced the Physiocrats Vauban and Boisguillebert should be recalled. In 1707 Vauban published *Dîme royale*; he said that a single tax on agricultural output was the best solution to France's fiscal problems.

In 1695 Boisguillebert published the *Détail de la France,* a collection of statistical information on the French economy, and in 1707 his *Dissertations sur la nature des richesses, de l'argent et des tributs* appeared. He stressed the importance of agriculture among various economic activities, and above all described the production and exchange of commodities in terms of a circular flow, a sort of selfregenerating circuit. Two other works which deserve mention are Melon's *Essai politique sur le commerce* (1734) and Herbert's *Essai sur la police des grains* (1754). But of the writers who exerted a major influence on Physiocracy, a special place is occupied by Cantillon. Other British authors were well known in France in those days, for instance

Child, Tucker and Hume, but Cantillon's impact on Physiocratic theory was much deeper.

At the beginning of the 1740s Mirabeau had a copy of Cantillon's *Essai sur la nature du commerce en général,* which he regarded as the fundamental text on economic matters, an opinion shared by Quesnay. Mirabeau published Cantillon's *Essai* in 1755. In many ways the Physiocrats followed Cantillon's general approach to economic analysis. Cantillon gave a framework in which to build up a theoretical model of the working of the whole economic system. Economics would no longer be a subject for pamphleteers, merchants and practical men, but would become a topic of separate theoretical speculation. Practical matters would be examined in terms of the theories' fundamental principles. Cantillon's analysis left clear marks on Physiocratic economics, such as, for example, his classification of the people of a kingdom into three main classes: landlords, entrepreneurs and workers. His analysis of the distribution of income was related to these classes; he spoke of the farmers' 'three rents', which make up the value of the products and each rent is the income of one class (Cantillon 1755, p. 43). Like the Physiocrats Cantillon emphasized the productive role of the farmers as entrepreneurs. Finally, Cantillon considered expenditures of revenue as the most important element in the determination of the prices of commodities and the level of activity of the sectors other than agriculture. It is thanks to the landlord's expenditures of their revenues that these activities can exist. Through Cantillon the Physiocrats were also influenced by Sir William Petty.

With regard to Physiocratic theory it must be remarked that almost all the main contributions are due to Quesnay. As to their philosophical views they believed that civil societies were only a mirror of natural order. The Physiocrats believed that societies are characterized by the existence of laws which govern the relationships between individuals. These natural laws can be studied, and their knowledge provides the foundation for the proper administration of the country. It must be noticed that the Physiocrats' attitude towards natural laws and natural order is somewhat different from most of their French contemporaries and from Adam Smith. Natural laws operate quite independently of men's will (INED 1958, vol. 2, p. 526), but at the same time they are not so powerful as to be ignored. These laws have been inscribed in nature by God himself (Mirabeau 1764, vol. 2, pp. 9–11; INED 1958, vol. 2, p. 934), but their working can be hampered and their effects can be modified by unwise ruling of society and by powerful social groups. Therefore natural laws do not necessarily overwhelm men's actions, and civil societies cannot be analysed as if they were a mechanical system which always gives the same results. The Physiocratic concept of natural order is a peculiar mixture of objective laws and of socio-historical modifications. Natural laws exist, and can be studied and precisely singled out, but there is also room for active human intervention. This view of the natural order has far reaching implications. The Physiocrats believed that societies evolve through definite specific stages (Meek 1976, pp. 72, 99). But this evolutionary process can be stopped for long periods. They regarded England as the country where natural law displayed its positive effects, and which reached the highest stage of economic development. However, in France civil laws and historical traditions prevented the full unfolding of natural laws and the country was still in a backward condition. Thus, the Physiocrats did not take a deterministic approach to the study of societies, even if they believed in the existence of objective natural laws. Natural order is a sort of normative situation which describes the features of an ideal society.

How can these natural laws be discovered? Quesnay wrote an article entitled *Evidence* in which he maintained that the laws of natural order reveal themselves in day-to-day events. The Physiocrats were also influenced by Descartes, a fact which helps to explain their belief in knowledge through evidence. In some way natural laws seem to be inborn in men, and this is why the system of natural order should be clear to everyone.

Which are the fundamental principles of natural order? Here too the Physiocrats' answer shares some features of contemporary French culture but also presents some peculiarities. Quesnay and

Mercier de La Rivière contributed to the development of the philosophical and political views of the school. In 1765 Quesnay wrote *Le droit naturel,* where he mentions the natural rights of men, which, however, are discussed mainly in relation to the economic features of society. Thus, freedom implies the abolition of privileges and regulations in all markets. Free competition must rule in the labour market as well as in domestic and foreign trade; people must be entirely free to decide how to spend their revenues. For the Physiocrats freedom meant universal competition, and was regarded as the basis for the increase in private and public wealth.

They regarded private property as a fundamental right of men, but by this they meant that land ownership was part of the natural order of societies, and the King was considered to be co-owner of all French soil. But the Physiocrats also emphasized the importance of guaranteeing the farmers and their families the ownership of the capital employed in agriculture and the fruits of farming.

Private ownership excludes the possibility of equality between men; indeed development of the economy will cause more inequalities. Differences among people are necessary in order to have an efficient economic system, capable of yielding a high net product. Therefore the political structure of a country reflects its economic and social circumstances. For the Physiocrats the major forces which explain historical changes in societies must be sought in their economic structure. This economic interpretation of history (Meek 1962, p. 376) underlines the fact that economic systems are based on the existence of different social groups which have separate economic functions. The Physiocrats distinguish French subjects into three classes: the landlords, including the King and the Church who represent the First and Second Estate; the people working in agriculture; and the industrial workers. This tripartite distinction is a hybrid since it is based partly on intersectoral differences and partly on property relationships. But in Physiocracy there is also a more detailed class analysis. In agriculture there are both farmer entrepreneurs and salaried peasants; with some ambiguity the same distinction between employers and employees exists in the industrial sector too. Then there are the merchants and all the people related to trade, and here too a whole class is identified with a sector of the economy. However unsatisfactory this approach may be, it was to be extremely important in the development of economic theory. First, following Petty, Boisguillebert and Cantillon the Physiocrats consider the economy as a system which is made up of different social groups, and which tends to reproduce both its economic and social relationships. Second, these classes are defined according to their role in the process of production and circulation of commodities. These two features are typical of the whole of classical political economy. Of course, the main limitation of the Physiocratic analysis of classes is the fact that they tend to identify social groups with the sectors of the economy, even if there are also hints of a distinction based on political and economic power relationships.

The Physiocrats' concept of natural order deeply affects their political views. In general they argue that the principles of political order must accomplish those of the natural order. The particular way in which this connection between the two orders comes about is through the form of government which they call *despotisme légal.* The supreme authority is that of the absolute hereditary monarchy which does not need to be legitimatized by the subjects. Of course this view was criticized by many authors of the time. According to the Physiocrats the only authority was that of the sovereign and that came directly from God. The King was also the natural owner of all the territory; *despotisme* was also patrimonial; the King was also the highest tutor of all forms of property. He was a legal despot, because he guaranteed security and freedom in property. Property is the key notion in the foundations of a political order. But according to the Physiocrats the authority of the King was moderated by the fact that he had to exert his power as an enlightened sovereign. By this the Physiocrats meant that the King had to be aware of natural laws and had to favour their implementation in civil society. The King's knowledge of natural laws was the decisive element which had to secure the existence of appropriate civil laws and just administration. No confrontation could exist between the sovereign and his subjects because the King, properly instructed about natural order, knew that his interests coincided with those of citizens.

The Physiocrats envisaged only two limits to the King's power. On the one hand there was public opinion, which was also instructed in the principles of natural order, so that the people could react to a situation where the King ignored natural laws. On the other hand the fact that the King was the owner of the whole country did not entail exploitation of his subjects. Customs and habits about the fiscal system could not be modified by the sovereign's own decision alone.

A final peculiarity of the Physiocrats' political thinking is their view that only agriculture produces a surplus. In an agricultural country like France the merchants and all the owners of monetary and financial wealth are not part of the nation because their interests are in opposition to those of the state. The only true citizens are the landowners, the wealthy cultivators, and the other people directly linked to agricultural production; the artisans of the industrial sector were somehow tolerated. It is clear that Physiocrats aimed at a political system based on the alliance of all social groups linked to agriculture and the King.

The distinctive feature of Physiocratic economics was the doctrine of the exclusive productivity of agriculture; only activities directly linked to nature could yield a net product over costs. To justify their views Quesnay and the Physiocrats used many different arguments. Agriculture was superior to other economic sectors because it produced the raw materials and the necessities for all other occupations. The subsistence of all people could only come from farming (INED 1958, vol. 2, p. 775). Industrial and commercial activities could exist only because the peasants were producing more foodstuffs than was required for their own subsistence. Moreover, France had been endowed by nature with a large and fertile territory and was surrounded by countries whose soil was much less suitable for farming and who were potential buyers of French products (Le Trosne 1777, p. 988; INED 1958, vol. 2, pp. 600–1).

The fiercest attacks by Physiocracy concerned the view that industrial and commercial activities were sterile. The Physiocrats believed that in all trading activities there was only an exchange of commodities of equal value, but these values had already been produced elsewhere.

All merchants and middlemen who operated in ‘resale trade’ were a burden to society, since they had to be maintained without adding anything to national wealth (INED 1958, vol. 2, p. 947; Mercier 1767, p. 278). The Physiocrats saw that some traders were making large monetary fortunes, but this was not a proof of their productiveness; on the contrary, this was the result of a violation of natural laws. Merchants could become rich thanks to unequal exchanges due to exclusive trading privileges. These regulations contradicted the natural principle of free and unobstructed competition in all markets. Industrial activities simply transformed the products of agriculture into different types of commodities, whose exchange values had already been determined (INED 1958, vol. 2, pp. 496, 865). The sterility of industry was then explained by the fact that, according to the Physiocrats, the value of its product was equal to the value of its expenses and there was no net product left.

The profitability of farming is the most important requirement for the accumulation of capital in agriculture. Hence commercial policy must be designed to sustain the exchange value of the products of land. Free trade was the main way to raise the prices of primary commodities and induce the farmers to reinvest their profits in farming (INED 1958, vol. 2, p. 602).

It is important to notice the Physiocrats considered laissez-faire instrumental in the establishment of favourable trading conditions for French farmers. Quesnay and his disciples were not in favour of a generalized free trade, and they were not particularly interested in the commercial conditions of manufactures; their only aim was the achievement of high exports of primary products. They looked to a positive balance of trade for French agriculture, since France should have become the granary of Europe. Moreover, Physiocrats regarded foreign trade as necessary only because the French domestic market was too small and too poor to guarantee the profitable sale of French corn (INED 1958, pp. 848–9). With a larger domestic market there would be no need to export corn.

Quesnay was quite aware of the important role of markets; a large consumption was necessary to sustain the prices of agricultural commodities. The Physiocrats believed that there was no lack of potential demand for corn, since it was a fundamental item. The main problem of French agriculture was not the lack of potential consumers but the lack of effective consumption (INED 1958, pp. 528, 963). The exchange value of corn was affected by the number of effective consumers and by their wealth (p. 824): these were the true causes which determine the price of corn. The demand of those people who were not rich enough to pay for corn at its proper price was of no interest for the economy, according to the Physiocrats. They argued that landlords should spend most of their revenues in the purchase of agricultural products to increase the effective demand for French foodstuffs. Landlords were the social class which received most of the surplus, as rent, and all activities depended on the expenditure of this revenue.

The Physiocrats noted that the way in which revenue is spent influences society's economic structure. For instance, if the landlords buy many primary commodities and few manufactures, agriculture grows at a faster pace than industry (Kuczynski and Meek 1972, p. 12). Of course the Physiocrats were in favour of high consumption of agricultural products which they called *luxe de subsistence,* and were against the purchase of industrial goods, *luxe de décoration* (Baudeau 1767, pp. 190, 217). The Physiocrats attacked luxury because they wanted to encourage the profitable sale of agricultural products. They also opposed savings and the hoarding of money which would end up in monetary stocks to be lent at interest (Mirabeau 1764, vol. 2, p. 343). Monetary and financial fortunes were not a true form of wealth, but represented a deduction from the process of circulation of agricultural commodities.

The concept of the net product is the Physiocrats' main contribution to economic theory. This notion is related to that of advances, a term they used to indicate the means of production. The social product must include all the goods which make up the advances, and for each of them the quantity produced must be at least equal to the quantity which has been used as input.

Physiocratic analysis of the different types of advances is the first classification of the means of production, or capital, in the history of economic theory. The *avances foncières,* or land advances, included all the operations necessary to prepare a piece of land for farming. *Avances annuelles* are another important type of advances, this time annual ones. They are made by farmers and consist of products which must be invested in cultivation at each productive cycle because they are completely consumed during the process of production. These commodities include raw materials and necessaries which allow the peasants and their families to work during the year, but some interpreters of Physiocracy maintain that they also include some manufactured goods (Meek 1962, pp. 274–5; Eltis 1984, pp. 29–31). Annual advances are a typical kind of circulating capital.

The original advances, *avances primitives,* are made up of instruments and equipment which last for more than one year; they also include livestock (Eltis 1975, p. 189). All these commodities must be regarded as fixed capital lasting for many years (INED 1958, vol. 2, p. 798). In fact Quesnay indicated that the average life cycle of the *avances primitives* lasted ten years. Productivity increases are closely related to capital accumulation (ibid., pp. 427 ff.). A prosperous economy is characterized by large-scale farming, where agriculture employs a large stock of *avances primitives.* This view of the ideal economic system has been called 'agrarian capitalism', since agriculture is the most advanced capitalist sector (Hoselitz 1968).

According to Quesnay, in ideal agricultural production the value of the fixed capital must be five times that of the annual capital and is assumed to be ten 'milliards'. Given an annual rate of decay of ten per cent, the farmer must repay a fixed amount of capital equal to a half of the circulating capital. Therefore, the overall *réprises,* or returns, which make up the value of all the means of production annually consumed is given by the sum of the whole annual advances plus '1 *millard livres*' depreciation of *avances primitives* (Meek 1962, p. 154).

At the end of the 1770s the political reactions to the economic policy suggested by the Physiocrats caused a decline in their intellectual influence. Echoes of Physiocratic economics survived in some European countries such as Russia, Poland, Germany, and Tuscany, and in the United States.

But Quesnay and his followers left important marks in the history of economic theory. At the end of the 18th century and at the beginning of the 19th century several British economists looked quite favourably on many ideas of the Physiocrats. In different ways, John Gray, William Spence and Thomas Chalmers defended the superiority of agriculture over industrial activities (Meek 1962, pp. 345 ff.). Because of the way in which they stressed the importance of demand and consumption in sustaining economic activities, the Physiocrats were also regarded as forerunners of underconsumption theories. Lack of consumption and the excess of expenditure on luxury goods could cause economic crises. Thus, the Physiocrats recognized the possibility of economic breakdown. From this point of view Physiocracy can be related to Sismondi and Malthus (Meek 1962, pp. 313 ff.). The *Tableau économique* does not only describe the necessary economic relationships between some economic magnitudes, but it can also indicate why and how the ideal conditions of production could break down. Quesnay himself provided several examples of *Tableau* 'in disequilibrium' (Eltis 1975).

The major merit of the Physiocrats is that of having given a fundamental contribution to the rise of that stream of thought which was classical political economy. They precisely defined the concepts of surplus and capital; they introduced the distinction between productive and sterile activities. The Physiocrats clearly distinguished the social classes according to their role in production. Therefore the Physiocrats can properly be regarded as the first inspiration of that economic theory which goes by the name of the surplus approach. In the *Theories of Surplus Value* (Marx 1864–5, vol. 2, ch. 2), Marx indicated the Physiocrats as the first authors who adopted this approach for the analysis of economic systems. One aspect of Marxian economics which is derived from Physiocracy is the description of the economy by means of reproduction schemes. It must be noticed that the first two sectors in Marx's reproduction schemes coincide with those of Quesnay, that is, agriculture and industry (Marx 1867–74, vol. 2, part 2).

The Physiocratic distinction between productive and unproductive labour can be found in all major classical economists, from Smith to Malthus and Ricardo, even though they gave different solutions to this problem.

The surplus approach, which was characteristic of classical economists and of Marx, was again brought to the fore in the 1960s thanks to Piero Sraffa's book *Production of Commodities by Means of Commodities.* Sraffa refers to the Physiocrats as one of his sources (see Sraffa 1960, appendix D). Physiocratic economics also influenced other aspects of modern economic theory. Leontief's input–output analysis finds an important forerunner in the *Tableau économique*, while the distinction between productive and unproductive labour has been the focus of renewed interest and has been used to investigate the failures of some modern economic systems (Bacon and Eltis 1976, preface).

The influence of the Physiocrats on Adam Smith deserves special attention. Smith was in France for three years between 1763 and 1766, and was in touch with some Physiocrats and with Turgot. Certainly Smith was well aware of the debates which were taking place during those years about Physiocratic economics, and it is generally admitted that he borrowed some specific concepts from Quesnay. These are the concepts of net product, its difference with the capital advanced, and the distinction between production and unproductive labour. These concepts did not appear in Smith's economic writings before his visit to France, but played an important role in the *Wealth of Nations.* The Physiocrats' influence on Smith is further proof of their important place in the building of classical political economy. In the *Wealth of Nations* Smith dedicates many pages to explain Physiocratic economics (Smith 1776, book 2, chapter 9). He criticized many aspects of Physiocracy; for instance, while accepting the idea that agriculture was the most important economic sector of the country, he did not agree that industry was sterile. For Smith many features of Physiocratic economics were not appropriate to explain the workings of modern commercial societies like England. Physiocracy was too influenced by the economic conditions of 18th-century France, and was thus particularly useful to study agricultural societies. But for Smith, Physiocracy was greatly superior to mercantilism and it was the necessary basis on which to found the new economic science, or as Smith wrote ‘the nearest approximation to truth’ (Smith 1776, vol. 2, p. 199).

Born in Amsterdam, 7 February 1839; died in Heemstede, 24 December 1909. A Dutch economist of international reputation, Pierson dominated economics in the Netherlands during the second half of the 19th century. He started his career in the commercial and banking world of Amsterdam. He became President of the Dutch Central Bank, Minister of Finance and Prime Minister. As an economist he was a self-educated man, just like David Ricardo, but he was nevertheless invited to become Professor of Economics at the University of Amsterdam. He taught in the Faculty of Law from 1877 onwards until 1885. Broadly speaking, he advocated the main ideas of the Austrian school of thought in economic theory, although he maintained a material concept of welfare and production. On money, banking and taxation he was a well-known authority, who stimulated Cohen Stuart to write his famous dissertation on the application of utility theory to taxation. His knowledge of the history of ideas was outstanding and he was one of the first to recognize the significance of the Italian authors of the 17th and 18th centuries.

As a political economist, Pierson was basically in favour of a market economy. He was a critic of Marxism, but still not against a modest degree of state intervention. He advocated, in particular, the importance of high-level education, organized by the government, in order to improve the condition of the working class.

In 1863 he wrote a booklet on the future of the Dutch Central Bank, in which he strongly defended the monopolistic position of the Bank with regard to the creation of banknotes (Pierson 1863). An English translation of his very popular textbook also appeared (1902a).

Pierson's analysis of value in a socialist society (1902b) is of lasting significance.

Pigou, Arthur Cecil (1877–1959)

Nahid Aslanbeigui

Abstract
Arthur Cecil Pigou founded welfare economics by synthesizing Marshall's theoretical framework and Sidgwick's categories of market

failure and imperfections. His view of welfare economics was expansive, including resource allocation, income redistribution, business cycles, and unemployment. Pigou made important contributions to other areas of economics as well: the theory of value, public finance, index numbers, and evaluation of real national income. The most neglected aspect of Pigou's work is his investigation of a remarkable range of labour-market phenomena explored by subsequent economists – implicit contracts, internal labour markets, wage rigidity, labour market segmentation, human capital theory, and collective bargaining.

Arthur Cecil Pigou was founder of welfare economics, long-time occupant of the Chair of Political Economy at Cambridge University (1908–43), and author of hundreds of articles, pamphlets and books.

As Alfred Marshall's successor, he embraced, refined and extended the analytical framework that his master had painstakingly constructed. He also lived long enough to witness its disintegration at the hands of a generation of economists who had lost their tolerance for its limitations.

Life and Career

A.C. Pigou was born on 18 November 1877 at Ryde, Isle of Wight, England, and died in Cambridge on 7 March 1959. He attended Harrow (1891–96), emerging as a brilliant scholar and athlete who harboured a shyness of women that bordered on panic. Contrary to common belief, Pigou was no misogynist. He advocated paid maternity leaves for factory workers, voted for women's degrees at Cambridge University, and played a decisive role in creating a lectureship for the young Joan Robinson.

Pigou entered King's College, Cambridge on a Minor Scholarship in History and Modern Languages (1896). However, his interests spanned poetry, moral philosophy, politics and economics. His achievements were stunning: a First in the undivided History Tripos (1899) and another in Part II of the Moral Sciences Tripos with special distinction in political economy (1899), the Chancellor's Medal for English Verse (1899), the Burney Prize (1901), the Cobden Prize (1901) for an essay that secured him a fellowship at King's (1902), the Adam Smith Prize (1903) for work that formed the basis of his Jevons Memorial Lectures at University College, London (1903–4), and a Girdlers' lectureship (1904) that he held until his election to the Chair of Political Economy (30 May 1908).

Although significantly influenced by Henry Sidgwick, Pigou was the foremost disciple of Alfred Marshall, who was impressed by his protégé on several grounds. Pigou's 'exceptional genius', evident in his masterful thesis, foretold a future as 'one of the leading economists of the world'. He knew the proper role of economic theory: an instrument for social betterment, not intellectual gymnastics. Pigou fought for Marshall's brainchild, the independent Economics Tripos (established in 1903), and personally funded lectureships, prizes and book acquisitions. He shared Marshall's commitment to free trade, using his publications (Pigou 1904, 1906) and superb oratory skills – honed at the Cambridge Union Society of which he was President (1900) – to promote it. Together with Marshall, he signed the notorious Economists' Manifesto that rejected the Tariff Reform Proposal (1903) of Joseph Chamberlain. It is not surprising that Marshall's face beamed with delight when Pigou was chosen as his successor. He had manipulated the election in favour of the 30 year-old Pigou, embittering his old friend H.S. Foxwell, a serious contender.

Pigou's *Wealth and Welfare* (1912) – a synthesis of Marshall's engine of analysis and Sidgwick's categories of market failure and imperfections – laid the foundation for *Economics of Welfare* (1920), *Industrial Fluctuations* (1927a), and *A Study in Public Finance* (1928b). Taken together, these books covered most of the territory of general economics. *Industrial Fluctuations* was later complemented by *The Theory of Unemployment* (1933), which received a harsh and sophistical critique at the hands of J.M. Keynes in *The General Theory of Employment, Interest, and Money* (1936). Although faithful to the classical doctrine, *Employment and Equilibrium* (1941) – arguably the first textbook in macroeconomics – employed an IS-LM version of *The General Theory* and offered a careful analysis of the differences between Keynesian and classical economics. Pigou's other works included *Unemployment* (1913), *The Political Economy of War* (1921), *The Economics of Stationary States* (1935), many collections of essays, as well as books and pamphlets that he characterized as 'low-brow', among them the highly successful *Socialism versus Capitalism* (1937b), *Lapses from Full Employment* (1945) and *Income: An Introduction to Economics* (1946). The rise of a Cambridge School of economics was in large measure due to Pigou's articulation of Marshall's organon (see, for example, Pigou's classic exposition of Cambridge monetary theory, 1917). Generations of economists – among them Dennis Robertson, Joan and Austin Robinson, and Richard Kahn – learned Marshall in Pigou's lectures, which were legendary for their clarity and logical rigour.

Pigou was not a public man. His aversion to discussions of economics outside 'the home' extended to a distaste for conferences. Acting on his sense of public obligation, he served on several government committees – among them the Chamberlain Committee on the Currency and Bank of England Note Issues (1924–5), which recommended a return of sterling to its pre-war level, imposing immense costs on British labour. Disillusioned by British economic policies in the 1930s, he withdrew from public life, making only occasional ritually obligatory appearances before commissions.

Pigou's personal life also became increasingly hermetic. By the 1940s, the high-spirited, companionable young man of the Edwardian era was regarded as a recluse. As a conscientious objector, he never recovered from the experience of the carnage of the Great War, which he observed first-hand as a driver in the Friends' Ambulance Unit, commanded by his student and friend Philip Noel-Baker. Beginning in the mid-1920s, severe cardiac fibrillation (irregular heartbeat) curtailed his mountaineering – he was a deft climber introduced to the sport by the economic historian J.H. Clapham. This condition left him permanently anxious over his health. Finally, Pigou watched with dismay as the Keynesian Revolution destroyed the Edwardian intellectual culture of high civility in Cambridge economics. In time, he rose above his own angry response to Keynes's gratuitous depiction of classical economists as 'a gang of incompetent bunglers' (Pigou 1936, p. 115). But as relations between Keynes's disciples and Dennis Robertson became increasingly hostile, he grew more remote and diffident. In his judgement, Joan Robinson's dogmatic instruction of Keynesian economics turned undergraduates into 'identical sausages', and under Keynes's stewardship in the 1930s the *Economic Journal* violated its mission of representing different schools of thought 'with equal impartiality'.

Theoretical Contributions

Pigouvian economics is grounded in utilitarian moral philosophy: creating the greatest good –

Pigou's cognate of welfare – for the greatest number of people. Its analysis is limited to economic welfare: satisfactions that, directly or indirectly, can be related to the measuring rod of money. Up to a point, money, which measures the intensity of desires, performs well as a proxy for satisfaction. However, the human 'telescopic faculty' irrationally discounts future satisfactions, resulting in inadequate savings, insufficient investment in tunnels or forests, depletion of natural resources, and extinction of animal species. Pigou assumes that, as a rule, economic and total welfare are positively related. Anticipating contemporary research on happiness, he also recognizes the importance of factors that contribute to non-economic welfare such as relative status, social capital, political freedom, and moral quality of life.

Economic welfare may improve if its objective counterpart, the national product, is increased in size, distributed more evenly, and made more stable.

Optimal Resource Allocation

Integrating Marshall's marginal analysis and Sidgwick's distinction between private and public interests, Pigou produces some of the most important concepts (1912) and diagrams (1910) of welfare economics: marginal private and social net products (benefits and costs in contemporary parlance). In the absence of 'costs of movement' – associated with geographic and occupational reallocation of resources – the allocation of resources by competitive markets achieves universally equal marginal private net products. However, the production of ideal output requires equality of marginal social net products. Where private and social net products diverge, there is a prima facie case for reallocation of resources (1932, p. 136).

In Pigou's competitive economy, social and private benefits diverge in three different respects. First, a principal–agent problem arises when owners of land contract out its use to tenants. Since some benefits of the agent's investment accrue to the principal on termination of the contract, investment levels are not socially optimal. Pigou's remedies are limited to modifying contractual specifications between the two parties, presumably because low transactions costs render government action unnecessary.

Second, economic transactions between two agents may render incidental services or disservices to third parties, who cannot be forced to pay for the benefits or compensated for the costs. Unlike contemporary economists, Pigou does not distinguish public goods and externalities. Positive spillovers are a combination of public goods and beneficial externalities: lighthouses that benefit free-riding ships; private parks and forests that improve air quality; roads and tramways that improve the value of neighbouring land; privately owned lamps that shed light on streets; items of smoke-prevention equipment that benefit buildings, vegetables, clothes, and air quality; and 'most important of all' scientific research that leads to inventions, innovations and 'discoveries of high practical utility' (1932, p. 185). Negative spillovers are harmful externalities: a landlord raises rabbits that overrun a neighbour's property; a firm builds a factory in a densely populated area, destroying its amenities and injuring family health and productivity; automobile operators drive cars that wear out the surface of roads; and producers sell alcoholic beverages that increase crime. The 'crowning illustration' of negative externalities is women's factory work, especially immediately before and after childbirth, which damages the health of the fetus and increases infant mortality (1932, pp. 185–7).

Since it is difficult to internalize positive or negative externalities through contractual modifications, the state may offer 'extraordinary encouragements' or 'extraordinary restraints' as remedies, most obviously taxes and 'bounties'. In Pigou's era, a variety of taxes had already been imposed on alcoholic beverages, roads, gasoline and car licences. Bounties ranged from complete government provision (police protection and cleaning slums) to grants for scientific research. Pigouvian solutions went beyond taxes and subsidies to include patent enforcement, provision of information and training, and paid maternity leaves. In cases such as urban planning, where 'the inter-relations of the various private persons affected [are] highly complex', the state may have to exercise 'authoritative control' because the invisible hand fails to 'tackle the collective problems of beauty, of air and of light' (1932, pp. 193–6; also see 1947, pp. 94–100).

Careful readers of Pigou will note that much of Ronald Coase's critique of his analysis (Coase 1960) is misplaced. Pigou stressed that on issues of policy he always spoke with an 'uncertain voice' (Pigou 1932, p. 10), carefully considering the costs and benefits of proposed solutions. Government action entails allocative, administrative and political costs. Redeployment of labour, land and capital is also costly. It follows that the goal of achieving ideal output should be subjected to a cost–benefit analysis that shows 'at which point the advantage of getting closer is outweighed by the complications, inconvenience and expense involved in doing so' (Pigou 1932, p. 315).

Third, in his early work (1912), Pigou argued that private and social benefits diverge if industries exhibit increasing or decreasing costs. Under decreasing returns, a small increase in the output of one firm creates external diseconomies for the industry by increasing the price of fixed factors. Under increasing returns, a small rise in the output of one firm creates external economies for the industry. A prima facie case could therefore be made for taxing increasing-cost and subsidizing decreasing-cost industries. Pigou's critics – Allyn Young and Dennis Robertson – pointed out that the two types of returns are essentially different phenomena: external economies – technological change and managerial breakthroughs – are irreversible social gains. External diseconomies – increased factor prices – are not social costs since they merely transfer purchasing power from producers to factor owners. The second edition of *The Economics of Welfare* (1924) conceded this point, with the proviso that foreign owners do not capture the increased rents.

In 1926, Piero Sraffa argued that increasing and decreasing returns are incompatible with Marshall's competitive, partial-equilibrium assumptions. Under increasing costs, for instance, a marginal increase in the output of a firm in a given industry increases the price of fixed factors for all industries that use them. Relative prices may change as a result, rendering Marshallian assumptions logically incoherent since industry supply and demand become interdependent. Although economies and diseconomies that are external to the firm but internal to the industry do not generate the same logical problem, they are rare empirically. Pigou (1927b) concluded that, although increasing costs were incompatible with his framework, he could not logically rule out external economies. In 1928, he published the standard textbook analysis of stable equilibrium in a competitive firm (1928b). The costs of the equilibrium firm (a theoretical entity based on Marshall's representative firm) are a function of its own output and that of the industry. Although the industry may experience increasing or constant returns, the equilibrium firm is always at equilibrium when industry price is equal to its marginal and (the minimum of) average costs. U-shaped average and marginal cost curves for the equilibrium firm complemented the mathematical treatment, perhaps the first time that such diagrams were published in English. External economies shift the equilibrium firm's cost curves.

As a rule, monopolistic conditions create discrepancies between private and social benefits. Pigou argues that their implications for welfare must be evaluated on a case-by-case basis. The incidence of discrepancies depends on whether a monopoly practices price discrimination of the first, second or third degree. State control and state operation of natural monopolies have different ramifications for welfare. Oligopolistic market structures, however, create unequivocal social costs irrespective of output: wasteful advertising, exploitation of workers – defined as payment below the value of marginal product – customer deception, reduction of upward mobility by forcing small entrepreneurs out of the market, constraints on inventions and innovations, and Tayloristic practices that dull worker initiative. Pigouvian remedies range from taxes and prohibitions to encouragement of small business.

Income Redistribution

Redistribution schemes that favour the poor but leave the national product intact are likely to improve economic welfare. However, both the expectation and the fact of such transfers may produce disincentives that reduce the national product. The implication is not inaction. Rather, the state should design redistributive measures based on a comprehensive knowledge of legal, psychological and institutional factors. If capital is subject to double taxation, its flight is less probable. If economic actors target a specific level of savings, inheritance taxes may not affect investment activity. If redistributed income is used to train workers with uncommon abilities, its rate of return may surpass the return on investment in physical capital. Finally, taxation may not discourage the rich if it leaves their relative income intact. Pigou's theoretical analysis of interdependent utility (welfare) – based on reference groups, relative income, snob and bandwagon effects – anticipates Duesenberry's and Leibenstein's by some 45 years (Pigou 1903).

Transferring one dollar from the rich to the poor increases economic welfare because 'it enables more intense wants to be satisfied at the expense of less intense wants' (Pigou 1932, p. 89). This proposition assumes that representative members of different income groups have equal capacities for satisfaction. In 1932, Lionel Robbins claimed that such interpersonal comparisons are normative judgments and have no place in science. The ensuing attempts to establish a positivist welfare economics engaged such luminaries as Hicks, Kaldor, Scitovsky, Little, Bergson and Arrow. The results produced a sophisticated theoretical apparatus but confirmed Pigou's belated response to Robbins that without such comparisons every 'apparatus of practical thought' will collapse (Pigou 1951, p. 292). In recent decades, the recognition that all sciences make normative claims has become received wisdom in the philosophy of science. With the demise of doctrinaire positivism, economists seem more willing to venture into the territory of interpersonal comparisons, as contemporary happiness research suggests. This research provides new grounds for reconsidering the unexploited resources of Pigouvian welfare economics.

Industrial Fluctuations and Unemployment

Long spells of unemployment have serious deleterious effects – malnutrition, permanent damage to the capabilities of youth, loss of skills and work ethic, alcoholism, a 'haunting' sense of insecurity and uncertainty, and the destruction of self-respect and self-confidence – that cannot be reversed in good times. Thus a prima facie case for macroeconomic stability is evident.

Pigou's theory of unemployment can be elucidated by using the language of supply and demand. Aggregate labour supply is vertical, even though individual labour supply curves may be upward sloping or backward bending. Aggregate labour demand – difficult to construct due to sectoral interdependence – is downward sloping and dependent on marginal product. Since unemployment is always positive, it can be explained only by movements in wages and the demand for labour.

Pigou distinguishes two types of unemployment. Short-run involuntary unemployment – a term he may have coined in 1913 – occurs because of frequent changes in labour demand and real wages. Although prices vary, real wages fluctuate because nominal wages remain sticky. (a) A perpetually flexible nominal wage is impracticable due to high administrative costs, which become more significant if 'elaborate and formal arbitration proceedings' are instituted to resolve capital-labour conflicts (Pigou 1913, pp. 92–3). (b) Some wage rigidity is preferred: while workers want stable living standards, employers are obliged to deliver products at prices previously negotiated. (c) The duration of recessions and recoveries is unpredictable; it is not worthwhile to alter wages if the state of the economy is ephemeral. (d) Due to mutual mistrust, workers and firms alike resist wage changes, fearing that they may be irreversible. (e) Employees and employers suffer from money illusion, the latter resisting wage increases and the former refusing wage cuts.

Contrary to Keynes's straw-man depiction, Pigouvian labour demand fluctuates due to general and wave-like swings in expectations of profits. Three sets of factors affect expectations: real causes such as crop size or technological breakthroughs; monetary variables, which are restricted to exogenous shifts in credit under the gold standard; and psychological factors, which occur spontaneously or as a consequence of the other two variables. Undue pessimism or optimism may be magnified because psychology, output, and debt–credit linkages create sectoral interdependence.

The amplitude of business cycles depends on the institutional structure of the economy: monetary policy, the pricing strategy of firms, income maintenance programmes, wage policy and unions. Although limited by the quality and quantity of data at his disposal, Pigou tries to quantify factors that cause business cycles or affect their amplitude. Removing monetary or psychological factors would each reduce the amplitude by one-half, crop variation by one-quarter, wage rigidity by one-eighth and price rigidity by one-sixteenth. It is clear that Pigou does not regard high real wages as the single or even the most important cause of short-run unemployment. In many cases, high wages and unemployment are both effects of factors such as 'bursting of a gigantic bubble of unwarranted optimism, with a heavy fall in price' (Pigou 1929, pp. 200–1). Short-run unemployment can be reduced proactively through distribution of information, price stability, or interest-rate manipulation. Reactive policies that dampen the impact of unemployment range from (public work projects to guarantees of interest or subsidies for employers. Although Pigou favours wage flexibility at the theoretical level, he does not consider it a viable political option.

Pigou analyses long-run unemployment on stationary-state assumptions, ruling out changes in expectations, tastes, net investment, productivity, and technology. The only conceivable unemployment under these conditions is an 'intractable minimum' that resembles the natural rate of unemployment. It is caused by frictions, immobility, public opinion, the practical impossibility of setting wages according to marginal productivity, and unions. Collective bargaining introduces indeterminacy, which he analyses in a quasi-game-theoretic framework (Pigou 1905). Employers and employees negotiate money wages within a 'range of indeterminateness'. The upper limit depends on unions' reluctance to demand a wage so high that it would result in layoffs. The lower limit is determined by employers' recognition that a wage that reduces the available supply of labour is too low. Peaceful wage bargains are conducted within a narrower range determined by the 'sticking point' of each party: a certain minimum below which workers would rather strike and a maximum above which employers would prefer shutdowns.

Firms often have bargaining power to exploit workers but may choose not to, recognizing that low wages affect the productivity of workers they want to retain for the long period. This results in unemployment in a casual labour market. The magnitude of joblessness is determined by a Harris–Todaro comparison of the expected wage – 'the wage-rate multiplied by the chance of employment' (Pigou 1913, p. 55) – with wages elsewhere. Unemployment is not an inevitable outcome if outsiders (low-wage workers) know that insiders (high-wage workers) are irreplaceable.

To reduce long-run unemployment, the state may attempt to educate the unskilled and try to improve wage flexibility. The effective demand ramification of wage flexibility was a major point of contention between Keynes and Pigou (see Pigou 1937a; Keynes 1937). Although Pigou was finally persuaded by Kaldor (1937) to take such effects into account (Pigou 1938, 1941), he discounted them based on the well-known Pigou effect: lower money incomes and prices would increase the value of real balances, reducing and ultimately eliminating the individual's desires to save out of any assigned real income (Pigou 1943, p. 349). In Pigou's opinion, Keynes's true contribution was not substantive but analytical: no one before him had constructed a model of the aggregate economy that incorporated both real and monetary factors. But Pigou (1950) also maintained that Keynes's analytical framework was too limited to be suitable for direct practical application.

Legacy

Economists have generally judged Pigou's work on Robbinsian, Keynesian or Coasean premises, ignoring his important contributions to the theories of value, distribution, business cycles, public finance, index numbers, and evaluation of real national income. Pigou's neglected contributions to labour economics, which anticipate Hicks's work by a quarter of a century, are especially noteworthy. *Wealth and Welfare,* hailed by Schumpeter as 'the greatest venture in labor economics ever undertaken by a man who was primarily a theorist' (1954, p. 948), and his numerous other works on labour and unemployment demonstrate an acute understanding of the importance of a remarkable range of phenomena explored by subsequent economists – implicit contracts, internal labour markets, labour market segmentation, wage rigidity, human capital theory, and collective bargaining. Alfred North Whitehead famously held that 'a science which hesitates to forget its founder is lost'. Economists have not found it difficult to forget the founder of welfare economics, with regrettable consequences that Whitehead did not envision.

Pigouvian Taxes

Agnar Sandmo

Abstract

Pigouvian taxes are taxes designed to correct for negative external effects. The idea is originally due to Pigou (1920), and has received increased attention in recent years because of the concern with environmental issues. This article sets out the basic theoretical argument and considers the modifications of the theory that have to be made when these taxes are seen in the context of an otherwise distortionary tax system. It also briefly considers the issue of the 'double dividend' from a green tax reform.

'Pigouvian taxes' is the generic term for taxes designed to correct inefficiencies of the price system that are due to negative external effects. In partial equilibrium terms, the basic idea can be presented as follows: under competitive conditions, utility-maximizing consumers will equate their marginal benefit to the market price Q; we may write this as $MB = Q$. Similarly, profit-maximizing producers will set their marginal private cost equal to the price, so that $MPC = Q$. In the absence of externalities, marginal private and social costs coincide: $MPC = MSC$. Consequently, market equilibrium implies that $MB = MSC$, which is the condition for efficient resource allocation. If there are negative external effects related to the production or consumption of the good in question, the marginal social cost is higher than the marginal private cost: $MSC>MPC$. If the market prices facing producers and consumers are identical, this implies that $MB < MSC$. To restore efficiency, we may levy a tax on the commodity, so that the consumer price is Q while the producer price is $Q - t$. In the new equilibrium we have that $MB = Q$ and $MPC = Q - t$; it follows that $MB = MPC + t$. Since we wish the equilibrium to satisfy the condition that $MB = MSC$, we must have $t = MSC - MPC$, which we may define as the marginal social damage. Accordingly, the optimal Pigouvian tax internalizes the externality; producers act as if they took account of the marginal social damage associated with the production of the commodity.

This idea was first expressed by Pigou, especially in his *Economics of Welfare* (1920). He mentions a number of examples of what he calls divergence between 'social and private net product', for example, production activities generating smoke from factory chimneys that create adverse consequences for consumers in the form of damage to buildings, increased expenses for washing clothes, house-cleaning and indoor lighting. These inefficiencies can be corrected, he says, by 'imposing appropriate rates of tax on resources that tend to be pushed too far'; he also points out that cases of positive externalities where $MSC < MPC$ can be corrected by means of subsidies or 'bounties' (Pigou 1920; 1932, p. 184). In his later book, *A Study in Public Finance*, he claims that

> [there] will necessarily exist a certain determinate scheme of taxes and bounties, which, in given conditions, distributional considerations being ignored, would lead to the *optimum* result. (Pigou 1928; 1947, p. 99)

An interesting and important question concerns the choice of the tax base. On what should the Pigouvian tax be levied? From a theoretical point of view, the correct tax base is the one that affects the crucial margin of decision. In the factory smoke example, the best tax base is actually the amount of smoke emission. A tax on coal is an imperfect instrument to the extent that it also affects margins that are irrelevant for smoke emission, and this is even more true for a tax on the output produced by the factory. Some would therefore reserve the term 'Pigouvian tax' for the tax on smoke emission, but in the literature it has become common to use the concept to refer to all cases where the policy motivation is to correct for negative externalities.

For a long time, Pigouvian taxes led an obscure life in the public economics literature; thus, in the famous treatise by Musgrave (1959), the subject is barely mentioned. However, with the increased concern for the environment that rapidly gained ground from the late 1960s, economists became much more interested in this form of tax policy both as a tool for environmental policy and as an efficient source of revenue for the public sector.

Distortionary Taxes

The partial equilibrium approach is based on some simplifying assumptions. First, it focuses solely on the market for the 'commodity' (final good, factor of production or emission) that gives rise to the externality, while neglecting the interconnections with other markets. Second, it assumes, rather implicitly, that there are no other violations of the efficiency conditions in the economy, so that the design of Pigouvian taxes does not need to take into account the presence of other distortions. Third, as also emphasized by Pigou, it ignores distributional concerns.

All these simplifications must be overcome if one wishes to analyse Pigouvian tax policy within the context of the overall tax system. There is actually one tax system in which the partial equilibrium analysis is valid, and that is the assumption that the rest of the requirement for public sector revenue can be satisfied by means of individualized lump sum taxes. This leads to a 'first-best' allocation: tax revenue is raised without distortions of the price mechanism, and the desired income distribution can be achieved without loss of efficiency. The only commodity taxes that are used are the Pigouvian taxes on commodities that generate negative external effects. But lump sum taxes are not policy instruments that can be used realistically. Instead, governments have to rely on direct and indirect taxes, and these will create tax wedges and distortions of private incentives. What is the role of Pigouvian taxes within the context of an otherwise distortionary tax system?

One might perhaps come to think that in such a setting Pigouvian considerations should affect the taxes on all goods: for example, there might be a case for subsidizing substitutes and taxing complements to the harmful commodities. However, it was shown in Sandmo (1975) that in an optimal system of commodity taxes the integration of Pigouvian taxes with the Ramsey (1927) objective – minimizing efficiency loss for a given tax revenue – takes a strikingly simple form. If there is one commodity that creates a negative externality, the tax on this commodity can be expressed as a weighted average of Ramsey and Pigou terms, while other taxes contain only a Ramsey term. Formally, suppose that there are a number of taxed goods ($i = 1,..., n$) and that the externality is generated by the nth good. Suppose for simplicity that all cross-elasticities between the taxed goods are zero, so that Ramsey taxes can be characterized by the inverse elasticity formula.

Then the optimal tax system can be written as follows:

$$t_i = \alpha(-1/\varepsilon_i)(i = 1,...,n-1).$$

$$t_n = \alpha(-1/\varepsilon_n) + (1-\alpha)\delta_n.$$

Here ε_i is the own price elasticity of commodity i, and δ_n is the marginal social damage of commodity n. α is a parameter that characterizes the tightness of the government budget constraint. If the budget is extremely tight, all weight is on the need for revenue. Then $\alpha = 1$, the tax rates are chosen so as to maximize revenue, and Pigouvian taxes play no role in the tax structure. However, in the happy situation where the revenue from Pigouvian taxes is exactly sufficient to meet the government's revenue requirement, $\alpha = 0$, and no other taxes are desirable. It can be shown that the 'additivity' property of the optimal tax system continues to hold when distributional considerations are incorporated into the model, but in that case the weights on the inverse elasticity and the marginal social damage will have to reflect distributional concerns in addition to those of efficiency.

The Double Dividend and the Marginal Cost of Funds

In recent years there has grown up a strong interest in 'green tax reforms'. Such reforms would reduce conventional distortionary tax rates and compensate for the loss of tax revenue by introducing more Pigouvian taxes. A popular view of the gain from this kind of reform is that society would reap a 'double dividend'. First, higher Pigouvian taxes would create an improved environment; second, lower distortionary taxes would imply a more efficient tax system. This argument has a strong appeal to economic intuition; however, as often happens, when one comes to study it more closely, it turns out to contain some complicating elements. The crucial point to note is that the effects of Pigouvian taxes interact with those of the distortionary taxes. If for example the existing tax system has a high marginal tax rate on labour income, an increase of Pigouvian taxes together with a lowering of other indirect tax rates might exacerbate the labour market distortion if the externality-creating goods are complementary with labour supply. This argument does not imply that the argument in favour of the double dividend is groundless. It simply means that one has to be careful in taking account of the interaction between markets for taxed goods before predicting a double dividend.

Another version of the double dividend argument focuses on unemployment. If the basic cause of unemployment is that employers' labour cost is above the market-clearing wage, a promising tax reform might be to reduce the payroll tax while increasing Pigouvian taxes. The double dividend in this case would be a better environment and lower unemployment. Again, the consensus of professional opinion seems to be that this is indeed a possible outcome, but it is by no means assured. For example, in a unionized labour market much will depend on the combined incidence of a reduced payroll tax and higher indirect taxes on union wage demands. For further discussion of both versions of the double dividend, see Bovenberg (1999) and Sandmo (2000).

Related to the question of the double dividend is the relationship between Pigouvian taxes and the marginal cost of public funds (MCF), a concept whose origin can also be traced to Pigou: see Atkinson and Stern (1974). With distortionary tax finance, the direct resource cost of public goods should be multiplied with an MCF adjustment factor which exceeds one. Since Pigouvian taxes actually increase the efficiency of the market mechanism, one might expect that for this type of tax finance one would have MCF < 1. Theoretical analysis has shown that this is indeed likely to be true in a number of cases, but that here too one needs to pay attention to the interaction of distortionary and Pigouvian taxes.

Pirou, Gaetan (1886–1946)

Roger Dehem

Born at Le Mans in 1886; died in Paris, 1946. A doctor in law (Rennes, 1909) and economics (Paris, 1910), Pirou taught at the Institut Français in London (1913–14), at Rennes, Milan, Algiers and Bordeaux (1920–26) before his appointment to the chair of history of economic thought in Paris (1927). He later taught at the Ecole des sciences politiques (1940–46) and was editor of the *Revue d'économie politique* (1935–46).

Pirou was foremost a distinguished teacher and a keen historian of economic and social thought. With a traditional middle-class and legal background, he first searched for idealistic truths on the left of the intellectual spectrum, with studies on Proudhon and Sorel. He then wrote *Les doctrines économiques en France depuis 1870* (1925). The assessment of ideologies, systems and policy experiments in the 1930s was the subject of several essays. In economic theory, Pirou consistently adhered to the neoclassical paradigm. He contributed a comprehensive though non-mathematical survey of the Austrian and general equilibrium theories. His most original contribution can be found in a methodological introduction to political economy (1939).

Pirou is duly respected for his intellectual honesty, his balanced judgement, his search for objective truth beyond class prejudices. A constant concern of his was the contradiction between the power of scientific reasoning (Comte) and the persistence of irrationality (Sorel). He was an erudite scholar and an academic *par excellence*.

His work is to be appreciated as a pedagogic instrument rather than as a guide to action. Though eclectic, his thought was not without depth nor consistency.

Pissarides, Christopher (Born 1948)

Richard Jackman

Abstract

Professor Christopher Pissarides was awarded the 2010 Nobel Prize in Economics jointly with Peter Diamond and Dale Mortensen 'for their analysis of markets with search frictions'. Though Pissarides is best known for his work in this area, it is only part of a very extensive research agenda which has covered numerous topics in theoretical and applied macroeconomics, and in particular in the analysis of labour markets. Within search theory his main contributions have been in integrating search theory into models of economic equilibrium and in examining its implications for efficiency and labour market policy.

A native of Cyprus, Pissarides came to Britain in 1967 to study economics at the University of Essex. Essex was at that time a new university which had ambitions, amongst other things, to build up a top-class economics department with a strong emphasis on theory. On the strength of a first-class undergraduate degree, followed by a Masters with distinction, Pissarides left Essex in 1971 to study for his PhD at LSE. His thesis, on 'Individual Behaviour in Markets with Imperfect Information' (supervised by Michio Morishima) was the starting point for the extensive exploration of this topic in articles spanning close on 40 years.

Following a short spell at the University of Southampton, Pissarides returned to LSE as a Lecturer in 1976 and he has remained at LSE ever since. Throughout his career he has been a central figure in the LSE Economics Department, teaching macroeconomics at both undergraduate and graduate level, including in the recently revamped PhD programme. He became a Professor in 1986 and was Convenor (Head of Department) from 1996 to 1999. He has also been a leading figure in the LSE Centre for Labour Economics (which became the Centre for Economic Performance in 1990), where he was Programme Director for Macroeconomics from 1999 to 2007.

The late 1960s and early 1970s were a time of great intellectual ferment in many fields of economics, most significantly for labour market analysis by the development of search theory. The idea of search as the behavioural principle underlying the workings of decentralized markets was established most notably by the 'Phelps volume' (Phelps et al. 1970) and especially the paper by

Armen Alchian (1970). The papers in the Phelps volume stressed the role of imperfect information in price and wage setting by firms and in the labour and product market decisions of workers and consumers. One of its authors, Chris Archibald, had been at the University of Essex, but it is fair to say these ideas established themselves rapidly in the teaching of macroeconomics across the world, for example in the LSE MSc course then taught by Michael Parkin.

In the theory of unemployment the search model was something of a paradigm shift. Previously, unemployment had been analyzed mainly in terms of essentially static concepts, such as the level of aggregate demand or structural imbalances, rather than in terms of the behaviour of unemployed workers. The search model argued that unemployed workers would not want to sign up for any job, but would need to make some estimate of the best job they could reasonably hope to get over some realistic time horizon. They would then reject job offers (or perhaps more plausibly not apply for jobs) paying less than this estimate, and remain unemployed until they received a sufficiently good offer. The new approach allowed a more rigorous analysis of numerous labour market issues – for example the impact of unemployment benefits (which can clearly affect the relative advantages of taking a job today as against continuing to search for a better job tomorrow). For a survey of the development of search theory and the contributions of the three 2010 Nobel Laureates to it, see Albrecht (2011).

While most research in search theory focused on the microeconomic decision making of individual workers, Pissarides's distinctive contribution has been to integrate search theory into complete, general equilibrium models of the economy. The microeconomic decision for unemployed workers was seen as one of whether or not to accept a job offer. This problem was formalized, somewhat artificially, by assuming that each unemployed worker received one job offer in each period. Workers were assumed to be aware of the general distribution of wages prevailing in the economy. Their problem was to decide their cut-off, or reservation, wage such that jobs offering lower wages would be rejected while those paying at least the reservation wage would be accepted. An important insight of this model is that workers would set their reservation wage on the basis of their expectations concerning the wage distribution they faced, which might or might not be the same as the actual wage distribution. In this way, imperfect information could play a critical role in accounting for fluctuations in unemployment. For example if the actual distribution of wages was higher than expected, unemployed workers would more quickly come across jobs offering wages above their reservation wage and hence more quickly find a job they would accept. This would lead to a faster outflow of people from unemployment and hence a decline in aggregate unemployment.

Pissarides made numerous contributions, both theoretical and empirical, to the study of the search behaviour of unemployed workers, considering amongst other things the effect of state employment agencies, job advertising, taxes and subsidies, and more recently the analysis of on-the-job search (Pissarides 1994). His distinctive contribution, though, has been the development of general equilibrium models incorporating search. This work appeared in a series of papers published during the 1980s, culminating in his classic text *Equilibrium Unemployment Theory* (Pissarides 1990, 2000).

The general equilibrium approach as developed by Pissarides highlighted the significance of job vacancies as the demand side counterpart to unemployment. Whilst, for example, the 1970 Phelps volume (cited above) makes almost no reference to job vacancies, in Pissarides's equilibrium model a key element is the matching function, which relates job hires (the outflow from unemployment) to unemployed workers and job vacancies. Having a ‘quantity’ variable on the demand side (in place of the assumption of job offers arriving at a constant rate) allows the search model to engage with key questions about variations in demand conditions in the labour market. Rather than receiving one job offer per period, the probability of a worker getting an offer depends on the ratio of vacancies to unemployment in the relevant labour market. The matching function, and the vacancy/unemployment ratio, took over from the reservation wage as the key concepts in the analysis of search unemployment.

The matching function was itself not invented by Pissarides but may none the less claim an LSE parentage. The relationship between unemployment and job vacancies has intrigued British economists for a long time, and the graphical representation of the relationship over time, in the form of the unemployment/ vacancy (u/v) curve was first charted by Beveridge (1944). The idea that the u/v curve might be generated from a matching function is due to another LSE author, Richard Lipsey (1960).

If vacancies are central to the theory it is clearly necessary to understand when firms choose to establish new jobs. Clearly this would depend not only on the return from having another worker in post, but also on the wage that the firm would pay and on the time it would take to fill the position. But wages and recruitment are of course linked, in that the higher the wage offer the easier it is to fill the vacancy. A complete model requires a theory of wage determination also. Given imperfections of information, both firm and worker have to ‘invest’ in a process of job search, and a successful job match must therefore offer a return adequate to compensate for this investment. The distribution of this return between firm and worker is determined by the wage. There are various approaches to how the wage gets determined, but, as may seem consistent with the decentralized approach of search theory, Pissarides assumed it would be the outcome of an individual bargain between firm and worker, and hence assumed the Nash bargaining solution. With these elements in place, it is possible to solve for the equilibrium of the system.

The comparative static properties of the equilibrium are fairly intuitive; in particular that unemployment will be higher if the replacement ratio (the ratio of unemployment benefits to the wage) is higher, because benefits support lengthier search; that for a given replacement ratio, unemployment will be unaffected by labour productivity; and that a more rapid rate of job destruction will increase unemployment.

Perhaps more interesting is the behaviour of the system out of equilibrium. For example, an increase in demand makes it profitable for firms to open up more vacancies, thus increasing the number of matches and hence the outflow from unemployment. As unemployment falls, firms find it more difficult to fill their vacancies and hence raise the wage they are prepared to offer. But higher wages make it less profitable to open up new jobs, so the number of vacancies falls back again. One of Pissarides’s best known papers (Pissarides 1985a) formalises this process. This paper is based on the assumptions that, while the rate of job separations (quits and lay-offs) is assumed exogenous, a firm can adjust its stock of vacancies immediately in response to changes in demand, and likewise that wages could also be adjusted instantly. The number of unemployed workers can, however, only change slowly. This is because the inflow into unemployment (job separations) is proceeding at a given exogenous rate, while the outflow from unemployment (job hirings) was also determined, albeit endogenously, by the stock of unemployed workers and of job vacancies. (Of course the rate of job hirings would increase immediately the number of vacancies increased, but it would still take time for the stock of unemployment to fall.) The model did not allow for the ‘sudden death’ of jobs that can arise where there are bankruptcies or firms suffer financial distress, and which would lead to a jump increase in unemployment.

To complete this analysis, then, involved a theory of job separations and in particular of jobs coming to an end, or job destruction. The key paper in this area was co-authored by Pissarides and fellow Laureate Dale Mortensen (1994). Within this model, a firm can close down jobs, just as it can open up vacancies, instantaneously in the face of some shock. This, however, introduces an asymmetry – a firm facing a positive shock can open up vacancies instantaneously and hence start recruiting, but hiring takes time, so unemployment falls only slowly. A firm facing a negative shock can close down jobs instantaneously, but this will lead to a sharp rise in unemployment.

The other main area within search theory on which Pissarides has worked is on the efficiency of the search equilibrium and the implications for labour market policy. The role of externalities in the search process and their impact on the efficiency of the search equilibrium were explored by fellow Laureate Peter Diamond in the early 1980s, and the issue was followed up in a number of papers by Pissarides, perhaps most notably in his paper on search intensity, job advertising and efficiency (Pissarides 1984). The idea here is that while more intensive job search involves a cost to the individual of more time and effort, it also offers the benefit of greater probability of finding work. But this benefit to the individual is not necessarily a benefit to society, since the job is no longer available for any other unemployed job-seekers. On the other hand, the more actively the unemployed search for work, the easier it will be for firms to recruit and hence the more willing they will be to open up vacancies. So there may be too much or too little job search, and labour market intervention may be needed to achieve something close to the optimal level.

In fact, of course, the intensity of search is already greatly affected by financial interventions, such as unemployment benefits, taxes and specific labour market inducements, such as subsidies for firms taking on particular types of workers. Most contentious in this area has been the implication of the search model that unemployment benefits reduce the incentive to search, to apply for jobs and to accept job offers. The design of unemployment compensation of course involves many other considerations (insurance against job loss, income support etc.) and has been the subject of innumerable studies. At a theoretical level Pissarides's most notable contribution was the analysis of the effects of benefits in a full equilibrium model (Pissarides 1985b), though given the offsetting externalities inherent in the search model it is unsurprising that the policy impact of this work has been quite limited.

Pissarides has made many other contributions to the theory of labour markets with search frictions, which have ranged from work on job-to-job movements to the integration of search to models of balanced growth. There is not space to describe this work in any detail. It may be noted though, that with the exception of the matching function, which is a quasi-macroeconomic type of relationship (essentially an empirical generalization based on aggregate data), Pissarides's work is very 'pure' -it assumes throughout that all agents behave rationally and all individual opportunities for profit are exploited. The *Equilibrium Unemployment Theory* book contains no facts, numbers or regressions. The equilibrium model abstracts from institutional factors, such as price rigidities or collective action, which in other models may lead to problems, though whether this is a strength or a weakness may be a matter of opinion.

Though not part of the Nobel citation, Pissarides also has an impressive range of empirical work. Clearly any macroeconomist working in the 1970s and 1980s cannot have ignored the global inflation in the 1970s nor the relapse into 'world-wide stagflation' in the early 1980s. At LSE, Pissarides was closely involved with the empirically orientated work being developed at the time at the Centre for Labour Economics (CLE) under the leadership of Richard Layard and Stephen Nickell. Even in the depths of the recession in the UK in the early 1980s, some CLE economists were struck by the observation that the number of job vacancies remained quite high, which they interpreted to mean that the high unemployment of that time was substantially an equilibrium phenomenon rather than the result of deficient demand. This provided an empirical counterpart to the significance of vacancies in Pissarides's theoretical work. Pissarides co-authored one of the key papers in this area with Richard Layard and Richard Jackman (Jackman et al. 1983). This was followed by a large number of papers by Pissarides and other CLE authors analysing the nature and causes of high unemployment and discussing policies to reduce the equilibrium (or natural) rate of unemployment.

Pissarides has made important empirical contributions to many issues in labour market policy.

These include structural issues such as regional imbalances and migration, skills shortages and technological change and questions of wage flexibility, perhaps most notably a paper co-authored with Dale Mortensen on technology shocks (Mortensen and Pissarides 1999). He has also written on employment protection and employment taxes and labour force participation, including female participation and, most recently, the impact of variability of hours. All these studies are characterized by a strong empirical grounding and a focus on policy, and in many cases are the product of joint work with other researchers at CLE/CEP.

Although it is not the main focus of his own work, Pissarides has also thrown his weight behind the work of Richard Layard and others at CLE on unemployment persistence and tackling the problems of long-term unemployment. He has one important paper on this subject (Pissarides 1992). But, unlike some of his LSE colleagues, Pissarides has not published a unified vision of the workings of the labour market based on his empirical findings, perhaps because many of the results, and the policies which follow from them, may be specific to time or place, rather than having any more universal application.

In addition to all this work on labour markets, Pissarides has a variety of other papers on various other major topics in macroeconomics, including political economy, education policy (e.g. Pissarides 1982) and, more recently, growth with structural change (e.g. Ngai and Pissarides 2007) as well as papers on political economy, consumption, saving and retirement, together with a number of more general articles on macroeconomics.

Given the range and quality of Pissarides's work, it is unsurprising that it has been widely recognised outside LSE. He was the winner of the IZA prize in labor economics (jointly with Dale Mortensen) in 2005, and is currently President of the European Economic Association. He is also a Fellow of the British Academy, the Econometric Society and the Society of Labour Economists, and a research fellow of the Centre for Economic Policy Research (CEPR) and of the Institute for the Study of Labor (IZA, Bonn). He has also been a consultant on labour market issues for the World Bank, the European Commission, the Bank of England and the OECD.

Pissarides has therefore achievements across the whole range of professional economics, in teaching and research spanning pure theory, empirical work and policy analysis. It may be that the Nobel Committee, perhaps mindful of Keynes's assertion that it is ideas which rule the world, have focused their citation on the innovative developments in the theory of markets with search frictions. But the economics profession should recognize the many important contributions over a much wider area.

Place, Francis (1771–1854)

R. K. Webb

English Radical, born in London on 3 November 1771, died in London on 1 January 1854. Apprenticed to the leather-breeches trade, he developed his radical activism while a member of the London Corresponding Society from 1794 to 1798. A comfortable fortune made as a master tailor after 1799 made possible his second career in politics, beginning with the startling radical victory he engineered in the Westminster election of 1807. Deeply involved in the parliamentary reform agitation of 1830–32, he devised the famous placard, ‘To Stop the Duke, Go for Gold’, intended to prevent the Tories from taking office by forcing a run of the Bank of England. He drafted the People’s Charter in 1838, though he took no part in the later, more extreme phase of Chartism, and was active in the early stages of the Anti Corn Law campaign.

For many years, the library behind his shop in Charing Cross was a gathering place for metropolitan radicals. Introduced by James Mill to Jeremy Bentham around 1809, Place was a vital mediating influence between working-class leaders and radical intellectuals. His sole contribution to economic literature is *Illustrations and Proofs of the Principle of Population* (1822), provoked by William Godwin’s second reply (1820) to Malthus. More sanguine than Malthus about the reform of institutions, he rejected Godwin’s inconsistency and naiveté, His defence of Malthusian principles and methods testifies to his own faith in individual effort and to the improvements in civilization he witnessed in his lifetime. Place launched the first ‘neo-Malthusian’ campaign for contraception, and in 1824–5 was the organizing genius of the successful effort to legalize trade unions and to repeal the ban on export of machinery and emigration of artisans.

Planned Economy

Alec Nove

'Planning; planned: Intended, in accordance with, or achieved by, a careful plan made beforehand'. This is the Chambers Dictionary definition. Of course in this sense we all plan, whenever we think carefully of what we might do in the future. All economic decision-making relates to the future, since all transactions take time, and in the course of time some circumstances might have changed, and so plans are frequently unfulfilled, or have results different from the original intention.

However, we will have in mind here the deliberate actions of *public* authorities, primarily the state, while referring from time to time also to plans made in the private sector. Plans can be of many kinds. The Soviet version is '*directive* planning' or command planning. The authorities issue binding instructions to subordinate management, telling it what goods and services to provide, from whom to obtain the required inputs, and, as we shall see, much else besides. Then there is *indicative* planning, when the state uses influence, subsidies, grants, taxes, but does not compel. There is also *sectoral* planning, which concerns, for instance, a road network, urban rapid-transit, the coal industry, the national health service. This need not be related to any overall plan for the economy as a whole.

Then there are differences in purpose, reason, objectives. One is to impose the centre's priorities, to replace or combat spontaneous market forces, i.e. deliberately to achieve what would not otherwise occur. This applies most evidently to a war economy, but also to Stalin's economic strategy of the Thirties, with its mass mobilization of material and human resources to create a heavy-industrial base in the shortest possible time. On a less drastic scale these considerations also apply to programmes of rapid development in some Third-World countries, that is, to conscious attempts to transform a country's political economy. In such cases the market is seen as an enemy, to be limited or combated (as in Preobrazhensky's phrase about the battle between 'primitive socialist accumulation and the law of value'), and the same was at least partly true in war economies in the West: prices were fixed, materials allocated, free-market deals in controlled commodities were treated as black-market criminal offences.

However, other kinds of public-sector planning have, or need have, no such hostility to the market, can and do coexist with it. The motive to plan them relates partly to what may be called public goods (e.g. the road network, street lighting, rubbish collection), and partly to externality generating sectors, where the profit-and-loss account of the enterprises concerned constitutes a misleading criterion even on narrowly economic grounds, and/or where private and the more general interests conflict. Examples are many: thus urban public transport, docks, airports, are in the public sector even in the United States. Environmental protection is another important factor: thus in a number of countries deforestation threatens ecological disaster, while in the North Sea it is essential to act to preserve fish stocks, while short-term private profit dictates the cutting of trees and overfishing respectively. There are also natural monopolies, where competition is unnecessary or wasteful: electricity, water, posts, until recently also telephones, are examples; the choice here lies between a regulated private monopoly and state ownership and control. The choice may be influenced also by considerations of public policy. Thus if it is desired to provide a comprehensive postal or telephone service, to supply all houses with pure water, and even remote Scottish islands with electricity, then clearly the public-service aspects must be given some priority: it has always been evident that some of the above activities cannot be profitable.

Some confusion is engendered by the inability to distinguish between *responsibility* for provision of a good or service and the way in which it is provided. Thus, to cite some examples, the public authorities must ensure that city rubbish is collected and disposed of, but this no more requires the rubbish collectors to be public employees than responsibility for road-building requires those who build the roads to be civil servants!

Then there are sectors to which economic profitability considerations may be held not to apply at all: education, health, pensions, are widely held to be the proper subject of planning and provision by public authorities.

Finally, there is the species of planning designed to facilitate and encourage the operation of market-orientated private enterprise. This ranges from infrastructural investment to what is usually called indicative planning, which is not compulsory or imposed, but which helps to fill a most evident gap in the pure free-market doctrine, which is concerned with large-scale investment. Long ago G.B. Richardson (1960) pointed out that, on the assumptions of perfect competition and perfect markets, it is hard to imagine how or why investment should take place, since the profitable opportunity is, by definition, equally visible to all the competitors. Therefore imperfect knowledge and/or collusion, neither of which are in the model, are preconditions for investment. The important role of the state in the success of the South Korean and Japanese export-orientated strategies is inexcusably ignored by the *laissez-faire* ideologists, who can see the success and attribute it wholly to free-market entrepreneurship. Planning of this sort, reinforced by unofficial pressures and fiscal incentives, could be described as a form of stateorganized collusion. In addition there is the role of the state in ensuring macro-balance, or taking counter-cyclical action, which used to be accepted quasi-universally as necessary, though this is now vigorously questioned by the revived *laissez-faire* school, which considers that the economy is basically self-righting.

So only in one of its versions is planning to be seen as in inherent contradiction with the market; in all the others they supplement each other, or plans are actually made operational *through* the market.

Socialist Planning

Socialist planning has a long history. Generations of socialist thinkers, including Marx and his followers, contrasted the deliberate planning that would occur under socialism with the 'anarchy' of capitalism, in which production was for profit, not for use. The 'associated producers' would join together to discuss what is needed and how best it could be provided. As Engels put it, they would compare the useful effect of products with the time necessary to produce them.

Some, for example Kautsky and Lenin, saw a socialist society of the future as if it were one giant enterprise, a single all-embracing factory or office. There would be no 'commodity production', that is, production will be for use, not for exchange. Labour would, when applied, be 'directly social', that is, its use will be validated not *ex post*, through the market, but *ex ante*, by the all-embracing plan, which will express society's needs. Costs would be measured in terms of what was seen as the one ultimately scarce resource, human effort.

Critics, such as Barone and L. von Mises, pointed out some major weaknesses in this approach to socialist planning: the number of calculations required would be enormous, the economic criteria for decision-making would be lacking without meaningful prices. Yet, with but few exceptions, socialists in the marxist tradition persisted in their belief that such planning would be 'simple and transparent' (Marx), that) 'everything would be simple without the so-called value' (Engels); 'capitalism had so simplified the task of accounting and control . . . that any literate person can do it' (Lenin), 'The society of the future will do what is called for by simple statistical data' (Bukharin).

Planning in practice proved to be very complicated indeed. It must be emphasized that it did serve its purpose when that purpose was analogous to that of a war economy: to concentrate resources for the priority objectives determined by the central political authority. When the war did break out, the USSR's survival, after initial military disasters, was in no small degree made possible by the ruthlessly-imposed priority of military requirements. In Western countries too, though in lesser degree, central controls were tight, resources were allocated, and the resultant bureaucratic deformations had much in common with Soviet-type planning. Yet these must be seen as a cost, in the circumstances a necessary cost, of imposing the priorities of war. It was Lange who once likened the Soviet planning system to a war economy, *sui generis*.

In normal times, the priorities become more diffuse, also more numerous. The growth of the economy itself presents new problems and challenges. A Soviet scholar remarked that, if the size of the economy grows six-fold, the number of links to be planned grows to the square of that (or any other) number, i.e. 36-fold, and indeed this can be seen as one expands the number of items included in an input–output table.

The Soviet economy today contains several hundreds of thousands of enterprises, in mining, manufacturing, agriculture, construction, transport, distribution, catering, services. The large number is not due to their excessively small size. On the contrary, it has been argued that Soviet agricultural and industrial establishments are too large, certainly much larger than is the case on average in Western capitalism. Because neither production nor the supply of inputs is based on horizontal, market-type relations, each of these hundreds of thousands of enterprises needs to receive, from some unit in the planning hierarchy, specific instructions as to what to produce, what materials to obtain and from whom, while other plan targets relate to labour productivity, wages, costs, material utilization, investment, technical progress, fuel economy and much else besides. The number of identifiably different products and services, fully disaggregated, has been estimated as upwards of twelve million. The sheer scale of the task of the planners is probably *the* most important source of inefficiency and imbalance. Though Soviet experience shows that a planned economy of this type can function, this same experience strongly supports Barone's conclusion, arrived at in 1908, before there was any practical example to study: it would be difficult but not quite impossible to arrive at a) 'technically' balanced plan, that is, one where the needed inputs match the intended output, but *quite* impossible to see how one could approach an *economic* optimum. Thus it is indeed very hard for those institutions responsible for material allocation to ensure that the needed inputs are provided, but they seldom have the practical possibility or the information to ensure that the inputs are those which are most economical.

This is but one of the difficulties attributable to the sheer scale of the required coordination between multi-million plan-instructions. Academician Fedorenko quipped that next year's plan, if fully checked and balanced, might be ready in approximately 30,000 years time.

It is necessary to distinguish between *long-term* and *current* planning. The long- (or medium) term plan looks forward to the end of a quinquennium, or in some instances as much as fifteen years; thus in 1985 some targets were published relating to the year 2000. These plans are necessarily highly aggregated, and contain broad objectives relating primarily to productive capacity (and so to investment), rather than to the product mix, which will be adapted to requirements which cannot be foreseen in advance in detail. A long-term plan must be balanced in an input–output sense, and planners proceed by so-called material balances for major products, ensuring that planned availability matches planned utilization. These plans are not yet operational, that is, they have no 'addressee': no specific enterprise is instructed to act. Or rather the addressee is the planning and administrative mechanism itself. It is true that there have been proposals, and even decisions, about the need to incorporate enterprises' own quinquennial plans into this process, and indeed to make these plans stable and to relate various norms and incentives to them. However, this has not been possible in practice. Indeed, stable 'micro' plans for five years ahead are surely an impossibility, when even annual plans are notoriously unstable, being altered repeatedly during the period of their currency to cope with the unexpected or to correct errors belatedly identified.

The drafting of the relatively aggregated 'unaddressed' longer-term plans does not present an impossible task, there being only several hundred items. It is the operational annual plan, broken down by quarters and by months, which presents formidable problems. It is drafted in the last few months of the previous year. According to one Soviet source, output plans are made for about 48,000 products, which implies that on average each will contain about 250–300 subproducts or varieties. To go into greater detail would cause inordinate delay. But since each of the 48,000 requires numerous inputs, which must be provided through the allocation mechanism, and since every enterprise must receive specific plan-instructions relating to output and inputs, even in relatively aggregated form the burden on the planners is huge. The essential task of coordination is rendered the more complicated by the fact that responsibility is necessarily shared by numerous separate planning departments and economic ministries.

Centralized Planning

The centralized planning model is based upon the supposition that 'society' (i.e. in practice the planning agencies, under the authority of the political leadership) knows or can discover what is needed, and can issue orders incorporating these needs, while allocating the required means of production so that the needs are economically met. It is worth noting that in some sectors this supposition is close to reality. Thus electricity is a homogeneous product, power stations are interlinked into a grid, information on present and estimated future needs is best assessed at the centre, as it is also in many Western countries. The centre is also the obvious place for decision-making on armaments production. However, a very wide range of goods and services, both producers' goods and consumers' goods, are supplied in a wide variety of types, models, sizes, to serve specific needs. Choice of technique, decisions on new products, possible alternative uses of agricultural land, are matters on which the centre has little relevant information which could serve as a basis for micro-commands. Also it is an evident fact that management possesses vital information as to the production potential of the enterprise, and the planners must rely on an upward flow of proposals and suggestions if they are to issue the correct orders. 'Many if not most commands in a command economy are written by those who receive them', remarked a wise Hungarian, in conversation.

Devolution of authority is thus not only necessary, but inevitably occurs, since plans are frequently late, contradictory, aggregated, and their implementation requires much managerial ingenuity, which frequently has to stretch the boundaries of legality. But the system lacks any criterion for managerial decision-making other than the plan-targets to which management's bonuses and promotion prospects are related. Since prices do not, in either theory or practice, reflect supply-and-demand relationships, relative scarcities or demand intensity, profitability cannot serve as a rational criterion for micro decision-making. Furthermore, because of lack of time and imperfect knowledge, the planners are compelled to proceed on the basis of past performance, introducing the so-called ratchet effect: output targets in the next plan period will be a little higher, costs a little lower, than in the previous period, and indeed all concerned proceed on the assumption that no major changes in past supply or delivery arrangements are likely to occur. It is this which enables the system to function, but Soviet sources understandably criticize these methods, since they are not only conservative, but stimulate undesirable behaviour by management. The latter, judged by plan-fulfilment, seeks a plan easy to fulfil and avoids doing too well in case the following year's target is set too high. Fears of supplies not arriving, and of arbitrary plan changes, also stimulate hoarding of labour and materials, and over-application for inputs.

Attempts to fulfil aggregate plan targets, in roubles, tons, square metres or whatever, engender some familiar distortions, when management produces not for the customer but for plan-fulfilment statistics. This can generate the sort of waste which is typified by the building industry (whose plan is in roubles spent) trying to use the dearest possible materials, and metal goods which are unnecessarily heavy to 'clock up' the necessary plan tonnage. It proves to be remarkably difficult to express a plan for heterogenous products in any unit of measure which does not result in unintended distortions. The weak position of the customer is due to two causes: the supplier is a *de facto* monopolist, and there is a chronic tendency for shortages to occur, which finds expression in a) 'take-it-or-leave-it' attitude on the part of the supplier. But perhaps the most fundamental cause is the one already mentioned: the model requires the centre's plans to incorporate requirements in a degree of detail which is impossible in the complex multiproduct real world, and yet it is these necessarily aggregated plan-targets which serve as the basis for micro-economic activity of enterprises, since they are judged by their fulfilment of these targets.

Initiative is likewise (unintentionally) frustrated. It is not only that management is riskaverse, since risk-taking is not as such rewarded. It is that any new action requires not only motivation but also information and means. Thus innovation, whether in product design or in production methods, is frequently rendered impossible because the required machines or materials are not obtainable, these being allocated by remote bureaucratic offices.

While enterprises are supposed to operate on so-called) 'economic accounting', in fact money and prices generally play a passive role, priority being given to plan-fulfilment indicators. The absence of any built-in incentive to economize has meant the proliferation of compulsory cost-cutting and material-economy plans, which can conflict with the objective of providing what the customer requires. While citizens are free to spend their wages on goods in state shops at state-fixed prices, there is no direct economic link or feedback from these prices to the wholesale prices received by the producing enterprises.

Such a planning system as this becomes increasingly unable to cope with the challenges of what has come to be known as) 'intensive growth', that is, growth based on the more efficient use of scarce resources. However, this same system does give to the political authorities, that is, party and state officials, a high degree of control over material and human resources. There also has developed a kind of informal social contract with the masses: security of employment, toleration of slackness at work, prices of necessities and rents kept low. Any major changes, towards some species of 'market socialism', would thus encounter considerable resistance at all levels of society.

Market Socialism

The Hungarian New Economic Mechanism (NEM), introduced in 1968, sought to overcome the deficiencies of the Soviet model by the limited use of the market mechanism as the basis of current enterprise operations. That is to say, enterprises made their own output plans, based upon negotiated contracts with customers, and purchased their inputs without having to apply for an administered allocation. The 'addressed' current obligatory plan was eliminated. State plans were now to be concerned mainly with investment, that is, with the creation of new capacity and structural change. Prices, market forces, profitability, were to play a major role in guiding the actions of management. However, state-owned enterprises remained under the ultimate authority of economic ministries, and, as also in the Soviet Union, party officials can issue orders on almost any subject.

Hungarian experience can only be seen as a partial test of the viability and effectiveness of the 'market-socialist' model, and this for a number of reasons. One of these has little to do with the model itself: Hungary was hard hit by adverse terms of trade in the Seventies, and the resultant strains led to adverse effects on living standards and to the imposition of tighter controls than was envisaged within the logic of the model, and this included controls over prices. Another 'external' factor was that Hungary trades mainly with other communist-ruled countries, and this trade is predominantly based on annual inter-governmental bilateral deals, a procedure inconsistent with the 'market' logic of the NEM. But there were other problems, which may highlight some contradictions inherent in 'marrying' the principles of market and of socialism. Thus the market requires competition, but there is little competition in Hungarian industry, partly because it is a small country with few producers, but also because of mergers. Competition in turn generates winners and losers, but the commitment to full employment and the pressures from the unsuccessful result in there being no bankruptcies: the loss-makers receive a subsidy, while extra taxes are levied on those judged to be too successful. For all these reasons, the micro-economic logic of the NEM's 'mix' of plan and market has had only limited success.

The success is particularly visible in two sectors: agriculture and distribution (trade, catering, services). In agriculture cooperative (collective) farms are freed from compulsory delivery quotas, freed also from the need to apply to the planners for authority to purchase their inputs (usually they are able to buy them without any permits). There is much more autonomy, much less outside interference, than in the USSR, and also greater flexibility in providing incentives for peasants, and in allowing scope for peasants' private activities as well as for non-agricultural activities of the farms themselves. Since agriculture is notoriously unsuitable as an object of central planning, this is indeed a sector which benefits from reliance on decentralization and the market. Trade and catering benefited both from realistic pricing (persistent shortages of many goods in the USSR were at least in part due to the tendency to underprice them), and also from the legalization of a sizeable private sector: thus many shops and restaurants in Hungarian cities are either privately owned or leased from the state by private operators. Competition has a visible effect on quality and service. Private ('second economy') activities are legal also in construction, repairs, transport (private taxis are allowed) and a range of small-scale manufacturing. In the USSR most of these activities would be illegal, but a sizeable underground second economy exists there also. Thus in Hungary one can observe both the advantages and difficulties which arise when plan and market are allowed to coexist – though of course the particular) 'mix' that exists in Hungary is not the only possible one.

It is noteworthy that Poland and China have formally adopted a model which resembles the Hungarian NEM, though one difference concerns agriculture: in Poland the bulk of the peasantry have remained private smallholders, while in China the 'household responsibility system' introduced after 1979 has effectively de-collectivized the peasantry. In the Polish case the serious economic difficulties which persist have been an obstacle to the implementation of these reforms. In China the resolution adopted in October 1984 explicitly asserts the need to recognize the role of market forces as well as of state planning, and, along with greater freedom for peasant agriculture, petty private trade and ownership have been legalized. This is a 'mix' reminiscent of NEP in the Soviet Union in the early Twenties. However, it is too soon to conclude that the Chinese have a new and durable plan model. One of their leaders remarked that, while managers must be allowed to show enterprise and spread their wings, and they had been confined to too small a cage, insisted that there must be a cage: 'otherwise the bird will fly away'. There appears to be considerable differences of opinion among Chinese party leaders as to the meaning of present policies. Is the use of the market, and the opening to foreign capital, a temporary phase, as NEP was in Russia, with some sort of real socialist planning to follow? Or is the mix between plan and market a long-term model of socialist planning? The rapid growth of income inequalities, the corruption of many officials, a speed-up in inflation, could lead to a counterattack, to the reimposition of more central planning. This is not the place to speculate on such matters, only to note that the Chinese are still seeking their own model.

Yugoslavia's combination of plan and self-management was also based in principle on the use of the market mechanism. The micro-economy was to function on the basis of contractual relations between self-managed enterprises, guided by material advantage and by realistic free-market type prices. The problems related to self-management are treated elsewhere (see ▶ Market Socialism). Yugoslavia's economy has run into serious difficulties, not least because the necessary minimum degree of central planning was absent. Tinbergen wisely remarked that under conditions of self-management, 'it can be convincingly shown that in an optimum order some tasks must be performed in a centralized way and cannot therefore be left to the lowest levels (Tinbergen 1975).

Part of the problem was republic–regional fragmentation, complicated by a long history of local nationalisms, so that each republic tended to make its own investments, to keep its own earnings from exports, to run its own finances, which helped to disintegrate the economy of what is, after all, a small country. There is a moral here of wider application about regional planning powers; a regional authority will tend to divert resources for the use of its own region, even if it harms others, if it has the power to do so. But this is but one aspect of a more general problem: the interests of the parts do not necessarily add up to the interests of the whole. There are economies (and diseconomies) of scale, and externalities, which cannot be ignored. Furthermore the self-management model itself tends to encourage excessive income distribution and discourage labour-intensive investments, a situation which can and did give rise to serious unemployment combined with accelerating inflation. The latter was also due to lack of adequate control over credits issued by the (numerous) banks, and to what for several years was a negative real rate of interest.

Yugoslav experience does not prove that either self-management or the market mechanism were wrong. It does strongly point to the need of economic powers at the centre, not only to ensure macro-economic balance but also to devise and enforce the ‘rules of the game’ for the micro-economy. It also demonstrates the limitations and dangers of ‘socialist *laissez-faire*’. If the USSR’s economy is stifled by allembracing central controls, then Yugoslavia shows the consequences of having no systematic central controls at all.

This criticism can be extended to some early models of a decentralized socialist economy, such as that of Oskar Lange and Abba Lerner. These do contain a Central Planning Board, but it is imagined as functioning only via the fixing of parametric prices, to which management is supposed to react in accordance with the best neoclassical principles. Intended to show, in reply to critics (notably Mises), that socialist planners do not require to solve innumerable simultaneous equations, Lange’s counter-model contained neither growth nor indeed any plan at all. Nor, or course, did the world of Mises. What was shown was that equilibrium with efficient allocation would be possible, on the abstract assumptions common to both protagonists. It is worth reminding oneself of Kornai’s dictum: few indeed are those who take decisions on the basis only of information about price (especially when, in taking investment decisions, the relevant prices are those of the future).

Those critics of socialist planning who emphasized the alleged impossibility of solving too many simultaneous equations had grounds for alarm when the computer, programming, input–output techniques, appeared to make the impossible possible. After all, whereas in a capitalist planless society there was and could be no operational objective function, a centrally planned economy could – it might be supposed – use the new techniques to arrive at the most economically efficient way of achieving the objectives defined by the supreme political authority, which is simultaneously in command of the economy. Indeed some members of the Soviet mathematical school explored in very interesting ways how this might be attempted, and Kantorovich, who received the Nobel prize for his pioneering work on linear programming proposed a system of plan-valuations which could be used in calculations designed to achieve optimal allocation (and had to defend these valuations from criticism from dogmatic defenders of the labour theory of value).

It turned out that progress along this route was disappointingly slow. We can now see more clearly why. Firstly, the ‘objective function’ proved to be operationally indefinable, despite efforts by able mathematical economists to define it. What could be the objective basis for an optimal plan, what could be the criterion by which to judge if any given plan were optimal? The objectives of the political leadership cannot serve as such a criterion, since (as one Soviet economist remarked) it seeks advice as to what the plan objectives should be, and would not thank those economists who replied that its wishes were their criterion. Any real society generates numerous inconsistent objectives, and in a one-party state these are also present, and find expression within the one party. Then the ‘curse of scale’ must again be emphasized. Botvinnik, the former world chess champion, estimated that the number of possible moves in a chess game exceed substantially the number of words spoken by all human beings since the Pyramids were built. A chess board has only 64 squares, and rules of the game are known. An economy or a society has many more, and the human ‘pieces’ play different games and dispute about the rules. So even if one day a chess grandmaster might have trouble beating a chessplaying computer, the idea that computers could replace markets and make Soviet-type centralized planning ‘efficient’ is surely a chimera. It is true that computers can aid the centre in making calculations. They have numerous uses at micro, i.e. decentralized levels, as a source of data, or in design bureaux, etc. However, one can scarcely imagine that the centre can administer through a computerized programme a fully disaggregated micro-plan for millions of products, distributed among hundreds of thousands of enterprises. Not only would there be too much information to handle (and check), but decisions involving quality, or judgement as to uncertain outcomes can hardly be left for computers. Scale is also a hindrance to the use in practice of prices based on central computerized programmes (the ‘objectively determined valuations’ of Kantorovich). At operational disaggregated level there is no such thing as *the* price of ‘agricultural machinery’ or ‘ball-bearings’, or ‘footwear’: there are hundreds or thousands of different products under each of these heads, which need to be provided, and priced, for different requirements or preferences.

Plan and Market

Plan and market have been seen as incompatible opposites, both by dogmatic socialists and by dogmatic anti-socialists. However, a strong case can be made for the proposition that a mix of the two is essential in any modern society. True enough, a long list can be made of distortions and deficiencies directly attributable to planning. Disastrous indeed have been some comprehensive redevelopment schemes devised by well-meaning urban planners, and some of the housing has later had to be dynamited. Planning foreign trade in a number of countries, especially in the Third World, has been a means of personal enrichment for those entitled to issue import licences. Development plans have sometimes been grandiose and wasteful. From these and similar experiences some have drawn the conclusion that planning is ‘bad’, that reliance on the market mechanism will provide the right answers to all economic problems, and that state intervention should confine itself to controlling the money supply and to providing a minimum range of so-called public goods, such as defence and lighthouses. Conversely, socialists see that the operation of the free market generates excessive income inequalities, gives rise to monopolistic abuses, to trade-cycles, to unemployment. The market inspires acquisitiveness, substitutes conflict (between classes, and also between competitors) for the desired harmonious cooperation.

Yet both sets of dogmatists appear to be mistaken. The evils which they have noted do indeed exist, and require to be explicitly recognized and combated. The difficulties faced by centralized marketless socialism have already been discussed at length, and it is hard to see how decentralization could be envisaged without some sort of market mechanism which would link the parts together. *Laissez-faire*, the belief that virtually all public-sector planning or provision is either harmful or unnecessary, ignores much of what did or does happen in the real non-textbook world.

Investment is clearly one relevant sector. Given the degree of uncertainty facing private investors, their understandable desire for security, the attraction of high interest rates (and the negative effect of such high rates on would-be borrowers), it would seem to be a remarkable act of faith to imagine investments, especially in the longer term, would be rational, let alone optimal. Various forms of indicative planning, reinforced by the state’s own investment plans (e.g. in infrastructure), become an important contribution to guiding private investment decisions. As already mentioned, the South Korean government played a key role in the process of developing highly successful exporting sectors. If interest rates are (say) 15 per cent, whose private concern should it be to think about (for instance) the consequences for Great Britain of the exhaustion of North Sea oil or gas supplies by the end of the century? It requires ideological obstinacy of a high order not to see that an energy plan might be desirable, in the national interest. The devotees of 'methodological individualism' go so far as to assert that there *is* no national interest, distinct from the individual interests of the citizens. Even on so extreme an assumption it must still be recognized that individual or sectoral interests can conflict with one another; the elementary example of many people wishing to park cars in a narrow street is but one of many instances when people literally get in each others' way, and public authority has to sort out the mess. One returns, too, to examples cited earlier concerning external effects. Docks, airports, rapid-transit systems, have wide-spreading effects – on industrial profitability, property values, congestion, etc. – which do not show up in their respective profit-and-loss accounts. It does seem absurd to assert that the Washington or Montreal (or Moscow, or Munich, or Budapest) metros should not be part of a transport plan for their respective cities, or should not be provided because – as is the fact – they do not 'pay'. But the) 'methodological individualists' are plainly mistaken. In virtually any institution, from the state to a firm or a university, it is frequently possible for the perceived interest of the part to conflict with that of the whole. While it is too complex and time-consuming to attempt to 'internalize' all externalities, it is essential to try to identify contradictions and conflicts of interest when these are important, and not to evade the issue by pretending that – with appropriate legal and institutional arrangements – they will not exist. State intervention is one form of dealing with these problems, in the general interest.

Businessmen, especially at times characterized by uncertainty and high interest rates, have a short-time horizon. Thus Nobel laureate Wassili Leontief wrote: 'Our [US] business man investor expects to get back his capital in about four-and-a-half years. So really he is not very worried about what will happen beyond these four and a half years' (*The Federalist*, March 1985, p. 66). This is not necessarily in the long-term interest of the firm, let alone of the entire economy or of society.

Some extreme anti-planners need reminding of the fact that trade-cycles existed even when trade-union powers were minimal, that chronic unemployment may be as irrational a waste of resources as anything that happens in a centrally planned economy. The notion that labour markets 'clear' but for remediable imperfections is surely a myth derived from general-equilibrium analysis. Real competition *requires* unused capacity, necessarily involves winners and losers, otherwise how could competition actually proceed? This is apart from the serious danger of technologically induced long-term unemployment, which may pose a major threat to overall stability. Yet to combat unemployment by an expansionary policy can engender accelerating inflation unless consideration is given to an incomes policy, itself part of a plan.

It is true that, in the effort to plan and control, major errors have been and could be committed. However, to take one last example, the fact that dreadful mistakes in town-planning have occurred does not prove that no town-planning powers should reside in public authorities.

The whole subject remains highly controversial, and ideologies of both left and right heavily influence both policies and theoretical formulations. At present in many Western countries it is the advocates of planning that are fighting a rear-guard battle.

Formally, planning in an economic context can be identified with a constrained maximization problem. The objective, whether it is simply social welfare or multiple individual utilities, is maximized subject to the resource and technological constraints. It needs to be emphasized that the planning problem is not simply one of characterizing the solution to the maximization problem but also of defining a computational procedure to obtain the solution. A planning process can be defined as an iterative procedure which, through successive approximations, finds a solution to the maximization problem.

The literature on planning processes goes back at least to the debate of the 1920s and 1930s on the possibility of economic calculation in a socialist state. While the formal versions of the welfare theorems, as presented by Arrow (1951) and Debreu (1954), were not available then, it was fairly well recognized that the competitive mechanism would, in equilibrium, satisfy the marginal conditions in terms of the equality of prices and the relevant rates of substitution and that this would constitute an efficient method of allocating resources. In what seems, at least in retrospect, to be an argument one may well be tempted to make if one was aware of the second welfare theorem, Mises (1922) argued that since the markets for capital goods, and hence their prices, would not exist in a socialist economy, it would be impossible for such an economy to allocate its resources rationally. However, Pareto (1897), in comparing the market to a computing machine, had already pointed out that a procedure similar to the competitive process of the market could be used to determine a plan. His argument had been further elaborated by Barone (1908). The focus of Mises's criticism was somewhat changed by Hayek (1935) who did not rule out the theoretical possibility of a planned economy being able to allocate resources rationally. The scepticism was centred around the ability of the planning authority, say the Central planning Board (CPB), to solve the 'hundreds of thousands' of equations necessary to achieve the objective. Partly in response to this criticism, iterative processes were presented, in what are now famous papers by Taylor (1929) and Lange (1936–7), to show that a planned economy could allocate resources in much the same way as the competitive system. They formalized a planning process which would follow the competitive rules to allocate resources; the trial and error method for finding the optimal allocation was similar to Walrasian tâtonnement. The arguments presented by the sceptics were turned on their head; the planned economy could play the competitive game just as well as the market, perhaps better.

While, in the classical environment, a process which imitates the competitive market has the clear advantage of leading, in equilibrium, to a Pareto optimal allocation, the dynamic properties of such a process were analysed much later. Samuelson (1949) showed that in a linear economy, such a mechanism led to indefinite oscillations. Arrow and Hurwicz (1960) rigorously formalized Lange's process, for an economy with a single utility function, and showed that strict concavity of the utility function and the technological constraints were crucial in establishing the convergence of the dynamic process.

In the subsequent development of this literature considerable attention has been paid to developing processes which converge to an optimal plan. Other criteria for comparing different processes have also been formalized (see for example Hurwicz 1960, and Malinvaud 1967) and we shall discuss these in more detail in section "The Formal Model and Definitions". At this stage it is, however, worthwhile to point out that a planning process which mimics the competitive process has considerable appeal. In the classical environment it leads to an allocation which is Pareto optimal. It also retains the attractive informational processing properties of the competitive mechanism; the CPB is not required to collect all the information on the economic environment nor does it need to solve the entire programming problem by itself since various stages of the optimization process are conducted at the individual level. Subsequent literature on planning processes has, quite justifiably, concentrated on processes which are in some sense decentralized. Processes applicable to non-classical environments have also been formulated.

There is also a considerable literature on general allocation processes in which the CPB is not assigned a distinguished role (see for example Arrow and Hurwicz 1977). In this article we shall concentrate only on planning processes. In particular, we consider an economy with many firms and a CPB. Except for the section on public goods where we consider many consumers, the CPB is assumed to have the objective of maximizing a single utility function. Section "The Formal Model and Definitions" will set out the model and the criteria which may be used to compare different processes. Processes designed for the classical environment are considered in section "The Classical Environment". Sections "Increasing Returns" and "Public Goods" deal respectively with economies with increasing returns and with public goods. Due to limits on space, we shall not deal with other non-classical environments that have also been studied in the literature on allocation process (see for example Section III of Hurwicz 1973). Another important aspect of planning which is not covered here is that of incentive compatibility. Moreover, the discussion is not intended to cover all the details of the processes under consideration and the reader may find it useful to consult the cited papers. Notable among the surveys in this area are Heal (1973), Hurwicz (1973) and Tulkens (1978).

The Formal Model and Definitions

We shall consider an economy with k commodities, indexed by l, and $n + 1$ agents, n firms and the CPB. Agents will be indexed by

$$i, i = 1, \ldots, n, n + 1.$$

We shall also find it convenient to index the firms by j, $j = 1, \ldots, n$. Firm j's technology is represented by production set $Y^j \subseteq R^k$. The environment of firm j is simply $e^j = Y^j$. The CPB has a continuous utility function U: $X \rightarrow R$ where X is the consumption set. The aggregate endowment of the economy is denoted $\omega \in R^k$. The economic environment of the CPB is $e^{n+1} = (X, U, \omega)$. The economy can be described in terms of its environment $e = (X, (Y^j), U, \omega)$.

D.1. A program (x, y) consists of a consumption plan $x \in X$ and a collection of production plans $y = (y^j) \in Y = \Pi_j Y^j$.

D.2. A program (x, y) is said to be feasible if $x = \Sigma_j y^j + \omega$.

D.3. A program (x, y) is said to be Pareto optimal if it is feasible and there does not exist another feasible program $(\bar{x}, \bar{y})$ such that $U(\bar{x}) > U(x)$.

A planning process is an iterative process in which messages are exchanged between the firms and the CPB. Agent i chooses a message m^i from a set M, taking into account the environment and the messages received in the previous period. Let m_t^i refer to agent i's message in time period t and

$$m_t = \left(m_t^{\,1}, \ldots, m_t^j, \ldots, m_t^{\,n+1}\right).$$

The response of agent i may then be defined in terms of a response function $f^i : M^{n+1} \rightarrow M$ where M^{n+1} refers to the $n + 1$ fold Cartesian product of M and

$$m^i_{t+1} = f^i(m_t; e).$$

An equilibrium message is simply defined as a stationary message. The equilibrium of the process is determined by an outcome function h which translates the equilibrium message into the equilibrium program or plan. We can now formally define these concepts:

D.4. Given an environment e, a *planning process* is defined as $\pi = (M, f, h)$ where $f : M^{n+1} \rightarrow M$ and $h : M^{n+1} \rightarrow X \times Y$.

D.5. An *equilibrium message* for a process π is an $m \in M^{n+1}$such that $m = f(m; e)$.

D.6. An *equilibrium program* (or an *equilibrium plan*) for a process π is a program (x, y) such that $(x, y) = h\ (m; e)$ and m is an equilibrium message.

We shall now discuss some of the desirable properties that a planning process may have. These properties may be broadly classified in terms of the performance of the process and its informational efficiency. We begin by presenting the performance criteria introduced in Malinvaud (1967).

Clearly convergence to a Pareto optimal allocation is a requirement that any planning process ought to satisfy.

D.7. A process π is said to be *convergent* if an equilibrium program exists and is Pareto optimal, that is, as $t \rightarrow \infty$ $\text{Lim}_t h(m_t; e)$ is Pareto optimal.

Malinvaud also stresses the importance of the following properties which may, in practice, be even more important if the process needs to be terminated before equilibrium is reached.

D.8. A planning process $\pi = (M, f, h)$ is said to be feasible if $f(m, e)$ and $h(m, e)$ are nonempty and $h(m, e)$ is feasible for all $m \in M^{n+1}$.

D.9. A planning process π is said to be *monotonic* if $U(x_{t+1}) \geq U(x_t)$ for all t, where x_t is the consumption plan corresponding to $h(m_t; e)$. It is *strictly monotonic* if it is monotonic and $U(x_{t+1}) = U(x_t)$ implies that $h(m_t; e)$ is Pareto optimal.

Hurwicz (1960, 1969) formalized the notion of informational efficiency associated with a process. His definitions are applicable to general allocation processes in which a CPB is not assigned a distinguished role and we shall suitably modify his concepts to apply specifically to planning processes. The definitions which follow are aimed at formally defining a decentralized process, a definition which is intended to include but not be synonymous with the competitive process. An important characteristic of the competitive system is that initial information is dispersed among the agents: firm j knows only its own environment Y^j while a consumer knows only his or her utility function and endowment. A process in which the ith agent's response functions depends only on e^i is said to be *external*. A process is *anonymous* if the agents do not know the source of their messages. Since there is only one planning authority, this requirement may not be relevant for the firms; if certain kinds of messages are transmitted only by the CPB the firms would know the source of these messages. As far as the CPB is concerned, it would be desirable if messages did not have to be identified with particular firms. In particular, if the aggregate response of the firms is all that the CPB needs to determine its message, this must be considered a significant advantage. Clearly, this would be a stronger requirement than anonymity and a process satisfying this requirement will be called *aggregative*. Another informational requirement that Hurwicz (1969) imposes on a decentralized process is that the message space M be R^k. Calsamiglia (1977) considers a somewhat less restrictive condition on the amount of information that needs to be transmitted. He defines a process to be *point valued* if M is some finite dimensional Euclidean space.

D.10. A process $\pi = (M, f, h)$ is *informationally decentralized* if it is external, aggregative and point valued, that is if

$$m^j_{t+1} = f^j\left(\sum_{)j(} m^j_t, m^j_t, m^{n+1}_t; e^j\right),\ m^{n+1}_{t+1}$$

$$= f^{n+1}\left(\sum_j m^j_t, m^{n+1}_t; e^{n+1}\right)$$

and

$$M = R^s,$$

where $\Sigma_{)j(}m^j$ refers to the summation cross the messages of all except the j-th firm and s is a positive integer.

While most of the planning processes in the literature are external and aggregative, many of them are not point-valued in the above sense. In particular, Malinvaud's (1967) process is one in which the agents transmit point-valued messages in every time period but the response of the CPB depends also on the messages received in the past. Such a process would not be informationally decentralized according to the above definition; however, there is something to be said for making a distinction between messages and memory, and between a process in which messages at each point in time are infinite dimensional and one in which finite dimensional messages are transmitted but the CPB has a memory of past messages. Processes of the later variety have also been termed decentralized and while this may not be unreasonable, it has led to some confusion (see Cremer 1978).

The Classical Environment

In this section we discuss planning processes designed for the classical environment in which there are no externalities, production sets are convex and the utility function is quasi-concave. In this setting, the competitive allocation has the attractive welfare properties that it is Pareto optimal and any Pareto optimal allocation can be sustained as a competitive allocation with a redistribution of initial resources. In an economy with a single utility function, a competitive allocation is unambiguously optimal.

We begin by considering Lange's process as formalized by Arrow and Hurwicz (1960). As mentioned earlier, the Lange–Arrow–Hurwicz (LAH) process is closely related to the Walrasian tâtonnement. Arrow and Hurwicz consider the following process: the CPB announces prices p and the firms choose profit maximizing production plans. The CPB computes a consumption plan to maximize $U(x) - px$. The prices are then varied in proportion to excess demand.

Arrow and Hurwicz formulate the planning problem as a programming problem and apply the gradient method (or method of steepest ascent) to find its solution. They formulate their process in continuous time in the activity analysis framework. We now formally describe the LAH process in its discrete version, as transposed by Malinvaud (1967) to the model presented in section "The Formal Model and Definitions" above. Given prices p, firms choose their profit maximizing plans and the CPB chooses the consumption plan which maximizes $U(x) - px$. The price of a commodity is then increased by an amount proportional to its aggregate excess demand, the coefficient of proportionality being a positive constant ρ provided this change does not make the price negative. The responses of the agents can now be defined formally:

(i) for all $z \in Y^j\}j = 1, \ldots, n, .$
(ii) $x_t = \{x_t \in X|\ U$
$(x_t) - p_{t-1}x_t \geq U(z) - p_t z$ for all z, $\in X\}$,
(iii) $p_{t,l} = \max\Big\{0, p_{t-1,l} + \rho\Big(x_{t-1,l} - \Sigma_j y^j_{t-1,l}$
$-\omega_l)\}\ l = 1, \ldots, k.$

It is clear that in order for the process to be convergent, a Pareto optimal allocation must exist. This in turn will be guaranteed if, for example, all the production sets and the consumption sets are compact. The assumption that the above mappings are all single-valued, that is, there is a unique production plan that maximizes profits for each firm, given *p* and a unique consumption plan that maximizes $U(x) - px$, also turns out to be important for the convergence properties of the process. While the process in continuous time is convergent (see Theorem 12 in Arrow and Hurwicz 1960), Uzawa (1958) showed that the discrete version of the LAH process converges only approximately. The following result is the version presented in Malinvaud (1967).

Theorem 1 If there is a unique Pareto optimal allocation $(\overline{x}, \overline{y})$ and the functions defined by (i) and (ii) are single-valued, the process defined by (i), (ii) and (iii) is approximately convergent in the following sense: for any $\varepsilon > 0$ there exist ρ_0 and t_0 both depending on ε such that if $\rho \leq \rho_0$ then for $t \leq t_0$ the distance between $h(m_{t;e})$ and $(\overline{x}, \overline{y})$ is no greater than the distance between $h(m_{t-1}, e)$ and $(\overline{x}, \overline{y})$ and for $t \geq t_0$ the distance between $h(m_t; e)$ and $(\overline{x}, \overline{y})$ is no greater than ε.

It is easy to see that this process is not feasible since, out of equilibrium, aggregate excess demand for some commodities may be positive. There is also the problem that, since the function $\rho(\varepsilon)$ is not known, it is not possible, given some ε, to choose the value of ρ to be most efficient.

Malinvaud (1967) proposes two other processes which are feasible, monotonic, and convergent but are not decentralized according to D.10 since the CPB is required to remember the messages conveyed by the firms in the past. Malinvaud's first process is designed only for a linear economy and is based on Taylor's (1929) proposal. Each firm is assumed to have a set of fixed coefficient techniques that can be operated under constant returns to scale. The CPB announces prices corresponding to which firms respond with a cost minimizing technique. The CPB then solves the open Leontief model to obtain prices which would make firms' proposed techniques earn zero profits and a consumption plan which maximizes utility at these prices. This process is then shown to satisfy Malinvaud's criteria under certain conditions. Malinvaud's second process covers a more general environment and we shall now discuss this in somewhat more detail.

This process is an application of the Dantzig and Wolfe (1961) decomposition algorithm to the planning problem. The CPB builds up an approximation of the firms' production sets based on messages received from them in the past. At each stage firms reveal their profit maximizing production plans, given the prices conveyed by the CPB. Assuming that all the production sets are convex, the CPB can construct a subset of a firm's production set by taking the convex combination of all the production plans revealed by that firm in the past. The CPB then solves the programming problem of maximizing utility subject to the resource constraints and the technological constraints as given by its construction of the firms' production sets. In the next stage the shadow prices obtained from the programming problem are announced as prices and the process continues. For the process to start it is assumed that the CPB has initial information about at least one feasible production plan for each firm.

We can now define the process formally. Let Δ denote the $k - 1$ dimensional simplex and $Y_t^j = \mathrm{Con}\left(y_t^j, y_{t-1}^j\right)$ where Con denotes convex hull. Let $(\overline{x}_t, \overline{y}_t)$ denote the allocation which solves the programming problem at *t*, that is,

$$\begin{aligned}(\overline{x}_t, \overline{y}_t) = \{(x, y) \in XxY | x_t \\ \leq \sum_j y_t^j + \omega \text{ and } U(x_t) \\ \geq U(z) \ \text{ for all } z \in \sum_j \text{ con } \left(Y_t^j\right) + \omega \}.\end{aligned}$$

We shall say that $p \in \Delta$ supports the allocation $(\overline{x}_t, \overline{y}_t)$ if

(a) $U(x) \geq U(\overline{x}_t)$ implies $px \geq p\overline{x}_t$
(b) $y \in Y^j$ implies that $py \leq p\overline{y}_t^j$ for all *j*.

The process is defined by the following equations:

(i) $y_t^j = \{y \in Y^j | py \geq p\overline{y}$ for all $\overline{y} \in Y^j\}, j = 1, \ldots, \mathrm{n}.$
(ii) $p_t = \{p \in \Delta | p \text{ supports } (\overline{x}_t, \overline{y}_t)\}.$

The plan at stage *t* is simply defined as $\left(\overline{x}_t, \overline{y}^j{}_t\right)$.

The following assumptions are sufficient for this process to satisfy Malinvaud's criteria. (A1) X is closed, convex and bounded from below. $U(x)$ is continuous, quasi-concave and locally non-satiated (A2) Y^j is convex and compact for all j. (A3) the CPB knows a feasible program (x_1, y_1). We can now state:

Theorem 2 (Malinvaud 1967) If (A1), (A2) and (A3) are satisfied the process defined by (i) and (ii) is feasible, monotonic and convergent.

To see that this process is feasible notice that, given (A2), (i) always has a solution and, given (A1) and (A2), the programming problem, for any t, has a solution and this solution constitutes the plan for that time period. We can appeal to the second welfare theorem (see, for example Theorem 6.4 in Debreu 1959) to assert that (ii) also has a solution. Monotonicity is an obvious property of this process since the constraint sets in the programming problem of time t are contained in the constraint sets of time $t + 1$. Convergence is established by considering a limit argument, using the fact that all the plans lie in a compact set. We refer to Malinvaud (1967) for the proof.

As the above theorem shows, this process has better performance properties than the LAH process. However, its information requirements are much stronger. The CPB is required to have memory and to know of a feasible allocation. It also solves a rather complicated programming problem at each stage. Moreover, to implement the plan the firms are instructed to follow the production plans computed by the CPB. While these plans are consistent with profit maximization, a specific instruction has to be issued to each firm. But this problem can be avoided in the simpler case where all production sets are strictly convex. In this case, the equilibrium plan can be implemented simply by announcing shadow prices and letting the firms find their unique profit maximizing production plans.

Weitzman (1970) proposed a process which is in a sense a dual of Malinvaud's process. The CPB has a belief about a firm's production set, which is not necessarily correct, and, given these imaginary production sets, it solves the programming problem and provides each firm with a production plan as a target. If the firm finds that this target is not feasible it responds with an efficient plan and a corresponding marginal rate of substitution. The CPB then constructs a new production set which is the intersection of its previous one with the half space determined by the firm's announced efficient plan and marginal rate of substitution. The CPB again solves the programming problem and announces new targets (see Fig. 1). Not only is this process convergent, if the production sets are polyhedral, convergence is achieved in a finite number of steps. However, it is not feasible since the CPB's targets may not be feasible for the firms.

Another process which uses production quotas rather than prices as signals is one due to Kornai and Liptak (1965). Their process is formulated for a linear economy in which the CPB's utility function is separable among the firms' outputs. The CPB allocates resources to the firms which respond with rates of substitution and the CPB reallocates resources in response to the value of the allocated resources at the shadow prices. They model the interaction between the CPB and the firms as a game and show that the process is convergent.

Increasing Returns

Heal (1969) proposed a non-price gradient process which locates local maxima even for economies with increasing returns. The CPB allocates the inputs among firms which then respond with efficient output levels and marginal productivities. The CPB then reallocates the inputs towards the firms with higher marginal productivities. The process can be most easily understood in the simple setting in which all firms produce an identical output using m primary resources. Departing from our notation of section "The formal Model and Definitions", we shall denote by y_i the amount of output produced by firm i and by f_i firm i's production function. The amount of input j used by firm i is denoted x_{ij} and the technological constraints may be stated as follows,

Planning, Fig. 1

$$y_j = f_i(x_{i1}, \ldots, x_{im})\ i = 1, \ldots, n,\ \ x_{ij} \geq 0, \text{for all } i \text{ and } j.$$

Let R_j denote the aggregate endowment of the jth resource. The resource constraints can be stated as

$$\sum_i x_{ij} \leq R_j \text{ for all } j.$$

The objective of the planning process is to find $((x_{ij}))$ to maximize $\Sigma_i y_i$ subject to the technological and resource constraints. Let f_{ij} denote firm i's marginal productivity of the j-th input and let a dot over a variable denote its rate of change. The process starts with the CPB allocating x_{ij} to the firms subject to the resource constraints. The CPB then raises the allocation of input j to a firm if its marginal productivity is greater than a certain average productivity and lowers it if it is lower than the average, subject to the non-negativity constraints. Formally, the rate of adjustment is determined by the following equations

$$\dot{x}_{ij} = f_{ij} - \mathrm{Av}\left(K_j\right)f_{ij}, \text{if } i \in K_j\ \ 0\ \ \text{other wise},$$

where $\mathrm{Av}(K_j)f_{ij}$ denotes the average of f_{ij}'s contained in the set K_j. The set K_j is constructed (see Heal 1969) so that the non-negativity constraints are not violated in applying the adjustment equations and it satisfies the following property

$$\mathrm{K}_j = \left\{ i \middle| x_{ij} > 0 \text{ or } x_{ij} = 0 \text{ and } f_{ij} > \mathrm{Av}\left(K_j\right)f_{ij} \right\}.$$

K_j includes firms with positive allocations of input j or firms with a zero allocation but a marginal productivity higher than the average.

We can now state the following theorem, which applies to the simple model we are considering but also extends to the more general case where firms produce different commodities.

Theorem 3 (Heal 1969) If all f_i have continuous, finite first derivatives and the initial allocation is feasible, the process defined above is feasible and monotonic. Moreover, every limit point of the process satisfies the necessary conditions for Pareto optimality. If the initial allocation is not a local minimum, then the limit points are to local minima.

To see that the process is feasible, notice that

$$\sum_i \dot{x}_{ij} = \sum_{i \in K_j} \left[f_{ij} - (1/K_j) \sum_{i \in K_j} f_{ij} \right] = 0, \text{for all } j.$$

Thus, if the initial allocation is feasible so are all other allocations. To establish monotonicity, we consider

$$\dot{y} = \sum_i \sum_j f_{ij} \dot{x}_{ij}$$

which can be written as

$$\begin{aligned} \dot{y} &= \sum_j \sum_{i \in K_j} f_{ij} \left[f_{ij} - (1/|K_j|) \sum_{i \in K_j} f_{ij} \right] \\ &= \sum_j \sum_{i \in K_j} \left[f_{ij} - (1/|K_j|) \sum_{i \in K_j} f_{ij} \right]^2 \geq 0. \end{aligned}$$

Thus, $\dot{y} \geq 0$ and $\dot{y} = 0$ if and only if $f_{ij} = f_{kj}$ for all i and $k \in K_\mathrm{j}$ for all j. It is easy to see that the equality of f_{ij} for all i in K_j is the necessary condition for optimality. This implies that y increases monotonically except when the necessary conditions for optimality are satisfied. In particular, if the initial allocation is not a local minimum, the equilibrium allocation, arrived at through monotonic increases, cannot be a local minimum. Hori (1975) showed that the convergence to a point of inflection is unlikely in a well defined sense. A discrete version of this gradient process would also be approximately convergent in the sense described in Theorem 2 above.

Since this process requires the CPB to respond with allocations to firms, the informational requirements are much stronger than those of a price guided process in which a common price vector is given out to the entire production sector. In the general case where firms produce many commodities the CPB uses marginal valuations not only to allocate inputs but also output combinations to each firm (see Heal 1973, ch. 8). However, unlike the Malinvaud or the Weitzman process, the CPB is not required to have a memory. It is also possible to modify this process to take advantage of the informational efficiency which is characteristic of the price guided processes. Such a mixed planning process was formulated by Heal (1971) and is similar to one proposed by Marglin (1969). In Heal's (1971) process the CPB allocates resources to the firms and also provides them with prices of the final goods. The firms inform the CPB of their profit maximizing output bundles and also of the marginal productivity of the inputs. The CPB reallocates inputs as in the previous process and announces new output prices which reflect the marginal rates of substitution in consumption. The performance of this process is similar to that of the previous one with the important difference that the CPB does not determine the complete allocation at each step. The substitution of one output for another is carried out by the firms depending on the common price vector for outputs announced by the CPB. Aoki (1971a) proposed a mixed planning process which combines the LAH process with Heal's (1969) process. He considers an economy with increasing returns in which there is one input such that if this is fixed, each firm faces decreasing returns with respect to all the other inputs. The CPB allocates this input to the firms in accordance with its marginal profitability and the LAH process is then used to allocate all the other resources. This process is clearly more complex since the LAH process is used at each step in which the essential input is reallocated, but it does converge to a local maximum.

Another approach to planning in economies with increasing returns is the modified LAH process. Arrow and Hurwicz (1960) showed that their process could deal with linearities and nonconvexities if the Lagrangian is suitably modified so that it becomes strictly concave and the gradient method is then applied to locate a saddlepoint of this concavified Lagrangian. There is, however, a significant difference. The modified Lagrangian expression is no longer a sum of functions each involving a different variable and it is no longer simply possible to determine demands and supplies given the prices. The CPB and firms need the entire price schedule and this makes this modified process less informationally decentralized than the original LAH process.

All the processes that we have so far considered in this section, depending as they do on first order properties of the relevant functions, cannot guarantee convergence to a global optimum. They also seem to be less informationally decentralized than processes for the classical environment. The natural question to be raised at this stage is whether it is possible to formulate a decentralized process which converges to a global optimum in an environment with increasing returns. Calsamiglia (1977) showed the answer to this question is no. He begins by making a rather important point about the interpretation of a local maximum. He provides an example of an allocation which is a local maximum but does not satisfy aggregate production efficiency. While at a local maximum it is not possible to make marginal changes to increase utility, it may be possible to increase utility simply by reorganizing production among the firms to produce more of each commodity. But, as he then proves, even in simple economies with increasing returns there does not exist a decentralized process which converges to a global optimum.

It is however, possible to construct a process which has nice convergence properties at the cost of giving up decentralization as defined in D.10. This was shown by Cremer (1977). He considers a quantity–quantity algorithm in which the CPB, as in Malinvaud (1967) and Weitzman (1970), possesses a memory and builds up successive approximations of the firms' production sets and solves the programming problem. This process is in many respects similar to Weitzman's process. Convexity of the production sets was used crucially in Weitzman's process to ensure that when the CPB constructs a new production set, by considering the announced marginal rate of substitution, it knows that no point above the corresponding hyperplane need be considered again. In the presence of increasing returns this is no longer true and in Cremer's process firms do not respond with marginal rates of substitution. The CPB only knows that if a firm responds with a feasible production plan then all production plans which are greater than it can be ruled out of further consideration. Figure 2 shows how the CPB revises its information about the firm's technology. It is assumed that the CPB knows that the optimal production plan $y^* \leq w$. It announces w as a target. If this is not feasible the firm responds

Planning, Fig. 2

v^2
w
y*
y^1
v′

with some y^1 which is feasible and strictly less than w. The CPB then knows that it must now consider only points less than or equal to either v^1 or v^2.If the utility at v^2 is higher than at v^1 the CPB considers its new approximate production set to be the set of all points in Y^1 but equal to or less than v^2. Under certain boundedness conditions it can be shown that this process converges to a global optimum. Since the targets are not necessarily feasible nor is the process.

Public Goods

This section draws heavily on Tulkens (1978). We begin by considering the simple setting of an economy with a single private good y and a single public good z. There are n consumers with continuously differentiable and strictly quasi-concave utility functions $U^i(x^i)$, where $x^i = (y^i, z^i)$. The public good is produced according to the technology of the form $w = g(z)$, where w represents the private good input and g is assumed to be convex. A feasible allocation $((x^i))$ satisfies the conditions that

$$\sum_i y^i + \ w = \sum_i \omega i, \ \ z^i = z \ \text{ for all } \ i \ \text{ and } \ w = g(z).$$

Lindahl (1919) in his positive solution to the public goods problem proposed a process, the convergence properties of which were analyzed by Malinvaud (1971). The Lindahl process concerns a two consumer economy in which the public good is produced under constant marginal cost γ. Each consumer is assigned a share, θ^i in the price of the public good so that $\theta^1 + \theta^2 = \gamma$. Consumers take as given their personalized prices or unit taxes θ^i to determine their demands for the public good. The supply of the public good is made equal to the lower of these two demands and the CPB adjusts the unit taxes by raising the tax on the consumer with the higher demand and lowering it for the other. The process continues as long as the utilities of both the consumers rise. Malinvaud (1971) showed that utilities would not rise monotonically until the two demands become identical and, therefore, this process does not converge to a Lindahl equilibrium. He suggested a modification which ensures convergence to a Pareto optimal allocation (though not necessarily to a Lindahl allocation). In this modified process the CPB announces not only unit taxes but also lump-sum taxes, T^i such that $\Sigma_i T^i = 0$. Let $d^i(\theta^i, T^i)$ refer to consumer i*'s* demand for the public good and $\overline{d}$ the corresponding average demand. The CPB adjusts i's unit tax in proportion to the difference between d^i and $\overline{d}$. Supply is made equal to the average demand and T^i is adjusted to compensate i for the change in θ^i. Formally the adjustment equations are, (i) $\dot{\theta}^i = a\left[d^i - \overline{d}\right]$ for all i, (ii)$T^{\cdot i} = -(1/n)\sum_i d^i \theta^i$ for all i, where a is a positive constant. While this process converges to a Pareto optimal allocation, it is neither feasible nor monotonic.

An alternative would be to consider a process in which the CPB responds with quantities rather than prices. The Malinvaud–Drèze–de la Vallée Poussin (MDP) process, formulated by Malinvaud (1970–71) and Drèze and de la Vallée Poussin (1971), is a quantity guided process in which the CPB announces an allocation and the agents respond with rates of substitution. Starting with a feasible allocation, the firm reports its marginal cost γ and each consumer reports his or her marginal rate of substitution of the public good for the private good π^i. The adjustment takes place according to the following differential equations, (i) $\dot{z}_t = \dot{z}^i{}_t = a\left(\sum_i \pi^i{}_t - \gamma_t\right)$ for all i, (ii) $\dot{w}_t = \gamma_t \dot{z}_t$ (iii) $\dot{y}^i{}_t = \pi^i{}_t \dot{z}_t \ + \delta^i a\left(\sum_i \pi^i{}_t - \gamma_t\right)^2$ for all i, where a is a positive constant and $\delta^i \geq 0$ for all i and $\Sigma_i \delta^i = 1$.

Since the process starts at a feasible allocation, (ii) ensures that the process is feasible. It has also been shown that it converges to an allocation at which the first order conditions for optimality are satisfied, that is, the sum of the marginal rates of substitution equals the marginal cost. The MDP process is also monotonic. To see this consider

$$\dot{U}^i = U^i y^i\left(\cdot^i + \pi^i \cdot\right).$$

Using (i) and (ii) this can be rewritten as

$$\dot{U} = \ U^i y^i \delta^i a \left(\sum_i \pi^i - \gamma \right)^2 \geq 0$$

While the MDP process converges to some Pareto optimal allocation depending on the choice of the distribution profile $((\delta^i))$, Champsaur (1976) has shown that the process is neutral in the sense that given any initial allocation and any Pareto optimal allocation which is Pareto superior to this allocation, there exists a distribution profile with which the MDP process converges to the given optimum. A discrete time version of the MDP, with the same performance properties, was provided by Champsaur et al. (1977).

Malinvaud (1970–71) and Drèze and de la Vallée Poussin (1971) also extend the MDP process to an economy with many private and public goods by considering the MDP process as described above for public goods and a quantity guided process for the private goods. Another alternative, considered in Aoki (1971b), Malinvaud (1972) and Champsaur et al. (1977), is to construct a process which combines the MDP process with a price guided process for private goods. These processes, however, have to deal with a well known problem, namely one of ensuring convergence of a price guided process in an economy with many consumers without making the gross substitutability assumption.

Aoki (1971b) considers an economy with many private and public goods and many firms and consumers. He avoids the income distribution problem by specifying a social welfare function. The CPB announced prices of the private goods and quantities of the public goods. Firms maximize profits and report input demands and marginal costs for public goods. The CPB increases private goods prices according to the difference between marginal utilities and prices and the public goods levels are adjusted according to the difference between marginal utilities and marginal costs. This process is feasible, monotonic and convergent.

Malinvaud (1972) formulates a price guided process for allocating not only private goods but also public goods. The gross substitutability assumption is avoided by specifying individual incomes as proportions of aggregate income and revising them during the process (notice that Malinvaud's 1971, price guided process also made use of lump-sum transfers). This process converges locally but is neither feasible nor monotonic.

Champsaur et al. (1977) present a process which combines in a sequential way an MDP process for public goods allocation with a price guided process for private goods allocation. Given public goods' levels a price guided process is used to allocate private goods. Then keeping fixed the levels of all except one numeraire private good, the MDP process is applied to allocate public goods. This process is shown to be feasible, monotonic and convergent to some Pareto optimal allocation.

Given the difficulty in using a price guided process when there are many consumers, it is perhaps not surprising that a satisfactory process which converges to a Lindahl equilibrium has not been established, although some results are available in this direction (see Milleron 1974).

Plant, Arnold (1898–1978)

Ronald H. Coase

Sir Arnold Plant, Professor of Commerce (with special reference to Business Administration) at the London School of Economics, was born in 1898 in Hoxton, in East London, the son of a municipal librarian. He died in 1978. He served on numerous government committees, particularly in the years after World War II, and was knighted in 1947. Most of his important contributions to economics were reprinted in *Selected Economic Essays and Addresses* (1974).

On leaving school he joined a mechanical engineering organization and in 1920 became manager of the Steam Fittings Company. Advised by William Piercy (later Lord Piercy) that he ought to learn something about management before doing much more of it, he enrolled at the LSE, where he studied for the BCom as an external student and the BSc(Econ.) as an internal student, specializing in modern economic history. He was awarded the BCom in 1922 and the BSc(Econ.) in 1923. The teacher who most influenced him was Edwin Cannan, the Professor of Political Economy, whose views and commonsense approach to economic analysis and economic policy were to be reflected in Plant's own work.

In 1923, Plant was appointed Professor of Commerce at the University of Cape Town. The only one of his writings in South Africa reprinted in the 1974 volume was an essay published in 1927 dealing with the economic relations of the races. It was a trenchant attack on the South African government's policy of separation of the races. This policy, Plant argued, arose out of a desire to stifle competition from the native peoples and was economically injurious to South Africa. He advocated the provision of educational opportunities and other measures designed to bring the natives into Western society. While at Cape Town he gathered materials later used in the chapter on Economic Development which he wrote for the volume on South Africa of the *Cambridge History of the British Empire* (1936).

In 1930 Plant became Professor of Commerce at LSE. In addition to his lectures to the BCom students, he also taught in the postgraduate Department of Business Administration, of which he later became Head. His analytical system was unsophisticated but powerful. He thought of the economic system as essentially competitive, with monopoly transitory and relatively unimportant. The State had a role in providing law and order but State intervention commonly promoted monopoly and, as in South Africa, was designed to promote the interests of groups with political power. He was especially interested in attempting to understand the reasons which led to the adoption of various business practices.

Inspired by David Hume's treatment of the subject, he developed an interest in property and the economic function of ownership. This led Plant to write in the early 1930s two articles, one on patents for inventions and the other on copyright in books (both reprinted in the 1974 volume). These articles rank as his major achievement in economics. He questioned the need for property rights in patents and copyright. They did not arise out of scarcity but created scarcity by establishing a monopoly. He pointed out that British authors had received handsome incomes in America although they possessed no copyright there while much invention goes on even though the resulting improvements are not patentable. If the existing law was to be retained, he suggested that modifications should be made such as making Licenses of Right the normal practice in the case of patents.

Plantations

Adrian Graves

The economic, social and political importance of plantations in many regions, the longevity and ubiquity of the institution, its association with slavery and other forms of bonded labour and with colonialism, has given rise to an extensive and rich literature which spans many scholarly disciplines including history, sociology, politics, psychology, anthropology, archaeology and geography. Economists and political economists have been preoccupied with explaining the origins of plantations and evaluating their social and economic effects, both locally and in the broader context of the world economy. A survey of the intellectual origins and thrust of the most recent economic literature, however, illustrates the immense difficulties of theorizing the plantation. The failure to derive universally applicable definitions of the plantation and of the plantation economy lies at the heart of the problem.

The meaning of 'plantation' has changed markedly over time. Originally, it referred to a plot of ground set with plants or trees. With the onset of British overseas expansion, plantation officially designated a group of settlers or their political units, hence 'Ulster Plantation' or the 'Caribbean Plantations', but this usage was eventually replaced by 'colony' and the use of 'plantation' became restricted to farms or landed estates. In this sense, the word has been applied especially in tropical or subtropical countries though units of agricultural production in temperate or non-tropical zones, such as in parts of Europe and the Middle East, have also been referred to as plantations.

The range of plantation crops is also extremely diverse, including sugar, coffee, tobacco, tea, cocoa, bananas and other tropical or sub-tropical fruits, chewing gum (chicle), rice, tree spices, such as nutmeg, cloves, cardamon, mace, vanilla, cinnamon, garden crops like ginger and pepper and industrial raw materials such as cotton, indigo, copra, oil palm, sisal, cinchona and rubber. Although plantations are frequently typified as monocultural institutions, many plantation products were grown either as subsidiary crops or they were combined with the cultivation of cereals, temperate zone fruits such as citrus, market garden crops and even with livestock production.

Most plantations combined an agricultural with an industrial process, though they were not of necessity bifurcated institutions. The scale and sophistication of the technological forms on plantations and associated infrastructures, as well as the structures of ownership and control of plantations have varied markedly according to time and location. Plantations have also seen many modal transformations, being based on slavery, a variety of feudal forms, peonage systems, long contract migratory or indentured labour and free wage labour. There are many examples of plantations, for instance in Latin America, that operated on a mixture of labour forms, in economies which articulated around a variety of modes of production. The extraordinary diversity of geographical location, crops, sources of labour, ownership or control and technological forms over time have created major difficulties for the scientific definition of the plantation.

All definitions of the plantation attempt to differentiate it from other agricultural or agro/industrial institutions, frequently, by very general characteristics such as climate, crop type or specialization, export orientation, spatial size, number of employees, or by its system of power or authority structure. Some writers lay particular stress on labour force characteristics, its degree of bondage, skill levels, the tendency of work to be organized cooperatively around gangs, the stability or permanence of the workforce, and cultural and ethnic or racial criteria. For others, factor proportions are paramount although the emphasis on specific factor ratios varies widely in the literature. Whereas a number of writers emphasize the capital intensive nature of plantation production (such as Paige's high capital/labour approach: Paige 1975), others (e.g Stinchcombe 1961) define plantations as peculiarly land intensive units of production (see Pryor 1982, pp. 289–91).

Since most definitions are developed to service the analysis of a particular economy, region or timespan, the enormous degree of variability in plantation production has led to a plethora of definitions stressing markedly different criteria which are frequently contradictory. This is particularly evident, as we have already noted, in the literature which typifies plantations according to factor proportions, or that which lays stress on the level of work skill, which is particularly low according to some writers (e.g. Baldwin 1956; Stinchcombe 1961) and especially high according to others (e.g. Wolf and Mintz 1957). Precise definitions of the plantation inevitably exclude institutions which might justifiably be considered as such: the stress on the unfree nature of the plantation labour force, for example, rules out consideration of plantations based on wage labour. The most general definitions, however, inevitably incorporate a wide range of other agricultural institutions, including production units as varied as Roman latifundia, large estates in Byzantine Egypt, feudal estates, colonial agricultural missions, cooperative estates, state farms, modern capital or labour-intensive sugar or cotton estates, ranches or pastoral stations, and large corporate farms. Needless to say, the scholarly difficulties of defining plantations are reflected in the attempts to theorize the broader concept of the plantation economy.

The theory of the plantation economy has a long and rich intellectual pedigree, drawing upon classical and marxist traditions. Its classical intellectual origins can be traced back to the debates on land/labour ratios in the early 19th century which involved Ricardo, Wakefield, Torrens, Merivale and John Stuart Mill. Merivale, in particular, stressed the dominant role of the plantation in the ex-slave economies of the West Indies. It was left to the Dutch scholar H.J. Nieboer to expand the scope of the debate by transforming the undifferentiated notion of the influence of the plantations in the tropical economies into a general theory. He characterized differing types of colonial society according to the theory of open and closed resource systems, identifying the initial absence of permanent settlement as a pre-condition of plantation production, the necessity of formal compulsion of the labour force, and the subsequent engrossment of the optimum available land as the hallmarks of plantation production and subsequently of plantation economies and societies. In the 1930s and 1940s, Edgar T. Thompson incorporated the concepts of open and closed resource systems into a theory of social change in plantation society, through which he attempted to identify disintegrating forces inherent in the plantation which also emerged as important factors in the wider economy and society.

The influence of Nieboer and Thompson was extended by studies of wage and slave plantations undertaken in the 1950s and 1960s. The work of Mintz and Wolf stands out in this respect, especially in an important article on plantation society in Central America and the Caribbean which distinguished haciendas from plantations and developed the notion of old and new style plantations (Wolfe and Mintz 1956). Whereas the former were precapitalist with surpluses directed at conspicuous consumption, the latter were typified as capitalist enterprises driven by the process of surplus extraction to service capital accumulation. This work opened up associated discussions in marxist theory on the nature of a mode of production in which distinctions between slave plantations and capitalist institutions continue to play an important part. But it was the work in the late 1960s and early 1970s, of a group of Caribbean social scientists known as the New World Group, most prominently Lloyd Best and George Beckford, that attempted to integrate the classical literature on slave plantations with the then emerging marxist debate on underdevelopment as a means to analyse post slave plantation production. This work has been extremely influential in the most recent literature on plantation production and warrants closer examination.

Best’s contribution has been to try and develop a universally applicable model of a ‘pure plantation economy’. In so doing, he drew heavily upon the intellectual heritage of Nieboer and Thompson, incorporating also Erving Goffman’s notion of the) ‘total institution’:

Where land is free to be used for subsistence production the recruitment of labour exclusively for export production imposes a need for ‘total economic institutions’ so as to encompass the active existence of the workforce. The plantation which admits virtually no distinction between organisation and society, and chattel slavery which deprived workers of any civil rights including the right to property, together furnish an ideal framework (Best 1968, p. 287).

This conceptualization was subsequently elaborated by Beckford (1972) to include a vigorous critique of the dual economy and, most significantly, to demonstrate the meagre spread effects of modern plantation production.

Beckford distinguished between the mainly temperate) 'colonies of settlement' (Australia, New Zealand, Canada and the United States of America) and tropical 'colonies of exploitation', observing that the pattern of agricultural production which emerged in the two types of colonies was significantly different. Generally speaking, Beckford's attempts to develop a theory of modern plantation production rests upon this basic distinction, (as does the more recent work of de Silva 1982) with plantations being identified firmly with the tropical colonies of exploitation. Although he specified two exceptional types of plantation economy the plantation sub-economy (USA, north–eastern Brazil, Honduras, Guatemala, Costa Rica and Panama) and the enclave plantation economy (Liberia, Kenya, Rhodesia and South Africa) Beckford based his argument about the meagre spread effects of plantations on a general model of the plantation economy, namely,

> Those countries of the world where the internal and external dimensions of the plantation system dominate the country's economic and social and political structures and its relations with the rest of the world . . . wherever several plantations have come to engross most of the arable farm land in a particular country which is predominantly agricultural, that country can be described as a plantation economy or society and its social and economic structure and external relations will be similar to those described for the plantation system (Beckford 1972, p. 12).

Whilst he recognized that the potential for efficient resource use within the firm or particular plantation, Beckford argued that plantation agriculture was essentially unproductive, and that plantations exercised a pervasive economic, social and political influence over their areas which reinforced and perpetuated the underdevelopment of those economies. The fact that these local characteristics occurred within the wider context of dependent, exploitative, metropolitan/periphery financial and trading relationships is an important component of Beckford's argument concerning the meagre spread effects of plantation production. His general conclusion was that) 'regardless of the type of plantation that predominates in any given situation, the result is always the same – a persistent tendency towards underdevelopment (Beckford 1972, p. 213). It is important to appreciate that Beckford's typology of plantation production was meant to be appropriate for all major areas of plantation production regardless of whether or not the institution had originated in the slave based mercantilist empires of the New World.

The most recent studies of plantation economies have built upon the important work of the New World Group. Mandle in particular owes a great debt to Beckford, but he also incorporates other long-standing assumptions in the literature on plantation production. Thus he puts great stress upon the innate inefficiency and inflexibility of plantation production. While this was due to a number of factors, the characteristically coerced and cheap plantation labour force was the 'key' to low productivity, because it provided planters with little incentive to innovate at the critical level of cultivation technology or to escape from their dependence upon international markets. It was partly through his stress on labour force characteristics, that Mandle underlined the importance of going beyond the analysis of the plantation merely as a productive unit (compared, for example, with the approach of the frequently quoted William O. Jones: see Jones 1968) to embrace the distinctive kinds of social and production relations which derive from the plantation structure. On this basis, he distinguished from the growth-oriented capitalist mode of production, his notion of the) 'plantation mode of production' by which he meant the) 'growth inhibiting social structure' typical of plantation economies. Four attributes characterize Mandle's plantation mode of production; large-scale agriculture dominates the society; the domestic labour supply is inadequate to meet the labour demands of the agricultural sector; labour is mobilized and allocated by non-market mechanisms (coercion) which in turn define the nature of class relations in the society; and these class relations are reinforced by a distinctive culture (Mandle 1982, pp. 37–8). The pivotal idea in Mandle's work, that the plantation mode of production inherently constrains its own technological advance and therefore the broader development of the forces of production in the plantation economy, has been supported in important studies of Louisiana agriculture by Ferleger (e.g. Ferleger 1984) and although it does not necessarily imply Mandle's model, the phrase 'plantation mode of production' is assuming a wider currency in the literature.

Although it has contributed considerably to our understanding of the institution's economic, political and social impact, the recent literature illustrates the formidable difficulties of developing a dynamic economic theory of the plantation. For one thing, it confuses model building with theorizing. Theory in history must incorporate process. Unquestionably, the recent theorists of the plantation recognize that the current state of the economies they address has historical roots. In the final analysis, however, the 'theories' of Best, Beckford and Mandle, go little beyond listing a set of distinctive, generalized characteristics of the plantation and of the plantation economy. To that extent, their typologies are static and therefore ahistorical. At another level, the primacy they place on the nature of the plantation itself and its function in the wider economy and society, effectively denies a role to human agency in the history of plantation economies.

To the extent that the literature incorporates the notion of underdevelopment, it is subject to the same sorts of criticisms which have more recently been marshalled with some force against André Gunder Frank and others (including Immanuel Wallerstein) by writers from both the marxist and neoclassical perspectives. In particular, Beckford's concern to identify the domination of the world market and the demands of capital reproduction as the arbiter of the rate of capital accumulation in plantation economies deprives his typology of the plantation of any laws of motion. Do plantation economies merely vegetate 'on the periphery of an industrializing Europe like a vast reservoir of labour-power periodically called into action by the spasmodic actions of metropolitan capital,' like the underdeveloped ex-colonies of Frank and Laclau's Latin America? (Banaji 1977, p. 14).

As to the 'plantation mode of production', other writers have noted the analytical difficulties of the more general concept of mode of production. Even within Marx, the application of the concept is confusing and even contradictory (does it mean the 'labour process' or an 'epoch of production': Banaji 1977, pp. 4–5). But the problems of that idea are compounded substantially when it is ahistorically applied to forms of production which cover a wide chronological range, incorporating changing, even co-existing, different patterns of production relations, as McEachern (1976) has demonstrated in his criticisms of Alavi's 'colonial mode of production'. The same sorts of criticisms can be addressed to Mandle's apparently timeless notion of the 'plantation mode of production'.

Beyond these broad points, a major weakness of the recent literature arises from its tendency to generalize about the impact of (exclusively sugar cane) plantations on the basis of a Caribbean/American paradigm. In respect of that region alone, other research casts doubt on the supposed inflexibility and inertia of plantation production even under slavery (Fogel and Engerman 1974; Drescher 1977; Ward 1985) but also under systems of indentured labour (Saha 1970; Beechert 1987). Moreover, the characteristics and performance of sugar plantations in other regions, both in micro and macro terms, do not fit the Beckford/Mandle typologies. In 19th-century Queensland, Natal and Hawaii, for example, plantations did not of necessity dominate their areas and they proved to be not only highly flexible and dynamic institutions experiencing revolutionary changes in production over relatively short time periods, they stimulated rather than retarded local economic development, as have plantations more recently in Kenya (Graves and Richardson 1980; Pryor 1982; Beechert 1987). Recent studies of colonial Latin America show that dynamic growth and flexible response was also a feature of plantation production in underdeveloped economies as well, not only in respect of cane sugar production but also in coffee, an important crop which is all but ignored by the theorists of the plantation economy (Duncan and Rutledge 1977).

There is no doubt that much of the dynamism of plantations, especially in the late 19th century, was due to a revolution in the processing technology of the major plantation crops. This performance, contrary to the claims of the Mandle model, was also attributable on sugar plantations to significant innovations in the plantation cultivation process under production imperatives and structures which were unambiguously capitalist. While it is true that cane harvesting equipment was not successfully employed until the mid-20th century, the immense technical difficulties of that sort of machinery cannot be underestimated. Important innovations in cultivation technology were not confined to the more developed economies which supported plantation production. Java, for example, boasted a long history of agricultural research and development in the 19th and early 20th centuries which saw amongst other achievements, the emergence of the famous P.O.J.100 cane variety which transformed cane cultivation on an international scale. Less spectacular but no less significant innovations in the cultivation process were frequently introduced in many plantation economies by workers to raise their productivity under piece rate regimes, such as the redesigning of cane knives to suit local conditions.

Despite its weaknesses, the best recent literature on plantation production has attempted the important and urgent task of identifying the distinct economic rhythms and movements of modern colonial plantation production. Whilst the literature owes a rich debt to the classical formulations on plantations, it has also accommodated more recent theoretical approaches to colonialism and metropolitan–periphery relations. It is evident, however, that it is extremely difficult to theorize the plantation. Whilst the immense problems of defining a plantation suggest that its use as a descriptive term of agricultural organization its itself problematic, the scientific rigour of 'plantation' has very severe limitations. It appears to be unable to make analytic distinctions between agricultural production of tropical produce under the markedly different labour forms of slavery, feudal labour service, indentured labour, peonage, short-contract immigrant workers, or free labour. Nor does it distinguish between monopolistic and competitive land conditions. The revolutionary impact of changes in technology has not been sufficiently well accommodated.

Studies of plantations outside the Caribbean and the Americas indicate that the 'plantation economy' cannot be understood merely in terms of the logic and form of the plantation as a productive unit or of the plantation sector, but in the various combinations of relations of production which characterize the particular economies within which plantations operate. The explanation for the character, persistence or transformation of plantations therefore, must go beyond the discrete analysis of the institution itself and be sought more explicitly in the demands of capital accumulation under specific and changing conditions of capital markets and land ownership, labour availability and productivity, the changing technologies of cultivation and industrial processes and the consumption and distribution structures of plantation products. Only then will the laws of motion of the plantation become apparent, as will the forces tending to undermine or conserve this form of production. There is no doubt that the considerable gaps in our knowledge about plantations, despite an extraordinarily rich scholarly literature on the institution, is due to the paucity of rigorous empirical studies which address the wider conceptual issues. While that remains the case, economic theories of the plantation and of the so-called plantation economies will continue to remain unsatisfactory.

Playfair, William (1759–1823)

H. E. Egerton and F. Y. Edgeworth

Playfair attempted in his youth with little success to combine the positions of inventor and tradesman. He went to Paris, and in 1789 became agent to an American Land Company, the operations of which were disastrous to those sent out. On returning to London he opened a 'Security' Bank, which, however, soon collapsed. After Waterloo he returned to Paris as editor of *Galignani's Messenger*, but had to leave France to avoid imprisonment on a judgement in an action for libel. His publications were very numerous; many were directed against the French, and he advocated the issue of forged assignats. In the *Gentleman's Magazine* (1823, pt. i. 564) is an imperfect list of forty-one pamphlets and books, among which are *A General View of the Actual Force and Resources of France* (1793); *Better Prospects to the Merchants and Manufacturers of Great Britain* (1793); *Letter to Sir Wm. Pulteney on the establishment of another Public Bank in London* (1797); *Statistical Tables, from the German of Boetticher* (1800); *Statistical Account of the US from the French* (1807).

He published anonymously in 1785 *The Increase of Manufactures …*, a proposal to establish a fund for lending sums of money at an interest suited to the circumstances of each case. In 1786 appeared *The Commercial and Political Atlas* (brought up to date in two successive editions 1787 and 1801), remarkable for the application of the graphical method to the statistics of finance. The method is thus introduced:

Suppose the money that we pay in any one year for the expense of the navy were in guineas, and that these guineas were laid down upon a large table in a straight line and touching each other, and those paid next year were laid down in another straight line, and the same continued for a number of years, these lines would be of different lengths as there were fewer or more guineas; and they would make a shape, the dimensions of which would agree exactly with the amount of the sum (*Atlas*, 1st edition; the illustration is varied in subsequent versions).

By this method 'as much information may be obtained in five minutes as would require whole days to imprint on the memory ... by a table of figures'. Thus ordinates at points on a horizontal line represent the amount of exports and of imports at each epoch; the difference between them – forming a stream of varying width – represents the balance of trade. That Playfair should give prominence to this conception is remarkable, as his observations on our trade with France evidence a just sense of the mutual interests of the parties to international trade.

The *Real Statement of the Finances and Resources of Great Britain* (1796) contains some good remarks on the depreciation of money: 'If money should decrease in value faster than the debts increase, then the burdens of the people, though nominally augmenting, may be actually diminishing.' The rudimentary idea of an index number may be noticed in the Appendix, p. 29.

In the *Inquiry into the ... Causes of the Decline and Fall of ... Nations*, which appeared in 1805, Playfair pretends to apply his method to ancient history. In the preface he acknowledges obligation to his brother Professor John Playfair for the idea of the new method. In the same year (1805) Playfair published an edition of *Wealth of Nations*, which contains some acute criticisms; for instance, on Adam Smith's doctrine that 'the more a man pays for the tax the less he can afford to pay for the rent' [of a house] (*Wealth of Nations*, V, ch. ii); and on Sir Matthew Decker's observation approved by Adam Smith that) 'certain taxes are in the price of certain goods, sometimes repeated and accumulated four or five times' (ibid.). These are supplementary chapters on occurrences in finance subsequent to Adam Smith's time, and on the French 'Economists'. Playfair evinces some acumen as an economist as well as some originality as a statistician.

Pleasure and Pain

F. Y. Edgeworth

Pleasure and pain are the only motives taken account of in political economy in so far as 'it makes entire abstraction of every other passion or motive but the desire for wealth; except those which may be regarded as perpetually antagonizing principles to the desire of wealth, namely, aversion to labour and desire of the present enjoyment of costly indulgences' (Mill, *Unsettled Questions*, p. 138). This abstraction, legitimate within limits, is liable to be strained too far in several directions.

(1) Because economic action is ascribed to utility, it is not to be taken for granted that, as utilitarians have postulated, all action is motived by pleasure. For perhaps 'all that mathematical economics need to assume is that a material quantity of goods will be in a certain proportion to a greater or less strength of motive; whether the motive be taken as "pleasure" or not is not essential' (Bonar, *Philosophy and Political Economy*, p. 224; cf. Sidgwick, *Political Economy*, Bk. i, ch. ii, § 2 note; Marshall, *Principles of Economics*, 3rd edn, pp. 77, 78, note; and *Economic Journal*, vol. iii, p. 388). However, when equilibrium is regarded as the position of greatest advantage to all concerned

(cf. Marshall, *Principles of Economics*, 3rd edn, 526–7, and note xiv), the mechanical analogue being not so much the equality of forces (conceived by Jevons in his analogy of the lever, *Theory*, ch. iv) as the maximum of energy (indicated by Irving Fisher in his *Mathematical Investigations*), there is taken for granted the possibility of summing up pleasures which some opponents of utilitarianism have refused to grant.

(2) For the most abstract part of economics, the theory of exchange, it need not be postulated that each party acts from self-interest, but only that he is not actuated by regard for the interest of the other parties, those with whom he competes or bargains. The efforts and sacrifices which are required to supply markets – including the labour market and the loan market – are often incurred for the sake of one's family rather than oneself. The action of the family affections 'has always been fully reckoned with by economists, especially in relation to the distribution of the family income between its various members, the expenses of preparing children for their future career, and the accumulation of wealth to be enjoyed after the death of him by whom it has been earned' (*Principles of Economics*, Bk. i, ch. v, § 7, 3rd edn).

(3) The limits within which self-interested action must be postulated may be even narrower than those indicated in the last paragraph. What is postulated is that action should be regular and therefore calculable, rather than that it should be self-interested (*Principles of Economics*, Bk. i, ch. v). 'The range of economic measurement may gradually extend to much philanthropic action.'

Plekhanov was a major figure in the development of Marxist economic and political philosophy during the late 19th century. His importance springs from four principal sources. He was the first Russian intellectual to apply Marxist theory to Russian conditions. In so doing, he undermined the intellectual foundations of the Populists (*Narodniki*) and showed the relevance of Marxist economic determinism to Russia. Secondly, he exerted a profound influence upon the Russian revolutionary intelligentsia, persuading many of them to abandon Populism in favour of Marxism. Plekhanov was one of the founders of the Marxist Russian Social Democratic Party. Thirdly, the originality and perception shown in Plekhanov's own voluminous and wide-ranging writings show him to be an outstanding Marxist theoretician. Finally, the approval given Plekhanov's writings by Marx and, especially, Lenin (despite their later disagreements) has assured Plekhanov of an honoured place in Soviet histories of the development of socialist philosophy. Indeed, Plekhanov was one of the two figures whose writings were specifically acknowledged by Lenin as leading to his own conversion to Marxism; the other was Marx.

Plekhanov was born on 29 November 1856 in the village of Gudalovka in what was then the province of Tambov (Lipetsk Oblast). He was the son of a wealthy nobleman and attended military college in Voronezh and the Konstantin Cadets' College in St Petersburg in 1873–4 before entering the St Petersburg Institute of Mines. Here he became influenced by the revolutionary movements of the time and was eventually expelled in 1876 for his part in such activities. In 1875 he had joined the Narodniki and in the following year he joined the newly formed *Zemlya i Volya* (Land and Liberty) *Narodnik* organization – Russia's first political party. This group believed that Russia's future lay with the peasant masses, and that the peasants should be given land. Plekhanov soon became one of the leading *Narodnik writers* and activists, and took part in the 'going to the people' movement. He also gave a speech at a major demonstration organized in 1876 by *Zemlya i Volya* in front of St Petersburg's Kazan Cathedral.

In 1879 the *Narodnik* movement split, the majority faction advocating the use of terrorist tactics. Plekhanov favoured a more moderate approach, and together with a small group of other leading *narodniks* (including Pavel Axelrod and Leo Deutsch) formed the non-violent *Cherny Peredel* movement (Black Repartition – that is, the movement wanted repartition of the fertile Black Soil lands to the peasantry).

In January 1880 Plekhanov emigrated to Europe to escape persecution from the tsarist authorities. He remained in exile until 1917, living in Switzerland, France, Italy and elsewhere, travelling widely throughout the continent. In western Europe he made contact with numerous other Russian revolutionary exiles and also became deeply interested by Marxist thought. From about 1882 he became a fervent advocate of Marxism, and in his writings he now sought to establish the relevance of Marxism to Russian conditions and to undermine the intellectual foundations of Russian Populism. In 1883 Plekhanov founded in Geneva Russia's first Marxist Social Democratic organization, the Liberation of Labour. The group translated into Russian and published many works by Marx and Engels, Plekhanov himself translating the *Communist Manifesto*.

During the 1880s and 1890s Plekhanov wrote his most influential works, denouncing not only the Populists but the Legal Marxists and the Economists (Marxist factions which developed after 1895), and he put forward his own interpretation of the path towards socialism which Russia was to follow. The root of his philosophy was in what he termed 'scientific' historical materialism, exposing the *narodniks* as 'unscientific'. In Plekhanov's view, revolution could not succeed unless it has the support of the class-conscious masses. Revolution could not come from the agrarian peasantry, and must come from the urban proletariat. As he argued in *Socialism and the Political Struggle* (1883) and *Our Differences* (1885a), the utopian socialists (Blanquists) were mistaken in their reliance on intellectual conspiracy alone: revolution could succeed only as a result of a class struggle emanating from the working classes. It therefore became important for Plekhanov to demonstrate that Russia's path towards socialism could not come, as the *narodniki* argued, from the village-based commune (*mir*) and the peasantry. Capitalism in Russia was a necessary phase of historical development and was not 'accidental' or 'non-Russian'. Indeed, in Russia of the 1880s capitalism was already a reality.

To be sure, Plekhanov's theories contained many obscurities and contradictions.

Fundamental were the dichotomies between economic determinism and the role of the revolutionary, and also between the reliance on the class-conscious urban masses and the evident industrial backwardness of Russia. Plekhanov 'solved' the problems, albeit unsatisfactorily, by arguing that the Russian revolution could be accelerated by the role of the revolutionary intelligentsia, whose activities were to compensate for the lack of a middle class. He wrote in *Our Differences*: ‘Our capitalism will fade without ever having flowered.’

Particularly influential was Plekhanov’s *The Development of the Monistic View of History*, which was brought to Russia by the Marxist publisher Potresov in 1894. Here Plekhanov elevated the ‘objectivism’ of Marx in contrast to the subjective values of the *Narodniki*. He wrote, ‘the criterion of truth lies not in me, but in the relations which exist outside of me’. Thus, objectivity was possible in social theory. Plekhanov drew from Marx, and from the traditions of the English economists and German historicists, the fundamental principle that economic forces determine social development.

Plekhanov was active in the Second International (1889) and attended its Congresses in Zurich (1893), Amsterdam (1904) and Copenhagen (1910). Together with Lenin, Martov and Potresov, Plekhanov founded *Iskra* (The Spark) in 1900 – the first Russian Marxist newspaper. In 1903 he worked jointly with Lenin to draw up the programme adopted at the famous Second Congress of the Social Democratic Party, but it was shortly after this that Plekhanov broke with Lenin and the Bolsheviks and sided with the Mensheviks. During the Revolution of 1905.

Plekhanov advocated an ‘opportunist’ alliance with the liberals, while in 1914 he supported the war against Germany for the defence of Russia (in opposition to Lenin and the Bolshevik position). In that year he formed the *Yedinstvo* (Unity) group, which was designed to bring together the Mensheviks and the anti-Lenin Bolsheviks, but its influence was negligible.

After the Revolution of February 1917 Plekhanov returned to Russia, supporting the Provisional government and the continuation of the war. He denounced the Bolshevik coup of October 1917, and shortly afterwards fell ill with tuberculosis. Ostracized by Lenin and terrorized by the Cheka, Plekhanov’s wife took him to Finland, where he died on 30 May 1918.

Despite his differences with Lenin and the Bolsheviks after 1903, Plekhanov’s writings continued to be highly regarded and widely studied in the Soviet Union. During the 1920s his library and archives were gathered from a number of European centres and taken to Leningrad, where the Plekhanov Library was established, and his complete writings were published.

Pluralism in Economics

Sheila C. Dow

Abstract

This article explores the meaning of pluralism in economics and the arguments put forward in support of it. In particular, the distinction is drawn between methodological pluralism (support for variety in methodological approach) and a pluralist methodology (one which employs a variety of methods). Methodological pluralism usually takes the form of arguing that it is in the nature of knowledge about social systems that there will be variety of methodological approaches. But prescriptive arguments for a particular pluralist methodology may accompany the argument that this is the single best methodology (methodological monism).

Pluralism is the advocacy of plurality (Mäki 1997), or variety, and has been featured increasingly in discussions of economic methodology. Indeed, the International Confederation of Associations for Pluralism in Economics (ICAPE) is an umbrella organization for around 40 international economics organizations.

The term 'pluralism' was first used in modern methodological discourse by Bruce Caldwell (1982) in *Beyond Positivism*. Here he charted the growing dissent from a positivist methodology that had been put forward within a monist approach, that is, the advocacy of a single, best methodology. Positivism had prescribed progress in knowledge by means of empirical testing of propositions. Yet it had proved impossible to express all propositions in testable form, and difficult to derive definitive empirical tests for those propositions which were quantifiable (partly because of the so-called 'Duhem–Quine problem'). Caldwell concluded that, rather than searching for some other, elusive, monist methodological approach, economists should accept that a range of approaches could legitimately be sustained (though he later expressed the hope that there would some day be agreement on one best methodological approach: Caldwell 1989). We will use Caldwell's term 'methodological pluralism' for pluralism at this level of methodological approach.

The implication of methodological pluralism is that methodologists should study (critically) a range of methodologies rather than seek to identify one (universally) best methodology. Practising economists must, however, choose one methodological approach or another, but may nevertheless support methodological pluralism by accepting that, while they may have good reason for their choice of approach, they accept that its superiority cannot be demonstrably proven. This chosen methodology itself may (or may not) be pluralist, that is, employ a variety of methods. Similarly, there is scope for plurality at the theoretical level, whether or not there is methodological pluralism, or a pluralist methodology. Thus, for example, Colander (2000) draws the distinction between the theoretical pluralism of mainstream economics and its monism in terms of formalist method (see also Goodwin 2000). There has been considerable confusion in the literature between the meanings of pluralism at these different levels. No doubt this stems in part from the fact that many who support pluralism at one level also support it at another; but one does not necessarily entail either of the others.

Since Caldwell's initial proposal, a range of further arguments has been developed for methodological pluralism. Samuels (1997) has been a consistent exponent in practice of methodological pluralism, even before it had been explicitly identified (Caldwell 1997). His support arises from a critique of prescriptive epistemology, on the constructivist grounds that our knowledge of the economy is situated, and the economy itself is a social construction, so that there is no scope for a common methodological approach to knowledge. Samuels's argument is consistent with the postmodern critique that emphasizes the absence of independent facts by which to test theories, which follows from the subjective and fragmented perceptions of experience (a plurality of understandings). Samuels is explicitly prescriptive at the meta-methodological level – he positively advocates methodological pluralism (but that is the limit of his prescription). Postmodernists agree with Samuels that there is no basis for any form of limitation on plurality, but go further in arguing that there is no role for prescriptive methodology at all. It follows that methodological pluralism has no meaning for them, since it is a prescriptive position.

Weintraub (1989) and McCloskey (1983) draw the distinction between prescriptive, 'large M', Methodology and descriptive, 'small m', methodology. Thus the science studies and rhetoric approaches, respectively, see a role for the second in providing descriptive accounts of different methodological approaches. This takes the form of recognizing methodological plurality as a feature of the subject matter, while not advocating it. Although not prescriptively methodological pluralist themselves, Weintraub and McCloskey nevertheless support a weak form of pluralism, which takes the form of an ethical argument. If there is a plurality of methodological approaches to economics (that is, economics is not defined by a particular methodological approach), then our discourse should be structured in such a way as to take that on board. Thus there are injunctions to practising economists to respect the legitimacy of expressions of methodological difference, be polite and so forth (McCloskey 1996; Screpanti 1997).

While much of the support for pluralism has focused on knowledge limitations, others (including Caldwell 1997) have extended the argument to the nature of reality. Dating back to Keynes's (1921) *Treatise on Probability*, it has been argued that the organic nature of the social world means the absence of law-like behaviour. It is not just that the capacity for knowledge is limited, but that the basis for laws is not there to be found. Since the social world is believed to be open, it requires an open system of knowledge, one which allows both for change and variety in methodological approach (Chick and Dow 2005).

Keynes had argued further that reliable knowledge is derived from accessing a range of sources, given that there is so little scope for establishing demonstrably true knowledge. In the absence of certainty as to premises, classical logic is of limited use, so reason employs 'human logic'. While rationalism is inadequate as a basis for action, human logic rather involves drawing on evidence and theoretical knowledge, supplemented by conventional opinion and intuition. The weight of argument is greater, the greater the number of sources of knowledge which support the hypothesis. This is to be distinguished from the probability that the hypothesis is correct, which probability may rise or fall with new evidence. This is an argument for a pluralist methodology, that is, a methodology that employs a range of methods. Inevitably this means methods beyond mathematical formalism, since one of the main attractions of that method is that all arguments can be expressed commensurately and can therefore be collapsed into one formal argument, or model. But the reasoning can also be applied to the meta-methodological level, to support methodological pluralism. If a policymaker perceives support for a particular policy from a range of methodological approaches, weight is added to the view that the policy is a good one.

If no single methodological approach can be demonstrated to be universally the best one, then it is to be expected that there will be a range of methodological approaches, even without the added, Keynesian, argument that this is desirable. This range is bound to have some limits, given that science operates within loose communities, requiring shared understandings of reality (ontologies) and of meanings of terms, and shared views as to how to proceed to build up (fallible) knowledge. These communities can be understood in Kuhnian terms as paradigms (Kuhn 1962). This advocacy of variety of methodological approach limited according to the requirement for viable scientific communities is termed variously 'critical pluralism' (Caldwell

1997), 'principled relativism' (Davis 1999) or 'structured pluralism' (Dow 2004). Each of the range of methodological approaches involves a different set of views as to how best to build up knowledge. Some will be pluralist, advocating the use of a range of methods, but this does not necessarily follow from the application of methodological pluralism. There are trade-offs involved in whatever methodology is chosen, and the benefits of a single commensurate method may be judged to outweigh the epistemological costs. But those approaches which adopt a pluralist methodology will be distinguished by the selection of methods employed. This in turn follows from ontology, the understanding of the nature of the subject matter. An understanding of economic relations in terms of class implies one set of methods, in terms of competitive markets another, and of individual entrepreneurial creativity another, for example.

The focus on the ontological level for the case for pluralism owes much to critical realism (Lawson 1997, 2003). However, critical realists themselves take a particular position on pluralism. The case is made that the real world is open, requiring an open-system epistemology. The open-system nature of the real world means that knowledge is situated and contestable, and therefore there is likely to be a range of methodologies; to that extent critical realism is methodologically pluralist. But, since there is one external real world, there is only one ontology, and one open-system meta-methodology. Different methodologies simply reflect different 'commitments' with respect to that common ontology; beyond that no judgement is to be expressed on the content of these methodologies. This approach differs from the structured pluralist position outlined above, whereby different methodological approaches follow ultimately from the plurality of ontological understandings (with respect to a common external real world). However, critical realists also support the idea that methodologies should be pluralist, adopting a range of methods suited to the chosen focus of analysis.

Finally, the argument that plurality of methodology is not only inevitable but desirable is supported by means of a biological metaphor (Hodgson 1997). The view that the real social world is open involves the view that it undergoes structural change. Even if it were generally agreed that a particular methodological approach is best suited to the current economic structure, it is not unlikely that this approach would not be capable of addressing change in that structure. In the biological world, a dominant strain of a species may not be able to survive an environmental shock. Unless there is a range of alternative strains, including one better suited to the new environment, the species will die out. Since the nature of environmental shocks in general cannot be predicted, it is necessary for the survival of the species for there to be a range of alternative strains available at any time. The same argument can be made for different methodological approaches to economics.

Plutology (Gr. πλοῦοσ, Wealth)

A. W. Flux

This term was used by Courcelle-Seneuil to describe that part of his treatise on political economy which dealt with what is described by some more modern writers as ‘pure theory’; that scientific study of the results of the action of economic motives on men and societies to which the terms ‘economics’ and ‘economic science’ have been applied in the effort to escape the confusions which arose from embracing under the general title) ‘political economy’, both these more abstract investigations and the application of the knowledge thus gained, with that derived from other sources, to problems of practical statemanship. To this second part of the subject the eminent French economist applied the term *Ergonomy*. The Australian W.E. Hearn adopted the title for his work, *Plutology, or the Theory of the Efforts to satisfy Human Wants*.

Polak, Jacques Jacobus (Born 1914)

S. C. Tsiang

Born in Rotterdam, Polak was educated at the University of Amsterdam, where he obtained an MA (Econ.) degree in 1936, and a PhD (Econ.) in 1937. His early research work as an economist with the League of Nations was concerned with the study of business cycles and he assisted Jan Tinbergen in the latter's work on business cycles under the sponsorship of the League of Nations. Later they co-authored Polak and Tinbergen (1950).

After World War II Polak moved to the IMF, where he worked first as the chief of the statistics division, and then as the deputy director, and eventually became the director of the research department. His research interests then turned towards the monetary analysis of income determination and the balance of payments. His work in this area to some extent anticipated later developments in the monetary theory of the balance of payments by the Chicago School, although he himself might have been influenced by the earlier works of his colleagues at the IMF, for example by S.C. Tsiang's studies of the balance of payments improvement of Denmark in 1951 and the exchange reform of Peru (1950–54).

As a prominent IMF official, he was deeply involved in the mid-1960s in the design of the Special Drawing Rights (SDR), which were an application of the original Keynesian suggestion of 'Bancor' and which greatly expanded the lending capacity of the Fund.

In 1981 Polak became Executive Director for Cyprus, Israel, the Netherlands, Romania and Yugoslavia at the International Monetary Fund (IMF), Washington, DC.

Polanyi was born in Vienna in 1886 and grew up in Budapest, where he studied law and philosophy. He served as an officer in the First World War, after which he turned to economic journalism as foreign editor of Vienna's *Osterreichisiche Volkswirt* throughout the 1920s. He emigrated to England in 1933, where he worked in adult education, as a lecturer on world affairs for the Workers' Educational Association and for the Extramural Delegacies of the Universities of Oxford and London. He became intensely interested in the origins of the British Industrial Revolution and the enormity of its economic and social consequences, the subject of his book, *The Great Transformation* (1944), written while he was a resident scholar at Bennington College in Vermont between 1940 and 1943.

John Maurice Clark was sufficiently impressed by the book to invite Polanyi to Columbia University as a visiting professor of economic history in 1947 (when Polanyi was already 61). Polanyi remained at Columbia until his retirement in 1953. He continued doing research until his death in 1964 at his home in a suburb of Toronto.

The Great Transformation remains in print 45 years after its publication. It argues a triple thesis: (i) that in Great Britain and Western Europe, the coming of machine technology to mercantilistic national economies that contained governmentally regulated markets induced enormous growth in all input and output markets and the removal of governmental controls from some of them – what Polanyi calls an attempt to create a 'self-regulating' market system; (ii) that nationally integrated market systems in which labour, land, and money as well as produced goods were transacted as market commodities were historically unique (that such full-blooded capitalism dominated by market transactions for factor inputs as well as produced outputs was a new kind of economic system markedly different from any that preceded it); (iii) although machine technology producing within a market system was enormously productive – an 'unbound Prometheus' in the vivid phrase used by David Landes – its destructive consequences (that is, sporadic unemployment, the business cycle, large inequalities in income and wealth) culminating in the Great Depression of the 1930s, forced governments from the early 19th century onwards to initiate market controls, monetary and fiscal policy to mitigate its destructive consequences, what we now call 'managed' and 'welfare state capitalism'.

Polanyi's second big book, *Trade and Market in the Early Empires* (1957), which also remained in print after 30 years and which has also been translated widely, created a theory of pre-industrial, non-market economies of interest to economic archaeologists, economic anthropologists, and those economic historians who study early, pre-industrial economies throughout the world. Polanyi invented a conceptual vocabulary to specify the core attributes of such early and primitive economies much of which is employed today in standard fashion: 'reciprocity', 'redistribution', 'special-purpose money', 'port of trade', 'politically administered trade', 'economy embedded in society'. This part of Polanyi's work is widely thought to illuminate the nature of early money, early foreign trade, and the economic organization of early kingdom-states.

Polanyi's continuing significance is reflected in the Karl Polanyi Institute of Political Economy, founded at Concordia University, Canada, in 1987, which in addition to scholarly activity that is motivated by Polanyi's thought, maintains an archive of his works.

Polarization

Gordon Anderson

Abstract

Polarization means the tendency of economic agents to form different groups and acquire identities that enhance differences from other groups. It is both cause and consequence of much economic behaviour. It has been employed, for example, in describing the diminution of the middle class in wage, income and wealth distributions, in studying growth and convergence issues, and in examining the plight of the poor. Although polarization is closely associated with trends in inequality, increased polarization can correspond to an increase, a reduction or no change in inequality.

Polarization, or the tendency of economic agents to collect into different groups and to feel increasingly different from members of other groups, is both cause and consequence of much economic behaviour. The essence of informal and formal club formation, polarization is born of an increasing sense of identity within the group members and an increasing sense of distance from members of other groups. The terminology is gaining increasing currency in economics. Akerlof (1997); Anderson (2004a, b); Beach and Slotsve (1996); Beach et al. (1998); Bossert et al. (2004); Corak (2004); D'Ambrosio and Wolff (2001); Dinardo and Lemieux (1997); Foster and Wolfson (1992); Jenkins (1996); Jones (1997); Keefer and Knack (2002); Levy and Murnane (1992); Quah (1997) and Wolfson (1994, 1997) constitute an extensive but not exhaustive list of its use. In the list will be seen applications in describing the diminution of the middle class in wage, income and wealth distributions, in studying growth and convergence issues, and in examining the plight of the poor; it has also been used in the study of inter-generational income relationships and in discriminating between competing matching models of marriage partners. These literatures broadly interpret polarization as the disappearance of mass at the centre of an empirical distribution of a characteristic, or the increasing distance between, and intensity of, multiple points of modality of the distribution as it evolves through time. It is inherently a dynamic process involving the comparison of the anatomy of states at different points in time, essentially examining how the shape of the distribution of a characteristic (or a collection of characteristics) has evolved during the process. Thus, the objective is to detect trends in shapes of distributions over time that reflect the polarization or de-polarization (sometimes referred to as 'convergence') of that group of agents. Although polarization is closely associated with trends in inequality, it is distinguishable and quite different from changes in inequality in that increased polarization can induce an increase, a reduction or no change in inequality.

The concept need not be confined to the study of changes within a population's distribution of a particular characteristic, but can be used in assessing the relative movements of two or more distributions as they evolve (for example, polarization between ethnic groups, genders, and nations). In this context polarization takes the form of distributions becoming 'less alike' in a particular fashion; as such it involves comparison of complete distributions, not just their location or scale characteristic. While the identification of polarization within and between populations presents quite distinct empirical challenges, polarizations have many common features which can be exploited in understanding the nature of the phenomenon. Indeed, it is convenient to contemplate within-distribution polarization phenomena as the consequence of that population distribution being a mixture of sub-population distributions which are themselves polarizing (this notion is at the heart of the initial formalization of a Polarization index in Esteban and Ray 1994, and Duclos et al. 2004). Such a construction will highlight why within distribution polarization is sometimes hard to detect in the absence of sub-population information.

Polarization: An Axiomatic Foundation

Indices of polarization were formulated in Esteban and Ray (1994) and Duclos et al. (2004) (see also Wang and Tsui 2000) by positing a collection of axioms whose consequences should be reflected in a Polarization measure. The axioms are founded upon a so-called Identification–Alienation nexus wherein notions of polarization are fostered jointly by an agent's sense of increasing within-group identity and between-group distance or alienation. The four axioms may be loosely summarized as follows:

Axiom 1 A mean preserving reduction in the spread of a distribution cannot increase polarization.

Axiom 2 Mean preserving reductions in the spread of sub-distributions at the extremes of a density cannot reduce polarization.

Axiom 3 Separation of two sub-densities towards the extremes of the distributions range must increase polarization.

Axiom 4 Polarization measures should be population-size invariant.

The polarization index developed for discrete distributions as a consequence of these axioms (Esteban and Ray 1994) may be written as:

$$P_\alpha = K\sum_{i=1}^{n}\sum_{j=1}^{n}\left|x_i - x_j\right|\pi_i^{1+\alpha}\pi_j \qquad (1)$$

Here K is a normalizing constant, π_i is the sample weight of the i'th observation and where $\alpha \geq 0$ is a polarization sensitivity factor chosen by the investigator. It may readily be seen that $\alpha = 0$ yields a sample weighted Gini coefficient.

The continuous distribution analogue (Duclos et al. 2004) may be written as:

$$P_\alpha(F) = \int_y f(y)^\alpha \int_x |y - x| dF(x)dF(y) \qquad (2)$$

Again, α is the polarization sensitivity factor which in this case is confined to [0.25,1].

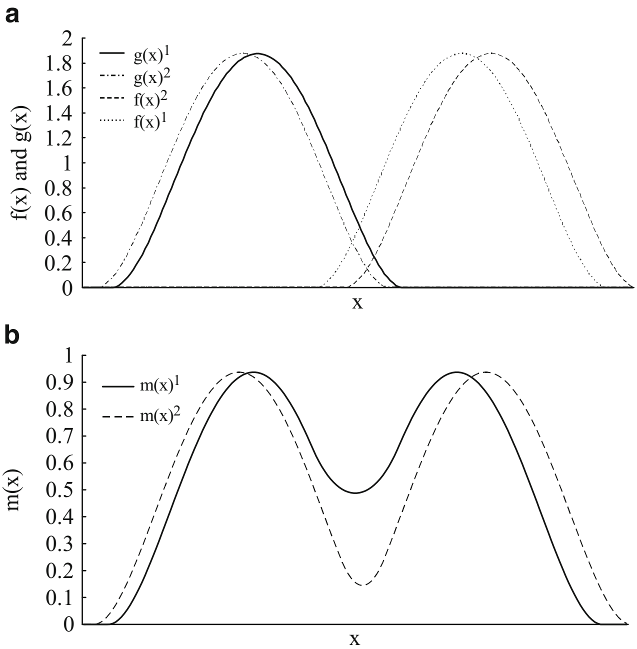
The Anatomy of Polarized States

For expositional simplicity in exploring the anatomy of polarized states, a population is represented by the equi-probable mixture of two sub-distributions (in reality more than two subgroups are possible), representing two subgroups or clubs which make up the population. The initial sub-distributions, which are identical except for having different means, are subjected to various transformations which are characterized in Figs. 1a, b, 2a, b, 3a, b and 4a, b.

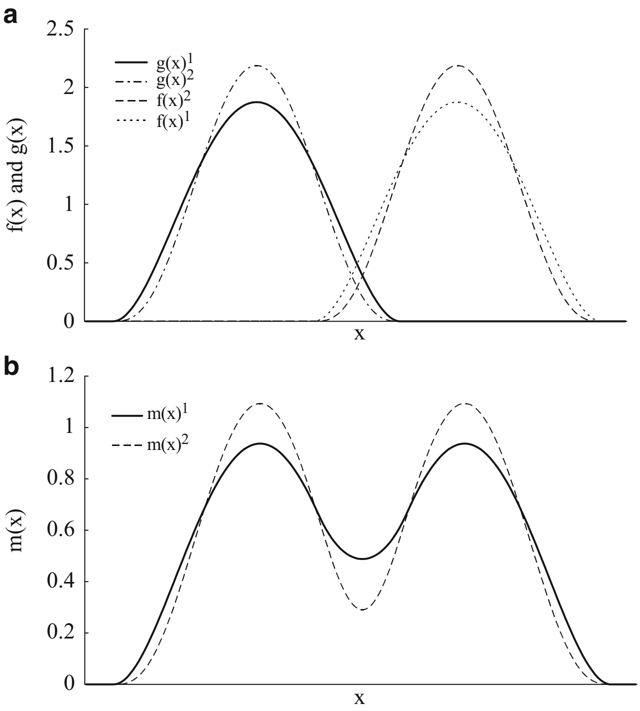
Following the spirit of Axiom 3, the simplest form of polarization occurs when the sub-populations exhibit divergence in their means. Here there is no increase in within-group identity but there is an increase in the distance between members of different groups (alienation). Figure 1a exemplifies this situation in terms of the sub-populations and its consequence for the mixture is illustrated in Fig. 1b. As may be seen, the overlap of the two sub-distributions diminishes, and the centre of the mixture becomes hollowed out. Note that when the means are relatively close together there is no hollowing out but simply a flattening of the unimodal peak of the mixture distribution, implying that polarized or polarizing states need not be characterized by the existence or emergence of bimodality. (For example, for mixtures of equal-variance normal distributions, bimodality will not emerge under any mixing scheme until the difference in means exceeds $4.5^{0.5}$ standard deviations). Thus, bump-hunting techniques available in the statistics literature (Good and Gaskins 1980; Hartigan and Hartigan 1985) which seek out inflections in the probability density function will not necessarily be useful in the analysis of polarization.

Figure 2a, b illustrate another form of polarization when sub-population means remain constant but their variances diminish. This is much in the spirit of Axiom 2 and characterizes a situation of increased identification within the groups without an increased sense of alienation between them. Again, the overlap of the sub-populations diminishes and the centre of the mixture becomes hollowed out, but in this case the anatomical change is not unequivocal. Finally, when both locations and spreads remain constant but the lower distribution skews left and the upper distribution skews right, the overlap again diminishes

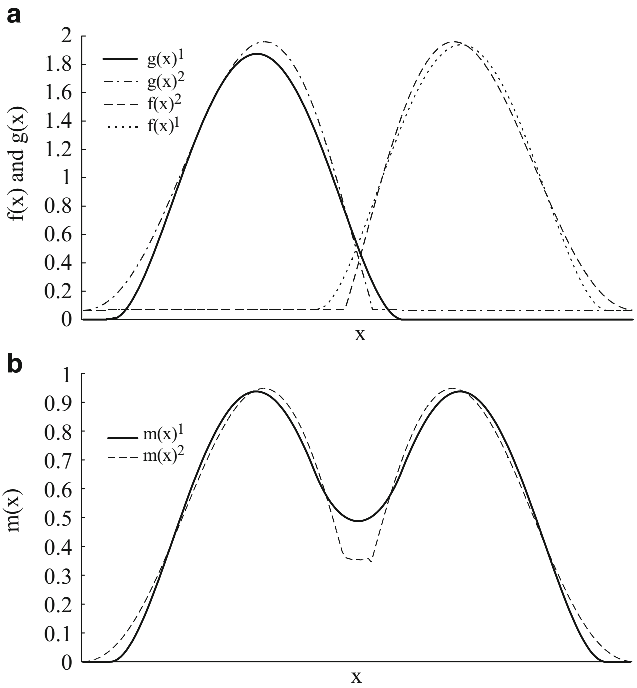
Polarization, Fig. 1
(**a**) Divergence in means between population polarization.
(**b**) Divergence in means within population polarization



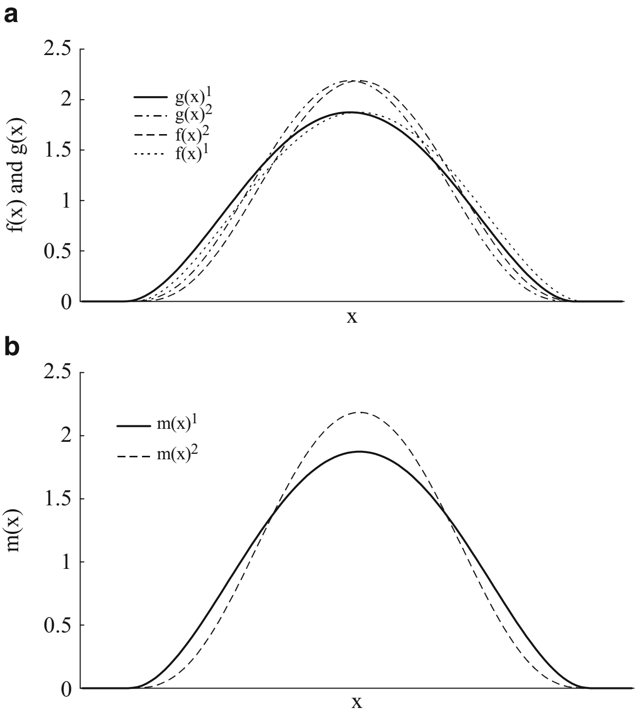
Polarization, Fig. 2
(**a**) Increased concentration between population polarization. (**b**) Increased concentration within population polarization



Polarization, Fig. 3
(**a**) Opposite skewness between population polarization. (**b**) Opposite skewness within population polarization



Polarization, Fig. 4
(**a**) Increased concentration between population polarization close means.
(**b**) Increased concentration within population polarization close means



and the centre of the mixture distribution again hollows out, as Fig. 3a, b illustrate.

One thing these examples demonstrate is the potential for changes in the overlap measure to provide a general test or indicator of polarization. But this is not without qualification. Figure 4a, b return us to the increased identification case and demonstrate that, if the subgroup means happen to be close together, the extent of overlap can increase and the mass at the centre of the mixture distribution is enlarged with increased polarization. This highlights what is in effect a potential statistical identification problem associated with polarization when only the mixture of sub-distributions is observed. The tenuous link between polarization and inequality is also illustrated in this example. If we consider the mixture $f(x)$ to be an equally weighted mixture of normal distributions $N\left(\mu_\mathrm{i}, \sigma_\mathrm{i}^2\right), \mathrm{i} = 1, 2$, then the variance of x (for our purposes a measure of inequality) which will be $0.5\left(\sigma_1^2 + \sigma_2^2 + (\mu_1 - \mu_2)^2\right)$ can be seen to either increase, decrease or remain unchanged with an increase in polarization interpreted as any combination in reductions of sub-population variances and increases in the difference of sub-population means.

Alternative Between-Group Polarization Measures

Distributional Overlap

The anatomy analysis suggests that one technique for assessing polarization between two groups is to evaluate how much they have in common. Such a measure corresponds to non-alienation, and its negative (or some negative function of it) corresponds to a degree of alienation. Anderson (2004a, b) proposes an overlap measure as an index of convergence and a function of its negative as a measure of alienation. The extent to which two distributions $f(x)$ and $g(x)$ overlap is given by:

$$OV = \int_{-\infty}^{\infty} \min(f(x), g(x))dx \qquad (3)$$

Clearly it is a number between 0 and 1 with 0 corresponding to no overlap and 1 to the perfect matching of the two distributions. It follows that $1-\ OV$ is a measure of the extent to which the distributions do not match or are alienated. When $f(x)$ and $f\,(y)$ are specified to the extent that all of their parameters can be estimated and the intersection points of $f(x)$ and $g(x)$ calculated, OV can be estimated parametrically (see Anderson and Ge 2004). When $f(\cdot)$ and $g(\cdot)$ are unknown, given independent samples from $f(\cdot)$ (represented by x) and $g(\cdot)$ (represented by y) of sizes n_x and n_y respectively, its empirical counterpart may be implemented by choosing $K + 1$ mutually exclusive and exhaustive partitions of the range of x whose upper bound is defined by x^k, $k = 1, \ldots, K + 1$ and calculating

$$OV^e = \sum_{i=1}^{k+1} \min\left(\frac{\sum_{j=1}^{n_x} I\left(x_j, x^i\right)}{n_x}, \frac{\sum_{j=1}^{n_y} I\left(y_j, x^i\right)}{n_y}\right) \qquad (4)$$

where $I(z,w^\mathrm{i})$ is an indicator function equal to 1 when z is in the interval $(w^{i\,-\,1}, w^\mathrm{i})$ and 0 otherwise. The statistical properties of such an estimator are discussed in Anderson (2005). The nonparametric measure is prone to two sources of bias: the first, due to the intersection points of the underlying distributions not coinciding with partition points, is actually not that large provided k is not small and the partition points are chosen judiciously; the second, due to the estimator being implicitly a conditional estimator, can be large when the measure is either close to 0 or 1. However, these biases do not appear to impede its use in calibrating changes in overlap. The main problem with this particular instrument arises when distributions do not actually overlap; for that purpose the following measures may prove useful.

Gini-Based Between-Group Polarization Measures

Starting with the classic Gini inequality coefficient which, with x_i being the income of the i'th agent for agents $i = 1,\ldots,n$ and where for convenience and without loss of generality incomes are arranged in ascending rank order, may be written as:

$$Gini = \frac{1}{2n^2\mu}\sum_{i=1}^{n}\sum_{j=1}^{n}\left|x_i - x_j\right| \qquad (5)$$

where μ is the mean of the *x*'s. Suppose the rich and poor groups are defined by a poverty cut-off somewhere between x_p and x_{p+1} where $1 < p < n$ (what Yitzhaki 1994 refers to as perfect stratification of groups, that is, no overlapping): then Gini may be thought of as the sum of the average mean normalized differences between agents in the poor group, between agents in the rich group, and between poor- and rich-group agents. In measuring alienation it is only the last group of comparisons that are relevant, that is, the average normalized difference between the rich-group and poor-group agents. In this case the new 'PGini' index could be written as:

$$PGini = \frac{1}{p(n-p)\mu}\sum_{j=p+1}^{n}\sum_{i=1}^{p}\left(x_j - x_i\right) \qquad (6)$$

Clearly this is still a number greater than 0 (but it is no longer guaranteed to be less than 1), which reflects the mean normalized average distance between the poor group and the rich group, and as such it is easy to show that it is the overall mean normalized difference between the subgroup means. Indeed, the formulae can be generalized to general group differences where there is not perfect segmentation, that is, where the subgroups overlap.

Observe that the same index would be arrived at if one were to work with $x_i - z$ and $x_j - z$, the corresponding distances from the poverty line *z* which facilitates a link to the well-known FGT family of poverty and welfare indices introduced by Foster et al. (1984), as follows. The formal representation of this family is given by:

$$POV_\theta(x,z) = \int_0^z \left(\frac{z-x}{z}\right)^\theta dF(x) \qquad (7)$$

where *F*(*x*) is the cumulative density function (with p.d.f. *f*(*x*)) describing the population of incomes, *z* is the maximum of the poor, and $\theta(\geq 0)$ is a parameter defining the nature of the poverty index and corresponds to a measure of poverty aversion. As a consequence POV_0 corresponds to the proportion of people in the poverty group,POV_1 is a normalized measure of the intensity of relative deprivation and so on. POV_i/POV_0 may be construed as the expected value of a weighted function of the normalized income deficiency where the weights are the $(i-1)$'th power of the normalized income deficiency itself. Thus increasing *i* increases the weights attached to those furthest from the poverty line. Interestingly, as *i* becomes very large the index becomes a Rawlsian measure in focusing almost entirely on the poorest agent. All of these measures obey the focus axiom, which holds that poverty measures should depend only upon the incomes of the poor. As such they are not in any sense related to the status of the rich.

Along similar lines *RIC*(*x,z*), an index of weighted relative distances of incomes above the poverty line, may be contemplated whose theoretical representation is of the form:

$$RIC_\theta(x,z) = \int_z^{xmax} \left(\frac{x-z}{z}\right)^\theta dF(x) \qquad (8)$$

In this case *x* max corresponds to the maximum possible income. Here RIC_0 corresponds to the proportion of the population above the poverty line, RIC_1 is a normalized measure of relative well-being of the non-poor, RIC_2 is a measure of the intensity of the relative well-being of those above the poverty line, and so on. In this case as α becomes very large the index becomes almost entirely focused on the richest person, RIC_1/RIC_0 corresponds to the expected normalized income surplus over the maximum poverty income, and so on. For all $\theta > 0$ all of these indices are essentially measuring relative weighted distances from the poverty line, and it is in this sense that they are considered relative measures. However, both *RIC* and *POV* are completely uninformed with respect to the distribution of incomes in the other group, which accords with the focus axiom mentioned above. For the purposes of reflecting the notion of alienation between the poor and non-poor groups, this axiom needs to be violated. Indeed the population analogue of PGinican be shown to be a specific member ($\theta = 1$) of a general class of polarization measures defined by

$$POL(z,\theta) = \left(\frac{z}{\mu}\right)^{\theta}\left(\frac{RIC_\theta}{RIC_0} - \frac{POV_\theta}{POV_0}\right) \tag{9}$$

where $\theta \geq 1$.

Tests for Polarization

Given the distribution of the above indices, tests for increases or decreases in polarization in terms of movements in the indices can be readily established. But, although indices provide complete orderings, much like the Gini coefficient with which they are associated, they can be ambiguous. Direct tests of the anatomy of polarization based upon degrees of separation or stochastic dominance between density functions can provide an unambiguous (though not complete) orderings of the states of polarization. These tests can be developed by employing combinations of stochastic-dominance conditions, tests for which have been proposed by Anderson (1996, 2004a), Davidson and Duclos (2000), Barrett and Donald (2003), Linton et al. (2002), and McFadden (1989). The conditions can be used in combination to compare the right separation of the upper distribution with the left separation of the lower distribution and thus establish a statistical criterion for polarization both within and between distributions. Anderson (2004b) provides a taxonomy of such tests.

An Alternative Approach: The Growth and Convergence Literature

The endogenous growth literature has for a long while been concerned about issues of polarization specifically in the form of convergence or de-polarization. Early attempts at identifying the phenomenon via panel data regression techniques (see, for example, Barro 1998) ran into difficulties in interpretation (Bernard and Durlauf 1996). The phenomenon has been studied via the use of probability transition matrices implicit in the Markov chain methods employed by Quah (1997) (see also Durlauf and Quah 1999). (These techniques have also been applied to the problem of intergenerational Income relationships; see Corak 2004, and city sizes, Dobkins and Ioannides 2000, Anderson and Ge 2004). If we let *f*(*y*) be the distribution of income *y* in some future period, and *f*(*x*) the distribution of income *x* in the present period, the issue to be addressed is the relationship between the two distributions, that is, the extent to which, and manner in which, *f*(*y*) and *f*(*x*) are related. If for the moment we think of *x* and *y* as having the joint distribution *f*(*y*,*x*) so that *f*(*y*) and *f*(*x*) are the respective marginal distributions, at one extreme there is a sense of no relationship – that is to say, when *x* and *y* are independent $f(y, x) = f(y)f(x)$ – at the other there is the completely deterministic environment whereby $y = a + bx$ and the joint distribution is degenerate. If *y* and *x* are partitioned into *k* mutually exclusive and exhaustive regions where *p*(*y*) and *p*(*x*) are respectively the vectors of marginal probabilities of falling into those regions, interest centres on the elements of the square matrix *T* defined by $p(y) = T(y, x)p(x)$, the matrix in the square brackets in the following equation. *T* is of course the matrix of conditional probabilities formed by the product of the two square matrices in the equation, so that:

$$\begin{pmatrix} p_1(y) \\ p_2(y) \\ . \\ p_k(y) \end{pmatrix} = \left[\begin{pmatrix} p_{11}(y,x) & p_{12}(y,x) & . & p_{1k}(y,x) \\ p_{21}(y,x) & p_{22}(y,x) & . & p_{2k}(y,x) \\ . & . & . & . \\ p_{k1}(y,x) & p_{k2}(y,x) & . & p_{kk}(y,x) \end{pmatrix}\begin{pmatrix} p_1(x) & 0 & & 0 \\ 0 & p_2(x) & & 0 \\ . & . & . & . \\ 0 & 0 & . & p_k(x) \end{pmatrix}\right] \times \begin{pmatrix} p_1(x) \\ p_2(x) \\ . \\ p_k(x) \end{pmatrix} \tag{10}$$

which is a matrix of conditional probabilities – that is, $T = \|p_{ij}(y, x)/p_j(x)\|i$, $j = 1, \ldots,$ k–familiar in the convergence literature and made popular by Quah (1997). As such its properties are well known, as are the techniques for its estimation. The i'th column of T is a conditional probability density function describing the distribution or reallocation over states of the i'th element of $p(x)$ the initial income distribution, to the elements of $p(y)$, the resultant income distribution, after one period. If this process is thought to be time invariant, then letting p_s be the vector of $p_i(x)$'s s periods ahead, $p^s = T^s p$ corresponds to the s period ahead distribution, and the solution to $p^\infty = Tp^\infty$ (if it exists) is what is known as the long-run ergodic mass function. By interpreting these ergodic distributions as 'characterizations of tendencies', one can infer a tendency towards polarization if they display multiple peaks. Polarization can be examined in two ways in this context. When the diagonal elements of T are large relative to the off-diagonal elements, the system is said to exhibit persistence; if the diagonal is particularly large in the high and low ends it indicates a tendency towards polarization. Alternatively, one could compare p^∞, the long-run distribution, with $p(x)$, the initial distribution. If the former exhibits multiple peaks whereas the latter does not, a polarizing tendency may be inferred. One difficulty here is that no theory of inference has as yet been outlined for examining the 'multiple peakedness' of these ergodic functions.

Multivariate Polarization

When agents are characterized in terms of more than one characteristic, their polarization or otherwise will be reflected in more than one dimension. The empirical problem is then altogether much more challenging; the extension of the analysis to a multivariate measures can be somewhat problematic. Multivariate Gini coefficients have been developed (see Anderson 2004c, and Koshevoy and Mosler 1997) but adapting them to the current context is complex; it requires defining a poverty cut-off for each characteristic (or some poverty boundary in multidimensional space), but even then extending the analogy to multivariate measures of FGT indices is not possible. One simple approach is to take a weighted geometric mean of the various Gini coefficients in each dimension; but then the weights have to be determined in an inevitably arbitrary fashion.

On the other hand, extension of the overlap measure OV to a multivariate overlap measure MOV is very straightforward, since MOV is of the form:

$$MOV = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty}\min(f(x,y\ldots,z),\; g(x,y\ldots,z))dxdy\ldots dz \tag{11}$$

In the corresponding empirical measure MOV^e, given suitable partitions in each dimension, the indicator function would simply be modified to a multivariate version accordingly (Anderson 2005, provides an example) and $1 - MOV$ would provide an appropriate polarization measure.

Poles of Development

N. Hansen

The term 'development pole' was first introduced by François Perroux (1955), who argued that analyses of economic development should concentrate on the processes by which various economic activities appear, grow in importance, and, in some cases, decline or disappear. Like Schumpeter, Perroux maintained that entrepreneurial innovation is primarily responsible for the development process, which involves a succession of dynamic sectors, or poles, over time. Although Perroux emphasized relations among industrial branches, the implications of the development pole notion have been elaborated mainly in terms of the geographic location of population and economic activities (Boudeville 1972; Hirschman 1958; Myrdal 1957).

The concept of geographic development poles, or growth centres, gained particular prominence in the context of the balanced versus unbalanced growth controversy of the late 1940s and 1950s. A number of economists held that economic development would best be accelerated by the simultaneous balanced growth of many interdependent undertakings. The principal rationale was that investments in both directly productive activities and infrastructure that would not be profitable in isolation would become profitable for the ensemble because of mutually beneficial external economies. However, the applicability of this strategy to newly developing countries was properly questioned on the ground that the resources required for carrying it out would be so great that a country disposing of such resources would not be underdeveloped in the first place. Critics of the balanced growth approach further pointed out that economic development does not in fact appear simultaneously and uniformly throughout an economy. Hirschman (1958) in particular maintained that development strategies for developing countries should concentrate on a few sectors rather than attempt to do too much at once with very scarce resources. In his view, development is communicated from leading sectors to the followers, from one firm to another. The advantage of this phenomenon over balanced growth, where every activity expands in step with every other, is that it leaves considerable scope to induced investment decisions, and therefore economizes the principal scarce resource, namely, genuine decision-making. However, Hirschman recognized that investments may well become overconcentrated in one or a few large cities because their external economies tend to be overrated by investment decision makers in the belief that nothing succeeds like success. Nevertheless, he believed that in the long run public investments would cease to be so concentrated in primate cities, because of national equity and unity considerations. In this regard he was clearly overly optimistic. Finally, Hirschman suggested that while infrastructure investments may be indispensable for the development of lagging regions, this would still represent only a permissive inducement mechanism. The essential task is the provision of continuously inducing activities in industry, agriculture and services.

During the 1960s it was widely held that, as a result of Keynesian macroeconomic policies, the economies of industrialized nations could continue to experience steady growth with relatively low unemployment and inflation rates. At the same time there was increased interest in structural problems that persisted despite the favourable aggregate context. For example, the growth of large metropolitan areas and the concomitant decline of some relatively peripheral regions became a concern in many industrialized countries, as well as a continuing concern in newly developing countires. It was frequently alleged, if not proven, that large urban agglomerations were too big, in the sense that the marginal social costs of further growth outweighed the marginal social benefits. Yet such places continued to grow because new entrants benefited from economies of agglomeration but did not bear the full costs associated with their entry. Critics argued that under these conditions, congested large cities and the nation as a whole would benefit if the growth of population and economic activity could be diverted to mediumsize development poles, whose accelerated growth could be induced by government policies with respect to infrastructure, taxation, capital subsidies and similar incentives. Proponents of this development pole strategy emphasized the advantages of economies of agglomeration in a relatively few urban centres and argued against policies that would spread development outlays too thinly over the national territory. The induced development poles would thus be economically efficient counter-magnets to the spontaneous development poles deemed to be too large. It was further argued that the induced development poles would generate beneficial ‘spread effects’ to their surrounding hinterland areas, so that in the long run the entire national territory would be characterized by ‘balanced growth’. An example of this strategy was the French spatial development policy of the 1960s, which designated eight metropolitan areas whose favoured growth would, it was hoped, counteract the growth of the Paris region.

The development pole strategies that were adopted in the 1960s fit in well with the hierarchical diffusion of innovations paradigm popular at the time. This approach to spatialtemporal development processes maintains that there are two principal features that characterize the spatial organization of economic activities: (1) a hierarchical system of cities, arranged according to the number and quality of functions performed by each city; and (2) a corresponding set of urban spheres of influence (urban fields) surrounding each of the cities in the system. Within this framework, development-inducing innovations are transmitted simultaneously in three ways: (1) outward from one or a few dominant national metropolitan ares to major regional urban centres; (2) downward from higher-order to lower-order cities in the urban hierarchy, in a pattern of hierarchical diffusion; and (3) outward from urban centres into their surrounding hinterland areas, that is, through radiating spread effects. The hierarchical diffusion of innovation paradigm is essentially a top–down model of development because it places considerable emphasis on continuing innovation adoption in the largest cities as the critical element for the subsequent extension of development over the entire urban-economic system.

Given this general setting, the role that induced development poles play in regional development can be regarded as a particular case of the general process of innovation diffusion. More specifically, development pole policies can be introduced if diffusion mechanisms are perceived to be operating too slowly, if ‘cumulative causation’ leads to increasing regional income disparities rather than to their reduction, or if institutional or historical barriers impede diffusion processes. The purpose of spatially selective public investments in development poles would be to hasten the focused extension of development to lower echelons of the urban hierarchy in peripheral regions, and to link the development poles more closely to the national urban system via higher-echelon cities in the urban hierarchy. It should be remarked that the innovation diffusion justification for a development pole policy does not deal with the issue of the actual or potential social costs of very large cities. Such places are viewed in an exclusively positive light, as the seedbeds of innovation, or at least the initial adopters of innovations conceptually generated elsewhere.

In retrospect, what have development pole policies accomplished? This is difficult to evaluate because it is hard to find any example of a development pole policy that has been vigorously implemented in practice. In many countries, development pole strategies have not really passed the stage of paper plans, and in many others the resources committed to implementing the plans have been too few to represent a genuine test of the strategy. Yet another pervasive problem has been the political difficulty of being selective in the choice of geographic development poles. Policies that have begun by attempting to concentrate investments in a relatively few urban centres have been diluted over time by pressures to include ever more centres, thus precluding the inducement of extensive economies of agglomeration in any one place.

In addition to the foregoing problems, the context for regional development policies has altered considerably over time, and especially since the mid-1970s. Here it is instructive to distinguish between the advanced industrial countries and the newly developing countries.

In the industrialized nation context, mounting evidence indicates that the hierarchical diffusion paradigm cannot be supported empirically. Development-inducing linkages run not only from larger to smaller cities, but also in the reverse order as well as between cities of similar size. Moreover, the notion that induced development poles will in turn induce development in their respective hinterlands has been undermined by evidence that interfirm and intersectoral linkages for the most part involve relatively distant locations. From the viewpoint of regional development policy, the problem of how to create local linkages has yet to be resolved. Although large city size is associated with technological progress in the hierarchical diffusion paradigm, there is no evidence that this is necessarily the case. Even in broadly regional terms, new industrial sources of innovation increasingly are widely dispersed. Finally, in many countries the aims of development pole strategies have tended to be realized since 1970, though few would attribute this phenomenon to such policies. Very large metropolitan areas have been declining in population or else have experienced much slower rates of growth than in the past; and many once stagnant or declining peripheral areas have experienced at least a modest degree of population increase and economic revival. In general, then, while spontaneous development poles continue to emerge outside of older industrial regions, the impetus to formulate deliberate policies to promote induced development poles has receded.

Development pole policies in newly developing countries have taken a number of forms. Some have concentrated on infrastructure in order to provide a critical minimum level of power, water, transportation and other public overhead facilities. Others have been based on the intermediate or heavy manufacturing activities of public enterprises; these projects have typically involved industrial complexes organized around such sectors as iron and steel, aluminium, petrochemicals and heavy engineering. What all these efforts have had in common is emphasis on the direct use of large-scale investment resources to generate structural changes through accelerated economic growth. However, the selection of development pole locations has typically been based on urban population growth projections and/or on national sectoral projections, but not on the development potential or demand of the surrounding hinterland areas. Consequently, polarized development under-takings have had only a very limited impact on their surrounding areas because the linkages involved in the development process have been largely with distant suppliers and markets, and because the derived demand for labour and for agricultural outputs has often stimulated migration and supplies from outside the regions where development poles haver been located. In addition, the highly capital-intensive nature of development pole activities has generated relatively low levels of employment in view of the considerable total resources invested.

In general terms, the principal criticism of polarized development strategies as applied in developing countries has been their failure to improve the social and economic well being of the large numbers of poor persons who live in rural peripheral regions. In recent years there has been a broadly based reaction against ‘top–down’ development efforts in favour of ‘bottom–up’ approaches that emphasize highly divisible, labour-intensive technologies applied to agriculture and to small and medium-size enterprises with direct linkages to agriculture and to rural and small town markets.

Despite criticisms of development pole policies, they are still being formulated in some countries, including Mexico and South Korea, where in each case decentralization away from the large, congested national capital is a major national objective. The evidence suggests that if such policies are to be successful they need to be broadened to include political, social and institutional changes as well as sectoral measures. Induced development poles need to be placed within a larger human settlement system framework, and human resource development policies need to be integrated with spatial-sectoral policies. The dissipation of scarce resources should be avoided by greater selectivity in location choices, and measures need to be taken to reduce the enclave nature of development poles. And political will needs to be sustained in the context of sufficiently long planning horizons.

In brief, then, prevalent attitudes toward development pole strategies have passed from an initial phase of optimism, to one of pessimism, to an emerging broader perspective that would include induced development poles as but one aspect of more comprehensive development planning (Hansen 1981).

Policy Reform, Political Economy of

Sharun W. Mukand

Abstract

Policymakers face political constraints that make enacting reform difficult. Since the late 1980s economists have developed a framework to analyse the deeper political underpinnings of policy inefficiency. This article develops a framework for delineating the key findings of this literature. It then briefly sketches out the role of institutions in facilitating policy reform.

Good policymaking is difficult. Inefficiencies abound in all areas of policymaking, due to constraints faced by the policymaker, be they informational, administrative or political. The subject of the political economy of policy reform is concerned with the *political* factors that make it difficult to reform policies and institutions. This field has focused on examining the impact of different political institutions on exacerbating or alleviating the ability to carry out reform, the consequences of these political constraints on policy outcomes as well as normative issues of institutional design that impinge on a policymakers' choice of policy.

The systematic exploration of the political economy underpinnings of policy reform began with two developments. First, there was an attempt to understand why governments in many developing countries failed to reform policies and institutions, despite low growth and stagnation and overall inefficiency (Rodrik 1996). Second, there were new developments in rational choice political economy. In particular, there was growing recognition of the power of the public choice critique of traditional policy analysis due to Buchanan and Tullock (1962). This literature emphasized that policymakers' preferences may be quite distinct from those of social planners and result in inefficient policy choices – that is, government failure. Therefore, policymakers' choices may be driven by a desire to retain office or may give very different weight to the preferences of some individuals (or groups) than might those of social planners. However, the insights from the public choice tradition were not explicitly grounded in a rational choice framework. This is where the literature on time-inconsistency spawned by the classic contribution of Kydland and Prescott (1977) played a crucial role. This literature demonstrated the importance of clearly specifying the policymaker's objectives and the constraints within a framework of optimization. However, the study of the political underpinnings of policy reform took off when insights from this 'new' political economy were used to deepen our understanding of economic crises, poverty traps and institutional inefficiencies in developing and transition economies.

Policy reform is difficult to achieve. Indeed, understanding the persistence of inefficient policy choices has been one of the central themes of much of the literature on policy reform. We can delineate the mechanisms proffered by the literature by focusing on two kinds of conflicts that make all policy reform more or less difficult. The first is the distributional conflict between different groups of citizens and individuals, be it due to differences in income, occupation, ethnicity or even religion. Given that much of policymaking is an attempt to balance these competing interests, the ability of a society to resolve this conflict is likely to affect its ability to reform. Second, the ability of a society to reform a failed policy may be due to conflict of interests between the politician–policymaker and those of the public. Institutions lie at the heart both these conflicts. Therefore, much recent work on the political economy of reform has focused on the interaction between political institutions, policy choices and inefficiency.

Distributional Conflicts and Policy Inefficiency

During the 1980s Latin America witnessed a number of macroeconomic crises due to delays in the enactment of any stabilization policy (Rodrik 1996). The puzzle was, why were these stabilizations delayed? In a near classic in this field, Alesina and Drazen (1991) addressed this issue. They showed that policy reform can be delayed due to a 'war of attrition' between two groups. Given uncertainty about the other group's willingness to bear a disproportionate burden of the adjustment costs, each group delays adjustment in the hope that the other caves in first. The economic crises worsens before one of the sides caves in and reform takes place.

At its broadest level inefficiency in policymaking in democracies arises from a commitment problem. Governments, which are vulnerable to losing power, are unable to commit to future policy outcomes. This failure in commitment can result in inefficient policy choices due to a variety of reasons (see Besley and Coate 1998). In particular, most policy reforms have distributional consequences, resulting in winners and losers. However, there is a time-inconsistency problem with promises of future compensation (see Acemoglu 2003; Robinson 1998, for an elaboration). Therefore, what is key is the inability of a government to credibly commit to compensate losers from economic reform. Not surprisingly, if losers are in a majority (or politically influential) they will be not only opposed but will be able to prevent the implementation of such a policy reform – even if it is efficient. Now, if a government through some form of taxes and transfers could credibly commit to compensate losers for their losses, then policy reform would be much easier to achieve. In part, the difficulty in making credible promises to compensate losers is that the gains and losses from policy choices are spread out over time, while the winners may not have enough resources to compensate the losers up front for their subsequent losses (see Dixit and Londregan 1996).

However, inability to compensate losers is not in itself sufficient for there to be a failure to adopt policy reform. If individuals are risk neutral, then they may well be willing to adopt a policy which has winners and losers. For example, consider an economy where 100 risk-neutral voters face the prospect of voting for or against a policy reform. If enacted this policy reform will result in 51 winners, each of whom gains five dollars, and 49 losers, each of whom stands to lose one dollar. We may suspect that since (in expected terms) all individuals stand to gain from the adoption of this policy reform, it will always be adopted, whether or not winners compensate the losers. In an important contribution, Fernandez and Rodrik (1991) suggest that this is not the case. They argued that, even in a world with risk-neutral agents, individual specific uncertainty about the identity of winners and losers from a reform may prove to be crucial. In particular, to continue with our example, consider the case where the identity of 49 of the 51 winners is common knowledge. In this case there is individual-specific uncertainty amongst the remaining majority about their identity as a winner or a loser. Observe that this uncertain majority has a negative expected payoff from the reform and will vote it down. Therefore under individual- specific uncertainty a majority may vote against a policy, despite the fact that a majority stands to benefit from it. In an extension, Jain and Mukand (2003) show that policy reform may fail to get enacted, despite the existence of tax-transfer compensation instruments.

Therefore, social conflict across groups coupled with a failure of credible and efficient means of conflict resolution result in a persistence of inefficient policies. In contrast to the above, the other class of models in this literature has focused on the agency conflict between the politician and the citizen.

Political Losers, Agency and Policy Inefficiency

Once in power, politicians earn both economic and non-economic rents. As such there may be a failure to enact any policy reform if it adversely affects the rents earned by the current incumbent politician. A number of mechanisms have been studied.

The prospect of earning rents from a status quo policy can make the adoption of policy reform by the politician much more difficult. Coate and Morris (1999) show that the mere introduction of a policy encourages the affected parties to make investments that increase their willingness to pay for retaining these policies in the future. If, in the future, the efficient policy is no longer the status quo policy then there may be a problem. Any government attempting to reform the status quo policy is likely to be vulnerable to lobbying by the now entrenched firms.

Indeed, in the presence of uncertainty about the policy choice, this inefficiency is exacerbated. For instance, many commentators wondered why US President Johnson persisted with military escalation in Vietnam though it was apparent to him (and most others) that such a policy was unlikely to work. Similarly, many analysts have been puzzled by the persistence of policymakers in many Latin American countries with extreme neoliberal policies, despite the fact that they seemed to not work. Majumdar and Mukand (2004) suggest that the reason is perhaps reputational. In particular, suppose that the initial choice of policy is a function of the policymaker's ability. In this case even if the policy seems to be failing, the policymaker may persist with it even if it is not efficient to do so. This is because a policy reversal by the incumbent will call into question the incumbent's competence in choosing this course of action in the first place. Fear of the adverse reputational (and electoral) consequence that such a policy reversal entails results in inefficient policy persistence.

We have delineated above a number of political mechanisms that make policy reform difficult. In response to the difficulty of reforming policies, recent work has focused on the implications of institutional innovations.

Institutions and Policy Reform

A country's institutional structure affects the political context of policymaking. Any inefficiencies in policy reform are likely to arise from an inability of existing institutions to mediate and resolve conflicts between groups or politicians. This central point about the role of institutional structures in stifling policy reform and growth has been made by Dixit (2004), Rodrik et al. (2004) and Acemoglu et al. (2004) among others. Accordingly, recent work has focused on issues of institutional design and the appropriate intervention most likely to change political (and economic) outcomes.

Broadly described, there have been two kinds of institutional interventions that can potentially alter the political equilibrium. The first is directed at resolving policy inefficiency arising out of distributional conflicts. The classic institution that facilitates conflict resolution is of course democratization and regular elections. While democratic elections bring their own inefficiencies, they have a positive first-order effect in that they give the electorate an opportunity to replace a policymaker who fails to undertake policy reform. Alternatively, a constitutional change in the nature of local government can help resolve policy inefficiencies. For instance, explicit political reservations for women and disadvantaged groups can directly alter an existing political equilibrium to one where policy reforms that benefit these groups will be more likely to take place (see Duflo and Chattopadhya 2004). The second kind of institutional intervention is one that helps limit the possibility of rent- seeking activity by the government. This may involve insulation of some of the policymaking apparatus from political pressures (as in an independent judiciary or central bank) or it may involve term limits or greater decentralization.

Final Remarks

Since the late 1980s the study of the political economy of policy reform has become an active area of research in political economy. Indeed, many of the seminal contributions to the area of the 'new political economy' were first made in an attempt to understand policy inefficiencies in developing countries and their failure to reform. Many empirical puzzles such as the inefficient delay in enacting reforms and the reversal of optimal policies have been addressed. In addition, the study of policy reform has given the initial impetus to the literature on institutions and underdevelopment.

However, much remains to be done. At an empirical level, we need to understand what institutions are likely to facilitate reform and prevent inefficiency. The need for micro-based studies is particularly important given the vast differences in history and socio-cultural norms that may result in both economic and political markets functioning in unexpected ways. Furthermore, more work needs to be done to understand the political economy of institutional change and its impact on policy reform. In particular, the role of leadership in catalysing institutional change and policy reform is poorly understood.

The term ‘political arithmetic’ predates the term ‘political economy’. It was coined by Sir William Petty, a founder member of the Royal Society, who – being a scientist by education and a government economic adviser by career choice – deliberately set out to apply the new scientific methodology of the 17th century to the practical economic problems of the modern nation state. For the leading spirits of the scientific revolution which reached a climax in the second half of the 17th century, the common article of faith was a belief in the unity of theory and practice, combined with a conviction that the first step in the advancement of human understanding in any sphere of knowledge – whether in astronomy or in chemistry or in industrial or social technology – was to lay a foundation of direct, empirical observations. To quote Bacon’s *Novum Organum*:

> The roads to human power and to human knowledge lie close together, and are nearly the same; nevertheless, on account of the pernicious and inveterate habit of dwelling on abstractions, it is safer to begin and raise the sciences from those foundations which have relation to practice and let the active part be as the seal which prints and determines the contemplative counterpart.

That was the inspiration which underlay the foundation of the Royal Society and allowed men like Graunt and Petty, Newton and Boyle, Flamsteed and Hooke, to feel themselves part of the same intellectual community. That was also the inspiration for the first exercises in political arithmetic.

Sir William Petty was a medical practitioner (as was his contemporary Locke, and Quesnay a century later), and his interest in economic problems had been stimulated in Ireland, to which he went in the early 1650s as physician to the Cromwellian army of occupation. There he persuaded the civil authorities, faced with the problem of consolidating the conquest by making an orderly distribution of forfeited lands, to give him the task of organizing a comprehensive land survey. It was on the basis of this massive research project that he wrote *The Political Anatomy of Ireland* in the 1670s. But by then he had already published his *Treatise on Taxes and Contributions* (1662), which contained a miscellany of sharp observations, incisive economic analysis and forthright policy advice, mainly focused on English problems of public finance. He had also written (during the 1665–7 conflict with Holland) an essay in a similar analytical mould, concerned with the practical problems of financing the war, and it was in this connection that he produced his first estimates of national income and wealth for England and Wales (published posthumously as *Verbum Sapienti*).

Most of Petty’s pamphlets on economic questions were circulated privately and published posthumously, for the second half of the 17th century was an age in which giving politico-economic advice to governments was a perilous occupation. However, the distinctive message running through these writings was the importance of basing public economic policies on systematically compiled empirical evidence and reasoned quantitative estimates of the nation’s human and material resources. In the 1670s he spelt out and developed this theme in his most path-breaking work, *Political Arithmetick*, subtitled: ‘A discourse concerning the extent and value of lands, people, buildings, husbandry, manufacture, commerce, fishery, artisans, seamen, soldiers, public revenues, interest, taxes, superlucration, registries, banks, valuation of men, increasing of seamen, of militias, harbours, situation, Power at sea, etc. As the same relates to every country in general, but more particularly to the Territories of His Majesty of Great Britain and His Neighbours of Holland Zealand and France.’ Written in order to rebut those commentators who were lamenting the nation’s economic decline, Petty’s *Political Arithmetick* was an explicit attempt to apply a Baconian methodology to economic analysis. According to his preface:

> The Method I take to do this is not yet very usual; for instead of using only comparative and superlative Words and intellectual Arguments, I have taken the course (as a Specimen of the Political Arithmetick I have long aimed at) to express myself in terms of *Number, Weight* or *Measure*; to use only Arguments of Sense and to consider only such Causes as have visible Foundations in Nature, leaving those that depend on the Mutable Minds,

> Opinions, Appetites and Passions of particular men, to the Consideration of others.

Petty concluded his preface in the self-consciously undogmatic spirit of the 'new science' by inviting other seekers after truth to confront his results with rational criticism and new data:

> I hope all ingenious and candid Persons will rectifie the Errors, Defects and Imperfections which probably may be found in any of the Positions upon which these Ratiocinations were grounded. Nor would it misbecome Authority itself to clear the Truth of those matters which private Endeavours cannot reach to.

Petty is sometimes credited with having founded the first 'school' of economic thought. But it would be more accurate to say that he had launched the first scientific research programme in political economy. Indeed, in carrying over a Baconian scientific ideology to an analysis of public financial issues, he was simply epitomizing the spirit of his age, for political arithmetic was not narrowly economic in its scope. It was his friend John Graunt, for example, a London draper, who in 1662 published a pamphlet entitled *Natural and Political Observations Made upon the Bills of Mortality* and who, by applying a logical technique of coordination and deduction to the limited vital statistics that had been collected for London over the preceding century, took the first steps in the formulation of the modern science of demography. Using the death returns and other data regularly published in the London Bills of Mortality, plus some personally assembled data for a few country parish records, Graunt made the first reasoned estimates of total population, not only for the metropolis, but also for the country as a whole, and even set up the first life table. Significantly, Graunt's election to the Royal Society was made within a month of the publication of the first edition of his pamphlet, and was strongly supported by Charles II who (according to Sprat, the first secretary and historian of the Royal Society) 'gave his particular charge to His Society, that if they found any more such tradesmen, they should be sure to admit them all, without any more ado'.

It was indeed Graunt rather than Petty who inspired Gregory King to produce his demographic estimates in the 1690s, for Petty's way with figures was somewhat impressionistic. In particular, his results were less likely to be systematically crosschecked against the results suggested by alternative data sources, or by different sets of assumptions, than was the case for either Graunt or King. By the same token, Gregory King's estimates of national income were more meticulously justified, more detailed, more internally consistent, and hence more credible in their delineation of the dimensions of the economy and in international or intertemporal comparisons than were Petty's. Graunt and King, that is to say, were both more sophisticated economic statisticians than Petty. On the other hand, it was Petty's imaginative and ambitious use of his estimates as a basis for economic analyses and policy prescriptions that earned him his reputation as the leading political arithmetician. It is doubtful whether King's estimates, for example, would have had more than an ephemeral currency had they not been so brilliantly applied in the course of the polemical analyses of Charles Davenant – an MP and a public official of some weight, who had held inter alia the posts of commissioner of the excise 1683–9, inspector general of exports and imports 1705–15, and secretary to the commission set up to negotiate the Union with Scotland.

The half-century following the Restoration was the golden age of political arithmetic, but as a method of economic analysis it failed to develop appreciably during the next two centuries. Petty's (or occasionally King's) estimates of national income were often cited by mercantilist pamphleteers without any attempt at updating. True, there were from time to time new aggregative valuations of the nation's total income or product designed to put into perspective a polemical argument relating to a particular sector. For example, in 1760 Joseph Massie updated King's 'Scheme of the Income and Expence of the several Families of England Calculated for the Year 1688', in order to establish a framework for his own estimates of excise tax incidence in a polemic robustly entitled *A Computation of the Money that hath been exorbitantly Raised upon the People of Great Britain by the Sugar Planters in one Year from January*

1759 to January 1760; shewing how much Money a Family of each Rank Degree or Class hath lost by that rapacious Monopoly . . . Similarly, Arthur Young, who was mainly concerned to prescribe for and defend the economic interests of the agricultural sector, made some reasonably careful and well-informed estimates of the nation's agricultural output in the course of his reports on his *Tours* of the northern and eastern counties of England, and associated these estimates with more casual calculations of value added in manufacturing, commerce and various other industries. Young, who had a deservedly high reputation as an agricultural economist, but was undistinguished as a general economist, was probably the last of the political arithmeticians in the original sense of the term. Certainly he was the last economist to write under that banner, which by the 1930s had been annexed by the demographers. His treatise, entitled *Political Arithmetic, Containing Observations on the Present State of Great Britain and the Principles of her Policy in the Encouragement of Agriculture, to Which is Added a Memoir on the Corn Trade*, was a commentary on current agricultural issues which incidentally summarized and reconsidered some of his earlier national product estimates originally published in the Tours.

No doubt because the new discipline of political economy that took shape in the late 18th and early 19th centuries took off in more theoretical, less Baconian directions, political arithmetic lost its capacity to attract innovative exponents. Perhaps Adam Smith gave the *coup de grâce* to the whole approach when he announced in *The Wealth of Nations* that he had 'no great faith in political arithmetick' – though he was not above borrowing some of the political arithmeticians' estimates when they served the purpose of his argument. The third (1787) edition of the *Encyclopedia Britannica* (which did not include an entry for political economy) contained a lengthy piece on political arithmetic, defined as 'the art of reasoning by figures upon matters relating to government, such as the revenues, number of people, extent and value of land, taxes, trade, etc. in any nation'. The explanation went on: 'These calculations are generally made with a view to ascertain the comparative strength, prosperity etc. of any two or more nations.' Most of the entry was devoted to citations from Petty, although it referred also to Davenant, King, Graunt, Halley (the astronomer who had constructed a life table) and to various contributors to the demographic debates which flared up in the second half of the 18th century – such as Brakenridge and Price. After the 18th century, however, political arithmetic ceased to rate an entry in the *Encyclopedia Britannica* in its own right, and even the entries on political economy failed to notice it as a substantial episode in the history of economic ideas.

True, the idea of quantifying the total national income or wealth did not die, and when decennial population estimates were introduced, from 1801 onwards, the bases for such calculations became less speculative. The significance of Petty's role was that he had broken new ground in setting his analyses and associated policy prescriptions within a framework of national aggregates on whose structural relationships and absolute magnitudes the nation's productive strength and taxable capacity evidently hinged. A long, if sporadic, stream of national income estimates was accordingly produced by diligent researchers following in Petty's or King's footsteps – usually in relation to questions of war finance or taxable capacity or comparative economic strength. At the turn of the century, for example, Pitt's plans to raise an income tax to finance the French war stimulated a flurry of national income estimates. At about the same time, George Chalmers put Gregory King's *Natural and Political Observations* in an appendix to the fourth edition of his bestselling *Estimate of the Comparative Strength of Great Britain* (1802); and the appearance in print (for the first time ever) of King's famous table of incomes by families inspired Patrick Colquhoun, then researching the poverty problem, to update King's 1688 results for his *Treatise on Indigence* (1806). Less than a decade later, Colquhoun carried his statistical enterprise even further (with the aid of the first two population censuses) by publishing elaborate and detailed estimates of national income and wealth for the United Kingdom as a whole. This set the stage for the subsequent stream 19th-century estimates of national income which began essentially with Pebrer in 1833 and ended with Mulhall's *Dictionary of Statistics* (1890). Most of these, however, were exercises in descriptive statistics rather than in economic analysis.

In effect, then, Petty's aggregative approach to quantifying and analysing the nation's resources fell into disuse among leading economists as the abstract notion of a self-equilibrating economic system gradually took precedence over the essentially political concept of the royal domain as the central object of economic analysis. What 17th- or early 18th-century economic advisers typically addressed themselves to were the practical problems of the nation state, and these were seen as analogous to the problems of managing a household. Petty, for example, had dedicated his *Political Arithmetick* to the king, because it was the royal domain whose resources he was endeavouring to assess, and its management problems that the quantification was designed to inform. No doubt it was inevitable that when economists founded their theories on the assumption that 'things will have their course' in the politicoeconomic as in the natural universe, and while the role of the state within the wider economic system was assumed to be constrained by the sheer futility of legislating against the 'laws of nature', there was little incentive to extend national income analysis beyond the rudimentary levels it reached in the golden age of political arithmetic. Accordingly, the analytical approach to the study of national income was largely ignored by economists until the middle decades of the 20th century when J.M. Keynes's macroeconomic theorizing revolutionized their discipline.

Political Budget Cycles

Allan Drazen

Abstract

Theoretical and empirical research on political budget cycles is surveyed and discussed. Significant political budget cycles are seen to be primarily a phenomenon of the first elections after the transition to a democratic electoral system.

Political budget cycles are cycles in some component of the government budget induced by the electoral cycle. More specifically, the term most often refers to increases in government spending or the deficit or decreases in taxes (including changes relative to long-term trends) in an election year which are perceived as motivated by the incumbent's desire for re-election for himself or his party. Though political budget cycles may be seen as just one type of political cycle in macroeconomic variables, most research on cycles in economic variables induced by elections now focuses on budget cycles, and it is useful to study such cycles independent of political cycles in economic activity (the political business cycle). The shift in focus is due in part to the lack of strong empirical evidence for the existence of a political business cycle in many countries.

In contrast to the literature on the political business cycle – where development of formal models preceded the bulk of empirical testing – much empirical research on political budget cycles is based not on explicit models but on more conceptual arguments, with sophisticated formal models being developed later to show how the existence of cycles could be consistent with rational voters. In this article, we first review the basic conceptual arguments and then the formal models before considering the empirical research. There are two key empirical questions. The first is whether political budget cycles in fact exist in a large number of countries. Recent evidence, discussed below, suggests that they do not on the aggregate budget level, except for new democracies. The second key question, which underlies the first, is whether manipulation of the budget is an effective tool in gaining votes. Though it is widely believed that deficit spending in an election year in general gains votes for the incumbent, empirical research does not support this view.

Basic Conceptual Arguments

There are two main (and contradictory) views of pre-electoral fiscal manipulation. One is that politicians may be expected to engage in such manipulation and that empirically it is widespread. A simple argument supporting this view is that voters like low taxes and high government expenditures, and vote for incumbents who provide them. Opportunistic incumbents will therefore use expansionary fiscal policy before elections to increase the probability of re-election.

However, this simple argument is inconsistent with rational, forward-looking voters who are aware of government budget constraints both at a point in time and intertemporally. Since the non-smooth paths of taxes and government expenditures implied by election-year deficits are presumably costly, voters should dislike deficits in general and especially those seen as electorally motivated. They would therefore not reward incumbents who engage in election-year manipulation. Hence, the alternative view is that voters (especially in developed countries) are 'fiscal conservatives' who punish rather than reward fiscal manipulation. Evidence, discussed in greater detail below, suggests that this is the case in developed countries with established democracies.

A second argument is that if voters respond to good economic conditions by being more likely to vote for the incumbent, he will use expansionary fiscal policy to try to manipulate macroeconomic outcomes and provide higher growth. Hence, expansionary fiscal policy will help an incumbent's re-election prospects. However, even if good economic conditions help an incumbent's chances of re-election, it is not clear that fiscal manipulation will be effective – politicians may have very limited ability to manipulate the economy successfully, both because of a lack of technical ability to time the expansion accurately enough to happen just before the elections and because, as discussed above, rational, well-informed voters should not support such policies.

A more sophisticated argument on why rational voters may respond to pre-electoral fiscal expansions is that they have imperfect information about candidates' abilities or about the environment, and that a fiscal expansion signals incumbent ability or some other characteristic which voters value, so that it is effective in gaining votes. This was first formalized in the work of Rogoff, which is summarized below.

An alternative is that, if voters do punish election-year deficits or spending increases (as the data indicate for developed countries), electoral manipulation takes the form of changes in the composition of the budget rather than in its overall level (or the overall deficit). This may take the form of increases in spending that voters as a whole favour at the expense of those types of spending that voters may be believed to like less (or are less visible), or the form of expenditures targeted at some voters at the expense of other voting groups who are seen as electorally less valuable.

Signalling Models

The Basic Competence Model

Formal modelling of the signalling role of a pre-election fiscal expansion under asymmetric information was introduced by Rogoff and Sibert (1988) and Rogoff (1990). The models are based on unobserved 'competence', that is, the ability to deliver more public goods for the same level of taxes. Hence, more competent policymakers can generate higher welfare and so are preferred by voters. Competence is correlated over time, so that a candidate who is believed by voters before an election to be more competent than average (the presumed competence of his randomly drawn challenger, who is unable to signal) is expected to be more competent than average after the election as well. Voters therefore rationally prefer a candidate who delivers higher expenditures before an election, since this is a signal of higher competence.

The basic ideas can be represented by a simple version of the model in Rogoff (1990). There is an election at the end of the first period, with the leader who is elected remaining in office thereafter. Voters will choose the leader on the basis of any information they gather in the first period. The utility of the representative voter as of period t may be represented by

$$\Gamma_t = \sum_{s=t}^{T} \beta^{s-t}(g_s + v(k_s)) + \eta_t \tag{1}$$

where g_s is public consumption and k_s is public investment. The function $v(.)$ is assumed to be increasing, concave and satisfying the Inada conditions on its first derivatives as k goes to zero or infinity. The term η_t is a random shock in the election period $t = 1$ such that the outcome is not known *ex ante* to the incumbent setting policy. The voter maximizes the expected value of utility by choosing a candidate in an election at the end of the first period.

The production of public goods is represented as follows. If a leader has an 'administrative ability' or 'competence' ε, he can produce public goods at time t according to:

$$\varepsilon = g_t + k_{t+1} \tag{2}$$

where it is assumed that ε is not directly observable. Investment k must be chosen one period in advance, so that it is not currently observable. Hence, if a voter observes a high value of g_t, he does not know whether this reflects high ability of the policymaker (high ε) or high current public consumption 'bought' at the expense of a cut in some other component of public spending (here, public investment) at some point in the future. This is meant to represent the basic inference problem a voter faces when he observes high government spending before an election – does high observable government expenditure represent fiscal manipulation, in the sense of implying that taxes will be raised or other programmes cut in the future, or does it represent the ability of the leader to provide more goods or services without cutting future goods services?

Potential leaders are assumed to differ in their unobserved ability. Suppose there are two possible levels of ε: ε^H and $\varepsilon^L < \varepsilon^H$, where ability ε_j is expected to persist after the election. Let the prior probability that $\varepsilon = \varepsilon^H$ be $0 < \rho < 1$. The voter's inference problem is to use an observation of g to try to infer the probability that the leader is high-ability, that is, to form a posterior $\hat{\rho}(g)$.

The utility of the incumbent leader is given by:

$$E_t\Gamma_t + \left(\chi + q\sum_{s=t+1}^{T}\beta^{s-t}\chi\right)$$

where χ is the value of holding office and q is the probability of being re-elected at the end of the first period. A key point is that a policymaker's utility depends both on social welfare (the first term) and on his own private payoffs (the second term). If it depended only on social welfare, incumbents would choose the socially optimal fiscal policy and there would be no signalling. If it depended only on private payoffs, low-ability incumbents would mimic whatever high-ability incumbents do and there would only be a pooling equilibrium with no signalling.

At the beginning of period 1, the incumbent observes his ε^j, sets g_1 and k_2 (where k_1 is predetermined). Voters then observe g_1 and f_1 and then vote at the end of the period for either the incumbent or a randomly drawn challenger (who cannot signal his competence, which is average expected competence $\overline{\varepsilon}$ given the prior ρ.) In subsequent periods, the elected policymaker chooses g_t and k_{t+1} to maximize social welfare, given his competence ε. This first-best solution is given by maximizing (1) subject to (2), yielding $k^* = v'^{(-1)}(1/\beta)$ and $g^*(\varepsilon^j) = \varepsilon^j - k^*$. (This would also be the solution in period 1 if voters knew the incumbent's ε.) Since higher-ability incumbents provide more public goods, and thus higher utility, voters prefer a high-ability incumbent to the challenger of expected ability $\overline{\varepsilon}$, but prefer the challenger to a low-ability incumbent.

Under asymmetric information (that is, when the representative voter does not observe the incumbent's ε before voting, or cannot infer it because of imperfect information about the components of the budget), a voter's beliefs about an incumbent's ability are conditioned on his observation of g_1. These beliefs can be summarized as the posterior probability $\hat{\rho}(g_1)$ the voter assigns to the incumbent being of ability ε^H conditional on the value of g_1 observed. Given the voters' rational voting rule, an incumbent has an incentive to appear to be of high ability.

The equilibrium is a separating equilibrium in which the level of spending reveals the incumbent's competence type. A high-ability incumbent will spend just enough so that the low-ability incumbent will not find it optimal to mimic him. (Since a high-ability incumbent can invest $\varepsilon^H - \varepsilon^L$ in k_2 for the same level of g_1, and since politicians care about social welfare, concavity of $v(k)$ implies that the high-ability type can cut back on k at a lower marginal cost to himself than the low-ability type can, the signal of raising g_1 is less costly for him to send.) The low-ability incumbent will choose the first-best solution for his type, namely, $g_1 = g^*(\varepsilon^L) = \varepsilon^L - k^*$. Since this reveals his type he loses the election almost certainly.

If the values of ε^H and ε^L are far enough apart, then the high-ability incumbent can signal his type by choosing his first-best $g^*(\varepsilon^H)$, which the low-ability type won't mimic. However, if ε^H and ε^L are sufficiently close, then a high-ability incumbent can signal his type only by choosing $g_1 > g^*(\varepsilon^H)$. With a continuum of ability types, then each type separates from the type immediately 'below' him by choosing a $g_1 > g^*(\varepsilon^j)$, except for the lowest-ability type who plays his first best. Hence, there is the general result that there will be a fiscal expansion in an election year relative to non-election years, not because voters are naive but because they are sophisticated.

Timing of Signals

A question often raised about election-year expansions as a signal of competence (or some other desirable characteristic of a politician) is why the signal should be sent just before an election, rather than earlier in the politician's term. The argument in this sort of model is that information about such characteristics evolves over time, so that there is new information to be signalled in the time period before an election. At the same time the desirable characteristic must have some persistence, so that its preelectoral value provides information about its post-electoral value. (Formally, Rogoff modelled this by assuming there was an election at the end of every other period, with ability ε assumed to be the sum of the current period and previous period's i.i.d. shock, that is, an AR(1) structure. Therefore, information signaled by g_t in period t before an election was relevant for the post-electoral period $t + 1$, but not for the subsequent election at $t + 2$. This makes the incumbent's choice problem for choice of g_t fairly simple.)

Observability of Fiscal Policy

A key ingredient of this type of signalling model focusing on competence is voters' inability to observe the overall level of spending or of the deficit, for otherwise they could perfectly infer his competence. The reliance of this result on voters' lack of information is consistent with Brender and Drazen's (2005a) empirical finding of no statistically significant aggregate deficit or expenditure cycle in established democracies, where voters may be well-informed about fiscal outcomes. Gonzalez (2002) and Shi and Svensson (2002) extend the Rogoff model to study the effect of transparency on the magnitude of fiscal cycles. The basic result is that the higher the degree of transparency, the lower is the amount of distortion away from the first best in the political budget cycle. Shi and Svensson include a similar measure of transparency. Shi and Svensson further argue that, while the proportion of uninformed voters – who may be influenced by fiscal manipulation – is initially large, it is likely to decrease over time, thus decreasing the magnitude of budget cycles. They create a measure of the availability of information and show that as voters become more informed the magnitude of the cycle decreases. A key innovation of Shi and Svensson (2002) is that the policymaker chooses fiscal policy before he knows his competence level, so that all 'types' choose the same level of expansion. That is, the model focuses on moral hazard rather than signalling, as the other models do. An implication is a cycle in the aggregate deficit.

Unobserved Politician Preferences

The argument that, with high transparency, political cycles in aggregate expenditures or deficits are likely to be weak or non-existent (combined with empirical evidence on the absence of political cycles in budget aggregates in countries where transparency is seen as high) has led to alternative signalling models. If voters are fiscal conservatives, election-year fiscal manipulation may take the form of changes in the composition of the budget with overall spending and deficits held constant. These compositional changes may be either in categories of expenditures or in expenditures or transfers targeted to some voters at the expense of others.

Drazen and Eslava (2005, 2006) argue that, if it is the composition of spending or transfers, rather than their overall level, that is manipulated for electoral purposes, rational voters may be trying to infer something other than (or in addition to) competence from election-year fiscal policy. Voters who are targeted before an election want to know whether they will be similarly favoured after the election. They therefore suggest that a key unobserved characteristic of an incumbent politician is his preferences over groups of voters or types of expenditure. As in the Rogoff competence models, these preferences have some persistence over time, so that a voter who believes that the incumbent favours him before the election rationally expects some similarity in the composition of expenditures after the election as well. A voter thus faces an inference problem – whether receiving high targeted expenditures before the election signals a greater weight of his group in the incumbent's objective function than other voters or non-targeted expenditures, or whether it signals simply how 'swing' his demographic group is, meaning how many votes the incumbent can raise by targeting his group with expenditures. In both papers, Drazen and Eslava show the existence of an equilibrium in which voters rationally respond to election-year expenditures and politicians allocate expenditure on the basis of this behaviour. Politicians increase spending targeted to electorally attractive groups before elections, while they reduce other types of expenditure to satisfy the no-deficit constraint. As mentioned, a key result is that electoral manipulation arises even with fully rational voters. Drazen and Eslava (2006) further show that even when voters know how 'swing' their group is a political cycle may still arise.

There are several key differences between competence as the crucial unobserved characteristic and the approach of Drazen and Eslava, where a politician's preferences are unobserved and spending is targeted to some groups of voters or types of expenditure at the expense of others. First, in the latter approach, manipulation may occur even without affecting the aggregate deficit, consistent with empirical findings discussed below. Second, electoral fiscal manipulation arises even if voters can perfectly monitor the fiscal choices of an incumbent. Finally, political budget cycles in the Drazen and Eslava models arise even if all politicians are equally able to provide public goods.

Empirical Studies of Political Budget Cycles

Empirical studies of political budget began with the work of Tufte (1978) for the United States, followed by numerous other empirical studies for both developed and developing countries, as summarized in Drazen (2001). Political budget cycles were widely believed to be strongest for developing countries.

More recently, a number of papers have argued that, while these cycles are stronger in developing countries, they characterize democracies at all levels of economic development, and even non-democracies. Shi and Svensson (2002) find that, in a large panel of both democracies and non-democracies over the period 1975–95, the government deficit rises significantly in an election year in both developing and developed countries. (They show that the effect is far stronger in developing countries, consistent with earlier studies.) The economic effect is significant for the sample as a whole, the fiscal surplus falling on average in their full sample by one half to one per cent in an election year, depending on the estimation method they use. Persson and Tabellini (2003) restrict their sample to a group of 60 democracies from 1960 to 1998. They find a political revenue cycle (government revenues as a percentage of GDP decrease before elections), but no political cycle in expenditures, transfers, or the overall budget balance across countries or political systems. They argue that the electoral system (proportional versus majoritarian) and the governmental system (presidential versus parliamentary) is a key determinant of the nature of the cycle across countries.

However, Brender and Drazen (2005a) argue that the political deficit cycle in democracies is a phenomenon of recently democratized countries, that is, are found to be statistically significant only in the first few elections after a country has made a transition from being a non-democracy to a democracy (which holds true whether or not the formerly socialist economies are included). It is the strong political budget cycle in these countries that accounts for the political budget cycle in larger samples including these countries. Once these countries are removed from the larger sample, the political fiscal cycle disappears. This is true in both developed and developing countries. Hence, the stronger results previously found for developing countries reflect the fact that new democracies comprise a larger fraction of developing than developed country democracies. The 'new democracy' effect also helps explain previous findings of a stronger political cycle in weaker democracies (new democracies are a larger fraction of 'weak' than 'strong' democracies, with no significant cycle found in weak, old democracies). They also find that helps account for differences in the political cycle across government or electoral systems.

There is also a significant political expenditure cycle in the new democracies, with the very similar positive coefficients on the fiscal deficit and on expenditures in the analogous equations, while there does not appear to be a statistically significant revenue cycle. The deficit cycle in the new democracies thus appears to be driven by higher election-year expenditures.

Brender and Drazen suggest several explanations for their ‘new democracy’ finding. One is that fiscal manipulation may be used in new democracies because voters are inexperienced with electoral politics or may simply lack the information needed to evaluate fiscal manipulation that is produced in more established democracies. This suggests one way to reconcile the two contradictory views of preelectoral manipulation. The argument that politicians may be expected to engage in such manipulation may apply to new democracies, where it is possible to carry out such manipulation. The alternative that voters punish fiscal manipulation is applicable to established democracies, where voters have the ability to identify fiscal manipulation and punish such behaviour, so that politicians avoid it.

This is consistent with work by Gonzalez, Shi, and Svensson, discussed above, that focuses on information asymmetries in explaining budget cycles when voters are not naive. It is also consistent with findings by Akhmedov and Zhuravskaya (2004), who find similar evidence in regional elections in Russia after its transition to democracy. Using monthly data between 1996 and 2003, they found sizable but short-lived political budget cycles in local fiscal spending, which became significantly smaller over time and disappeared for most (but not all) fiscal instruments after two rounds of elections. Akhmedov and Zhuravskaya (2004) find similarly that measures of the freedom of the regional media and the transparency of the regional governments were important predictors of the magnitude of the cycle. Alt and Lassen (2006a) find that in OECD countries higher fiscal transparency also lowers the magnitude of the electoral cycle.

The absence of political cycles in budget aggregates in established democracies as a group does not, however, mean there are no electoral effects on fiscal policy. Established democracies appear to be characterized by cycles in the composition of spending rather than cycles in its overall level. Several papers find evidence of electoral composition changes in government spending at the sub-national level, including the United States (Peltzman 1992), Canada (Kneebone and McKenzie 2001), Colombia (Drazen and Eslava 2005), India (Khemani 2004), and Israel (Brender 2003). Drazen and Eslava (2005) present a signalling model of composition cycles with rational voters where the unobserved characteristic of politicians is their preferences for different types of expenditure, specifically those types of expenditure that voters as a whole prefer.

A second possible explanation for the new democracy effect follows from the Brender and Drazen (2005b) finding that fiscal balance has no significant effect on the probability of re-election, a surprising finding given the existence of a political budget cycle in new democracies. The authors suggest that these two findings may be reconciled by the possibility that fiscal expansions in election years in new democracies do not represent an attempt to gain voter support for the leader but reflect expenditures incurred in an attempt to consolidate democracy. Democracy is often not ‘consolidated’ in new democracies, that is, it is not accepted unconditionally by all citizens. An election year may be an especially dangerous time for the existence of the democracy itself, and thus may be a time when leaders have to spend money to retain popular support for the democratic regime to prevent its overthrow or subversion and the return to an autocratic system. One might then observe higher expenditures and deficits in an election year, but without fiscal expansion necessarily gaining votes for the incumbent over the challenger.

The Effect of Deficits on Re-election

In contrast to the fairly extensive direct tests of overall macroeconomic performance on election outcomes in the literature on political business cycles, there are few tests of fiscal performance on election outcomes, primarily at the sub-national level. These include Peltzman (1992), Brender (2003), and Drazen and Eslava (2005), who examine the direct effect of fiscal performance on re-election at the state and local levels in a single country (the United States, Israel, and Colombia respectively), and find that voters punish – rather than reward – loose fiscal policies in general, as well as in election years.

The only large cross-country study is by Brender and Drazen (2005b), who look at the effects of fiscal performance on re-election in a sample of 74 democracies (comprising 350 election campaigns) over the period 1960 to 2003. They estimate probit regressions giving the probability of an incumbent's re-election as a function of macroeconomic and fiscal variables. They find no evidence that expansionary fiscal policy helps a leader to get re-elected; in fact, it is likely to reduce the chances of re-election. In developed countries, especially established democracies, deficits lower the probability of re-election, with an effect that is both statistically and economically significant. In developing countries, the effect of deficits on re-election is close to zero and is not statistically significant. While voters in developing countries may be more tolerant of an expanding budget deficit in election years, even in these countries voters do not reward election-year deficits at the polls. Brender and Drazen find no statistically significant difference between the effect of deficits that are created by higher expenditures and of those that are created by lower revenue, although in the developed countries the effect of revenue reductions (as a share of GDP) is somewhat larger.

They also find that in established democracies in developed countries voters punish election-year deficits and deficits over the incumbent's term of office. The effects are quite substantial quantitatively. An increase of one percentage point in the ratio of the central government surplus to GDP over the term can increase the probability of re-election by 3–4.5 percentage points in the developed, established democracies, and an increase of one percentage point in the surplus during an election year increases the probability of reelection by between seven and nine percentage points.

The Brender–Drazen results indicate that controlling for the type of political system (parliamentary versus presidential) or the type of electoral system (majoritarian versus proportional) does not change the effect of the election year deficit and growth, nor does whether elections were held at their scheduled date or early. Similarly, they find no significant effect of the level of democracy on the finding that deficits do not help re-election chances of an incumbent.

Political Business Cycles

Allan Drazen

Abstract

Theoretical and empirical research on political business cycles, both opportunistic and partisan, is surveyed and discussed. The evidence for the existence of empirically significant opportunistic political business cycles is argued to be mixed.

Keywords

Central bank independence; Competence; Imperfect information; Infinite horizons; Inflationary expectations; Natural rate of unemployment; Opportunistic vs. partisan business cycles; Phillips curve; Political budget cycles; Political business cycles; Rational expectations; Rational voting; Signaling

Political business cycles are cycles in macroeconomic variables – output, unemployment, inflation – induced by the electoral cycle. (Political cycles in fiscal policy variables, termed 'political budget cycles', are treated in a separate article.) Key questions this literature addresses include the following. Are such cycles observed in the data? What are the political and economic mechanisms that lead to such cycles? What do they imply about voter behaviour?

There are two basic types of models. 'Opportunistic' political business cycles are expansions in economic activity induced by an opportunistic incumbent before an election meant to increase his chances of re-election. 'Partisan' political business cycles are fluctuations in macroeconomic variables over or between electoral cycles resulting from leaders having different policy objectives.

Opportunistic Models

Formal models of the opportunistic business cycle began to appear in the mid-1970s, the most influential of which was that of Nordhaus (1975). The structure of the economy is summarized by a downward-sloping Phillips curve, yielding a trade-off between unemployment and unexpected inflation. Inflation expectations are formed adaptively on the basis of past observed inflation. Identical voters base their voting decisions on aggregate inflation and unemployment outcomes relative to their most preferred outcomes. They have a preference for both low unemployment and low inflation, but, in evaluating incumbents on the basis of macroeconomic performance, they have short memories and no foresight. An opportunistic incumbent policymaker has no preferences over inflation and unemployment *per se* and cares only about re-election. The slow adjustment of inflation expectations to economic stimulation, combined with myopic voters, allows an opportunistic incumbent to manipulate macroeconomic time paths to his electoral benefit. He stimulates the economy before the election to reduce unemployment, with the inflationary cost of such a policy coming only after.

More formally, the basic opportunistic model may be simply represented as follows. The objective of the policymaker is to maximize his probability of re-election, where voting behaviour is retrospective in that it depends on economic performance under the incumbent in the past. Economic performance in a period is measured by the behaviour of current inflation π_t and unemployment U_t, so that voter dissatisfaction in any period can be represented by a loss function which is increasing in these two variables. Consider, for simplicity:

$$L(U_t, \pi_t) = U_t + \theta \frac{(\pi_t)^2}{2} \tag{1}$$

where θ is the relative weight the electorate puts on inflation deviations relative to unemployment and where (for simplicity of exposition) it is assumed that the representative voter's most preferred rate of inflation is zero.

One may then posit a retrospective voting function for an election at the end of period *t,* of the form:

$$V_t = \Psi\left(\sum_{s=0}^{T-1} \gamma(s) L(U_{t-s}, \pi_{t-s})\right) \qquad (2)$$

yielding the number of votes V_t for the incumbent as a decreasing function of loss from economic outcomes ($\Psi' < 0$). The exogenous length of time between elections is T periods, and $\gamma(s)$ is the weight voters put on a loss s periods in the past. $\gamma(s)$ is assumed to be decreasing in s, that is, past economic outcomes have a smaller effect on votes at t the further in the past they are. If $\gamma(s)$ is rapidly decreasing in s, very recent events are weighted most heavily. In the extreme, $\gamma(s) = 0$ if for $s > 0$, then only economic outcomes in the year of the election affect voting. The electoral mechanism is not made more specific. One could add a stochastic element to allow for the possibility of an incumbent losing the election.

In the Nordhaus model, the structure of the economy is summarized by an expectations-augmented Phillips curve relating the difference between the actual and the natural rates of unemployment U_t^N to the difference between actual and expected inflation π_t^e :

$$U_t = U_t^N - \left(\pi_t - \pi_t^e\right) \qquad (3)$$

To close the model one must specify the formation of expectations. Crucial to the main results of the above models is some form of backward-looking expectations, so that inflationary policy in an election period is not fully anticipated and can therefore lower the unemployment rate. A standard formulation of adaptive determination of the expected rate of inflation:

$$\pi_t^e = \pi_{t-1} + \alpha\left(\pi_{t-1}^e - \pi_{t-1}\right) \qquad (4)$$

where α is a coefficient between 0 and 1 representing the speed with which expected inflation adapts to past expectational errors. This may be solved to yield π_t^e as a weighted declining sum of past inflation rates.

This four-equation system may then be solved for unemployment and inflation over the electoral cycle. When voters have 'short memories' ($\gamma(s)$ small for $s > 0$) a political business cycle will emerge if the incumbent wants to maximize his probability of re-election. In the period immediately after the election the government engineers a recession via contractionary monetary policy to bring down inflationary expectations. The incumbent keeps economic activity low to keep expected inflation low until the period immediately before the next election, so that a given rate of economic expansion (induced by a monetary surprise) can be obtained at a relatively low rate of inflation. The government then stimulates the economy via expansionary monetary policy, unemployment falling due to high unanticipated money growth. The levels of monetary expansion and unemployment are those which maximize voter satisfaction in the election period. In the next election cycle the same behaviour is repeated, with contractionary monetary policy to bring down inflation expectations. Hence, the possibility of influencing the probability of re-election, combined with the structure of the economy, yields a cycle in economic activity which would not be present with a planner with an infinite horizon. The political cycle thus induces a cycle in economic activity and inflation.

Though these models capture the incentive for opportunistic policymakers to manipulate policy and the macroeconomic cycle that may result, a number of conceptual and empirical objections may be raised. First, incumbents running for re-election do not control monetary policy in countries with independent central banks. However, there is evidence that nominally independent central banks often accommodate the executive branch's pressures for monetary policy during election years in order to prevent sharp movements in interest rates (see, for example, Woolley 1984, for evidence for the United States). Hence, politically motivated monetary policy in an election year may be a good approximation to reality.

Second, one may question whether voters are really as unsophisticated as the basic models assume, both in the way they form expectations of inflation and in the way they assess government performance. Voters realize that 'election-year economics' may be used to win their votes and hence may be sceptical of an economic upturn in the months before an election. More formally, their expectations of inflation should take the possibility of an election-year monetary expansion into account (which would then nullify its effects since it is no longer a surprise). An intermediate view is that voters have less-than-perfect information about the causes of economic fluctuations and take good economic performance as indicating incumbent competence. Hence voting for the incumbent when times are good is consistent with rationality when voters have imperfect information. This has been argued by Nordhaus (1989) and has been formalized using signalling models, as discussed below.

Partisan Models

In partisan models, cycles are induced by differences among parties in their ideology and their economic goals. The basic partisan model is due to Hibbs (1977), based on different preferences over inflation and unemployment across parties. One replaces the voters' loss function (1) with one representing the preferences of a party j, for example,

$$L^j(U_t, \pi_t) = \frac{\left(U_t - \tilde{U}^j\right)^2}{2} + \theta^j \frac{\left(\pi_t - \tilde{\pi}^j\right)^2}{2} \qquad (5)$$

where $\tilde{\pi}^j$ is party j's target rate of inflation, $\tilde{U}^j$ is party j's target unemployment rate, and θ^j is the weight party j puts on deviations of inflation from target inflation relative to deviations of unemployment from target. The two parties, say a right-wing party R and a left-wing party L, are characterized, for example, by $\tilde{U}^L \leq \tilde{U}^R$, $\theta^L \leq \theta^R$, and $\tilde{\pi}^L \geq \tilde{\pi}^L$. Thus, the left-wing party will pursue a more expansionary monetary policy throughout its term. Using the same specification of the relation between unemployment and inflation as in (3) and a similar specification of backward-looking expectations (4), one may derive a cycle in which the level of economic activity and inflation varies with the ideology of the incumbent.

Rational Voters

Early models in both strands of the literature were often criticized in their modelling of expectations, since the backward-looking nature of expectations was crucial for some of the results. Hence, in both strands the focus has shifted to models in which voters form their expectations rationally, with the question being whether a political budget cycle will still exist with rational, forward-looking voters.

In the context of an opportunistic political budget cycle, the key argument is that some characteristic of policymakers is unobserved, and the voters' inference problem over an incumbent's 'type' will imply it is optimal to vote more heavily for the incumbent when economic outcomes are favourable. A leading unobserved characteristic is the incumbent's 'competence'. More competent policymakers produce better outcomes, and competence has some persistence over time. Therefore, good outcomes in the time period before the election may signal high competence of the incumbent (relative to a challenger who cannot signal), which is expected to persist after the election. Hence, when competence cannot be observed directly, it may be optimal for voters to vote more heavily for the incumbent if times are good.

This argument may be formalized in an imperfect information framework. The first formal models concerned political budget cycles in work by Rogoff (for example, Rogoff 1990). Persson and Tabellini (1990) and Lohmann (1998) present similar models of unobserved policymaker ability as applied to cycles in economic activity. High economic activity before an election signals a high-ability incumbent, that is, higher than the average expected ability of the challenger. Since ability has a persistent component, voters expect better economic performance from the incumbent than from the challenger after the election as well, and hence vote for him.

Alesina (1987) introduces rational expectations into the original partisan model of Hibbs, so that fluctuations in inflation and unemployment are driven by partisan differences combined with uncertainty about election outcomes. Close elections imply the sort of fluctuations Hibbs found, but because expansionary monetary policy by a left-wing policymaker (for example) is not fully anticipated before an election and therefore will lead to a fall in unemployment after the election. A key difference from the Hibbs model is that any effect on unemployment will no longer be present after inflation expectations are adjusted. Hence, the effects on unemployment will be concentrated early in a leader's term of office and disappear in the latter part of the term once the leader's preferences are known.

Empirical Testing

The existence of opportunistic political business cycles has been subject to extensive empirical testing. There are two key questions: are election years characterized by economic expansions? Do voters respond to 'good times'?

The standard test for the existence of a political cycle is to run an autoregression of an economic performance measure on itself, a small set of economic variables, and political dummies, that is, a regression:

$$Y_t = \sum_{i=1}^{s} a_i Y_{t-i} + b_0 + \sum_{j=1}^{k} b_j X_{jt} + d\,PDUM_t + \varepsilon_t \qquad (6)$$

where Y is an outcome variable such as output growth, the X_j are control variables, and PDUM is a political dummy variable (or set of variables) meant to represent a given political model. The autoregressive specification for Y_t is adopted as a parsimonious representation of the time series behaviour of Y, instead of using a structural model. The hypothesis that output growth, for example, is higher in election years would be represented by setting $PDUM_t$ equal to 1 in election years and zero otherwise, and testing whether the coefficient d is statistically significant.

The evidence for a political cycle in outcomes is quite mixed, with most studies finding little evidence of opportunistic political cycles in developed countries. Much of this evidence is summarized in Alesina et al. (1997) and Drazen (2000).

The evidence on voter response to economic conditions is also mixed. Generally, the effect of growth on re-election probabilities was found to be insignificant in most cross-section studies in developed countries (see Brender and Drazen 2005, for a summary). The United States seems to be an exception to these findings. The most influential paper on voter response in the United States is probably that of Fair (1978), who found that an increase in real economic activity in the year of the election, as measured either by the change in real per capita GNP or the change in unemployment in the election year, has a strong positive effect on the incumbent's vote total in US presidential elections. Alesina and Rosenthal (1995) find similar results.

Brender and Drazen (2005) confirm the insignificant effect of growth on re-election probabilities in developed countries in a large cross-section study of a sample of 74 democracies over the period 1960–2003. In contrast, they find that in less developed countries higher growth in real GDP has a positive and statistically significant effect on the probability of re-election. They then remove from the overall growth rate the part that voters might attribute to global developments and find that in the less developed countries it is the component of growth associated with domestic influences that accounts for the highly significant effect of growth on re-election, while the part attributable to global economic growth has no statistically significant effect on the probability of re-election. In the developed countries they find that neither the effect of global growth nor the effect of domestically induced growth is statistically significant.

There has been less empirical testing of the partisan political business cycle. The striking empirical regularity in the United States since the Second World War is that economic activity is substantially higher under Democrats than under Republicans in the first part of their four-year terms, but more similar in the second part of their terms, consistent with the Alesina model. However, Faust and Irons (1999) argue that the data do not give strong support to any partisan model. For the OECD, Alesina et al. (1997) find supporting evidence for the rational partisan model in a number of countries.

Overall, the focus of both theoretical and empirical research has shifted to political budget cycles, in large part due to the weak empirical evidence for the existence of an opportunistic political business cycle in many countries, combined with the widespread view that, nonetheless, election year manipulation of some sort is a common phenomenon.

Political Competition

David Austen-Smith

Abstract

This article is limited to interaction between candidates and voters and examines the cases of two-candidate competition and multiple candidate competition. It employs the spatial model of elections introduced to study single-issue politics and generalized to study multiple-issue politics in order to explain the alternatives strategically offered to voters by candidates or parties competing for electoral office.

Keywords

In its most general form, political competition concerns the struggle of ideas for organizing societies. This article, however, focuses explicitly on one concrete manifestation of this struggle, namely, electoral competition. Any convincing and general explanation of electoral competition must account for the role of money in campaigns, for the behaviour of interest groups and the implications of party organization. This article addresses only the interaction between candidates and voters. Although not the only framework for studying the topic, the spatial model of elections introduced by Hotelling (1921) and Downs (1957) for single-issue politics and generalized by Davis and Hinich (1966, 1967) to multiple-issue politics, is surely the most widely used. The principal goal of the theory is to explain the alternatives strategically offered to voters by candidates or parties competing for electoral office.

Two-Candidate Competition

A Benchmark Model

There are two candidates A,B, and a large finite set of voters $N = \{1, \ldots, n\}$. The policy space is a convex and compact set $X \subset R^k$, where $x \in X$ is a typical feasible policy. Each voter $i \in N$ has policy preferences on X representable by a continuous and strictly quasi-concave utility function $u_i : X \to R$; let $\mathbf{u} = (u_1, \ldots, u_n)$ denote the preference profile over X. Candidates too have preferences although they need not be defined directly on the policy space, X; candidates, for example, might plausibly be more interested in winning office than in policy per se, or in some combination of winning and the policy eventually implemented, irrespective of who wins. On the assumption of complete information on the part of voters regarding candidates' motivations and policy platforms, and on the part of candidates regarding voters' preferences, however, introducing policy motivations for candidates leads to no essential change in the predictions of the model with purely office-motivated candidates (Calvert 1985; Duggan and Fey 2005). Some implications of assuming that candidates are policy motivated when there is some uncertainty about payoffs are considered later; for now, suppose that each candidate is motivated solely by the desire to win office.

The election is for a single office and is determined by a plurality rule. On the assumption of no abstention, a voting strategy for any citizen $i \in N$ is a mapping $v_i : X^2 \to [0, 1]$, where $v_i(a, b)$ is the probability that i votes for candidate A when A chooses electoral platform $a \in X$ and B chooses a platform $b \in X$. Given a profile of vote strategies $\mathbf{v} = (v_i)_{i \in N}$, $V_j(a, b| \mathbf{v}) \in [0, n]$ is the expected number of votes cast for candidate j. Let $\Pi(a, b| \mathbf{v}) = V_A(a, b| \mathbf{v}) - V_B(a, b| \mathbf{v})$ denote A's expected plurality, so $-\Pi(a, b| \mathbf{v})$ is B's expected plurality. Then candidate j's payoff under plurality rule is 1 if her realized plurality is strictly positive, -1 if it is strictly negative, and zero otherwise.

The strategy space for each candidate is X. Maximizing j's payoffs in this setting is equivalent to maximizing j's expected plurality. Thus, A chooses $a \in X$ to maximize $\Pi(a, b| \mathbf{v})$ and B chooses $b \in X$ to minimize, $\Pi(a, b| \mathbf{v})$. Under the assumptions of no abstention and two candidates, maximizing $\Pi(a, b| \mathbf{v})$ is equivalent to maximizing $V_A(a, b| \mathbf{v})$. Later, I consider some implications of admitting abstention and multiple candidates where the equivalence fails. An equilibrium to the game is a vector of undominated strategies $(a^*, b^*, \mathbf{v}^*)$ such that each voter $i \in N$ is maximizing u_i conditional on (a^*, b^*) and the voting strategies of all $j \in N/\{i\}$ and, given $\mathbf{v}^*$,

$$\Pi(a^*, y| \mathbf{v}^*) \geq \Pi(a^*, b^*| \mathbf{v}^*) \geq \Pi(y, b^*| \mathbf{v}^*)$$

for all $y \in X$.

Existence of equilibrium in the model when candidates use pure strategies is a problem. The majority core, that is, the set of alternatives $x \in X$ such that no alternative is strictly preferred by a majority to x, is guaranteed to be non-empty only when the dimensionality of the policy space, k, is 1 (Plott 1967; McKelvey 1979; Schofield 1983) and it is not hard to see that the set of equilibria in pure candidate strategies coincides with the majority core. The most familiar example of this coincidence is the median voter theorem for $X \subseteq R$ (Downs 1957; Black 1958), predicting candidate convergence on the median most preferred policy. On the other hand, if a policy space of any finite dimension is approximated with a finite grid, irrespective of how fine the grid might be, the classical Nash equilibrium existence theorem implies the existence of an equilibrium in mixed candidate strategies. Furthermore, in the finite case with no majority indifference, the mixed strategy equilibrium is unique and symmetric (Laffond et al. 1993): both candidates adopt the same mixed strategy and thus, *ex ante*, the candidates are equivalent from a policy perspective, just as they are under the median voter theorem.

The difficulty in proving a general mixed strategy equilibrium existence result for the spatial voting model with a continuum of alternatives lies in the absence of sufficient continuity in the mapping that connects pairs of policy positions to vote shares: a small unilateral change in one candidate's position can result in the candidate's vote share changing from less to more than one-half of the electorate, thus inducing a discrete jump in her payoff. But these discontinuities often arise as a result of the presumption that indifferent individuals in the spatial model necessarily vote for each candidate with probability one-half. If this assumption is relaxed and individuals are restricted only to symmetric voting strategies, thus allowing the probability of indifferent individuals voting for one or other candidate to be sensitive to the platforms offered, then existence of a mixed strategy equilibrium is guaranteed (Duggan and Jackson 2004). Characterizing mixed candidate strategies, however, is not easy. McKelvey (1986) and Banks et al. (2002) provide some insight by showing that the support of any mixed strategy equilibrium (essentially) lies within the closure of the uncovered set: say that an alternative x is covered by an alternative y if x is strictly majority preferred to y and, further, that any alternative z that defeats x also defeats y; the uncovered set is then the set of alternatives that are not covered (Miller 1980). The uncovered set generally exists in the spatial model and, moreover, if a sequence of (continuous and strictly quasi-concave) preference profiles converges uniformly to a profile $\mathbf{u}^*$ at which the majority core is non-empty, then (loosely speaking) the associated sequence of uncovered sets converges to the core at $\mathbf{u}^*$. Thus, for any profile $\mathbf{u}$ 'close' to a profile $\mathbf{u}^*$ supporting pure strategy equilibria to the election, the realized policy platforms offered to the electorate at $\mathbf{u}$ are 'close' to the (pure strategy) equilibrium policies offered at $\mathbf{u}^*$.

Results on the uncovered set notwithstanding, a convincing interpretation of mixed candidate strategies in electoral competition is elusive. A satisfactory theory of elections therefore seems to require more structure than that presumed in the benchmark model. Important approaches in this regard are to introduce various informational limitations on the part of candidates and voters, to allow voter abstention and to admit the possibility of policy-motivated candidates.

Candidate Uncertainty and Abstention

Candidates for electoral office clearly do not know the details of every individual's preferences or voting criteria. Adding idiosyncratic non-policy characteristics to voters' decisions (for example, their attitude towards the social background of the candidates) and assuming candidates know at best the distribution from which these characteristics are drawn can induce sufficient continuity in candidates' assessments of how policy positions map into vote shares to admit a general equilibrium existence result in pure strategies. Specifically, let $p_i(u_i(a), u_i(b))$ be the probability that voter i votes for candidate A given platforms $a, b \in X$. Then A's expected plurality, given (a, b) and no abstention, is

$$\Pi(a,b) = 2\sum_{i\in N} p_i(u_i(a),u_i(b)) - n.$$

If we assume that p_i is strictly concave increasing (respectively, convex decreasing) in $u_i(a)$ (respectively, $u_i(b)$) and that u_i is strictly concave, there exists a unique equilibrium in pure candidate strategies and the equilibrium platforms coincide (Enelow and Hinich 1982; Coughlin 1992). More importantly, it turns out that the policy on which both candidates converge in equilibrium maximizes weighted aggregate utility (Couglin and Nitzan 1981; Banks and Duggan 2005).

On the other hand, if candidates $j \in \{A, B\}$ are policy-motivated and seek to maximize their expected utility defined by

$$\begin{aligned} E\left[u_j \middle| a,b\right] &= \Pr[A \text{ wins} \mid a,b]u_j(a) \\ &\quad + \Pr[B \text{ wins} \mid a,b]u_j(b), \end{aligned}$$

then, under suitable regularity conditions on the probabilities of winning, candidate convergence is not assured (Wittman 1977; Calvert 1985). Unfortunately, such regularity conditions are unlikely: for instance, if there is no abstention, then

$$\begin{aligned} &\Pr[A \text{ wins} \mid a,b] \\ &= \sum_{\substack{M\subseteq N \\ |M|>n/2}} \left[\prod_{i\in M} p_i(u_i(a),u_i(b)) \right. \\ &\quad \left. \times \prod_{j\in N/M} \left[1 - P_j\left(u_j(a),u_j(b)\right)\right]\right] \end{aligned}$$

which is not at all nicely behaved.

A conceptual difficulty with the probabilistic voting approach is that it seems ad hoc. Although idiosyncratic components to voters' decision calculus are plausible, the assumptions required on the distributions of such idiosyncrasies to insure existence – that they are uncorrelated with individuals' policy preferences and induce the appropriate concavity properties – are stringent. In particular, if the candidates' uncertainty regards voter policy preferences rather than some non-policy idiosyncrasies, then candidate objective functions again become discontinuous, leading to a breakdown in equilibrium (Ball 1999). An alternative approach in the same spirit is to say nothing about voter idiosyncrasies at the individual level but rather to assume that the winner depends on policy-oriented voting over platforms and the true state of the world, known only up to its distribution at the time of the election (Roemer 2001). The interpretation here is that the realized preference profile of voter preferences is conditional on the state. For example, if those who live closest to voting stations are the most likely to vote in bad weather, then the effective distribution of voter preferences is conditional on the weather. To insure electoral equilibria then requires imposing particular conditions directly on the distribution of states.

Voting is not costless and this fact gives rise to a problem for rational choice theoretic models of participation in large elections: given that the probability of being pivotal is negligible in large elections, the net benefit of voting is negative (Feddersen 2004, provides a recent survey of the literature on turnout). However, assuming that voting costs and (possibly) policy preferences are private information to individuals, with only their joint distribution being common knowledge, induces uncertainty on the part of both voters and candidates sufficient to yield existence of equilibrium in a model with all agents being fully instrumentally rational (Ledyard 1984; Myerson 2000). The idea is to note that, for any fixed and distinct pair of platforms $(0, b) \in X^2$, voters are confronted with a strategic decision whether to abstain or to vote for their favoured candidate. In a voter equilibrium relative to (a, b), the probability of being pivotal induces a level of expected turnout which in turn justifies the probability of being pivotal. Candidates then choose their platforms to maximize their respective expected pluralities, recognizing the implications for turnout from any pair of platforms. In this setting, under various assumptions on the joint distribution of preferences and voting costs, there exists a unique equilibrium when voter preferences are concave and, in equilibrium, both candidates adopt the policy that maximizes aggregate utility and turnout is zero. In effect, this model produces an efficiency result for electoral competition analogous to the First Welfare Theorem for competitive markets.

Voter Uncertainty and Commitment

Although voters are uncertain about the behaviour of other voters in the costly voting model discussed above, they are fully informed about the candidates' platforms and the policy that the winner will implement. Developing an understanding of how voter uncertainties about candidate policies and intentions affect electoral competition in multidimensional policy spaces has proved very difficult. Instead, most of the insights to date derive from one-dimensional models where, under complete information, the median voter theorem applies.

Suppose candidates for office have policy preferences over a one-dimensional policy space just like voters, but that these preferences are unknown to the electorate. Specifically, a candidate's type $t \in R$ parameterizes the candidate's preferences over policies and is private information; voters know only the distribution from which t is drawn. In a two-candidate election, the candidates, knowing their own types, simultaneously choose policy platforms on which to campaign; voters observe the platforms, update their beliefs about the likely types of the candidates, and vote accordingly. The winner is then free to implement any policy she chooses as government policy; in particular, she has an incentive to implement her ideal point. Assume that there is a cost to implementing any policy other than that on which the winner is elected and, further, that this cost increases with the distance between the electoral platform and the implemented policy. Then

Banks (1990) shows that, in any (appropriately refined) sequential equilibrium, relatively extreme candidate types, that is, those with preferences far from those of the median voter, offer revealing platforms but there is pooling on the median voter's most preferred outcome by an interval of relatively moderate types.

The model therefore predicts candidate divergence in equilibrium precisely in competitions in which at least one extremist is running for office; indeed, the observed equilibrium platforms in such instances can be far from the median. More importantly, as the cost of implementing any policy distinct from that on which the election was won goes to zero, the interval of types pooling on the median voter's preferred policy expands to include the entire type space. Conversely, if the cost goes to infinity, the interval of types pooling on the median voter's most preferred policy contracts to the median's ideal point. *Inter alia*, this result highlights the central role of policy commitment in models of electoral competition. If we leave aside concerns with legislative coalition formation and so forth, elected candidates are free to implement any policy they choose once in office. In the benchmark model with full information and purely office-motivated candidates, there is no reason for an elected official to implement anything other than her electoral platform. This is not so if candidates' motivations or preferences are unclear to voters. Unless candidates can make credible commitments to implement their electoral platforms conditional on being elected, electoral platforms are at best signals of candidate intentions; and there is no obvious way for candidates to make such commitments.

If candidates are assumed to have adopted distinct platforms and members of the electorate have private and (possibly) asymmetric information about which candidate is most likely to be their *ex post* preferred candidate, then Feddersen and Pesendorfer (1996, 1997) prove that, as the electorate becomes arbitrarily large, the winning candidate is almost surely the winning candidate under complete information. This is a remarkable result and suggests that questions of commitment and voter uncertainty need not be problematic in large elections. On the other hand, allowing for some strategic platform choice by candidates attenuates the result (Razin 2003; Gul and Pesendorfer 2004).

Dynamics

Parties, if not candidates, are often long-lived, and winning platforms in one election may be empirically hard to change for a following election. Assume the benchmark model of elections above is iterated over an uncountably infinite number sequence of elections $t = 1, 2, \ldots$ with all voters and the two candidates being myopic. Assume in addition that the electoral platform on which the period-t incumbent won office is necessarily the platform on which the incumbent contests election $t + 1$. The opposition candidate's choice of platform in period $t + 1$, however, is unconstrained. Then the non-existence results for equilibria discussed above imply that the two candidates alternate in office over time. More interesting is the fact that the winning platform converges to a neighbourhood of the minmax set, a centrally located set of alternatives that coincides with the majority core when the latter is non-empty: for any alternative x, let $\gamma(x)$ denote the maximal number of votes that any alternative policy y could attract in a pairwise vote against x (equilibrium non-existence implies $\gamma(x) > n/2$ for all $x \in X$); then the minmax set is the set of policies $x \in X$ for which $\gamma(x)$ is minimal (Kramer 1977).

The myopia assumption and the constraint on an incumbent's policy choice underlying the preceding result are not very satisfactory. A strategically richer framework is proposed by Banks and Duggan (2002). In their set-up, all individuals are far-sighted and instrumentally rational. Individual preferences are private information up to the common knowledge that utilities are continuous and strictly concave over the multidimensional policy space. The $t = 1$ incumbent is chosen randomly and implements a policy $x_1 \in X$; the incumbent's name and the policy choice are observed by all voters. In the period $t = 2$ election, the incumbent faces a randomly chosen challenger whose name is observed by voters. Voters then vote for one or other of the competitors. The plurality winner becomes the incumbent and (freely) implements a policy x_2

$\in X$; there is no restriction on the $t = 1$ incumbent's choice should he or she win a second term in office. This process then repeats for $t > 2$. The authors prove the existence of (stationary subgame perfect) equilibria in which voters employ a simple cut-off rule, that is, vote for the incumbent if her previous policy choice at least achieves an endogenously determined reservation utility value. The main result here is that there is eventual policy persistence in that the distribution of policy outcomes converges to a fixed platform as t goes to infinity. However, while this platform is necessarily centrally located because it must be acceptable to a majority of the population, there is no assurance in the multidimensional policy space that it is uniquely defined.

Multiple Candidate Competition

Fixed Number of Candidates

Political competitions with exactly two candidates are relatively unusual. In general there are at least two candidates in any election, and the possibility of multiple electoral competitors raises a variety of issues that are largely irrelevant when considering elections with two given candidates seeking a single office. For example, questions of candidate participation, or the number of candidates, in an election are finessed by assuming a given two-candidate contest, and proportional representation schemes for determining electoral success are irrelevant when only one office is at stake. As a result, important questions about the relative merits of various electoral rules cannot be addressed. Similarly, if the election is for a legislature and legislative policy decisions require, as is typical, majority support of the elected legislators, then rational voters and candidates make their respective electoral decisions taking account of the subsequent legislative bargaining and committee decision-making (Austen-Smith and Banks 1988; Baron and Diermeier 2001). Addressing these issues, among others, requires admitting a more general class of electoral rule for multi-candidate competition and providing a more complex analysis of voter behaviour.

There is fixed set of candidates $M = \{1, \ldots, m\}$ who compete for $l \geq 1$ elected offices, $m < l$, in an election decided by a normalized rank scoring rule. A normalized rank scoring rule for a fixed number of candidates m is defined by a vector $s = (s_1, \ldots, sm)$ such that $1 = s_1 \geq s_2 \geq \ldots \geq s_{m-1} \geq s_m = 0$ and a mapping that assigns a set of $l \geq 1$ winners for any profile of permissible ballots, where a permissible ballot is any permutation of the vector $(1, s_2, \ldots, s_{m-1}, 0)$. The normalization here refers to the joint restrictions $s_1 = 1$ and $s_2 = 0$ and is purely a convenience; the defining characteristics of rank scoring rules are that $s_t \geq s_{t+1}$ for all $t = 1, \ldots, m-1$ and $s_1 > s_m$. Not all rules of interest are rank scoring rules. For instance, approval voting is a scoring rule but not a rank scoring rule; under approval voting, the restriction that $s_1 > s_m$ is not required so voters may vote for, or approve of, any and all candidates should they so choose. Examples of rank scoring rules include single non-transferable voting ($s_t = 0$, all $t > 1$), a generalization of the simple plurality rule (where $l = 1$); single negative voting ($s_t = 1$, all $t < m$); and the Borda rule ($s_t = [m - t]/[m - 1]$, all $t = 2, \ldots, m - 1$). In each of these examples, the l top-scoring candidates are the winners, with ties being broken randomly.

An individual votes sincerely under a scoring rule if she always assigns higher scores to more preferred candidates. If we assume a one-dimensional policy space, say $X = [0,1]$, sincere voting and that candidates maximize expected plurality, now defined to be the difference between their vote share (aggregate score) and the maximum vote share among their competitors, Cox (1987, 1990) establishes a connection between the existence of equilibria in which all candidates converge and the average score $C(s; m) = \sum_{j=1}^{j=m} s_j/m$, the Cox threshold (Myerson 1999).

Specifically, suppose there is a continuum of voters with interior most-preferred policies (or ideal points) distributed over a policy space according to a strictly increasing and differentiable cdf, F and let α_t be the quantile implicitly defined by $\int_0^{\alpha_t} dF(x) = t, t \in [0, 1]$; then there exists an equilibrium in which all candidates adopt the platform αt if and only if $[1 - C(s;\, m)] \leq t \leq C(s;\, m)$.

The Cox threshold for single non-transferable voting is $1/m$, it is 1/2 for the Borda rule and it is $(m - 1)/m$ for single negative voting. The median voter theorem is therefore a direct implication of the theorem. Moreover, writing the Cox threshold equivalently as $C(s; m) \equiv \bar{s} = 1 - (s_1 - \bar{s})/(s_1 - s_m)$ makes clear that the threshold is decreasing in the extent to which the scoring rule provides an incentive to be ranked first rather than average relative to being ranked first rather than last. Hence, Cox's result implies that, the greater this incentive is, the greater is the incentive for candidates to differentiate their platforms.

While sincere voting is the unique undominated strategy for individuals when there are only two candidates, it is not obviously rational when there are the more than two candidates. Indeed, the fact that people typically try to avoid 'wasting' their vote by voting for an almost sure loser suggests that strategically rational voting is substantively significant. An important observation in this respect generalizes Duverger's Law, namely, that single non-transferable voting for a single office promotes only two-candidate competition. Assuming there are $m > 2$ candidates with fixed and distinct platforms competing for $l < m$ offices, Cox (1994) proves that voting equilibria in undominated strategies have the following form: the top l candidates receive identical (strictly positive) vote shares, with all other candidates receiving either no votes or the same vote share as the candidate with the $(l + 1)^{th}$ highest vote share, which in turn is less than or equal to that of the candidates with the l highest vote shares. Moreover, although not proved formally, equilibria in which the vote-share of the $(l + t)^{th}$ most successful candidate, $t > 1$, is positive are almost surely not robust, as any shock will move votes away from this candidate to one of the $l + 1$ top-ranked competitors.

Candidate Entry

The last result on Duverger's Law raises a question as to why candidates who are almost surely going to lose enter the electoral competition at all. In view of the canonical model of electoral competition, one natural starting point for understanding candidate entry is to fix a set of potential candidates, assume each candidate is concerned only with winning office, and ask what platforms such candidates would adopt if entry is costly and voters are strategically rational rather presumed than to vote sincerely under all circumstances. Then purely office-motivated candidates have no incentive to enter an electoral contest if they are sure to lose. On the assumption that voters have strictly concave preferences over a one-dimensional issue space, it can be shown that the number of entrants is constrained only by the ratio of benefits from holding office to the costs of entry and that all entrants adopt the median voter's most preferred policy as their platform (Feddersen et al. 1990). This result is in stark contrast to the implications discussed earlier of assuming a fixed number of competing candidates and sincere voting. As such, the value of this benchmark entry model derives from its appeal less as a reflection of any empirical reality (which is limited at best) and more as an analytical robustness check on models of multi-candidate elections that presume fixed numbers of candidates and sincere voting. While the latter certainly illuminate some incentives facing strategic candidates with several competitors, equilibrium predictions supported by the models appear fragile.

An alternative, and more plausible, approach to presuming a fixed pool of potential candidates is to recognize that candidates are voters too and to suppose the pool is exactly the electorate itself: every individual voter is eligible to run for office should he or she so choose (Osborne and Slivinski 1996; Besley and Coate 1997). In such a model candidate preferences derive directly from individual policy preferences, implying that the entry decision and the decision on which platform to run for office conditional on entering an election are equivalent. At least in the static setting without commitment, citizens who enter the race implement their respective ideal policies should they win office; it immediately follows that policy convergence is impossible if multiple citizens declare a candidacy, unless all such individuals share the identical ideal point. An equilibrium in this framework is a mutually consistent list of best-response decisions for individuals regarding whether or not to enter the election and, conditional on the realized slate of entrants, on how to vote. Given complete information on individuals' preferences and the inability of entrants to commit to implement any policy other than their ideal points, establishing a fairly general existence theorem for multidimensional policy spaces is straightforward. Furthermore, since candidates are also citizens with policy preferences, there are circumstances under which it is more rational for an individual to contest a costly election than when individuals are concerned only with winning office. Specifically, despite being sure that he or she will not win, an individual might enter an electoral race to affect the expected policy outcome by implicitly blocking the entry or exit of other potential or declared candidates.

The citizen-candidate perspective on political competition is quite intuitive and simultaneously gives rise to a theory of candidate entry and a theory of candidate preferences. On the other hand, the implication that, other things being equal, declared candidates are locked into implementing their ideal points should they win is restrictive. As a matter of fact, candidates do credibly adjust their policy positions and, even should they not do so, a theory of platform selection predicated exclusively on an individual's exogenously given policy preferences effectively reduces any account of collective policy outcomes to an account of which particular individuals choose to run for office. Although understanding who chooses to seek election is clearly important to a full theory of electoral politics, an account of collective choice based entirely on such a foundation is less compelling.

A different approach within the spirit of the citizen-candidate theory is to eschew candidates and parties altogether. Instead, the set of 'potential candidates' is assumed to be the full set of feasible policy outcomes, with each individual permitted to vote for any one policy or not at all. Assuming away candidates as agents or, equivalently, assuming there is a candidate for every possible alternative in the policy space, seems, at least prima facie, to be unreasonable for any sort of theory of electoral competition with a large number of voters. In so far as the focus of a model of elections is on understanding the behaviour of particular agents with given objectives (for example, maximizing the probability of winning), or on understanding the behavior of historically established political parties in a constrained (for example, two-party) environment, such a presumption is justified. However, if the focus is on understanding the deeper implications of using a given voting scheme to determine collective policy choices, then dispensing at the outset with the intermediary steps involved in candidates choosing platforms is reasonable. And in this respect the implications of plurality rule under costly voting and abstention are subtle and striking: in every voting equilibrium with risk-averse (and strategically rational) voters and a multidimensional policy space, exactly two divergent policy positions receive any votes at all (Feddersen 1992). Despite the absence of candidates or parties, strategic and costly voting under plurality rule leads to equilibria with two distinct platforms and positive turnout. The precise location of any given pair of equilibrium platforms, however, is in general indeterminate.

Concluding Comments

Despite the large literature on the spatial theory of elections, our understanding of political competition is still relatively primitive in many respects. There is, for example, much to be learned from dynamic models, and a compelling theory of candidate entry has yet to be developed. Similarly, a tractable theory of strategic voting in large populations, an essential component of a satisfactory theory of political competition, remains elusive.

This article provides a survey of the origin of the term 'political economy' and its changes in meaning, emphasizing in particular its first modern usage in the 18th century, its demise from the end of the 19th century, when it was gradually replaced by the word 'economics', and its revival in a variety of forms, largely during the 1960s, which have altered its meaning from more traditional usage. What follows is therefore largely definitional and etymological, designed to indicate the lack of precise meaning associated with both the term, 'political economy' and its more modern synonym, 'economics'.

The origin of words starting with 'econom' is Greek, from *eco* meaning 'house' and *nom* meaning 'law' in the sense appropriate to astronomy when it deals with 'the law and order of the stars' (Cannan 1929, p. 37). The traditional meaning of *oikonomike* or economics, was therefore 'household management'. Aristotle (1962, p. 30) used it in this sense when analysing households as 'three pairs: master and slave, husband and wife, father and children'. This meaning persisted in moral philosophy until the middle of the 18th century, for example, in Hutcheson (1755) and Smith (1763, p. 141). The Latin *oeconomia* likewise meant management of household affairs, extended to management in general including orderly arrangement of speech and composition. The French *oeconomie* or *économie* took over this wider meaning of management from the Latin and when combined with *politique* it signified public administration or management of the affairs of state. Arthur Young (1770) applied this wider meaning in the title of a treatise on agricultural management. Using 'economy' as a synonym for 'thrift', 'frugality' and careful management of the finances of households and other organizations also derives from the Latin adaptation. 17th-century concern with nation building gave the term) 'public administration' a wider scope, and given developments in France under Henry IV and Richelieu it is not surprising that the term 'political economy' made its first appearance there. This first use is generally attributed to Montch'retien (1615), but King (1948) indicates prior use in Mayerne-Turquet (1611). Because the relationship between state and economy it signified was so appropriate to the times, King suggests that other, perhaps earlier, uses may be found. Petty (1691, p. 181; cf. 1683, p. 483) used the term in England. As Cannan (1929, p. 39) surmised, he could as well have used 'political economy' as 'political anatomy' to describe his analysis of the Irish economy, considering he used 'political arithmetick' for the art of making more precise statements on the political economy of nations, interpreted as their comparative strengths (cf. Verri 1763, pp. 9–10, who speaks of the science of political economy in this manner). Cantillon (1755, p. 46) referred to an 'oeconomy' in the sense of an economic organism in which classes exist as interdependent units, but his book remained an 'Essay on Commerce'.

More precise formulations of political economy as a science of economic organization, though with continuing connotations of management, regulation and even orderly natural laws, are found in Physiocracy. Quesnay's early usage generally implies the traditional meanings, but in addition he applied the term to include discussions of the nature of wealth, its reproduction and distribution. This double meaning is particularly evident in his *Tableau économique*. It is therefore no accident that Mirabeau (1760) spoke of *économie politique* 'as if it consisted of a dissertation on agriculture and public administration as well as on the nature of wealth and the means of procuring it' (Cannan 1929, p. 40). During the subsequent decades the second meaning became more dominant, the word 'science' was added to it (an innovation attributed to Verri 1763, p. 9) and by the 1770s it almost exclusively referred to the production and distribution of wealth in the context of management of the nation's resources.

Sir James Steuart (1767) is the first English economist to put 'political economy' into the title of a book. Its introductory chapter explained that just as 'Oeconomy in general, is the art of providing for all the wants of the family', so the science of political economy seeks 'to secure a certain fund of subsistence for all the inhabitants, to obviate every circumstance which may render it precarious; to provide every thing necessary for supplying the wants of the society, and to employ the inhabitants . . . in such a manner as naturally to create reciprocal relations and dependencies between them, so as to make their several interests lead them to supply one another with reciprocal wants' (1767, pp. 15, 17). Steuart's full title gave the subject matter to be covered: 'population, agriculture, trade, industry, money, coin, interest, circulation, banks, exchange, public credit and taxes'. In 1771 Verri published *Reflections on Political Economy*, the preface of which referred to a new department of knowledge called political economy. Although Smith did not use 'political economy' in his title the introduction and plan of his book refers to 'different theories of political economy' and at the start of Book IV he defined the term as 'a branch of the science of a statesman or legislator' with the twofold objectives of providing 'a plentiful revenue or subsistence for the people . . . [and] to supply the state or commonwealth with a revenue sufficient for the publick services' (Smith 1776, pp. 11, 428). Elsewhere (1776, pp. 678–9) Smith indicated that he saw political economy as an inquiry into the nature and causes of the wealth of nations or, as the Physiocrats had initially suggested, the science of the nature, reproduction, distribution and disposal of wealth.

The association of the science, political economy, with material welfare proved to be particularly hardy, as was its association with the art of legislation. Bentham (1793–5, p. 223) put the matter concisely when he argued, 'Political Economy may be considered as a science or as an Art. But in this instance as in others, it is only as a guide to the art that the science is of use'. Torrens (1819, p. 453) also called it 'one of the most important and useful branches of science' while James Mill (1820, p. 211) and McCulloch (1825, p. 9) defined it as a systematic inquiry into the laws regulating the production, distribution, consumption and exchange of commodities or the products of labour. 'Confounding' the art with the science was criticized by Senior (1836, p. 3) as being detrimental to its development, a position likewise taken by John Stuart Mill (1831–3) and which also reaffirmed its moral and social nature. In this influential essay, Mill (1831–3, p. 140) defined political economy as 'the science which traces the laws of such of the phenomena of society as arise from the combined operations of mankind for the production of wealth, in so far as those phenomena are not modified by the pursuit of any other object'. This position was more or less adhered to in his later *Principles* (1848, p. 21), when he defined its subject matter as 'the laws of Production and Distribution, and some of the practical consequences deducible from them . . . '. Cairnes (1875, p. 35) condensed this to the statement that 'Political Economy . . . expounds the laws of the phenomena of wealth.'

The middle of the 19th century saw two criticisms of this meaning of political economy. Marx (1859, p. 20) identified the study of political economy with a search for 'the anatomy of civil society' or, as Engels (1859, p. 218) put in his review of this book, 'the theoretical analysis of modern bourgeois society'. This preserved the name but criticized the scope and method of political economy. Others suggested the name be changed because it had become misleading. Hearn (1863) put forward *Plutology* or the theory of efforts to satisfy human wants; MacLeod (1875) proposed 'economics', defining it as the 'science which treats of the laws which govern the relations of exchangeable quantities', a nomenclature of whose virtues he successfully persuaded Jevons (Black 1977, p. 115). When in 1879 the Marshalls published an elementary political economy text, they called it *The Economics of Industry*. The new name of MacLeod and the Marshalls was favourably referred to in the second edition of Jevons's *Theory* (1879, p. xiv) because of convenience and scientific nicety (it matched mathematics, ethics and aesthetics) and Jevons's last published book (Jevons 1905) bore the title *Principles of Economics*. Although Cannan (1929, p. 44) claimed Marshall (1890) induced acceptance of the new name, this only came with the later editions, and the change was not completed until the early 1920s (Groenewegen 1985). Even then, Marshall (1890, p. 1) appeared to treat the two names as synonyms: 'Political Economy or Economics is a study of mankind in the ordinary business of life; it examines that part of individual and social action which is most closely connected with the attainment and with the use of the material requisites of well-being.'

Just as J.S. Mill (1831–3, pp. 120–1) had attempted retrospective codification of scope and method in the 1820s, so Robbins (1932, p. 16) redefined economics in its marginalist form as 'the science which studies human behaviour as a relationship between ends and scarce means which have alternative uses'. This did more than supply a meaning for the new term, 'economics'. It destroyed the view classical economists had of their science, as Myint (1948) clearly pointed out. Others (for example, Knight 1951, p. 6) complained that Robbins's definition neglected the link between economics and the 'individualistic or "liberal" outlook on life, of which "capitalism", or the competitive system, or free business enterprise, is the expression upon the economic side, as democracy on the political'. However, the major drawback of the Robbins definition was its irreconcilability with Keynes's work with its proof of the possibility of unemployment equilibrium and hence contradicting Robbins's requirement for the existence of an economic problem that resources have to be scarce. Modern mainstream definitions of economics (Rees 1968; Samuelson 1955, p. 5) have simply combined the Robbinsian resource allocation problem with the new economics of employment, inflation and growth developed from Keynes's work.

Robbins's definition also aimed to make economics a 'system of theoretical and positive knowledge' (Fraser 1937, p. 30), preferring to reserve the older name, 'political economy', for applied topics such as monopoly, protection, planning and government fiscal policy, subjects included in his essays on political economy (Robbins 1939). Although Schumpeter (1954) held a similar opinion he was careful to warn that 'political economy meant different things to different writers, and in some cases it meant what is now known as economic theory or "pure" economics' (p. 22). These views of political economy conflict with the pragmatic Cambridge outlook on economics, derived from Marshall's description of economics as 'an engine for the discovery of concrete truth', encapsulated by Keynes (1921, p. v) in his famous introduction to the Cambridge Economics Handbooks: 'Economics is a method rather than a doctrine, an apparatus of the mind, a technique of thinking which helps its possessor to draw correct conclusions.' This sentiment is concisely summarized by Joan Robinson's view of economics (1933, p. 1) as 'a box of tools'.

Marxists had never abandoned the older terminology of political economy. Dobb (1937, p. vii) defended 'political economy' against the new term 'economics' because its controversies 'have meaning as answers to certain questions of an essentially practical kind', associated with the 'nature and behaviour' of the capitalist system. Likewise, Baran (1957, p. 131) argued for a 'political economy of growth' because an 'understanding of the factors responsible for the size and the mode of utilization of the social surplus . . . [is] a problem, not even approached in the realm of pure economics'. For the classical economists, use of the surplus had been a major research question. Political economy is therefore a very appropriate title for the endeavours of some contemporary economists to resurrect both practical and theoretical aspects of the classical tradition in what they describe as the surplus approach.

By the 1960s the radical libertarian right from Chicago and the Center for the Study of Public Choice at Virginia Polytechnic appeared to have appropriated the title 'political economy' for their wide application of Robbins's (1932) injunction that analysis in terms of '*alternatives*' is the key distinguishing feature of economics. This effectively replaced Robbins's question 'what is or is not economic in nature' with the far wider one of 'what can economics contribute to our understanding of this or that problem?' This opens up the way for an economics of 'family life, child rearing, dying, sex, crime, politics and many other topics' which some of its practitioners identify with Adam Smith's research agenda (McKenzie and Tullock 1975, p. 3). Others continue to associate the term 'with the specific advice given by one or more economists . . . to governments or to the public at large either on broad policy issues or on particular proposals' or, alternatively, as another term for 'normative economics' (Mishan 1982, p. 13).

At the approach of the 21st century, both terms – 'political economy' and 'economics' – survive. During their existence, both have experienced changes of meaning. Nevertheless, they can still essentially be regarded as synonyms, a feature of this nomenclature reflecting an interesting characteristic of the science it describes. In its sometimes discontinuous development, economics or political economy has invariably experienced difficulties in discarding earlier views, and traces of old doctrine are intermingled with the latest developments in the science.

'Political Economy' and 'Economics'

Peter Groenewegen

This article provides a survey of the origin of the term 'political economy' and its changes in meaning, emphasizing in particular its first modern usage in the 18th century, its demise from the end of the 19th century, when it was gradually replaced by the word) 'economics', and its revival in a variety of forms, largely during the 1960s, which have altered its meaning from more traditional usage. What follows is therefore largely definitional and etymological, designed to indicate the lack of precise meaning associated with both the term, 'political economy' and its more modern synonym, 'economics'.

The origin of words starting with 'econom' is Greek, from *eco* meaning 'house' and *nom* meaning 'law' in the sense appropriate to astronomy when it deals with 'the law and order of the stars' (Cannan 1929, p. 37). The traditional meaning of *oikonomike* or economics, was therefore 'household management'. Aristotle (1962, p. 30) used it in this sense when analysing households as 'three pairs: master and slave, husband and wife, father and children'. This meaning persisted in moral philosophy until the middle of the 18th century, for example, in Hutcheson (1755) and Smith (1763, p. 141). The Latin *oeconomia* likewise meant management of household affairs, extended to management in general including orderly arrangement of speech and composition. The French *oeconomie* or *économie* took over this wider meaning of management from the Latin and when combined with *politique* it signified public administration or management of the affairs of state. Arthur Young (1770) applied this wider meaning in the title of a treatise on agricultural management. Using 'economy' as a synonym for 'thrift', 'frugality' and careful management of the finances of households and other organizations also derives from the Latin adaptation. 17th-century concern with nation building gave the term 'public administration' a wider scope, and given developments in France under Henry IV and Richelieu it is not surprising that the term 'political economy' made its first appearance there. This first use is generally attributed to Montchrétien (1615), but King (1948) indicates prior use in Mayerne-Turquet (1611). Because the relationship between state and economy it signified was so appropriate to the times, King suggests that other, perhaps earlier uses, may be found. Petty (1691, p. 181 and cf. 1683, p. 483) used the term in England. As Cannan (1929, p. 39) surmised, he could as well have used) 'political economy' as 'political anatomy' to describe his analysis of the Irish economy, considering he used 'political arithmetick' for the art of making more precise statements on the political economy of nations, interpreted as their comparative strengths (cf. Verri 1763, pp. 9–10, who speaks of the science of political economy in this manner). Cantillon (1755, p. 46) referred to an 'oeconomy' in the sense of an economic organism in which classes exist as interdependent units, but his book remained an 'Essay on Commerce'.

More precise formulations of political economy as a science of economic organization, though with continuing connotations of management, regulation and even orderly natural laws, are found in Physiocracy. Quesnay's early usage generally implies the traditional meanings, but in addition he applied the term to include discussions of the nature of wealth, its reproduction and distribution. This double meaning is particularly evident in his *Tableau économique*. It is therefore no accident that Mirabeau (1760) spoke of *économie politique* 'as if it consisted of a dissertation on agriculture and public administration as well as on the nature of wealth and the means of procuring it', (Cannan 1929, p. 40). During the subsequent decades the second meaning became more dominant, the word 'science' was added to it (an innovation attributed to Verri 1763, p. 9) and by the 1770s it almost exclusively referred to the production and distribution of wealth in the context of management of the nation's resources.

Sir James Steuart (1767) is the first English economist to put) 'political economy' into the title of a book. Its introductory chapter explained that just as 'Oeconomy in general, is the art of providing for all the wants of the family', so the science of political economy seeks 'to secure a certain fund of subsistence for all the inhabitants, to obviate every circumstance which may render it precarious; to provide every thing necessary for supplying the wants of the society, and to employ the inhabitants . . . in such a manner as naturally to create reciprocal relations and dependencies between them, so as to make their several interests lead them to supply one another with reciprocal wants', (1767, pp. 15, 17). Steuart's full title gave the subject matter to be covered: 'population, agriculture, trade, industry, money, coin, interest, circulation, banks, exchange, public credit and taxes'. In 1771 Verri published *Reflections on Political Economy*, the preface of which referred to a new department of knowledge called political economy. Although Smith did not use 'political economy' in his title the introduction and plan of his book refers to 'different theories of political economy' and at the start of Book IV he defined the term as 'a branch of the science of a statesman or legislator' with the twofold objectives of providing 'a plentiful revenue or subsistence for the people . . . [and] to supply the state or commonwealth with a revenue sufficient for the publick services' (Smith 1776, pp. 11, 428). Elsewhere (1776, pp. 678–9) Smith indicated that he saw political economy as an inquiry into the nature and causes of the wealth of nations or, as the physiocrats had initially suggested, the science of the nature, reproduction, distribution and disposal of wealth.

The association of the science, political economy, with material welfare proved to be particularly hardy, as was its association with the art of legislation. Bentham (1793–5, p. 223) put the matter concisely when he argued, 'Political Economy may be considered as a science or as an Art. But in this instance as in others, it is only as a guide to the art that the science is of use'. Torrens (1819, p. 453) also called it 'one of the most important and useful branches of science' while James Mill (1820, p. 211) and McCulloch (1825, p. 9) defined it as a systematic inquiry into the laws regulating the production, distribution, consumption and exchange of commodities or the products of labour. 'Confounding' the art with the science was criticized by Senior (1836, p. 3) as being detrimental to its development, a position likewise taken by John Stuart Mill (1831–3) and which also reaffirmed its moral and social nature. In this influential essay, Mill (1831–3, p. 140) defined political economy as 'the science which traces the laws of such of the phenomena of society as arise from the combined operations of mankind for the production of wealth, in so far as those phenomena are not modified by the pursuit of any other object'. This position was more or less adhered to in his later *Principles* (1848, p. 21), when he defined its subject matter as 'the laws of Production and Distribution, and some of the practical consequences deducible from them . . .'. Cairnes (1875, p. 35) condensed this to the statement that 'Political Economy . . . expounds the laws of the phenomena of wealth.'

The middle of the 19th century saw two criticisms of this meaning of political economy. Marx (1859, p. 20) identified the study of political economy with a search for 'the anatomy of civil society' or, as Engels (1859, p. 218) put in in his review of this book, 'the theoretical analysis of modern bourgeois society'. This preserved the name but criticized the scope and method of political economy. Others suggested the name be changed because it had become misleading. Hearn (1863) put forward *Plutology* or the theory of efforts to satisfy human wants; MacLeod (1875) proposed 'economics', defining it as the 'science which treats of the laws which govern the relations of exchangeable quantities', a nomenclature of whose virtues he successfully persuaded Jevons (Black 1977, p. 115). When in 1879 the Marshalls published an elementary political economy text, they called it *The Economics of Industry*. The new name of MacLeod and the Marshalls was favourably referred to in the second edition of Jevons's *Theory* (1879, p. xiv) because of convenience and scientific nicety (it matched mathematics, ethics and aesthetics) and Jevons's last published book (Jevons 1905) bore the title *Principles of Economics*. Although Cannan (1929, p. 44) claimed Marshall (1890) induced acceptance of the new name, this only came with the later editions, and the change was not completed until the early 1920s (Groenewegen 1985). Even then, Marshall (1890, p. 1) appeared to treat the two names as synonyms: 'Political Economy or Economics is a study of mankind in the ordinary business of life; it examines that part of individual and social action which is most closely connected with the attainment and with the use of the material requisites of well-being.'

Just as J.S. Mill (1831–3, pp. 120–1) had attempted retrospective codification of scope and method in the 1820s, so Robbins (1932, p. 16) redefined economics in its marginalist form as 'the science which studies human behaviour as a relationship between ends and scarce means which have alternative uses'. This did more than supply a meaning for the new term, 'economics'. It destroyed the view classical economists had of their science, as Myint (1948) clearly pointed out. Others (e.g. Knight 1951, p. 6) complained that Robbins's definition neglected the link between economics and the 'individualistic or "liberal" outlook on life, of which "capitalism", or the competitive system, or free business enterprise, is the expression upon the economic side, as democracy on the political'. However, the major drawback of the Robbins definition was its irreconcilability with Keynes's work with its proof of the possibility of unemployment equilibrium and hence contradicting Robbins's requirement for the existence of an economic problem that resources have to be scarce. Modern mainstream definitions of economics (Rees 1968; Samuelson 1955, p. 5) have simply combined the Robbinsian resource allocation problem with the new economics of employment, inflation and growth developed from Keynes's work.

Robbins's definition also aimed to make economics a 'system of theoretical and positive knowledge' (Fraser 1937, p. 30), preferring to reserve the older name, 'political economy' for applied topics such as monopoly, protection, planning and government fiscal policy, subjects included in his essays on political economy (Robbins 1939). Although Schumpeter (1954) held a similar opinion he was careful to warn that) 'political economy meant different things to different writers, and in some cases it meant what is now known as economic theory or "pure" economics' (p. 22). These views of political economy conflict with the pragmatic Cambridge outlook on economics, derived from Marshall's description of economics as 'an engine for the discovery of concrete truth', encapsulated by Keynes (1921, p. v) in his famous introduction to the Cambridge Economics Handbooks: 'Economics is a method rather than a doctrine, an apparatus of the mind, a technique of thinking which helps its possessor to draw correct conclusions.' This sentiment is concisely summarized by Joan Robinson's view of economics (1933, p. 1) as 'a box of tools'.

Marxists had never abandoned the older terminology of political economy. Dobb (1937, p. vii) defended 'political economy' against the new term 'economics' because its controversies 'have meaning as answers to certain questions of an essentially practical kind', associated with the 'nature and behaviour' of the capitalist system. Likewise, Baran (1957, p. 131) argued for a 'political economy of growth' because an) 'understanding of the factors responsible for the size and the mode of utilization of the social surplus . . . [is] a problem, not even approached in the realm of pure economics'. For the classical economists, use of the surplus had been a major research question. Political economy is therefore a very appropriate title for the endeavours of some contemporary economists to resurrect both practical and theoretical aspects of the classical tradition in what they describe as the surplus approach.

By the 1960s the radical libertarian right from Chicago and the Center for the Study of Public Choice at Virginia Polytechnic appears to have appropriated the title 'political economy' for their wide application of Robbins's (1932) injunction that analysis in terms of *'alternatives'* is the key distinguishing feature of economics. This effectively replaced Robbins's question 'what is or is not economic in nature' with the far wider one of 'what can economics contribute to our understanding of this or that problem?' This opens up the way for an economics of 'family life, child rearing, dying, sex, crime, politics and many other topics' which some of its practitioners identify with Adam Smith's research agenda (McKenzie and Tullock 1975, p. 3). Others continue to associate the term 'with the specific advice given by one or more economists . . . to governments or to the public at large either on broad policy issues or on particular proposals' or, alternatively, as another term for 'normative economics' (Mishan 1982, p. 13).

At the approach of the 21st century, both terms – 'political economy' and 'economics' – survive. During their existence, both have experienced changes of meaning. Nevertheless, they can still essentially be regarded as synonyms, a feature of this nomenclature reflecting an interesting characteristic of the science it describes. In its sometimes discontinuous development, economics or political economy has invariably experienced difficulties in discarding earlier views, and traces of old doctrine are intermingled with the latest developments in the science.

Political Economy and Psychology

P. H. Wicksteed

If political economy is the science of wealth, then it deals with efforts made by man to supply wants and satisfy desires. 'Want', 'effort', 'desire', 'satisfaction', are each and all psychic phenomena.

It would therefore appear that psychology must be to political economy – like the deity of Boethius – 'path, motive, guide, original, and end'.

Yet it is obvious that the political economist as such is not engaged in the establishment of the ultimate principles of psychology. He has not, for example, to investigate the nature of a concept, or determine the relation of the Will to the Reason. So far it is clearly true (cf. J.N. Keynes, *Scope and Method of Political Economy*, pp. 87, 88) that although the laws of the political economist 'rest ultimately upon a psychological basis', he accepts psychological principles as his data rather than establishes them as his conclusions; unless indeed he should be compelled to make excursions into the psychological field proper, because he does not find his premises sufficiently elaborated to his hand.

But this does not justify the reduction of the psychological factor of political economy to a level with the physical factor. Cairnes indeed (*Logical Method of Political Economy*, 2nd edn, pp. 37 and 38, quoted and apparently endorsed by Keynes, p. 85) instances the law of rent, and maintains that, in establishing this law, the economist no more undertakes to analyse the motives of self-interest which dictate the conduct of the landlord and the tenant than he undertakes to analyse the physical qualities of the soil which determine the law of decreasing returns. Now this is very true. The economist starts with both psychological and physical data, which he need not analyse, provided he has satisfied himself that they are true. But the difference is this, that whereas his *data* are partly physical and partly psychical, his *quaesita* are, in the last resort, wholly psychical. For if the law of rent is anything, it is a formulating of the principles which we may expect to regulate the *conduct* of men, secured in certain possessions and privileges, actuated by certain motives, and in the presence of certain physical facts and laws. The laws of political economy then, being ultimately laws of human conduct, are psychical and not physical; and therefore psychology enters into political economy on something more than equal terms with physical science and technology.

It therefore seems clear that, although the economist, as such, is not concerned with the ultimate analysis of his psychological data, his quaesita or conclusions are themselves of the order of psychic phenomena. But within the limits thus laid down there is still ample room for diversity of opinion. It may be contended that the economist has to receive, and test, his psychological and physical data alike, to deal with them by the universal methods of dialectic (i.e. inductive and deductive logic, or mathematics, if applicable), and then hand over his psychological results to the sociologist. Or it may be argued that political economy is largely, or even prevailingly, *applied psychology*, so that the economist must from first to last realize that he is dealing with psychological phenomena, and must be guided throughout by psychological considerations. In that case the relation of psychology to economics will be as close as that of mathematics to mechanics, though not in all respects analogous to it.

It is easy to see that the controversy as to the inclusion or exclusion of Consumption as a separate and acknowledged division of political economy, has a decisive bearing upon this question. The whole theoretic study of consumption can be little else than the application of the great psychological law of diminishing returns of satisfaction or relief to successive increments of commodity or service supplied to the same subject. To admit 'consumption' then as a branch of political economy is to admit that applied psychology has its conspicuous place in the science. So that if we are justified in saying that the express study of 'consumption' has now been definitively admitted as within the scope of political economy, we are thereby admitting psychological method, as well as psychological data and conclusions, as a part of the science; and the importance of dealing thus expressly with consumption and the psychological phenomena on which this branch of this study rests may well be shown by typical popular fallacies. For instance, there was no more common application of political economy a few decades back than the dictum that) 'what people want they will pay for', and that therefore all subsidizing is a waste of effort, and is 'against political economy'. Here the datum is that if *one and the same man* wants A as much as he wants B, he will be willing to give as much for it, sooner than go without it. From this datum certain conclusions as to market values and the commercially wise direction of efforts and resources are reduced, and these in their turn are reinterpreted into the statement that if *one* of two men is unwilling to give as much for A as *the other* is willing to give for B, then the first man does not want A as much as the second wants B, and it would be a wasteful and mistaken philanthropy to supply No. 1 with A rather than No. 2 with B. Of course no economist would formulate such an absurdity, but if the economists exclude consumption from express and psychological treatment, they leave room for and almost invite such 'applications'.

So much then for 'consumption'. But Exchange is so closely connected with consumption, and the laws of value are now seen to be so intimately dependent upon the psychological law of diminishing returns of satisfaction, that it must be impossible henceforth to exclude applied psychology from the problems of value and of exchange.

An excellent illustration is furnished by the problems of the currency. Of all branches of economic enquiry those that are concerned with Money and with Foreign exchanges seem most nearly to approach the objectivity of natural phenomena; and what is known as the Quantity Theory has been cited as a proof case of an economic law which is not psychological. But the truth is that no single step can be safely made in monetary science, unless the investigator keeps himself in conscious touch with his psychological basis during his whole investigation. We cannot, without special examination, even say that, in virtue of the universal law of supply and demand, the more sovereigns there are the lower will be their exchange value. For in this universal law of supply and demand there is a psychological link. Why does an increased supply lower exchange value? Because an increased supply of any commodity satisfies the corresponding want more completely, and reduces the unsatisfied remaining want to a lower degree of importunity. Now in the case of money it is admitted that within wide limits the money function is exactly as well performed by x and by nx pieces, so that there is no unperformed money function and money want becoming less and less importunate for satisfaction as the number of sovereigns, but not the command of commodities in general, increases. Thus, if the law of demand and supply is regarded as objective and absolute, and the psychological link forgotten, its applications to monetary problems will have no demonstrative cogency.

We now turn to Production and Distribution, and here we note at once that the study of 'production' must include the theory of labour, in which everything turns upon the law of the increasing irksomeness of successive increments of effort, and the decreasing psychological value of successive increments of commodity, or other result of effort; and the same law invades the study of distribution at every point, allying itself with the better-known physical law of diminishing returns to successive increments of any one factor of production, the others remaining constant.

In all the four main divisions of political economy, then, we see that the direction taken by economic study in recent years tends to a more express and generous recognition of the close connection between psychology and political economy, and the necessity of constantly keeping in touch with our psychological basis even when pursuing those branches of economic inquiry which appear to be remotest from it.

But, especially in connection with 'production' and) 'distribution', another aspect of the question forces itself on our attention. We have hitherto enquired whether the psychological data of economics can be accepted absolutely as results and dealt with by general dialectic methods, or whether they can only be considered as principles, to be applied with constant reference to the psychological conditions of the special problem under investigation. We have now to ask further, are these psychological data, whether facts or principles, to include all the psychological considerations that actually bear upon the production, distribution, etc. of wealth, or are we artificially to simplify our psychology and deal only with the motives supposed to actuate the hypothetical) 'economic man'? In the latter case political economy will be a hypothetical science. In the former it will aim at positivity.

And here again it will hardly be doubted that the tendency of recent work has been in the direction of enlarging the psychological area from which the data of political economy should be drawn. This tendency is manifested in two characteristic movements in recent economic investigation, which have in their turn reacted upon it. Firstly, the field of economic study, like so many others, has been invaded by the passion for the concrete method of enquiry, whether applied to contemporary or remote conditions. Now the man who studies the history of a great strike or trade-movement in Europe or America, of the land tenure or village industries of India, of middle-class or artisan budgets in England or France, of the growth and organization of industry in the Hanseatic cities or the republics of Italy, of the fiscal systems of commercially related peoples, and so forth, finds himself studying the conditions of the production and distribution of wealth, but in a region in which the simplified psychology of Ricardo and Senior is wholly inadequate. So conspicuously is this the case that some economists are ready to admit that no general theory or science of economics is possible, but only a natural history of wealth, production, etc., while others are seeking to reconstruct the general theory of economics on broader and more universally applicable principles. And it is here that the second movement characteristic of recent times allies itself with the historical method. It is the much-discussed mathematical method, which from this point of view is the necessary complement of the historical or concrete method. For no sooner has the mathematical student given to the acknowledged psychological data of economics the form, at once rigorous and generalized, that his method demands, than he perceives that his formulae really embrace the general theory of the distribution of resources with a view to maximizing a desired result, independently of the nature alike of the resources and the result in question. This brings the economic conduct of man under the same laws as his conduct in general, and promises to give us the wider basis of which we are in search.

Our conclusions throw a curious light on the much-debated but little-understood contention of Auguste Comte (*Philosophical Positivism*, vol. iv. pp. 193 et seq.) that there is no specific science of wealth, with special laws and principles, and that the attempt to deal with the wealthgetting impulses of man in isolation must be essentially barren; but the special applications of general principles of philosophy to the industrial and commercial life may be prolific and illuminating in a high degree.

Political Economy Legacy of Institutions from the Classical Period of Islam

Lisa Blaydes and Eric Chaney

Abstract

This article describes the core political and economic institutions of Muslim societies during Islam's 'classical' period. We argue that the reliance of Muslim leaders on slave armies discouraged the development of a hereditary baronage in Muslim societies and contributed to the underdevelopment of private ownership of land. Societal resistance to sultanistic governance emanated not from land-owning elites but rather from religious leaders who came to enjoy high levels of moral authority through their role as mediators between state and society. Authoritarian governance, a weak tradition of private property rights and empowerment of religious elites in the realms of law and education had important implications for the economic development of Muslim societies.

Why is the Islamic world underdeveloped relative to other world regions? This question is particularly puzzling when one considers the region's historical leadership in fields as diverse as commerce and science. Over the past decade, a body of research has highlighted how Islamic legal institutions contributed to the region's underdevelopment (Kuran 2001, 2004, 2011). We argue that while Islamic legal institutions can be usefully viewed as one proximate cause of underdevelopment, the Islamic world's unique political equilibrium is the fundamental cause of its poor economic performance over the past centuries. We also explain how and why this political equilibrium materialised in addition to highlighting its impact on the political and economic development of Muslim societies.

The Emergence of the Classical Institutional Equilibrium

Following the death of the Prophet Muhammad in 632 CE, Arab armies conquered large swathes of West Asia and North Africa. Initially, the Arab-Muslim conquerors maintained the well-developed administrative bureaucracies of their conquered predecessors and largely lived in garrisons separate from the local populations. Eventually, Muslim rulers began to introduce new institutional forms for the maintenance of political order. The most important of these innovations was the introduction of slave armies by the Abbasid Caliphs in the ninth century and the diffusion of such armies across the dynasties of the medieval Islamic world. Historians have viewed the introduction of these armies as a 'major innovation in Middle Eastern history' (Lapidus 2014, p. 86) and their appearance is believed to have contributed to political instability in the region (Blaydes and Chaney 2013).

The widespread use of slave armies transformed Muslim societies in at least two ways. First, ruler reliance on slave soldiers who had been imported from non-Muslim lands meant that local holders of military power lost influence and were eventually eliminated as a social force. Second, as local military elites saw their power undermined, religious leaders emerged as the primary representative of societal interests and a key 'check' on executive power. Over time, with the growing conversion of local populations to Islam, Muslim religious leaders began to take 'charge of Middle Eastern communities' and to 'infuse them with their interpretation of Islamic identifications' (Lapidus 2014, p. 224). We call the political equilibrium which emerged as a result of these transformations the 'Classical Institutional Equilibrium' (henceforth, CIE). At its core, the CIE reflected a division of political power – broadly speaking – between Islamic religious leaders and Muslim kings reliant on slave armies, or in some cases slave armies without kings, as in Mamluk Egypt.

While elements of the CIE eventually spread to much of today's Islamic world, in our view the CIE best characterises regions incorporated into the Islamic world during the medieval period. In addition, we believe that although this political equilibrium emerged at different times in different regions, generally speaking it was fully developed by the twelfth century.

The Classical Equilibrium in Action

Thus far, we have argued that the institutions associated with the classical equilibrium reflect the interests of Muslim rulers dependent on foreign-born slave soldiers and Muslim religious elites. The social and political arrangements between these two groups reflected their collaboration on the one hand and the tension between them on the other. In this section, we describe the institutions generated by the CIE in two domains: property rights and human capital formation. In both cases, we highlight how outcomes reflect an accommodation between the two social groups at the core of the CIE.

Property Rights, Predation and the Waqf

Secure private property rights are seen as key to encouraging growth-producing investment. The system of property rights which predominated in the CIE may provide a partial explanation for why Muslim societies lagged behind Europe and other world regions in the development of those rights.

The widespread use of foreign-born slave soldiers was closely linked to forms of fiscal organisation which discouraged the emergence of secure property rights. In order to pay for these elite soldiers and to reduce their incentive to rebel, Muslim rulers allotted control over government-owned land or other rent streams to slave soldiers as compensation. In exchange for their loyalty and maintenance of social order in that territory, slave soldiers had the right to tax revenue from that land. In contrast to developments in medieval Europe, such assignments were generally short-term and not intergenerationally transferable. They were also revocable and exchangeable by order of the government (von Grunebaum 1970, p. 145). As a result, these land grants were qualitatively different from the feudal fiefs of medieval Europe, as slave soldiers rarely established enduring roots to the land and were often rotated from locale to locale. Given the relatively short time horizon they envisioned in any particular location, it is not surprising that land grant holders were more concerned with extraction of rents and less concerned with establishing secure property rights and other long-term investments in the areas to which they were assigned. (Olson (1993) would suggest, however, that Muslim sultans and their slave armies retained a sufficient interest in maintaining the productivity of land assets as to avoid the uncoordinated and competitive theft associated with 'roving' bandits.)

In the context of predation by rulers and their associated slave armies, there emerged a societal need for an institution to shelter wealth for those able to accumulate capital. It is in this context that we believe that the spread of *waqf*, or Islamic charitable trust, must be understood. Scholars have long argued that wealthy individuals used the *waqf* to both protect assets from predation and to better control how their assets would be divided following their death and thus escape the reach of restrictive Islamic inheritance laws.

*Waqf*s were under the jurisdiction of Islamic religious leaders who emerged as a key holder of domestic political power and a representative of societal interests in the CIE. In order to better serve their 'constituencies', religious leaders channelled many of the resources put into *waqf* towards public goods that the heavily militarised government in the CIE did not provide. These Islamic trusts often took the form of schools, rest houses for pilgrims, public baths, water fountains and hospitals. The *waqf* founder also benefitted from this arrangement. The founder was able to designate both the beneficiaries of the *waqf* as well as the compensated administrator (often himself or a member of his family). Why didn't Muslim rulers and their slave soldiers confiscate these Islamic trusts? If they had, religious leaders would have encouraged revolt against these regimes. Knowing this, the *waqf* remained relatively safe from predation.

Kuran (2001, 2004, 2011) has highlighted the importance of *waqf*s in his studies of economic development in the Muslim world. Kuran (2001, 2004, 2011) argues that the *waqf* immobilised assets in static perpetuity, creating significant inefficiencies. Because the founder of the *waqf* designated a particular purpose for the pious foundation at the time of its creation, rigidities built into this mandate became particularly dysfunctional over time.

While we agree with Kuran that the *waqf* tied up capital in ways that were bad for economic growth, we see the *waqf*, as an institution, as the outcome of the balance of political power in the CIE rather than an independent cause of economic stagnation. While the earliest *waqfs* likely date to late ninth and early tenth centuries, it was not until the twelfth century that the practice of 'of putting landholdings into the form of *waqf*, pious endowments, inalienable and not subject to government seizure, became common' (Hodgson 1974, p. 51). As it result, it is difficult to argue that the *waqf* was a direct, time-invariant derivative of Islamic doctrine. Instead, we see the growing usage of the *waqf* as the result of a political bargain struck between religious leaders, who emerged as a politically influential group as a result of the introduction of slave armies and rulers backed by these armies. This argument is consistent with scholars who focus on the political underpinnings of Islamic legal institutions (Malik 2012).

Religious Elites, Education and Human Capital Formation

Politically influential religious leaders could, to some degree, limit predation by rulers and their associated military elite; their influence did not end there, however. The emergence of the CIE coincided with the spread of educational institutions controlled by religious leaders, of which the *madrasa* is the best known. *Madrasa* education placed a premium on religious knowledge over other forms of learning. Over time, religious education crowded out the study of scientific subjects. In addition, the rise of this educational system is believed to have discouraged innovation and the development of broad forms of human capital.

Chaney (2015a) provides empirical evidence consistent with this hypothesis. In particular, he documents a decrease in scientific production that corresponds with the rise of *madrasa*s across the Islamic world. Such evidence complements work by historians noting that 'the institutionalization of Muslim scholarship' in *madrasa*s marked 'a significant change in Islamic social structure and Muslim community life' (Chamberlain 1994, p. 69).

The available evidence stresses that religious leaders sought to limit the study of some topics, particularly as related to science and mathematics, because they believed that certain forms of knowledge weakened their societal influence. For example al-Ghazali (1058–1111 CE), a well-known religious scholar, noted that 'he who studies mathematics is amazed by its precision and proofs. He then takes a more positive view of philosophy and reckons that all of the rational sciences are as clear and trustworthy as mathematics [. . .] and he says: if religion were true, then philosophers would have proved its veracity with their precise methods [. . .] we have seen many deviate from [Islam] in this manner' (al-Ghazali 1111 [1971], pp. 21–2). This suggests that scientific/innovative human capital formation decreased both the quality (through obedience) and quantity (through size of following) of a given leader's popular support. If true, this implies that religious leaders should work to limit the types of human capital formation that undermined their population-based forms of political power (Acemoglu and Robinson 2000; Chaney 2013). The net result was that after the emergence of the CIE research became increasingly limited to 'very narrow, and essentially unprogressive areas', as religious leaders, instrumentally, sought to limit the permitted areas of scholarly focus (Sabra 1987, pp. 240–1).

The decline in scientific output in the Muslim world contrasts sharply with the well-known increased production of scientific knowledge in Western Europe during the late medieval period (e.g. the Renaissance). This increase in European scientific production coincides with a decline in the focus on religious discourse in European political theory (Blaydes et al. 2016). Taken together, such evidence suggests that relatively high rates of human capital formation in Europe may be due – at least in part – to the greater constraints faced by European religious elites in the later medieval period.

The Long-Run Impact of the CIE on Political Institutions

Have the political institutions of the CIE had an enduring impact? We argue that insecure property rights and low levels of human capital formation damaged the economic and technological development in CIE regions, paving the way for European colonialism. There is little doubt that by the end of the seventeenth century Muslim societies increasingly struggled to keep pace with technological developments in Western Europe (Chaney 2015b). This represents a meaningful reversal when compared to the medieval period, when Western Europe clearly lagged behind the Islamic world on these dimensions.

Beyond growth-related outcomes, the CIE also impacted political institutions. Chaney (2012) provides evidence that the Islamic world's 'democratic deficit' is driven by areas which were subject to the Arab conquests and thus typified the CIE. The key contrast within the Muslim world, then, is between those countries – like Iran, Egypt and Syria – which Arab armies conquered in the early expansion of Islam versus Muslim-majority countries beyond the Arab conquest regions – like Bangladesh, Indonesia and Senegal – which exemplified the CIE to a lesser extent. Based on this evidence, Chaney (2012) suggests that the Islamic world's democratic deficit has less to do with Islam *per se* than the long-run impact of the CIE.

The political role of religious leaders in CIE regions today appears to have parallels with the historical experience. In particular, religious leaders, organisations and political parties are dominant contemporary social actors in Muslim societies. These organisations seem to exert high levels of political power, at least when compared to their counterparts in other world regions. This relatively high level of political influence has a significant impact on institutional development.

For example, Blaydes and Lo (2012) argue that democratisation in the Middle East has been hampered by the fact that religious associations are typically the best-organised and most important civil society groups. Because potential regime liberalisers in Middle Eastern autocracies suspect political openings could become a vehicle for Islamists to seize power through free elections, Middle Eastern autocrats are reluctant to provide openings for societal organisation. (This argument contrasts with scholars who suggest that Middle Eastern autocrats strategically cultivate Islamist opponents in a bid to force citizens into supporting status quo dictatorship versus religious extremists.) This suggests that the dominant position of religiously motivated civil society has decreased the possibility of political liberalisation in the Middle East. On this dimension, Middle Eastern societies differ from newly democratising states in Eastern Europe, Latin America and East Asia where civil society elites have typically been secular liberals.

Political Economy of Arab Uprisings

Adeel Malik

Abstract

This article frames the political economy of the 2011 Arab uprisings as a failure of the Arab development model, especially its inability to support an independent and competitive private sector. Based on a distorted legacy of intervention and distribution, this development model is structurally incapable of reconciling aspirations with economic opportunities. The contradictions associated with this development model are particularly apparent in the region's labour-abundant economies, where a shrinking resource envelope has led to an erosion of the social contract, resulting in a scaling back of public employment and welfare services. Worryingly, the space vacated by a shrinking state has not been filled by a vibrant private sector. This article analyses the crisis of the Arab state through the lens of an under-developed private sector. In much of the Arab world the private sector acts as an appendage of the state. Businesses tend to survive either when they are too close to the state, such as crony capitalists, or too far, which is the case with informal firms. While private sector development remains an important imperative, it is not simply a function of technocratic policy reform. Relieving greater competitive space for the private sector requires a political concession that grants autonomy to independent businesses and relaxes barriers to regional trade. I argue that an independent merchant class is difficult to visualise without connected regional markets.

The Arab revolutions that started in December 2010 in Tunisia and quickly spread across the region had a clear economic underpinning. They were fuelled by poverty, unemployment and lack of economic opportunity. At their heart was a yearning for social justice. While political repression in the Middle East remains a subject of regular debate, the scale and intensity of the region's economic repression has gone relatively unnoticed. The Middle East has long been trapped in a vicious development cycle, defined by an excessive dependence on natural resources, a Leviathan state and a weak private sector. This has prevented the rise of a strong constituency for economic diversification. This article argues that continuing political upheaval in the Middle East cannot be understood without fathoming the growing unsustainability of the Arab development model. Underscoring an inherent tension between the region's demographic and economic structures, I argue that, while the Middle East has undergone an unprecedented demographic transition, its economic structure remains rigid, unable to generate productive employment opportunities for new entrants to the labour force. The profound employment challenge that Arab societies face today cannot be met without conceding more competitive space to the private sector. But this is determined by political, not just economic, choices. Arab regimes face a difficult politics of private sector development defined by an inherent trade-off between employment and autonomy. While rulers wish to promote employment generation, they are unwilling to cede greater autonomy to the private sector.

An Evolving Demography, but a Rigid Economic Structure

A growing tension has developed in the Middle East between demography and economic structure. The Arab Spring has brought into sharp focus the profound implications of a demographic shift, whereby an overwhelming proportion of the region's population – in many countries about 75% – consists of young people under the age of 30. A significant proportion of this young population is also female and educated. While Arab societies have failed on several development fronts, they have had a resounding success in expanding access to education. Challenges of educational quality aside, many Arab countries, especially those in North Africa, have made impressive strides in educating their young and closing the gender gaps in education. In fact, of the top ten countries that have made tremendous progress in human development during the last 40 years, five were from the Arab world. The key problem, however, is that education is not matched with economic opportunity. While the public sector could absorb all new entrants to the labour force 40 years ago, it is stretched beyond its limits in many labour-abundant Arab countries today, resulting in some of the world's highest rates of youth unemployment. While education has enhanced aspirations unemployment has only resulted in grievance.

Many of these young people are not only unemployed, they are also *unemployable*. This is clearly a failing of both the education system and economic structure. Educational institutions churn out graduates who have credentials that make them eligible for public sector jobs, but skills that are largely irrelevant for the private sector. Given better wage remuneration and job security in government employment, the young are dissuaded from pursuing a career in the private sector. In many countries (especially in the oil-rich Gulf) this leads to a perverse division of labour between the public and private sectors. Typically, the public sector generates high-wage jobs for nationals, while the private sector is overwhelmingly reliant on expatriate workers. Such labour market segmentation has profound implications for political economy, since it prevents both citizens and the state from developing a genuine stake in private sector development.

The region's profound demographic shifts need not be a liability. As the East Asian experience suggests, they can be harnessed for growth and serve as a demographic dividend. The irony in the Middle East, however, is that, while demography is evolving, the economic structure remains unresponsive to the needs of its growing populations. With the public sector still acting as the employer of first resort, the Arab world suffers from a precarious employment strategy. In many of the region's labour-abundant economies this is further complicated by a weakening of the social pact that had initially ensured employment for all, but which is now growingly incapable of absorbing new entrants to the labour force (Cammett and Diwan 2014). This retreat of the welfare state has not been accompanied by the development of a strong private sector capable of picking up the slack in job creation. The private sector – despite its varying strength across Arab economies – remains weak and dependent on state patronage. Its failure ultimately emanates from a development model whose expiry date has long passed, but is being sustained through the regular injection of externally derived rent streams.

A Failed Development Model

In most Arab economies the state has typically remained the most important economic actor, eclipsing all other productive sectors. When it comes to the essentials of life – whether food, jobs, housing or public services – the state is the provider of first and last resort. The functioning of this system rests on a heavy dose of subsidies and economic controls, and a variety of other uncompetitive practices. While a centralised bureaucratic system has worked well for ruling elites and the narrow clienteles that thrive with their support, it has failed to deliver prosperity and social justice to ordinary citizens and firms. The interests of governing coalitions have proved more enduring than the force of ideology. Neither the socialism of the 1960s and 1970s nor the neo-liberal economic reform of the 1990s has been able to dismantle this system of centralised control, discretion and privilege. This development model is structurally incapable of reconciling aspirations with opportunities.

This state-centred development paradigm rests on the uninterrupted flow of external windfalls. In fact, many of the region's pathologies – whether a weak private sector, segmented labour markets or limited regional trade – are ultimately rooted in an economic structure that relies heavily on external rents, whether derived from fuel exports, foreign aid or remittances. Reliance on these unearned income streams is the ‘original sin’ of Arab economies. More than 80% of total merchandise exports in many Arab countries consists of oil and gas. The dependence on hydrocarbons is so pervasive that even in economies otherwise considered to be resource-scarce, such as Syria and Yemen, exports are dominated by oil. Up until 2005, for example, around 67% of the total exports in Syria consisted of fuels. In Yemen, fuel exports constitute 70% of total exports.

Where oil is relatively scarce, foreign aid replaces its role. Aid revenues, much like oil, tend to stifle economic and political incentives, turning economies away from production to patronage. By virtue of their strategic locations, Egypt and Jordan derive significant external rent streams through foreign aid. In Egypt alone – hardly a typical case of resource curse – two-thirds of foreign exchange revenues are derived from oil, aid and revenues from the Suez Canal. While the role of oil dominates the discourse on the Middle East, the influence of aid is often downplayed. It may come as a surprise that, as a region, the Middle East and North Africa (MENA) received the highest overseas development assistance on a per capita basis in 2008 ($73 compared to $49 in sub-Saharan Africa). Resource windfalls from oil and aid are complemented with remittances. As a ratio of GDP, the MENA region received the highest proportion of remittances. The external revenues from oil, aid and remittances sustain an adverse political economy predicated on a social pact that trades welfare distribution for regime security.

While these unearned income streams continue to finance the Arab social contract, the resource envelope in many Arab economies is not expanding as fast as the cost of the underlying social bargain. This is particularly apparent in economies that are labour-abundant but scarcely endowed with natural resources. While, initially, oil revenues in these economies were fiscally important, they have declined precipitously since the 1980s. This has been accompanied by a withdrawal of the state’s welfare functions and followed by a malign process of economic reform that replaced public monopolies with private cronies. The numbers are indicative of this dramatic shift. Since the 1980s oil revenues have more than halved in Egypt and Tunisia, paving the way for a significant downsizing of the state. The ratio of public expenditures to GDP in these countries has declined from 50% in 1980s to 30% by the early 1990s. The decline was particularly dramatic in Egypt, where the ratio fell from 61.5% in 1982 to 25.1% of GDP in 1998 (Diwan 2014).

This fiscal retreat of the state was accompanied by a decline in the quantity and quality of public spending. Public investment has borne the major brunt of expenditure cuts. Resources allocated for salaries and subsidies have declined. Notwithstanding the recent hike in subsidies, expenditures earmarked for subsidies originally fell from 9.7% in 1980s to around 1.1% of GDP in the 1990s (Diwan 2014). Such fiscal contractions have weakened the Arab social bargain in relatively resource-poor economies, leading to a scaling back of job opportunities and welfare services in health and education. While co-opted through initially generous welfare entitlements, the Arab middle classes, composed largely of state civil servants, are now growingly disaffected with this gradual erosion of the social contract (Diwan 2013). But, as recent survey evidence has suggested, such middle class ‘grievance’ is not uniform across countries and generations (Cammett and Silti 2014). In some countries, for example, the young cohort is more dissatisfied with welfare services and labour market opportunities than the older generation.

Importantly, the grievance is not just about incomes: it is also about opportunities. As public sector jobs decline, they are rationed by connection rather than competition. The welfare regime therefore faces the twin challenge of access and fairness. With the emasculation of the Arab welfare state, the burden has disproportionately fallen on the poor and the middle classes. The socioeconomic cost of this fiscal adjustment has heightened due to a weak institutional base. Rather than visualising a shared political settlement to compensate losers and achieve a more equitable sharing of the burden of adjustment, the ruling coalition has been further narrowed by restricting economic opportunity to the closed circle of family and friends. This was driven by a sound political logic. Authoritarian regimes need to placate both citizens and elites. Such appeasement is easier in oil-abundant economies, where pockets are deep enough to satisfy the two constituencies. In resource-poor economies, however, rents from government manipulation of the economy play a more crucial role in sustaining elite coalitions.

Connected elites in these countries are given control of vital access points to the economy. As long as these insiders monopolise the economic rent streams, their interests are aligned with the continuity of the regime. In many of the Middle East's labour-abundant economies state-led industrialisation offered precisely such opportunity to secure rents for the connected. But, as oil revenues fell and fiscal adjustment became a necessity, economic liberalisation shifted the rentier equilibrium. Liberalisation generated new rents for insiders through trade policy concessions, stakes in privatisation and new brokerage opportunities through partnership with foreign firms. Rather than a genuine levelling of the economic playing field, liberalisation simply gave rise to crony capitalism.

The emergence of such connected capitalism was most visible in Tunisia and Egypt. In Tunisia, Ben Ali and family ended up controlling 220 firms. Many of these firms operated behind high tariff and non-tariff barriers and were primarily active in sectors that required prior government authorisation and were subject to FDI restrictions (Rijkers et al. 2014). Recent evidence from Egypt suggests that politically connected firms operated behind high non-tariff barriers and had preferential access to subsidies and credit. In Egypt 71% of the connected firms were protected by at least three non-tariff measures relative to 3% of all firms included in the sample. Moreover, politically connected firms were four and a half times more likely to operate in energy-intensive sectors (Diwan et al. 2013). Even as the state contracted, releasing space for the private sector, it did not widen economic access to ordinary firms. Entry barriers remained intact, and large parts of the economy were still governed by licence requirements. Productive resources, such as land, were accessible only to a few.

Such insider advantage has profound social implications. While connected firms in Egypt accounted for 60% of net profits and 92% of loans, they accounted for only 11% of employment (Diwan et al. 2013). The unemployed usually ended up in unproductive subsistence activities in the informal sector. All across MENA's labour-abundant economies the bulk of job creation takes place in the informal sector. This generates an important political economy dilemma. While privileges are concentrated among politically connected firms, employment is concentrated among small informal sector firms. Since the onset of liberalisation, the default welfare model in the labour-abundant economies of MENA has been based on welfare provision for citizens and privileges for connected firms. While the system affords subsistence, the social mobility of both people and firms is compromised. This intensifies the divide between insiders and outsiders, traps educated populations into unproductive jobs and keeps social classes dependent and immobilised (Malik 2014).

With the shrinking resource envelope, it is no longer possible to accommodate the growing pool of educated unemployed in the public sector. As a result, the unconnected, young and females have become the new outsiders to labour markets (Assad 2014). Enterprises operating on the margins of the economy – whether small, medium or informal – suffer from institutionalised discrimination. For a long time the economics of concessions has trumped the economics of competition in the Middle East. To varying degrees, most Arab countries are witnessing a generational struggle for inclusion, where young people and firms are aspiring for mobility. Even in the resource-rich Gulf, where underlying social tensions are contained through regular resource injections, the ruling bargain that 'trades welfare distribution for political acquiescence' remains vulnerable (Malik and Awadallah 2013).

There is a growing realisation among ruling circles that the prevailing social contract is unsustainable in the face of rising energy demand at home, growing oil production from alternative sources, and fast expanding populations. For example: even with robust oil prices, Saudi Arabia is faced with long queues for public sector jobs. With 300,000 jobs needed annually to accommodate young Saudi graduates, the waiting period for public employment has increased tremendously (*Saudi Gazette* 2014). Changing demography, access to technology, growing food prices and a weakening distributive pact have scaled up the cost of repression and redistribution – the twin pillars of authoritarian order in the Middle East. Even as public expenditures have fallen in resource-poor economies, spending on repression (especially internal security) has remained both robust and resilient. For decades, the Arab state, regardless of whether it is a monarchy or a republic, has ruled through the fear of its security services. It has perfected the art of demolishing any commons imaginable. Social media have generated new spaces for collective action, however. These are the virtual commons that cleverly evade the long arm of the state.

In short, when faced with political shocks Arab regimes have typically fallen back on extended patronage commitments rather than strong institutions. Rulers in the resource-rich Gulf have tried to placate their populations with public sector jobs, salary increases, concessional loans, infrastructure contracts and one-off gifts. This can only purchase temporary stability. The Arab revolts of 2011 symbolised the yearning for a new social contract that could provide ladders for economic and social mobility – ladders that have been denied by the prevailing Arab development model. The region needs a new economic paradigm that is based on a competitive, entrepreneurial and dynamic private sector. But fostering such a private sector requires a new pattern of politics.

The Politics of Private Sector Development

The Arab Spring was not just a crisis of the Arab state – its inability to redistribute, reform and represent the interests of ordinary citizens. It was also a crisis of the private sector. The popular movements that overthrew Mubarak and Ben Ali were as much targeted against dictators as the crony capitalists surrounding the royal circle. In fact, the changing character of business–state relations provides an important window into understanding Arab political economy. As the state in labour-abundant Arab societies shrank, the space it vacated was not filled by the private sector. Rather, declining government employment was compensated by the informal sector. Recent micro evidence suggests that, as the share of workers employed by the government declined, the slack was largely picked up by the informal sector, which employed less than 5% of total Egyptian workers in 1970, but accounted for 40% of workers in 2005 (Assad 2014). By contrast, the share of employment in the private sector actually declined.

While private sector development is frequently recognised by official circles as essential for employment generation, both donors and national governments have viewed the underlying challenge largely through a narrow technocratic lens that is shorn of both history and politics. The problem is often framed as a result of defective policies, manifested through a high cost of doing business, a poor investment climate and weak indicators of global competitiveness. Developing a strong private sector is not simply about removing regulatory constraints, however. It is also a political and regional challenge. To the extent that an independent private sector can shape new patterns of economic and political power, it is considered a political threat by rulers. And there is also a strong regional dimension to private sector development. A crucial barrier to private sector growth is the persistent economic fragmentation of the Arab world into isolated geographic units that are, at best, weakly connected with each other. Connected Arab markets are crucial for affording scale economies to firms. These two dimensions are now considered separately.

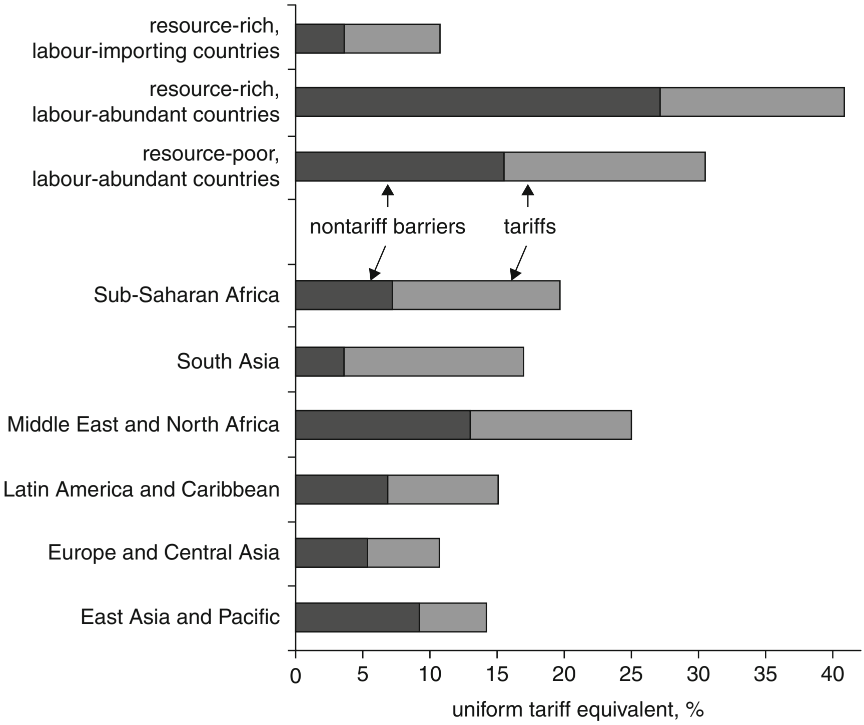
Amongst the list of constraints to private sector development, the role of politics stands out. There is growing evidence that the private economic domain in the Middle East is defined by privileges rather than competition. There is a sharp disjunction between the *de jure* and the *de facto*: even when productive activity is governed by laws, they are inconsistently applied, which indicates the inherently arbitrary and discretionary nature of economic policymaking. The private sector is usually a mirror image of the state: inefficient, controlled by a tiny clique of elite families tied to ruling regimes and part of an extensive network of patronage. Its profits depend less on entrepreneurial abilities and more on access to power. Exploiting new economic opportunities therefore becomes a game of insiders. With few exceptions, major business fortunes are accumulated through 'closed' deals with regime insiders.

Even in the Gulf, where the private sector is admittedly more vibrant, the boundaries between the public and the private are noticeably blurred. Rulers and businessmen are often indistinguishable. With the discovery of oil in 1950s the ruler–merchant relationship shifted firmly in the favour of rulers. Businesses are allowed to grow only so long as they remain loyal and dependent. Its impressive growth notwithstanding, the private sector lacks an autonomous political voice in Gulf countries (Hertog et al. 2013). Historical legacy offers some explanation as to why private enterprise has remained persistently weak in the Middle East. Independent sources of economic power have typically drawn fear rather than favour from Arab rulers. Merchants were largely absent from the power configuration in Ottoman Empire. Ottoman rulers were more inclined to grant economic concessions to European and minority merchants who were less likely to pose any direct threat to the Sultan's power. In many successor Arab states, independence was followed by the exodus of foreign merchants, leaving behind a vacuum that deprived the region of an important constituency that could have pushed for genuine economic reform. To make matters worse, whatever weak private economic activity survived after independence was nationalised by successor Arab states under the garb of socialism. This subjected merchants to relatively adverse initial conditions to begin with.

The Licence Raj established after independence has survived longer in the Middle East than elsewhere in the developing world. Today, severe restrictions remain in place on the movement of goods and labour across Arab borders. Although tariff barriers have been slashed, the more invisible and non-transparent behind-the-border barriers continue to be a source of trade frictions. The trade barriers that create economic enclaves for insiders are difficult to dismantle, since rents generated by such restrictions are used to manage ruling coalitions. In this sense, such barriers are not just procedural but also political barriers. This is an important reason why non-tariff barriers have remained more pervasive in MENA's labour abundant economies (see Fig. 1). It is consistent with the idea that, given their more extensive distributional commitments, labour-abundant economies tend to rely on alternative rents from government manipulation of the economy. Why would political incumbents, in this milieu, vacate space for new entrants when their survival depends on closing off economic access? If the incentive structure that governs private enterprise in MENA is the outcome of political choices, a simple insistence on technocratic reforms is unlikely to work. A competitive space for the private sector will therefore have to be negotiated as a political concession.

We next turn to the regional dimension. A core structural reason for the region's historically weak private sector lies in fragmented markets. Despite its rich trading past and common cultural heritage, the Arab world is one of the most divided regions in terms of productive economic linkages. In a region of 350 million people, mutual trade between Arab economies remains minimal, hovering around a paltry 10% of total merchandise trade. This is a colossal economic failure and has wider repercussions for the region than are commonly understood. The absence of a large connected market denies Arab firms economies of scale, which fuels both growth and diversification. The inability to produce for a larger market caps the growth potential of firms, reinforces the dependence of firms on state patronage and denies the private sector an opportunity to become an independent driver of socio-economic change.

But it is not simply about the absence of scale economies. Economic fragmentation prevents the emergence of regional supply chains – a key driving force behind global trade expansion. It also makes deeper trade reforms more



Political Economy of Arab Uprisings, Fig. 1 The politics of trade barriers in the Middle East (*source*: Shui and Walkenhorst 2010)

unlikely, since regional trade cooperation is often more helpful in identifying and dismantling non-tariff barriers. Thin markets also reinforce the political economy of protection, preserve the monopoly power of insiders and increase the returns to predatory behaviour. With divided markets, the market for second-hand capital goods remains underdeveloped, making new investments particularly risky as businessmen face the risk of being stuck with bad investments. Another cost – largely ignored in most literature – is the wasteful duplication of defence expenditures. As a region, MENA is the biggest global spender on defence (as a share of GDP). During the past decade, the region spent twice as much on defence as South Asia. Another cost of fragmentation is manifested in the under-provision of regional public goods. Connective regional infrastructure is one such public good. Since the benefits of regional transport infrastructure are likely to accrue to everyone in the region, individual countries are discouraged from investing in it, which generates a massive coordination failure.

The Arab world's economic fragmentation is puzzling, given its favourable geography. The MENA region lies at the inter-section of major trading routes, with easy access to markets in Africa, Asia and Europe. And, while, in Africa nearly 40% of the population lives in landlocked countries, there is not a single landlocked Arab country. North Africa provides a particularly dramatic illustration of this lost potential for development. Stretching from Egypt to Morocco, North Africa is blessed with thousands of kilometres of coastline. Its proximity to Europe and Africa makes it one of the choicest locations for other emerging markets. Everywhere else in the world, direct access to the sea translates into lower transport costs and better prospects for manufacturing. However, the Middle East defies the economic laws of gravity: it has coastal access without market access.

Another aspect of geography, where the Middle East is hugely favoured but is failing to materialise its inherent advantage, is urbanisation. At least 50% of the total population in the MENA region (excluding Yemen) resides in urban areas. Latest measures of urban concentration place the region ahead of other developing countries, including those in Latin America, making it one of the most urbanised regions of the world. Recent evidence suggests that urbanisation can deliver concrete benefits to firms: by locating in urban centres, firms enjoy not only proximity to markets but superior access to a range of mutually supportive activities (skills, machinery, suppliers, resources and the like). These agglomeration economies are simply absent in the Middle East.

Even if Arab economies do not suffer from the kind of structural geographic barriers that hinder prosperity in Africa, the region's divided equilibrium is supported by both political and geo-political imperatives. As discussed above, the region's pervasive trade barriers serve an important political function through a political economy of protectionism, where closed economic borders are part of a broader political strategy for regime survival. The rentier characteristics of Arab economies also engender a sense of autonomy from integration, since external windfalls from oil and aid have insulated the region from pressures for economic cooperation. Economic fragmentation is also underpinned by a geopolitical equilibrium that relies on the divide and rule strategies of regional and global hegemons. In short, the absence of a strong domestic constituency, internal rivalries and dependence on external powers have frustrated past attempts at regional economic integration.

It is true that part of this failure to integrate regional markets is rooted in production structures that look more similar than different, but an enabling policy response – through a regionally coordinated industrial policy, for instance – has also been lacking. Dismantling regional trade barriers has been an economically desirable but politically inexpedient step. The demographic and political shifts in the region call for a new logic of economic integration. Given the multiple costs of fragmentation outlined above, a vibrant private sector requires soft borders and thick markets. In this milieu, fostering regional economic cooperation is arguably the single most important collective action problem that the region has faced since the fall of the Ottoman Empire. The Arab world will ultimately need not just political commons, but also regional economic commons, that could serve as incubators for entrepreneurship, employment and growth.

Political Economy of Institutional Change: Illustrations from the Ottoman Empire

Metin M. Coşgel

Abstract

This article sheds light on the political economy of the Ottoman Empire through the lens of its policy on tax collection and technology adoption. Like all rulers, the Ottomans were constrained in their abilities to implement economic policies as they wished. In addition to having limited resources and technology, they faced political constraints that altered the feasibility, desirability and outcomes of economic policies. In taxation, they allowed the tax bases and rate structures to vary significantly across regions to balance revenue maximisation with political power. In technology, despite adopting advancements in military technology immediately, they waited almost three centuries to fully sanction the printing press because it would have undermined the ability of religious authorities to confer legitimacy.

Political incentives are crucial to explain economic policy choices. This article shows how political forces shaped economic policies and outcomes in the Ottoman Empire by focusing on its systems of taxation and technology adoption. Although conventional caricatures of the Ottoman Empire have sometimes painted it as a stagnant monolith, recent studies have shown that the rulers of the Empire accommodated both change and the status quo, depending on their political incentives (Coşgel 2015; Pamuk 2012).

Like all rulers, the Ottomans would have preferred to govern as they wished, but they faced numerous political constraints imposed by the reaction of the general public to their policies or by the interests of powerful organised groups, such as the nobility, the military or religious authorities, who sought to maximise their own welfare, even at the expense of others. The rulers did not have unlimited control over economic outcomes, because they depended on the general public for revenue and they drew power from organised groups who could lose their ability to provide legitimacy or revolt if their interests were sufficiently threatened. Because of the conflicts of interests, the rulers were ultimately constrained in their abilities to tax the population and regulate the economy.

For a simplified model of the political economy of an empire, consider a society that consists of a ruler, the general population and an organised group that acts as an intermediary between the ruler and the population and whose role it is to support (legitimise) the ruler. The people produce a surplus, part of which can be extracted by the ruler for his own consumption. The objective of the ruler is to maximise his consumption. The organised group, such as the nobility or the legal or military authority, has a choice between supporting the ruler or inciting a revolt against him. If it chooses to legitimise the ruler, the ruler can extract a surplus from the population in the form of tax payments. The group's support raises the size of the surplus by making the people view the ruler as legitimate and pay taxes without resistance. In return, the ruler shares his surplus with the group to elicit its support. Alternatively, rather than support the ruler, the group can choose to incite a revolt against him. If the revolt succeeds, the group would obtain the surplus, but if it fails, the ruler gets the surplus and the group gets nothing.

In the Ottoman Empire, the Sultan could acquire legitimacy mainly from religious authorities (*şeyhülislam* and the *ulamā*), nobility (*a'yān*) and military authorities (the *sipāhī* and janissary organisations). Religious authorities could confer legitimacy through loyalty, promoting the belief that the Sultan had the right to rule and the power to provide protection and other public goods and services – and that he should therefore have the right to collect taxes. Their power depended on their role in the transmission of knowledge, an essentially oral process in early Ottoman society prior to the introduction of the printing press. Secular authorities could also confer legitimacy through loyalty, based on their powers as eminent individuals who led tribes, owned land or other resources, belonged to prominent families, and mediated people's relationship with the state in their capacities as regional representatives, tax collectors and managers of public order and civil disputes. By contrast, military authorities could confer legitimacy through force, based on their comparative advantage in using manpower and weapons. Military commanders were in principle at the Sultan's disposal, ready to employ their troops to secure his legitimacy.

We now use this simplified setting to analyse how political forces affected economic choices in the Ottoman Empire, and more specifically in their policies on taxation and technology regulation. The argument, in a nutshell, is that in newly conquered lands the Ottomans implemented a tax system by considering not just the efficiency of rates, bases and collection methods, but their effect on the chances of establishing legitimacy. In regulating technology they adopted some of the new technologies, but banned others in a way that considered their effects on not just productivity but also on the abilities of organised groups to legitimise the ruler. We detail below how the legitimising relationships and conflicts of interest between the rulers, tax collectors and taxpaying public affected the system of taxation in newly conquered districts and how the ruler's relationship with the religious, secular and military authorities affected the introduction of new technologies.

Taxation

Starting from a small tribe settled in northwestern Anatolia at the end of the 13th century, the Ottomans kept expanding in the next three centuries and eventually built a vast Empire that spanned the area from the Black Sea in the north to Egypt and the Arabian Peninsula in the south, and from the Persian Gulf in the east to central Europe and North Africa in the west. Conquering land from multiple predecessor states, they inherited the tax systems of various legal and political traditions that needed to be moulded into a coherent whole and applied to local conditions. The Ottomans developed a tax system that reflected various regional idiosyncrasies from the customs and administrative practices of preceding states, indicating that some things were harder to change than others and that political economy constraints played an important role in shaping the final outcome.

To see regional idiosyncrasies of the tax bases and rate structures, consider the variation in personal taxes. Under the conventional system observed in Anatolia, personal taxes were based on adult males, and the tax rate varied by marital status and land ownership. The subjects in Hungary, on the other hand, paid personal taxes in terms of the gate (*kapı*) tax, for which the unit of taxation was the household, rather than adult males, and the tax amount did not change by marital status or land ownership. Moreover, personal taxes were not even fully implemented in all areas (though non-Muslim subjects throughout the empire paid a poll tax called *cizye*). In Jerusalem and surrounding districts, for example, the Ottomans did not introduce the *çift* tax or any other form of personal tax systematically levied on individuals or households. Trade and production taxes also varied a great detail among regions (Coşgel 2005, 2015).

With each new conquest, the Ottomans thus faced a basic choice between preserving the existing system of taxation in newly conquered lands or changing it to conform to the system prevailing in other parts of the empire. Although efficiency considerations (e.g. cost of collection, incentive implications) affected the choice, political constraints were also important.

Political constraints on taxation can be categorised into two broad groups: those originating from the reactions of the general population and others coming from legitimising agents who collected taxes on behalf of the government. To start with the first group, note that the general population naturally resents taxation and prefers stable, secure incomes, indicating that they would oppose (or even revolt against) the rates being raised significantly or the system being changed drastically. Opposition to tax policies has been one of the most common reasons for popular uprisings in history, most evident during conquests. Unless changing the tax system clearly eliminated excessively oppressive elements of previous taxes (as may have been the case for labour services), the general population likely preferred the status quo over change, for fear that change could mean higher taxes and worse conditions. They could flee the land or revolt against the new regime if the changes were perceived to be too burdensome. Even if the Ottomans discovered an existing tax system to be inefficient, they had to carefully weigh their desire to change it for efficiency gains against the rising likelihood of political instability and revolt against their regime. An inefficient tax system could survive if political constraints prevented a ruler from changing it.

The Ottomans were not free to change the tax codes as they wished because of political realities surrounding conquest, assimilation and stability. Even if they could have increased the tax revenues in Hungary by changing personal taxes from being based on the household as a whole to a differential rate structure based on the characteristics of its individual members, they would have met stiff resistance from those who would have paid higher taxes. Because of this resistance, they could not have implemented the change easily. Once the tax code of a region was adopted, changing it would have been difficult because the general population, accustomed to paying taxes under a familiar system, and powerful groups with vested interests in this system would have continued to resist the change and initiate a revolt against the Ottomans.

The second group of political constraints on taxation were related to the system of tax collection, the way the Ottomans appointed agents to collect taxes and allocated tax revenues among these agents. Organised in a multi-tiered system, the Ottoman government consisted of multiple hierarchical levels that divided the Empire into provinces, the provinces into districts and the districts into fiefs or other administrative units. To support offices at lower levels, the central government assigned some of the tax revenues directly to governors of provinces (variously denoted in the registers as *mīr mīrān*, *paşa*, *beylerbeyi*), district officials (*mīr liwā*, *sancakbeyi*), and holders of small and large fiefs (*tımār* and *za'āma*). In the resulting system of tax collection and revenue allocation, you could have one village paying taxes to the central government, their neighbours in the next village paying them to the provincial government and still others paying them to the district government or a local fiefholder (cavalrymen or military commander).

There were also tribal leaders who somehow possessed the right to collect the tax revenues of some villages and landholders, who similarly held the rights to collect taxes privately (*mülk*) or jointly with the government (under a system called *mālikāne dīvānī*). Typically, these were rights the Ottomans had preserved from the system that they inherited upon conquest or assigned through negotiations with powerholders.

The Ottomans allocated tax collection rights among their agents in part for economic reasons, such as to accommodate differential abilities of agents to assume risks (due to the variability of the tax base) or to measure the tax base. According to a quantitative analysis of tax assignment in the Ottoman Empire, revenues allocated to local government officials included a higher proportion of variable taxes than those allocated to the provincial and central treasury, indicating that the variance of the tax base affected the allocation (Coşgel and Miceli 2005). Economic factors also influenced the government's decision on which contractual form (rent, wage, share) to adopt in employing agents for tax collection.

For a complete explanation of how the Ottomans allocated tax revenues among private landholders, tribal leaders and other agents, we need to go beyond purely economic factors and consider how tax collectors affected the ruler's legitimacy. In general, tax collectors not only acted as government officials in their districts, but also as legitimising agents that could enhance the ruler's ability to extract the surplus. This ability gained even greater significance in newly conquered lands. Acting as local representatives of the new ruler, carefully chosen tax collectors could solidify his legitimacy and raise the share of the gross surplus that he could extract from the general population for his own consumption. In addition, using local elites for tax collection could significantly expand elite-coalition by serving as an important commitment device for ensuring their support for the centralised ruler.

Tax collectors could affect the legitimacy of the Ottoman sultans through both force and loyalty during this period (Coşgel and Miceli 2009). If a newly conquered population included powerful individuals who could be bribed into using their power for tax collection, the Ottomans could be better off relying on these individuals for the service than military officials appointed from the centre. In the same vein, if the local population included individuals with leadership qualities that could generate loyalty by encouraging the citizens to accept the Ottoman ruler's right to rule and his ability to provide protection and other public goods and services, the Ottomans could receive legitimacy more effectively through them than an Ottoman official appointed from the centre but unknown in this region. If the local leaders in newly conquered areas thus had superior ability to provide legitimacy through force or loyalty, these qualities could supersede economic considerations in the assignment of tax revenues, and the Ottomans could be better off using them as agents to raise the share of the surplus that the public would pay voluntarily as taxes.

By including political constraints in the analysis, we offer a more complete explanation of why the Ottomans appointed tribal leaders and private individuals as tax collectors in some areas. They preserved the rights of some landholders to collect taxes after conquest under the *mālikāne dīvānī* system in eastern Anatolia because in those regions these leaders had a comparative advantage in force and loyalty that was essential to collect taxes on behalf of the Ottomans, a right that was granted in exchange for a share of the tax revenue. The Ottomans similarly appointed tribal leaders in some regions as tax collectors so that the Ottoman rule would be established within the institutional constraints of conquest politics. They assigned some of the tax revenues to Bedouin tribes in the Fertile Crescent, for example, so as to establish the Ottoman rule in the desert frontiers. Although purely economic concerns of expanding into new territories might have suggested to the Ottomans that they should replace previous systems of taxation and collection with more efficient schemes that could be adopted from other parts of the empire, political constraints sometimes required them to work within the parameters of existing orders and capitalise on the comparative advantages of local agents who could better legitimise their regime through force and loyalty.

Technological Change

The Ottomans showed a mixed reaction to developments in technology. While readily adopting some of the new technologies, they rejected others outright or delayed their adoption for a long time. They paid close attention to advances in military technology (e.g. gunpowder, firearms and cannons) and assimilated them into the army and the navy swiftly. In adopting the printing press, by contrast, they took nearly three centuries after the invention of moveable type to sanction and offer explicit support for printing in Ottoman Turkish (in Arabic characters).

The delayed adoption of the printing press has attracted significant attention in the literature because of its implications for Muslim attitudes towards science and technology and for the indication that this may have contributed to the economic underdevelopment in the Islamic world. The generalist literature and Eurocentric approaches have typically offered *ad hoc* religious and cultural explanations of the attitude towards the printing press, such as religious conservatism towards Western technology and the inability of Muslim culture and institutions to keep up with changing times.

The problem with these approaches is their failure to explain why the rulers banned the printing press. For a complete explanation of this type, one would have to make controversial *ad hoc* assumptions about not just the conservative values of the general public but also about the motivations of Ottoman rulers in banning the new technology. This could be consistent with traditional analyses of government that viewed rulers as benevolent protectors who served the interests of the general public. If the printing press was expected to harm everyone, the ruler could be justified to ban it. Given the social and economic benefits of mass printing to the general public, however, this approach makes little sense and falls short of offering a complete explanation for why a ruler would reject a useful technology that had the potential to raise productivity. It does not seem justified to presume that the rulers and all organised groups had the same values and interests as the general public.

Contrary to traditional analyses of government, recent political economy models have made standard economic assumptions about the motivations of rulers. In this view, all members of the society, including the rulers, seek to maximise their own interests, even at the expense of the rest of the society. A society's reaction to a new technology would thus reflect not necessarily a unified social, cultural or religious concern, but an outcome of the strategic interaction of all affected parties.

In general, according to the political economy framework developed above, a society would adopt a new technology depending on its effect on the size of the surplus available to the ruler for taxation, the ability of religious and secular authorities to legitimise the ruler and the probability of a successful revolt. If the rulers expected new developments to raise the revenue available to them while having a positive effect on legitimacy or revolt, they would be eager to adopt them swiftly. But if the adoption of a new technology was likely to increase the probability of a successful revolt, despite its positive effects on productivity and output, they could oppose it if the net effect to them was negative. In the same vein, the general public and organised groups would be expected to favour technologies that improved their welfare and to oppose others. The final outcome would depend on a multitude of factors, including the direction and magnitude of how a new technology was likely to affect the welfare of the general population, the amount of the surplus available to the ruler, the probability of revolt and the abilities of organised groups to legitimise the ruler and the remuneration that the ruler was willing to pay for their services.

One of the possible outcomes was the quick adoption of a new technology. As noted, the Ottomans were usually eager to adopt new developments in military technology. Realising the advantages of gunpowder weapons, they integrated them into their army as swiftly as possible. They not only kept pace with developments in gunpowder, firearms and cannons, but displayed ingenious organisational skills by pioneering the establishment of a permanent standing army (the Janissaries) specialised in the use of these weapons, well before the European powers. They showed such remarkable success in assimilating gunpowder technology in their army and navy that by the mid-15th century they had achieved a clear logistical and firepower superiority over their European and Asian adversaries.

The Ottomans were generally eager to accept a new military technology because they expected it to raise the revenue available to them without significant adverse consequences to their basis for legitimacy or the probability of a successful revolt against their rule. A new military technology could raise the size of the surplus available to the Ottomans by expanding their revenue base through conquests and tributes or by helping them protect existing revenues from being confiscated by adversaries equipped with the new technology. Advances in military technology raised the ability of military authorities to legitimise the ruler without affecting the probability of a successful revolt significantly because the Ottomans took various measures to maintain their monopoly in organised violence. They controlled rural banditry by striking bargains with their leaders and incorporated bandits into the system by recruiting them as irregular soldiers. They also implemented a system of periodic rotation of offices through which government officials were rotated on a more or less regular schedule and were prevented from forming potential alliances with rebellious movements (Coşgel et al. 2013). Because advances in military technology could raise the size of the surplus available to them without having a significant effect on the legitimisation relationship between the rulers and the legal community or on the probability of revolt, the rulers accepted them eagerly.

Another possibility was an indifferent attitude towards a new technology. Two scenarios could lead to this outcome. First, the cost or benefit of a new technology on the ruler's surplus, his legitimacy or the probability of revolt could be too small to catch his attention or to provoke great enthusiasm or opposition. The introduction of various consumption goods invented elsewhere, such as eyeglasses and clocks, was often greeted with indifference, and consequently they were adopted by default. Similarly, despite their opposition to the printing press in the 15th century, the Ottomans were previously indifferent to the adoption of paper, a Chinese invention. Although these were great scholarly and scientific accomplishments, the cost and benefit to the ruler's surplus, his legitimacy and probability of revolt were often negligible, and there was no major reason for them to occupy the ruler's attention extensively. The Ottoman rulers typically did not show great enthusiasm (regarding their effect on their concerns) toward this type of development; nor did they oppose them vehemently.

Another scenario leading to indifference was when a new development could provide substantial benefits to one of the ruler's concerns (surplus, legitimacy or revolt), but was also accompanied by a similarly substantial cost to another concern. If, for example, a new technology was expected to raise the ruler's surplus significantly, but only at the cost of raising the likelihood of revolt by a comparable magnitude, the rulers could react to this technology with indifference. Despite expecting substantial benefits, they could be in no rush to adopt it quickly; nor would they have a great need to reject or delay its adoption, because the net effect could be negligible. Other concerns would determine the outcome.

While some developments were eagerly accepted and others faced lukewarm reception, still others were rejected outright. The preceding discussion has shown that just because a new development was likely to reduce the surplus available to the ruler did not mean it would be rejected. Despite causing a significant loss in surplus, it could still be adopted if the loss was offset by benefits in legitimacy and/or the likelihood of revolt. But if the ruler suffered a loss not just in surplus but also in legitimacy and likelihood of revolt, or if the loss in one of these areas was substantially greater than benefits in others, he could reject a new development immediately or delay its adoption. Some of the new developments in science, technology and institutions were rejected or regulated carefully because the net loss would have been too large.

As noted, a good example of this was the immediate opposition and significant delay in the adoption of the printing press. Within decades after the appearance of Gutenberg's first book published by moveable type in Germany, the Ottoman sultan is said to have issued an edict that banned printing in Ottoman Turkish (in Arabic characters) in 1485. Although the authenticity of this edit has been questioned, the evidence nevertheless indicates that some type of severe restriction on printing in Ottoman Turkish was in place. Despite clear awareness of the new printing technology and successful reproduction of it within Ottoman lands by religious minorities, the process of accepting the printing press was extremely slow. Even after the rulers started to relax the ban in 1726, they continued to regulate the operation closely by granting permission only to selected individuals, prohibiting publication on religious subjects and appointing a committee of scholars to review and proofread contents for accuracy. It was not until well into the 19th century that mass printing technologies became the convention and new techniques were adopted quickly and used commonly. The lithographic press was adopted within a few decades after its invention, and a press was established to print an official newspaper.

The Ottomans did not delay adopting the printing press because they were unaware of its invention or lacked the technical expertise. What makes the heavy regulation of the printing press puzzling is that its adoption could have raised the society's taxable surplus. Although the effect of printing on economic welfare would have been less in the Ottoman Empire than in Europe (because of differences in wage and literacy rates), it is reasonable to expect the effect on economic activities (indirectly on tax revenues) to be positive and substantial, directly through its effect on the market for books (e.g. the Quran and other religious texts) and indirectly through its effect on human capital and positive externalities that would have benefited other sectors. Judging solely by its effect on economic activities, Ottoman rulers would have been better off adopting the printing press immediately.

According to the political economy approach, the rulers were unenthusiastic about the printing press from its invention until the 19th century because they expected it might undermine the ability of religious authorities to confer legitimacy and might increase the likelihood of a successful revolt against their reign, even though it could raise the size of the surplus available to them. In early modern Muslim societies, the religious authorities had a monopoly on providing legitimacy through indoctrination because the transmission of knowledge depended on oral technology, and the authorities had a vast comparative advantage in this type of transmission. The introduction of the printing press would have altered this ability by changing the technology of transmitting knowledge and diminishing the comparative advantage of religious authorities. The general public could obtain knowledge directly from books or from literate individuals not necessarily affiliated with religious authorities. The rulers probably feared mass printing also because of its potential effect on successful revolt. Mass printing could be a very effective weapon in inciting rebellion, as was the case in the American Revolution and the Protestant Reformation. Although the printing press could have raised the surplus available to the rulers by a margin, Ottoman rulers still chose to ban it because it would have jeopardised their legitimacy and increased the likelihood of a successful revolt (Coşgel et al. 2012).

The examples on tax and technology adoption suggest that the institutional milieu in Ottoman Empire was not defined by an outright absence of change. Since changes in taxation or technology affected not just the productivity of the population but also the legitimising relationships between the rulers and their agents, institutional change was only permitted as long as it was consistent with ruler's incentives. In deciding whether to change the tax bases and rate structures in newly conquered territories and whether to adopt newly invented technologies, the Ottomans had to weigh economic concerns against political incentives carefully.

All of this highlights the primacy of politics.

Political Economy of Unearned Foreign Income

An Application for Non-oil Producing Muslim States

Faisal Z. Ahmed
Princeton University, Princeton NJ, USA

Abstract

This entry argues that foreign aid and remittances constitute a form of "unearned foreign income" that has affected the public finances and shaped political outcomes in the non-oil producing Muslim countries in North Africa, the Middle East, and South Asia. Aid and remittance flows have stabilized authoritarian rule in this "broader" Middle East and North Africa (MENA) region by reducing the likelihood of conflict, fostering corruption, and extending the duration of non-democratic governments.

Introduction

Unearned foreign income comprised of foreign aid and workers' remittances is an important source of income for many developing countries. Increasingly, scholars are evaluating the macro-*political* consequences of these capital inflows. One strand of this nascent scholarship conceptualizes aid and remittances inflows as a form of "unearned income" with non-tax like properties for government finances. In doing so, this strand of research links the political economy ramifications of aid and remittances to the politically pernicious effects associated with rentier states (e.g., authoritarianism, corruption, political violence). Building on this conceptualization, this entry argues that aid and remittance inflows have entrenched authoritarian governance and rule in many non-oil producing Muslim countries in North Africa, the Middle East, and South Asia (a region, I will call "broader MENA.")

Unearned Foreign Income and Authoritarian Governance

Aid and Remittances as Unearned Foreign Income

Unearned Income Unearned income is a concept in economics that has different meanings and implications depending on the theoretical framework used. Political economists broadly view unearned income as non-tax government revenue (e.g., Madhavy 1970; Besley and Persson 2010). For them, the distinction between non-tax and tax revenue has implications for political development: governments that derive a greater share of their revenues from taxation tend to be more democratic and more accountable to their populations (e.g., Tilly 1992).

Foreign Aid as Unearned Foreign Income Foreign aid is the international transfer of capital, goods, or service from a country or international organization ("donor") for the benefit of the recipient country (i.e., its government, its population). These transfers can involve financial resources, technical advice and training, or commodities (e.g., food or military equipment). In many instances, the resources can take the form of grants or concessional credits (e.g., export credits). In practice, the most common type of foreign aid is official development assistance

(ODA), which aims to promote development and combat poverty. The primary source of ODA is bilateral grants from one country's government to another, and while a small fraction of aid may "bypass" a recipient government to a non-government organization, the vast majority of aid directly enters a recipient government's revenue. Since this revenue is foreign and not derived from domestic taxation, it fits the definition of unearned income.

Remittances as Unearned Foreign Income Whereas foreign aid is a transfer of resources between governments, remittances do not directly enter a government's revenue base. A remittance is a transfer of money by a foreign worker to an individual in his or her home country. Frequently, this transfer occurs between family members. Measuring remittance flows can be arduous since they may flow through unofficial channels and many recipient (developing) countries often lack the capacity to accurately track, record, and tax these capital inflows (Chami et al. 2008). However, remittances may enter a government's revenue base indirectly. For instance, via an expenditure-switching mechanism, a government may reduce its provision of certain welfare goods (e.g., health care or education), forcing migrant households to purchase them instead. This mechanism frees resources for governments to spend elsewhere, such as on the military and government salaries (Abdih et al. 2012; Ahmed 2012).

Unearned Income and Authoritarian Governance

Unearned Income and Governance The ability to "collect" revenue is central to the viability of any state (Levi 1988); without it, the state cannot carry out its basic functions such as providing security. States can collect their revenue from taxation (e.g., from individuals, firms, land, capital, consumption, international trade) and non-tax sources (e.g., revenues from the state's production of natural resources, foreign aid). On the latter, the availability of unearned income as a viable and important source of government revenue (especially since the nationalization of oil production in many countries during the 1970s) has sparked an active research agenda that theorizes and empirically evaluates the effects of unearned income on politics, such as democracy, institutions, and civil war (Ross 2013).

Scholars of the Middle East were the first to articulate the relationship between unearned income and democracy, while investigating whether the prevalence of "rents" contributed to authoritarian governance in that region (Mahdavy 1970). The central argument in the rentier state literature is that governments funded by external rents are freed from the need to raise taxes, which makes them less accountable to their citizens and to less committed to democratic governance. Many qualitative and quantitative studies have empirically substantiated this relationship (see Ross 2013 for an overview).

This negative relationship between unearned income and democratic governance may depend on the quality of preexisting institutions. For instance, Tornell and Lane (1999) advance a model showing how, upon receiving a positive shock to fiscal capacity (e.g., a resource boom, foreign aid), a state with weak institutions may suffer from a "voracity effect" in which powerful groups compete for and squander the windfall, in addition to diminishing any pro-growth effects. Focusing on the political ramifications, Robinson et al. (2006) formulate a parallel model demonstrating that when institutions are weak ex-ante, increases in unearned income lead to excessive public employment and patronage (e.g., corruption). In these weak institutional settings, unearned income can finance additional forms of patronage goods such as the co-option of political rivals, religious leaders, business elites, and the military. The latter can strengthen a government's repressive capacity to fend off revolutionary threats (Bueno de Mesquita et al. 2010).

Unearned Foreign Income and Patronage in Non-democracies Patronage politics is particularly salient for political survival and stability in non-democracies (Bueno de Mesquita et al. 2003). As a consequence, when compared to governments in democracies, governments in autocracies will place greater weight on expenditures for patronage in their spending decisions. Building on this framework, Ahmed (2012) develops a game theoretical model in which foreign aid and remittances expand a government's revenue base (akin to traditional forms of unearned income) and finances patronage in non-democratic regimes. Unearned foreign income does so via two distinct channels: an income effect and a substitution effect.

As a transfer of resources between governments, aid directly increases government revenue. And since governments in autocracies tend to allocate a greater share of their revenues towards patronage, a higher share of their aid is spent towards patronage goods. This process constitutes an "income effect."

In contrast, remittances do not directly enter a government's revenue base. Rather, the model identifies a substitution effect. Households will spend a portion of their remittance income on certain substitutable welfare goods (e.g., better quality health care and/or education for their children). The government "observes" these expenditures and marginally decreases its own provision of that welfare good, diverting those unused funds towards patronage. In the model's equilibrium, autocratic governments have a greater incentive (i.e., higher utility) to divert resources towards patronage from higher levels of remittance income. Thus, the substitution effect is magnified in non-democratic regimes. In combination, Ahmed shows that higher levels of aid and remittances finance more patronage in non-democracies. Thus, aid and remittances should stabilize governments in non-democracies, for example, by lowering the likelihood of institutional change and government turnover.

Unearned Foreign Income in the Broader MENA Region

Within this theoretical framework, the next two sections present empirical evidence linking unearned foreign income to non-democratic governance in the non-oil producing Muslim countries in North Africa, the Middle East, and South Asia; a region I will call "broader" Middle East and North Africa (MENA).

Unearned Foreign Income in Broader MENA

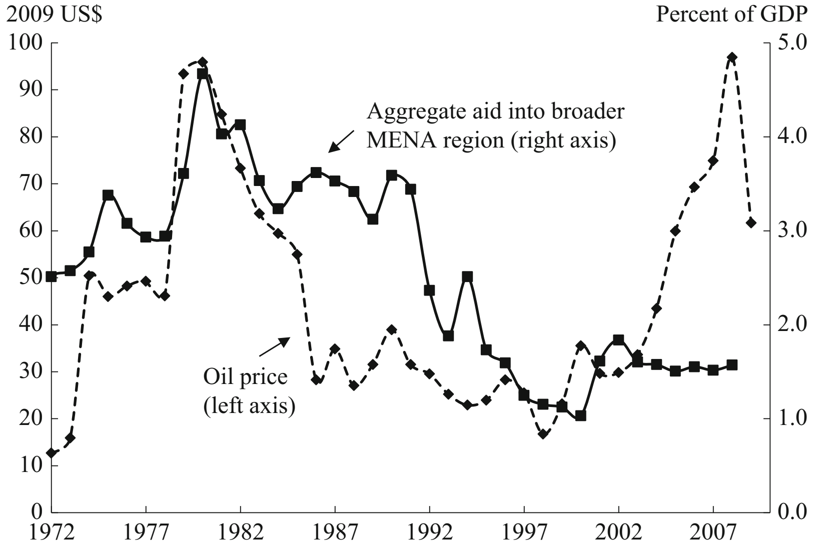
Since the 1970s, countries in the broader MENA region have received large sums of unearned foreign income; a substantial portion of which originates from oil producing countries in the Persian Gulf (e.g., Saudi Arabia, Kuwait, the United Arab Emirates). And, oil price booms and busts explain a large share of the temporal variation in these capital flows.

Gulf oil producers ramped up their aid disbursements following the first oil price shock in 1973. Between 1974 and 1994, Gulf donors doled out 1.5% of their GDP, which amounted to 13.5% of all aid given out over this period – overwhelmingly, this aid favoured non-oil producing Muslim countries (Neumayer 2003). Certainly, some of the motivation for this assistance was political, as the Gulf countries were at the same time trying to subdue unrest stemming from the huge inequality among their co-religionists (between the oil haves and have-notes), and seeking to "assure them[selves] a clear position of dominance within the Muslim world" (Kepel 2002, 69–70). Much of this Gulf aid looked like unearned income (e.g., oil rents) flowing to the state, as it came primarily in the form of block grants to recipient governments with comparatively few strings attached (Hunter 1984).

The oil boom in the 1970s also affected remittance inflows into the broader MENA region. In the aftermath of the 1973 oil crisis, labour from different countries in North Africa, South Asia, and Middle East migrated in great numbers to the oil-exporting countries in the Middle East. The first wave of workers (totaling about 500,000) migrated from non-oil producing Gulf States, such as Jordan, Palestine, and Yemen. In the latter part of the decade, Gulf States began to recruit a large number of South Asian workers from India, Pakistan, and Bangladesh. For example, it is estimated that the number of Pakistani workers jumped from roughly 500,000 in 1975 to over 1.25 million in 1979. By the early 1980s, there may have been some 3.5–4.65 million migrants, in a combined labour force of 9–10.2 million workers (Choucri 1986). This large movement of labour generated large capital flows in the form of workers' remittances from Gulf oil producers to a variety of non-oil producing labour exporting countries in the Middle East (e.g., Jordan), Africa (e.g., Mali), and South Asia (e.g., Pakistan).

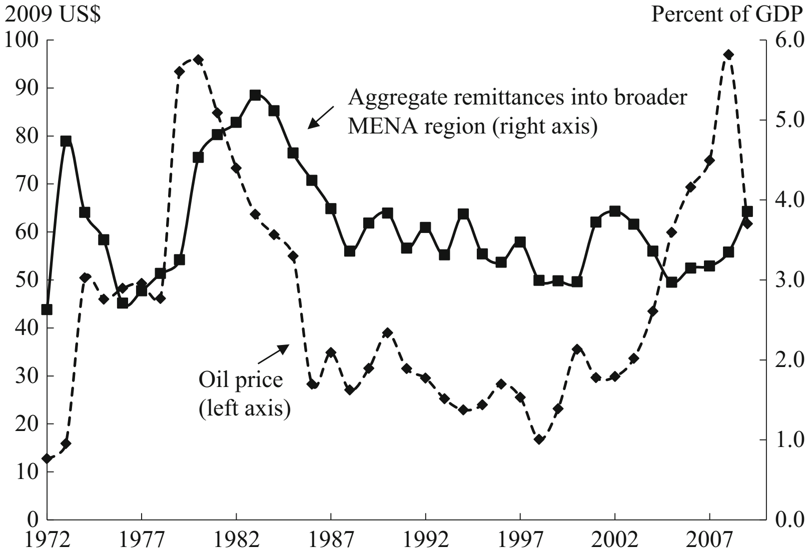
Temporal Variation

Inflows of aid and remittances into the broader MENA region have varied over time and tracked the world price of oil. Figures 1 and 2 depict movements in the price of oil (right axis) and superimpose the *aggregate* annual amount of aid (Fig. 1) and

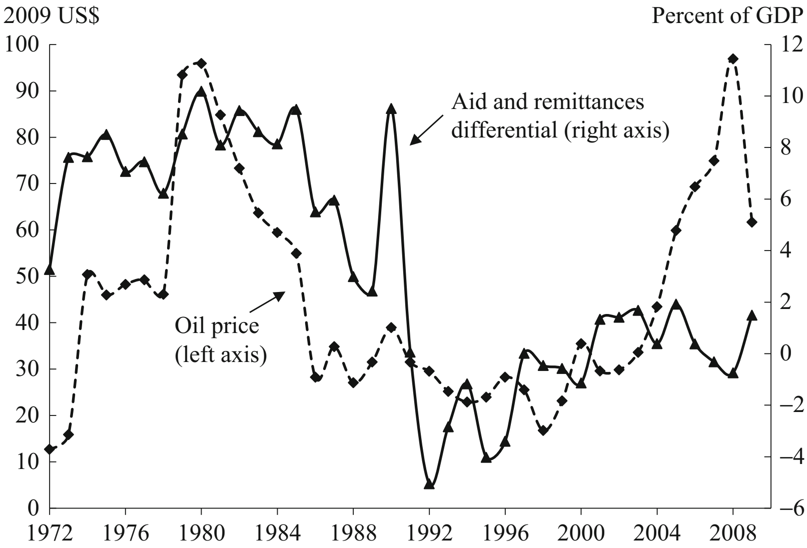


Notes: Foreign aid includes disbursements from all donors (as reported by the OECD) into the broader MENA region. This includes disbursements from both OPEC and non-OPEC (e.g., the United States, the UK) donors. Data from the World Bank World Development Indicators and the author's calculations

Political Economy of Unearned Foreign Income, Fig. 1 Aggregate foreign aid in the "broader MENA" region



Political Economy of Unearned Foreign Income, Fig. 2 Aggregate remittances in the "broader MENA" region (*Notes*: Remittances include flows from all countries (as reported by the World Bank) into the broader MENA region. This includes remittances from the Persian Gulf and elsewhere (e.g., Western Europe and North America). Data from the World Bank World Development Indicators and the author's calculations)



Political Economy of Unearned Foreign Income, Fig. 3 Difference in unearned foreign income between non-oil producing Muslim and non-Muslim recipients (*Notes*: Data from the World Bank World Development Indicators and the author's calculations)

remittances (Fig. 2) into the broader MENA region (measured as a share of the region's GDP). In the early 1970s, aggregate aid and remittance inflows were quite low but then increased sharply following the first oil shock in 1973. These inflows remained high through about 1984 and then declined after 1985 as oil prices tanked. As oil prices recovered in the 1990s, aid and remittance flows began to rise again. In the 2000s, the correlation (positive) between oil prices and these capital flows (in particular aid) tends to weaken. On balance, Figs. 1 and 2 suggest a strong correlation between oil price and aggregate flows of unearned foreign income into the broader MENA region.

Interestingly, the recipients of oil price-induced aid and remittance flows were primarily non-oil producing Muslim countries. Conversely, similar "shocks" resulting from variation in oil prices did not affect aid and remittances to non-oil producing *non*-Muslim nations. Figure 3 provides such evidence. It plots movements in oil prices (left axis) and superimposes the difference in average of foreign aid and remittance inflows between non-oil producing Muslim and non-oil producing non-Muslim countries (right axis). A positive differential implies the "typical" Muslim countries received higher amounts of aid and remittances (as a share of GDP) relative to the typical non-oil producing non-Muslim recipient.

Figure 3 shows that between 1970 and 2000, this "differential" in aid and remittances tracks the price of oil. As oil prices rose in the 1970s, so did the differential. Moreover, it remained large and positive during the decade of high oil prices (1974–1984). Countries in the broader MENA region tended to receive substantial inflows of aid and remittances (i.e., between 6% and 10% of additional GDP per annum) than non-Muslim recipients. As oil prices plummeted after 1986, so did the differential. On average, Muslim and non-Muslim countries tended to receive similar amounts of aid and remittances (as a share of their respective country GDPs).

Evidence

Establishing Causality

Evaluating the causal effect of unearned foreign income on political outcomes is problematic as these income flows are plausibly endogenous with the "politics" in the receiving states. Gauging a causal effect therefore requires some plausibly exogenous source of variation in these income flows that is uncorrelated with underlying political and economic conditions in the receiving states. Figures 1 and 2 show that foreign aid and remittances inflows into the broader MENA region are correlated with world oil prices, and these prices are plausibly exogenous to political and economic conditions in poor, non-oil producing Muslim countries (e.g., Jordan, Bangladesh). Thus, variation in oil prices can serve as a plausibly exogenous source of variation in aid and remittance flows to the broader MENA region. Moreover, Fig. 3 shows that in comparison to non-Muslim countries, Muslim countries were the main beneficiaries of the oil-price induced aid and remittance "shocks." Indeed, several studies leverage these facts to evaluate the causal effect of aid and remittances on various political outcomes in the broader MENA region.

Foreign Aid and Civil War

Ahmed and Werker (2015) evaluate whether foreign aid affects political stability. They argue that aid can "buy" political stability (often by strengthening a state's repressive capacity and autocratic institutions), while declines in aid foster instability. They measure instability using the incidence of civil war. To identify the causal impact of aid on conflict, they leverage a difference-in-differences (DID) strategy to show that periods of higher aid receipts (due to higher oil prices) are associated with a lower probability of conflict in the broader MENA region.

Figure 4 captures their core findings. The figure examines the relationship between the aid differential and the conflict differential across Muslim and non-Muslim countries. Muslim countries in the broader MENA region experienced less conflict than non-Muslim countries when they received comparatively more aid. As the aid differential reversed due to lower oil prices from the mid-1980s until the early 2000s, Muslim countries were substantially more likely to experience civil war.

The differential effects of aid on political violence are large and statistically significant. Ahmed and Werker (2015, Table 1) present DID estimates in which the aid windfall between 1973 and1985 made countries in the broader MENA region 7 percentage points more stable (i.e., less conflict prone) compared to non-Muslim aid recipients. The end of the windfall fostered a relative rise in political violence as Muslim countries became 11 percentage points more likely to be engaged

Robust standard errors clustered by government are reported in parentheses. *, **, *** = Significant at 10, 5, 1%, respectively. All specifications control for GDP per capita (% annual), log GDP per capita (1995 US$), log population, POLITY autocracy score, year trend, and country fixed effects. Remittances are instrumented with p(oil)*distance to Mecca. In columns 1 and 2, the dependent variable is ICRG corruption index (range: 1–6) where a higher value implies greater corruption. In column 3, the dependent variable is government transfers and subsidies (% government expenditures). In column 4, the dependent variable is government compensation of employees (% government expenditures)

in civil war, while non-Muslim countries became slightly more stable (around 1 percentage point).

Remittances and Corruption

Autocrats frequently permit corruption as a strategy of political survival. It can be a means to reward loyal supporters and erode the provision of public goods in favour of private government goods, such as patronage (Bueno de Mesquita et al. 2003). Thus, given the viability of corruption as a strategy to maintain political stability in autocracies, Ahmed (2013) investigates whether or not remittances may be a conduit for corruption. To that effect, Ahmed interacts oil prices with a Muslim country's distance to Mecca to construct a cross-national and time-varying instrumental variable for remittances received by countries in the broader MENA region. To hone in on patronage-based government corruption, Ahmed uses the ICRG corruption index, which measures "actual or potential corruption in the form of excessive patronage, nepotism, job reservations, 'favor-for-favors', secret party funding, and suspiciously close ties between politics and business."

Leveraging this research design, the paper establishes two key results. First, remittances foster corruption, particularly in countries with preexisting authoritarian politics. Second, remittances do so by allowing governments to divert spending from welfare goods to patronage. Table 1 reports a snapshot of the econometric analysis from Ahmed (2013), highlighting these main findings. The coefficient estimate in column 1 implies that a 3-percentage point increase in aggregate remittances raises the corruption index by about 1 index point. Column 2 evaluates whether a country's preexisting quality of authoritarian politics magnifies the effect of remittances on corruption. The positive coefficient on the interaction effect (Remit. x Autocracy) implies that remittances received in countries with more autocratic politics has a *greater* causal impact on corruption.

The remaining columns in Table 1 show that a substitution effect is a plausible channel through which remittances foster corruption. Columns 3 and 4 show that remittances cause governments in the MENA region to decrease their expenditures on welfare goods (column 3) and shift those to patronage in the form of greater compensation for government employees (column 4). The latter is a common measure of patronage in developing countries, as it frequently reflects the government's incentives to channel spending to targeted constituencies (Keefer 2007). Remittances are also negatively associated with government expenditures on health care and education (Ahmed 2013, Table 11).

Unearned Income and Political Stability

Finally, in combination, foreign aid and remittances have stabilized governments in the broader MENA region. Table 2 below reports the core results from Ahmed (2012). That paper employs an instrumental variables strategy to show that greater inflows of unearned foreign income in the broader MENA region caused governments to experience a lower likelihood of losing office between 1973 and 2004. The coefficient estimate in column 1 implies that a 1 percentage increase in unearned foreign income (relative to GDP) lowers the likelihood that a government will fall out of power by about 5 percentage points (in that calendar year). Moreover, this stabilizing effect is larger for governments in countries with stronger authoritarian political institutions (column 2). Since many of the governments in the MENA region were authoritarian over the sample period, the results in columns 1 and 2 imply that unearned foreign income increased the duration of autocrats in non-oil producing Muslim countries. King Hussein in Jordan, as well as the military dictatorships in Bangladesh and Pakistan during the 1970s and 1980s, illustrates this claim.

Column 3 presents evidence of both an income effect and a substitution effect associated with unearned foreign income inflows. In this specification, the dependent variable is a government's expenditures on transfers and subsidies as a share of total government expenditures. A negative regression coefficient implies that the variable shifts the allocation of government spending away from the provision of welfare goods to another type of government spending. Given this interpretation, the negative coefficient on aid and remittances implies that increases in unearned foreign income reduce a government's share of expenditures on welfare goods. This observation is consistent with a substitution effect. Of course, as Ahmed (2012) explicitly models, an autocrat may want to spend some fraction of its aid on welfare goods. The positive coefficient on aid is consistent with this income effect.

Conclusion

How governments derive their revenues can have important political ramifications. The availability of unearned income or non-tax revenue, in particular, can make governments less accountable to their populations and fund various strategies of political survival (e.g., patronage, repression). Governments in these states tend to be non-democratic. Building on this framework, this entry argues and presents evidence that foreign aid and remittances have constituted a form of unearned foreign income that has fostered authoritarian politics in countries in the broader MENA region.

Political Economy of Unearned Foreign Income, Table 2 Unearned foreign income and authoritarian stability

Dependent variable	Government turnover		Transfers (% gov exp.)
Method of estimation	2SLS	2SLS	2SLS
	(1)	(2)	(3)
Aid and remit. (% GDP)	−0.046		−1.509
	(0.022)**		(0.785)*
Aid and remit. × Autocracy		−0.294	
		(0.135)**	
Aid (% GDP)			1.363
			(0.777)*
No. obs	1639	1639	315

Notes: Results from Ahmed (2012), Tables 4 and 6. Estimation via 2SLS. Robust standard errors clustered by government in parentheses. *, **, *** = Significant at 10, 5, 1%, respectively. In columns 1 and 2, the dependent variable is equal to 1 if the government loses office in that year, and zero otherwise. In columns 1 and 2, the specifications control for log GDP per capita (1995 US$), GDP per capita growth (% annual), duration splines, and indicator variables for finite-term, incidence of low and high internal discontent, country and year fixed effects. Splines are duration time, duration time squared, and duration time cubed. Column 3 controls for log GDP per capita (1995$). These coefficients and a constant are not reported. Aid and remittances are instrumented with the p(oil) × Muslim country dummy

These findings offer broader insights on the political economy of unearned income. First, since a large share of the aid and remittances emanated from oil producing countries in the Persian Gulf (and was driven primarily by movements in oil prices), it stands to reason that the pernicious political and economic effects of the "resource curse" can be exported abroad via capital outflows (Ahmed et al. 2016). Second, since non-oil producing Muslim countries comprised the unique recipients of a shock in unearned foreign income in the 1970s (relative to non-oil non-Muslim countries), the processes described in this entry offer a plausible explanation for the "democratic deficit" that has emerged in Islamic states (Huntington 1993). Finally, while this entry has focused on the political ramifications of aid and remittances in the broader MENA region, there is no reason to assume that these effects manifest themselves only in this region (e.g., Ahmed (2017); Doyle 2015). Thus, a fruitful area of future research will assess whether or not unearned foreign income generates similar effects in other regions with different underlying political structures.

Political Institutions, Economic Approaches To

Timothy Besley and Torsten Persson

Abstract

Political institutions affect the rules of the game in which politics is played. Economists now have theoretical approaches to explain the impact of institutions on policy, and empirical evidence to support the relevance of the theory. This article sketches a framework to inform discussions about how political institutions shape policy outcomes. It does so using four examples: majoritarian versus proportional elections; parliamentary versus presidential government; whether to impose term-limits on office holders; and the choice between direct and representative democracy. Each example illustrates how theory and data can be brought together to investigate a specific issue.

Introduction

Political institutions play a key role in shaping economic policies. Economists now have theoretical approaches to explain this claim and empirical evidence to support it. Political institutions affect the rules of the game in which politics is played. For the most part the term ‘institutions’ is taken to mean formal rules as embodied in constitutions, and other forms of legislation. However, it may also refer to norms and informal rules.

Two basic categories of political institutions are electoral rules and forms of government. The former term refers to features such as district magnitudes and electoral formulas that translate votes into seats. It also refers to the rules for selecting candidates and for governing their tenure in office. The latter category refers to such questions as whether the systems is presidential or parliamentary, how decision making powers are divided between central and local governments or between executive and legislature, and whether citizens have a direct say in policymaking via referenda.

Our aim in this article is to sketch an intellectual framework that informs discussions about how political institutions may shape policy outcomes. We do this by way of specific examples, referring to recent research on the topic – we do not attempt to provide a comprehensive overview of theoretical modelling or empirical knowledge. In each case, the example illustrates the potential for theoretical frameworks to shape thinking on the topic backed up with empirical analysis.

When political scientists debate democratic institutions, they frequently use two metrics for their performance – accountability and representation. The former refers to the way in which political institutions make politicians (and to some degree bureaucrats) answerable for their actions. The second refers to whether the policies and/or policymakers fairly reflect the population as a whole.

Translated into the language of economics, these two performance dimensions correspond well to two main conflicts of interest that arise in representative democracies – those between politicians and citizens and those between groups of citizens with competing economic interests. Accountability deals predominantly with the former and representation with the latter. As normative criteria, the welfare underpinnings of these metrics are somewhat vague, but they do provide a useful way of thinking about the positive effects of political institutions.

Economic models for studying accountability are mostly based on some form of *agency* approach. Such models assume that there exist problems of hidden actions (moral hazard) and hidden types (adverse selection) in politics. Politicians typically have career concerns which lead them to seek re-election. Voters decide whether or not to re-elect based on the record of politicians. To make the problem interesting, there has to be some conflict of interest between politicians and voters. The simplest (and most widely used model) supposes that this is due to opportunities for rent seeking (or effort avoidance) among politicians. The question is then how much of this conflict of interest rubs off on to policy choice in equilibrium, that is, when voters and politicians are behaving rationally and optimally. There is now a large body of literature using such models. Political institutions can affect policy in such models in three main ways: affecting the information that voters have to assess politician performance, directly affecting incentives of politicians to extract rents, and affecting the kinds of people of who are selected for public office (See Besley 2006, for a broad survey of agency models and their uses).

Economic models for studying representation rely on some kind or another of a spatial framework. These models envisage citizens being located at different points in the space according to their underlying economics interests (such as their age or ability) and their social interests (such as ethnicity). The classic Downsian model of political competition (Downs 1957) falls in this class and many subsequent developments have built on its insights. More recent work has tried to make the framework more tractable by supposing that voting is probabilistic – there is a random element in the ballots cast by voters, and politicians can therefore not be exactly sure how policies translate into voting outcomes. In standard models, competition is directly over policies without regard to who is being asked to carry these policies out. More recent approaches have looked at the problem of picking policymakers to deliver these policies. This is particularly important when modelling the credibility of policies being offered (See Persson and Tabellini 2000, for a broad survey of spatial models of policymaking and their uses).

In this article, we illustrate the main themes of the recent literature by focusing on four examples of how political institutions shape policy. Two of these examples deal with electoral rules, two with forms of government, broadly defined. Two of the examples are motivated mainly from cross-country empirical applications, while the other two are motivated more from studies of within-country variation (Persson and Tabellini 2003, discuss empirical work on cross-country studies of political institutions, while Besley and Case 2003, survey within-country (cross-state) studies for the United States). Thus, Sections 2–5 discuss, in turn, the policy consequences of adopting proportional or plurality elections, the effects of parliamentary or presidential forms of government, the consequences of term limits for elected politicians, and the impact of direct or representative democracy. Section 6 concludes.

Proportional or Majoritarian Elections

Political scientists often describe a key trade-off in electoral systems: electoral formulas based on plurality rule promote accountability at the expense of representation, while formulas based on proportional representation (PR) errs on the other side of the trade-off. Recent theoretical work by economists has analysed the consequences for governments spending of having legislative seats awarded by plurality rules rather than PR – an issue closely related to representation. The key idea is relatively straightforward (see Persson and Tabellini 1999; Lizzeri and Persico 2001; Milesi-Feretti et al. 2002). If candidates with the highest vote shares win every seat at stake in a district, rather than seats in proportion to their vote shares, it becomes more attractive to target spending to small and geographically concentrated groups of voters (The same will hold true if each district has small magnitude, that is, represents a small share of the electorate). This tilts equilibrium policy towards spending programmes with benefits targeted to particular geographical groups, not the electorate at large, and (perhaps) towards higher overall spending.

Empirical work has sought to evaluate these predictions using cross-national data. Long-term inertia in the broad features of electoral systems makes it necessary to rely on the cross-sectional variation in the data, which, together with the nonrandom selection of electoral systems, raises a number of statistical issues. These issues are tackled by a variety of methods in Persson and Tabellini (2003, 2004), who classify actual electoral systems according to their electoral formula (classifying by district magnitude gives similar results) and approximate geographically non-targeted spending by welfare-state programmes, such as pensions and unemployment insurance. Their results indicate that a reform from an all-PR to an all-plurality-rule system would cut welfare spending by about two per cent of GDP in the long run. Such an electoral reform would cut overall government spending by a substantial five per cent of GDP.

The underlying theory works off the incentives of politicians and takes party structure as given. Yet it is a well documented fact that PR promotes a more fractionalized party system than plurality rule (see, for example, Lijphart 1990). Austen-Smith (2000) studies a model where redistributive tax policy is set in post-election bargaining, assuming that the number of parties is, exogenously, higher under PR than plurality rule. He shows that this produces higher taxes and spending under PR. Bawn and Rosenbluth (2006) and Persson et al. (2005) obtain a similar prediction but endogenize the number of parties. In their models of parliamentary democracy, they show that coalition governments spend more than single-party governments under each electoral rule. We should still observe higher spending in PR systems, but this is an indirect effect of a larger number of parties increasing the incidence of coalition government. Persson et al. (2005) derive an empirical way of discriminating between the indirect effect and the direct effect via the incentives of politicians. Using panel data for parliamentary democracies since 1960, they find that the higher overall spending observed under PR is entirely due to its more fractionalized party systems and hence more frequent coalition governments than under plurality rule.

A second body of theory relates to the accountability of politicians under alternative electoral systems. The key idea here is that extraction of rents – or, more generally, corruption – is better deterred the more swiftly the probability of re-election responds to performance (see Myerson 1993; Persson and Tabellini 2000). Large district magnitude achieves this by allowing easier entry and a larger number of candidates than small districts. Personal ballots impose individual accountability and stronger incentives than party-list ballots, which impose only collective accountability. In other words, systems where a larger number of lawmakers are elected in each district, and systems where they are elected on personal rather than party-list ballots, are both expected to reduce rent extraction by politicians. Empirically, Persson and Tabellini (2003) find quite sizeable effects in the hypothesized direction on different perception indexes of corruption, or on inefficiency in the delivery of government services.

Presidential or Parliamentary Government

How well voters can hold politicians accountable also depends on the form of government. This insight goes far back in political writing. For example, James Madison insightfully discussed various aspects of the separation of powers in his contributions to *The Federalist Papers*. Economists have recently produced modern versions of the argument as to how separation of powers across political offices may serve to limit conflicts of interest between voters and their elected representatives. Extending the agency model of Ferejohn (1986), Persson et al. (1997) show that separating the proposal powers over taxes and spending creates a conflict between politicians that enables voters to better discipline their power to extract rents when in office.

This approach is extended to include issues of representation by Persson et al. (2000), who analyse how different forms of government shape fiscal policy by embedding different forms of legislative bargaining in spatial voting models. They assume that presidential systems have a more extensive separation of powers across legislators than parliamentary systems. On the other hand, as in Huber (1996) and Diermeier and Feddersen (1998), parliamentary systems make the government subject to a confidence requirement of the legislature, whereas a presidential system does not (the president is directly elected). These two institutional features shape the legislative bargaining, such that legislative majorities in presidential systems become less stable than in parliamentary regimes. If majorities re-form, issue by issue, different minorities are pitted against each other for different issues on the legislative agenda. As a result, broad spending programmes suffer at the expense of targeted spending. Moreover, the lack of a stable legislative majority means that there is no well-defined residual claimant on government revenue. This reduces the incentives to boost overall taxation and spending. Overall, we should thus expect presidential regimes to be associated with lower total spending and smaller broad (non-targeted) spending programmes than parliamentary regimes.

Persson and Tabellini (2003, 2004) confront these predictions with data, in which real-world forms of government are classified as parliamentary or presidential, depending on whether the executive is subject to the continual confidence of the legislature. For broad welfare state programmes, they find the hypothesized result only among long established democracies, among which presidential regimes spend less, by about two per cent of GDP. For overall spending the results are very robust across samples and in line with the basic hypothesis. Whether the results are obtained by OLS, instrumental variables or matching methods, the finding is that presidential regimes have smaller governments by at least five per cent of GDP – again, a large number.

Term Limits or No Term Limits

Political accountability is achieved in part by re-election chances responding to performance while in office. This resembles the kind of contractual relations that arise in a market context and provide workers with incentives. However, the relationships between politicians and voters are not contractual – they resemble something closer to a fiduciary relationship. While political parties may have a role in disciplining politicians, the ultimate sanction is an electoral one: poorly performing incumbents are removed from office by the voters.

The frequency of re-election and the number of terms that a politician can serve become important institutional choices in shaping electoral accountability. The agency model of politics referred to above provides a tool to approach these issues. The theory suggests two ways of thinking about term limits: incentive effects and selection effects. Incentive effects arise because politicians who face a shorter time horizon are less obliged to please voters. Whether this increases or reduces the quality of policy is moot. On the one hand, politicians facing term limits may have less incentive to please voters and hence may follow their private agendas. But they may also pander to voters, eschewing hard decisions that impose short-run costs in exchange for long-run benefits. This latter effect can lead term-limited politicians to act more in the voters' interests. Either way, if electoral incentives matter, then we should expect term limits to shape political decisions. Terms limits will also induce a selection effect. Politicians have to be elected to lame-duck terms. Rational voters should anticipate this when deciding whether to (re)elect them, which will make politicians elected to lame-duck terms better than average. Such positive selection may counteract any adverse incentive effect.

US states provide a natural experiment for looking at the impact of term limits, because governors are subject to such limits in around half the states. This allows two kinds of comparisons: across time – governors when they are up against a term limit versus their first (non-term limited) period in office – and across states – term- limited versus non-term-limited governors.

Besley and Case (1995) identify the effect of a term limit from the difference between first and second terms in office for incumbents facing term limits. Controlling for state fixed effects and year effects, and using annual data from the 48 continental US states from 1950 to 1986, they find that a variety of policy measures are affected by term limits. Specifically, state taxes and spending are higher in the second term when term limits bind in states that have them. Such limits tend to induce a fiscal cycle, with states having lower taxes and spending in the first gubernatorial term than in the second. More recently, List and Sturm (2006) have applied these ideas to environmental policies at the US state level and also find evidence of a term-limit effect. They observe that the way in which environmental interests are represented in policy may depend on whether the governor is in his last term in office.

Term limits have also been advocated as solutions to institutional distortions in legislatures. A good example is the committee system in the US Congress, which puts a premium on seniority of politicians and thus, effectively, a lower performance threshold for incumbents with a resulting diminution in accountability (see Dick and Lott 1993, for development of this argument).

A host of studies look for effects of announced retirements on voting behaviour in Congress. On the whole, it has been difficult to find evidence of a last-period effect. For example, Lott and Bronars (1993) analyse Congressional voting data from 1975 to 1990 and find no significant change in voting patterns in a representative's last term in office. McArthur and Marks (1988) look at Congressional behaviour in a lame-duck session of Congress: in post-election sessions, members who have not been re-elected are at times called upon to vote on legislation before the swearing in of the new Congress. They find that lame-duck representatives were significantly more likely in 1982 to vote against automobile domestic content legislation than were returning members.

Direct or Representative Democracy

Whether polities should use some element of direct democracy as part of their political institutions is widely debated. The two most famous examples are US states and Swiss cantons, which display considerable variation in their reliance on citizen initiatives and referenda. From a theoretical point of view, issues of accountability and representation are important in thinking through these issues.

Some commentators (for example, Denzau et al. 1981) emphasize the role of initiatives in reducing rent-seeking by government and hence enhancing accountability in the political process. This underpins a number of studies investigating whether jurisdictions that permit initiatives have smaller governments. For example, Matsusaka (1995) regresses government expenditures and revenues on a number of control variables for a panel of 49 US states (Alaska excluded) sampled over a 30-year period at five-year intervals from 1960 to 1990. He includes year effects, but not state fixed effects, since the presence of initiatives is largely fixed within states over time. His main finding is a strong negative effect on expenditures of access to the initiative. Matsusaka (1995) also finds some evidence that the effect is strongest where the number of citizen signatures required for a referendum is low. Similarly, Pommerehne (1990) shows that Swiss cantons using the initiative indeed have smaller governments.

Others emphasize the fact that initiatives can change the representation of policy preferences. A large body of empirical evidence from political science supports the lack of congruence of policy and voter preferences on a variety of issues (see Besley and Coate 2000, for references).

Gerber (1999) considers how, given a set of policy preferences in a legislature, the availability of the initiative could change the equilibrium policy bargain. Moreover, the legislature may make such a change pre-emptively, that is, it is sufficient for legislators to anticipate the *possibility* of an initiative at a later date. Hence, the possibility of initiatives forces a greater agreement between voter preferences and policy outcomes, on the assumption that representatives elected to the legislature have views that are out of step with the citizens as large. Similar conclusions follow from the theoretical analysis of Besley and Coate (2000) but for quite different reasons. They develop a model in which initiatives affect electoral outcomes. They argue initiatives have an impact via *issue unbundling*. In general elections, many issues are decided at once, which may result in non-salient issues being distorted away from the preference of a majority. Initiatives allow such issues to be unbundled from other issues in the election. Besley and Coate show that this can change the probability distribution of a range of policy outcomes and the composition of candidates who are chosen to run. Both of these theoretical approaches, as well as many popular discussions of initiatives, imply that citizen initiatives are a device for bringing policy into line with public opinion.

One strand of empirical literature on initiatives has used data from US states to test whether public opinion and policy outcomes are closer together in initiative states. For example, Lascher et al. (1996) and Camobreco (1998) investigate whether the link between aggregate measures of policy outcomes and public opinion is closer when states allow citizens' initiatives. They find no significant effect. With respect to specific policy issues, Gerber (1999) uses cross-sectional state variation from the 1990s and compares stances on an array of policies. She finds significant differences (at the ten per cent level) for personal income taxes (initiative states lower); highway, natural resources and hospital spending (initiative states higher in all cases); and the implementation of three-strike legislation (initiative states lower). Gerber looks in greater detail at the death penalty and parental consent laws for abortion, using public opinion data to estimate median voter preferences. With cross-sectional data for 1990, she runs a logistic regression that interacts whether a state has an initiative with public opinion, and finds that states with initiatives mirror public opinion on abortion and the death penalty more closely, even though these policies are not directly determined via initiatives.

Final Remarks

The examples discussed above illustrate how knowledge in the field has benefited from research targeted towards understanding specific issues, even though these issues can be nested in broader debates about accountability and representation. Theoretical and empirical research on the boundary between economics and political science has uncovered systematic relationships between political institutions and policy outcomes, and is currently being extended to new domains of economic policymaking.

One challenge for the future is to study what determines changes in institutions over time. It is evident that studying how political institutions work, the focus of the discussion here, is a necessary part of research on institutional change. From a theoretical point of view, it is important to understand whose interests are served by particular institutional arrangements and how policies change as a consequence of them. For practical purposes, this will likely be a piecemeal agenda dealing with specific constitutional arrangements rather than examining constitution design from the ground up. This is why the kind of nuts and bolts issues illustrated in our four examples provides the basis for further progress in the field.

Much of the empirical research, so far, has adopted a relatively simple approach, in which political institutions are taken as given and the hypothesized institutional impact is the same across political, social and economic conditions. As is well known from the microeconometric treatment literature, this can easily lead to biased estimates. Current research has started to address non-random selection of political institutions as well as the likely existence of heterogenous treatment effects, where the effect of a specific institutional reform depends on social and historical preconditions. Measurement and econometric testing of these complex issues would benefit greatly from new theoretical research on the endogeneity and conditional effects of institutional reform.

Politics and Economics

V. K. Borooah

No great powers of persuasion are required to establish the connection between politics and economics. In democracies it is 'obvious' that, to quote Harold Wilson, former Prime Minister of Great Britain, 'the standing of a Government and its ability to hold the confidence of the electorate of a General Election depends upon the success of its economic policy'. Given this dependence of political popularity on economic performance it is equally 'obvious' that a Government will try to manipulate its economic policy in such a way as to produce the most favourable outcomes just before election day, leaving the less favourable outcomes to occur at other times. Such behaviour on the part of governments is described in the literature as generating a 'political business cycle'.

But is what is obvious also true? Economists and political scientists have spent a great deal of time and effort correlating movements in political popularity – usually measured by the responses of voters to the question, 'If there was an election tomorrow which party/candidate would you vote for?' – with movements in key economic variables like the inflation rate, the unemployment rate and the rate of growth of real income (cf. Borooah and van der Ploeg (1984) for a survey of the literature). By and large the consensus has been that the proposition that political popularity depends on economic performance does have statistical support for a wide cross-section of countries across a variety of time periods. To this broad conclusion must, however, be added a number of caveats.

First, the relationship between political popularity and economic performance does not appear to be a stable one. Indeed there is evidence that the electorate's criteria for judging the economic performance of a government changes over time and, in particular, changes between periods relating to different governments. The economic problems that are highlighted – and by implication the problems that are underplayed – differ between governments. This may be partly due to differences in ideology and partly due to a desire to take advantage of existing economic conditions. To some extent this alters voters' perceptions of what is important; to another extent voters judge governments by the criteria governments themselves set. Both factors combine to produce changes over time in the criteria of economic success (cf. Borooah and van der Ploeg 1984; Butler and Stokes 1974).

Second, the idea that governments are rewarded for good times and punished for bad times assumes that voters are agreed on what constitutes good and bad times. In fact the most interesting issues in politics and economics are those on which voters, through differences of self interest among them, are divided (cf. Stigler 1973). Thus for example the proposal that tax relief on mortgage interest should be removed would be of no personal concern to persons living in publicly provided housing but would greatly alarm owner occupiers of dwellings.

Third, the existence of common interests among individuals leads to the formation of 'interest groups' which then attach themselves to the political parties they perceive as best representing their interests. The intensity of this attachment might increase in bad times (and decrease in good times) so that one consequence of economic hardship might not be a general reduction of support for the ruling party but an increase of support for each party in the class whose interests it represents and a decline in the support for each party in the class whose interests it does not represent (cf. Converse 1958).

Turning to the other side of the question, do governments in formulating their economic policies take into account the likely electoral impact of such policies and, in particular, do they use such policies to extract votes out of the electorate? The answer to this is not clear cut. At the macro level, in terms of generating the 'political business cycle', the evidence is mixed. The core proposition here is that *before* an election, a reflationary boost to the economy leads employment and incomes to rise and elicits a favourable response from voters. The price in terms of higher inflation is paid *after* the election, in response to which, deflationary measures (with a consequent fall in employment and incomes), to check the rise in prices, are taken. The process is repeated with the onset of the next election.

However, there is no systematic evidence for the existence of such a cycle. In the United States, for example, President Nixon, in 1972, attempted to generate an election year expansion, but there were no such attempts during President Ford's brief tenure in office. President Carter succeeded in running the cycle in reverse; by contrast President Reagan's policies were entirely consistent with the political business cycle model. The pursuit of politically motivated macro policies is made difficult by the economic constraints that governments face. This is especially true of small open economies. Thus in the United Kingdom, a major reflation would, with the shortest of delays, inevitably lead to a balance of payments crisis. A further difficulty is the length of voters' memories; if voters forget only slowly they may not be capable of being systematically deceived.

There is more evidence however, that, at the microeconomic level, governments further their political interests through the use of economic policies. Thus, within the context of a particular macroeconomic stance, a government may tailor the components of its micro-policy to favour certain sections of the electorate over others. For example in the public expenditure reduction programme of the 1979–83 Conservative government in the United Kingdom, expenditure on publicly provided housing was relatively hard hit. It is of course no surprise to learn that the users of such housing were not natural supporters of the Conservative party. Instances of such 'politically inspired' microeconomic policy can be multiplied without number. They have escaped the attention of economists, however, partly because of economists' preoccupation with macroeconomic, to the exclusion of microeconomic, policies and partly because economists have ignored the lack of homogeneity and the diversity of interests that exist in society. It is precisely upon the existence of such diversity that the logic of political intervention at the microeconomic level is based.

Indeed both Marx and Kalecki exposited theories of the political business cycle based upon the existence of societal conflict. Thus in the Marxist view 'the goal of macropolicy is not to eliminate the business cycle, but to guide it in the interests of the capitalist class' (Boddy and Crotty 1975, p. 10). Marx's own view was that the conflict between labour and capital over their shares of the national income would lead to cyclical booms and slumps. In the expansionary phase of the cycle the share of profits in national income would fall with a corresponding rise in the share of wages; to end this squeeze on profits capitalists would generate a slump by slowing down the rate of capital accumulation.

With the birth of Keynesianism grew the assumption that the maintenance of full employment was a proper and feasible objective of governments; this assumption if true would of course imply an end to business cycles. Kalecki however argued that

> the assumption that a government will maintain full employment if it only knows how to do so is fallacious . . . the class instinct of [business leaders] tells them that lasting full employment is unsound from their point of view and the unemployment is an integral part of the normal capitalist system. (Kalecki 1943, pp. 138–9 and pp. 140–41)

The concept and the role of the state was of crucial importance to Marx and Kalecki; both regarded the state as the institution, beyond all others, whose function it was to maintain and defend class domination and exploitation. However, although Kalecki's views were grounded in Marx's theory of conflict, Kalecki's reasons for the basis of the conflict were more social than economic. In his view, businessmen's dislike of lasting full employment was based on the fear that their social position would be undermined with the growing self-assurance of workers that such full employment would engender.

The views of Marx and Kalecki on business cycles are political in a broad sense in that the mechanism generating the cycles is class conflict between capitalists and workers, with government aiding the capitalist class and the working classes constraining their ability to do so. This insight regarding the importance of societal conflict in determining the course of the economy has unfortunately been ignored by mainstream economics which has instead sought to seek the interaction between politics and economics within the more narrow confines of electoral behaviour. However, there is hope for the future development of the subject in the form of three expanding areas of research.

First there is the growing interest, generated by Olson's (1965) seminal contribution, in the role of interest groups and the role of such groups in the shaping of economic policy. Borooah and van der Ploeg (1984), Hibbs (1982) and van Winden (1983) have analysed the differential impact of economic outcomes on different subgroups of voters and have pointed to the scope this offers for 'manipulative' economic policy, particularly at the microeconomic level. Second, there is a growing interest in the institutions that formulate and implement economic policy. A government's economic policy is not the output of a homogeneous entity but evolves through the resolution of conflict between its different branches. This could be between elected legislators and bureaucrats or between state and central governments or between a central policy-making department and other departments. In any event, to understand the making of economic policy one needs to understand the political culture within which it is embedded (cf. Heclo and Wildavsky 1981). Research in this area is still in its infancy and has focused mainly on the behaviour of the bureaucracy.

Finally, there is an attempt to examine the relation between economics and politics at the level of the international economy (cf. Frey 1984). This has looked at two areas: the role of international economic organizations, their organization and working and the political economy of tariffs and trade restrictions. From all this it would appear that the area of interaction between politics and economics is particularly worth cultivating. To make the harvest worthwhile however, it is important to avoid the sterility of identical, optimizing agents so beloved of neoclassical economics and take on board instead, the ideas of conflict and division within society, that an earlier generation of economists had provided.

Pollution Haven Hypothesis

Arik Levinson

Abstract

The pollution haven hypothesis, or pollution haven effect, is the idea that polluting industries will relocate to jurisdictions with less stringent environmental regulations. Empirical studies of the phenomenon have been hampered by the difficulty of measuring regulatory stringency and by the fact that stringency and pollution are determined simultaneously. Early studies based on cross sections of data found no significant effect of regulations on industry locations. Newer studies that use panels of data to control for unobserved heterogeneity or instrumental variables to account for simultaneity have found statistically significant, reasonably sized effects.

The pollution haven hypothesis (or pollution haven effect) posits that jurisdictions with weak environmental regulations – ‘pollution havens’ – will attract polluting industries relocating from more stringent locales. The premise is intuitive: environmental regulations raise the cost of key inputs to goods with pollution-intensive production, and reduce jurisdictions’ comparative advantage in those goods. The Heckscher–Ohlin model provides the theoretical foundations by showing that regions will export goods that use locally abundant factors as inputs. Empirically, however, robust evidence that industries shift production to less stringent jurisdictions has proven elusive.

Econometric studies of the pollution haven effect have typically focused on reduced-form regressions of a measure of economic activity on some measure of regulatory stringency and other covariates:

$$Y_i = \alpha R_i + X_i' \beta_i + \varepsilon_i \tag{1}$$

where Y is economic activity, R is regulatory stringency, X is other characteristics that will affect Y, and ε is an error term. The pollution haven hypothesis is that estimates of $\partial Y/\partial R$ will be negative ($\widehat{\alpha} < 0$). The empirical literature contains a wide variety of implementations of (1). Some studies focus on international trade, where Y_i represents, say, net exports from country i, and the right-hand side contains country characteristics. Others focus on employment, foreign direct investment, or new manufacturing plant births. Equation (1) has also been used to examine the pollution haven hypothesis at the level of sub-national jurisdictions, such as US states or counties. Some studies have further disaggregated Y by industry, in the expectation that environmental regulations have a larger effect on polluting industries than on clean ones.

On the right-hand side of (1), finding an appropriate measure of regulatory stringency (R) is not simple. The problem is not merely one of collecting the appropriate data; merely conceiving of data that would represent R is difficult. What we want to know is how much more costly production is in a given jurisdiction relative to others, due to the jurisdiction’s environmental regulations. These environmental compliance costs could take many forms: environmental fees or taxes, permitting costs, regulatory delays, emissions limits that require installation of costly technology, the threat of lawsuits, product or process redesign, forgone output, and so forth. Some attempts to measure these costs involve creating indices by weighting various country or state characteristics such as environmental agencies’ budgets, public awareness of environmental problems, the number of international environmental agreements the country has joined, states’ congressional delegations’ voting on environmental issues, or other general indicators. Other studies have used measurements of pollution directly, arguing that, for example, high sulphur emissions are evidence of lax regulations. Studies based on US data have used measures of manufacturers’ pollution abatement expenditures by state or industry, using the US Census Bureau’s *Pollution Abatement Costs and Expenditures* (PACE) survey, which ran from 1973 to 1994 and resumed in 2005.

None of these measures of R is ideal for testing the pollution haven hypothesis. The compiled indices of stringency are inherently ad hoc, and typically not available in more than one cross section. Using pollution directly as a proxy for stringency is also problematic. High levels of pollution could be symptomatic of lax of regulations, or could mean that the jurisdiction, finding itself with a poor environment, must enact stringent regulations to reduce pollution. This is true in the United States, where counties that are out of compliance with national air-quality standards are required by the federal Clean Air Act to enforce stricter emissions laws. Even direct measures of abatement costs from the PACE are troublesome. States with the highest average abatement costs are those with the most polluting industrial compositions. Estimates of (1) in which average abatement costs proxy for R find that more polluting industries locate in places with higher abatement costs – the opposite of the pollution haven effect.

Even if we had available an ideal measure of regulatory stringency, R, two further econometric issues complicate estimates of Eq. (1): unobserved heterogeneity and simultaneity. The first problem is that some unobserved characteristics of the jurisdictions or industries being studied are likely to be correlated with both economic activity and regulatory stringency. A country with an unobserved comparative advantage in a polluting good (abundant high-sulphur coal or proximity to markets) is likely to both export that good and enact strict environmental regulations. This means that R and ε are correlated in (1), and estimates of $\hat{\alpha}$ will be biased. In fact, cross-section comparisons sometimes find that countries with higher stringency have more polluting activity, which is in turn easily mistaken for evidence of the Porter hypothesis that environmental regulations promote competitiveness (Porter and van der Linde 1995).

The simplest solution to the problem of unobserved heterogeneity is to estimate a panel-data version of (1) and include fixed effects by jurisdiction or industry, whatever the relevant unit of observation:

$$Y_{it} = \nu_i \ + \alpha R_{it} + X'\beta_{it} \ + \varepsilon_{it} \tag{2}$$

These fixed effects (ν_i) capture the unobserved characteristics of jurisdictions or industries that make them likely to have both strict environmental regulations and high levels of activity. However, including fixed effects requires panel data on regulatory stringency, which makes measuring stringency in the first place even more difficult.

The second econometric issue confronting estimates of (1) and (2) is that economic activity and pollution regulations may be determined simultaneously. The pollution haven hypothesis suggests that environmental regulations affect exports, but the reverse may also be true: exports may affect regulations. If trade increases incomes, and environmental quality is a normal good, trade could increase voters' demand for strict environmental regulations. Or, increased pollution caused by trade could increase local demand for strict environmental regulations. In theory the straightforward solution to this problem is to use instrumental variables. In practice this means finding instruments for a variable, R, that is difficult to measure in the first place. In the panel context (2), it means finding something that changes over time, is correlated with R_{it}, and is uncorrelated with ε_{it}.

The empirical studies that employ these techniques span more than 30 years, and are growing in number. While enumerating them here would be impractical, their broad lessons are becoming clear. The first generation of empirical work on the pollution haven hypothesis used cross sections of data and made no attempt to control for unobserved heterogeneity or simultaneity. Most of them found small insignificant effects of environmental regulations, a few found counter-intuitive positive effects, and none found robust significant support for the pollution haven hypothesis. This early literature is summarized in Jaffe et al. (1995, p. 157): 'Overall, there is relatively little evidence to support the hypothesis that environmental regulations have had a large adverse effect on competitiveness.'

In recent years, economists have begun to use panels of data and fixed-effects models to control for unobserved heterogeneity, and instrumental variables to control for simultaneity. In contrast to the earlier cross-section studies, this newer work has tended to find statistically significant, reasonably sized evidence of pollution havens. It is catalogued in detail by Brunnermeier and Levinson (2004), and summarized in Copeland and Taylor (2004, p. 48), who write that 'after controlling for other factors affecting trade and investment flows, more stringent environmental policy acts as a deterrent to dirty-good production'.

One example of this recent literature exploits the US Clean Air Act, which mandates that every county in the United States achieve the same minimum level of ambient air quality. Federal law requires counties that fail to attain this standard to implement more stringent regulations. A convenient aspect of this law for pollution haven research is that from the perspective of any single county the law is exogenous. Neither the law's first enactment in 1970 nor any subsequent tightening of the air quality standards has been a function of any one county's characteristics. This suggests that an indicator for whether a particular county is in compliance with the national standards makes a good instrument for the stringency of that county's environmental regulations. Non-compliance changes over time, is correlated (positively) with stricter regulations, and is unlikely to be correlated with ε_{it}. Using this strategy, Becker and Henderson (2000) find that a county's failure to meet the national air quality standards reduces the number of new plants being built by four heavily polluting industries by between 26 and 45 percent. Greenstone (2002) shows that these non-attainment counties had about 590,000 fewer jobs, $37 billion lower capital stock, and $75 billion lower output (in 1987 US dollars) between 1972 and 1987 than counties that met the national standards.

An important caveat should accompany findings of this type: they are positive, or descriptive, rather than normative. These tests of the pollution haven hypothesis merely measure whether industry relocates to less stringent jurisdictions; they have no welfare implications. Nevertheless, advocacy groups with widely varying agendas have seized on the issue. Some environmental groups express concern about pollution increases, resulting either from the trade-induced change in the pollution havens' industrial compositions or from the increase in overall economic activity due to trade. Manufacturing interests and labour unions in developed countries worry that the pollution haven effect means a loss of domestic profits and jobs. Free trade advocates fear that protectionist interests will use environmental regulations as a justification for trade barriers, or as a direct protectionist mechanism by lobbying for lower environmental standards as a form of subsidy to manufacturers. Anti-globalization protestors claim that trade liberalization will exacerbate all of these outcomes: degrading environmental quality in developing countries, weakening manufacturing in developed countries, and deterring all countries from setting sufficiently strict environmental standards.

In some cases these diverse parties have different or related interpretations of the pollution haven hypothesis. The most straightforward interpretation, represented by $\alpha < 0$ in Eqs. (1) and (2), is that environmental regulations cause polluting activity to shift to less stringent jurisdictions. Although virtually all of the empirical literature tests this descriptive hypothesis, much of the policy debate revolves around tangential issues with more normative implications.

One such related issue is whether trade liberalization exacerbates the pollution haven effect. Note the subtle difference. The straightforward pollution haven hypothesis is that environmental regulations affect trade. This extension claims that trade barriers disproportionately affect trade in polluting goods, and hence the environment. It seems that would be true only if the trade barriers had a larger effect on polluting industries than on clean industries. An empirical test of this extension would rewrite Eq. (2) to include trade barriers and an interaction between trade barriers and regulations:

$$Y_{it} = v_i + \alpha R_{it} + \gamma T_{it} + \theta R_{it} T_{it} + X' \beta_{it} + \varepsilon_{it} \qquad (3)$$

where T_{it} represents trade barriers such as tariffs (Ederington et al. 2004). The straightforward pollution haven effect is now $\partial Y = \partial R = \alpha + \theta T.$ The indirect effect of trade barriers on the pollution haven effect is $\partial\partial Y / [\partial T\, \partial R] = \theta.$

Given the difficulties in measuring both regulatory stringency and trade barriers, and the likely endogeneity of both, few studies have attempted to estimate this indirect effect of trade liberalization on pollution havens. Nevertheless, it is important to be clear that the basic empirical estimates of the pollution haven effect do not address this more complex extension.

A second concern related indirectly to the pollution haven hypothesis is that governments will engage in inefficient competition to attract polluting industries by weakening their environmental standards. A welfare-maximizing government should set standards so that the benefits justify the costs at the margin. This does not mean that environmental standards will be equal everywhere. Jurisdictions have different assimilative capacities, costs of abatement, and values regarding the environment. So heterogeneity in pollution standards is to be expected, and by extension industry migration to less stringent jurisdictions does not necessarily raise efficiency concerns.

There might be cause for concern, however, if jurisdictions compete for investment from polluting industries by setting environmental regulations below Pareto-efficient levels. They might do so, for example, if there were cross-border spillovers, and the benefits of hosting a polluting manufacturer outweighed the *local* costs. Alternatively, if the industry is concentrated and pays rents to outside shareholders, jurisdictions may compete away their ability to capture some of the industry's rents. In these types of case, countries may lower their regulations below the Pareto-optimal levels in a 'race to the bottom' in environmental standards. Depending on the costs and benefits of hosting a polluting industry, they may also raise their standards above the Pareto-optimal levels in what has been called the 'not-in-my-backyard' (NIMBY) phenomenon. Levinson (2003) summarizes the theoretical and empirical literature on inter-jurisdictional environmental competition.

These questions of trade liberalization and inter-jurisdictional competition, however, extend the central issue of the pollution haven hypothesis. Most empirical studies of the pollution haven hypothesis ask the straightforward, descriptive question: have pollution-intensive industries become concentrated in jurisdictions with less stringent regulations? Early analyses based on cross sections of data typically found that environmental regulations had small or statistically insignificant effects on industry location. However, recent studies using panel data to control for unobserved heterogeneity or instrumental variables to control for the simultaneity of regulations have found statistically significant, reasonably sized pollution haven effects.

Pollution Permits

Ted Gayer

Abstract

Government can reduce pollution by issuing permits to polluters in numbers below existing emission levels. Under a tradable permit programme, a firm with high abatement costs can buy permits from another firm with low abatement costs, leading to a reduction in the total cost of abating relative to a system where reduction levels are strictly assigned. For tradable permits to work effectively, the emissions must come from discrete point sources and be relatively easy to monitor. Aside from issuing the permits, the government's role is to enforce compliance and establish optimal penalties for non-compliance.

The government issues pollution permits to designate how many units of a given pollutant the permit owner is legally allowed to emit in a given period. The government can therefore reduce pollution from these sources by setting the total number of permits below their total existing emission levels. The cost savings of this approach result from allowing the pollution permits to be traded (Dales 1968). Under such a tradable permit programme (also known as a cap-and-trade programme), a firm that has high abatement costs can buy permits from another firm that has low abatement costs, leading to a reduction in the total cost of abating relative to a system where reduction levels are strictly assigned. For tradable permits to work effectively, the emissions must come from discrete point sources and be relatively easy to monitor. Aside from issuing the permits, the government's role is to enforce compliance and establish optimal penalties for non-compliance.

Tradable pollution permits can help address welfare losses caused by pollution. In a free market system goods are exchanged voluntarily. Buyers and sellers engage in trade only if both parties believe they will benefit from the exchange. These trades are coordinated by market prices, which convey information to all parties on the demand for the good and the cost of supplying the good. This system of mutual improvement results in an efficient allocation. However, inefficiency may result if a voluntary transaction between two parties imposes involuntary costs on a third party. These third-party costs are known as externalities.

The root of this market failure is that there are no clear property rights for the surrounding air. Consider an example of a firm which emits air pollution that imposes costs on its neighbours. If the firm's neighbours owned the rights to clean air, then the firm would need to compensate the neighbours in order to use the air in its production process. Similarly, if the firm owned the rights to pollute the air, the neighbours could pay the firm to reduce its emissions. In either setting, the market would incorporate both the costs of pollution to the neighbours and the benefits of pollution to the firm, resulting in an efficient outcome. Indeed, the key interpretation of the Coase Theorem (Coase 1960) is that efficiency results no matter who is legally assigned the property right to the air, so long as free exchange is possible and there are no transaction costs.

The necessary condition of no (or even low) transaction costs is likely to be violated when there are many sources of pollution and when many people bear the external costs of the pollution. This presents an economic justification for government involvement, since the absence of a working market for clean air will lead to an externality-induced inefficiency.

If high transaction costs preclude efficiency-enhancing bargaining between third parties and polluters, then the government can assume the role of the property right owner for the air. Because the 'government' is not an individual cost-bearing entity in the same manner as the affected third parties, and because government agents may have goals other than efficiency, it is not assured that government regulation will lead to an efficient outcome. Ideally, the role of government would be to assess the external costs associated with the production process and to determine the pollution reduction level that maximizes net benefits. The government could then issue tradable permits that yield this efficient level of pollution reduction.

It is undoubtedly difficult to determine the efficient amount of pollution reduction. However, no matter which target level is chosen, a system of tradable permits can help achieve the goal in the least costly way. In a cap-and-trade system, a firm with a high cost of reducing an additional unit of emissions could purchase a pollution permit from a firm with a lower marginal abatement cost. This trading will continue until the marginal abatement costs are equal across firms, thus minimizing the total cost. The cost-savings occur no matter if the government initially gives out the permits to firms for free (known as grandfathering), or if the government decides to auction the permits. Given a competitive market for permits, the initial allocation of permits has only distributional consequences, not efficiency consequences.

The freedom to trade permits across firms or to bank (or even borrow) permits across time results in cost savings without violating the long-term total pollution reduction goal. Additionally, by creating a property right for pollution, a cap-and-trade system establishes a market price for pollution and therefore provides firms with an incentive to find less expensive ways to reduce emissions (Carlson et al. 2000). In contrast, a regulation that rigidly sets technological standards for a firm does not provide this incentive.

Some environmental problems are difficult to address with tradable permits. For example, if the marginal damage of emissions varies by location (for example, due to variation in existing ambient concentrations or due to differences in the number of people exposed to the pollutant), then a tradable permit system might shift emissions from a low-damage to a high-damage location and thus increase total damages. A congestion of emissions in one location, known as a 'hot spot', could result in greater damage than if pollution were reduced uniformly across polluters. A cap-and-trade system can address this problem by making the required number of permits per unit of emissions a function of the marginal damage, or by establishing separate permit markets by region. However, these options do add a level of complexity. In addition, in order for a tradable permit market to work efficiently, it must be a competitive market composed of informed buyers and sellers. While tradable permits can minimize costs, in practice such programmes are grafted on to existing command-and-control regulations, which can affect the cost savings (Hahn 1989).

Since around 1985 the United States has adopted a number of tradable permit programmes to address a variety of pollution problems (Stavins 2000). These include the phase-out of leaded gasoline, chlorofluorocarbon trading, the Regional Clean Air Incentives Market (RECLAIM) to address sulfur dioxide and nitrogen oxides, and the recent Nitrogen Oxides State Implementation Plan (SIP) Call. The most notable example of a cap-and-trade system is the sulphur dioxide programme for electricity generating units, which was enacted under the Clean Air Act Amendments of 1990. This programme has achieved its pollution-reduction goals with estimated cost savings of approximately $1 billion a year compared with costs under a hypothetical command-and-control regulatory alternative.

Pontryagin's Principle of Optimality

M. I. Zelikin

JEL Classifications
C6

The meaning of the word 'economics' is closely related with that of 'optimality'. It is for this reason that methods used in the theory of optimal control find their natural practical application in economics.

In this entry we deal with the statement of Pontryagin's maximum principle and give an exposition of the results and the perspectives of its applications to macroeconomic optimizational problems. We are concerned with two lines in the development of macroeconomics – that of Ramsey and that of von Neumann. Pontryagin's maximum principle embraced both lines – they now coexist in the principle, being inseparable and yet unmergeable. We begin with the classical formulation of Pontryagin's principle.

Let the state of the given system be described by the vector $x = (x_1, \ldots\ldots, x_x)$; $x \in X \subset \mathbb{R}^x$ (X is an open domain). Control is described by the vector $u = (u_1, \ldots., u_y)$; $u \in U \subset \mathbb{R}^y$. The independent variable t is time. For control one can choose any piecewise continuous function $u(t)$, whose values belong to U. The dynamics of the system are described by the equations $\dot{x}_i = \varphi_i(t, x, u(t)), (i - 1, \ldots, n); x(t_0) = a$. The pair consisting of the control $u(t)$ and the corresponding path $x(t)$ is called the process. A smooth manifold M in the space (t, x) is given, and the first hitting time of this manifold M is taken as the moment of termination of the process. The hitting time is the moment of first arrival of the point x at the manifold M, i.e. $T = \inf\{t| x(t) \in \mathrm{M}\}$. In the case when M is the hyperplane $t = T =$ Const one says that this is a fixed time and free end problem. The criterion is the functional

$$x_0 = F(T, x(T)) + \int_{t_0}^{T} f(t, x(t), u(t))dt \to \sup.$$

In the case $f \equiv 0$ and $T =$ Const the functional x_0 is said to be terminal. It is assumed that the functions f, F and φ are smooth.

To formulate Pontryagin's maximum principle let us consider a dual (or an adjoint) vector $\psi = (\psi_{0,}\psi_1, \ldots. , \psi_n)$ and the Pontryagin function

$$H(t, \psi, x, u) = \psi_0 f(t, x, u) + \sum_{\alpha=1}^{n} \psi_\alpha \varphi_\alpha(t, x, u).$$

Pontryagin's Maximum Principle

If $u^*(t)$, $x^*(t)$ is the optimal process, then there exists a nontrivial, continuous vector- function $\psi(t) = (\psi_{0,}\psi_1(t), \ldots. , \psi_n(t))$ with the following properties.

1.The adjoint equations:

$$\dot{\psi}_0 = 0;$$
$$\dot{\psi}_i = -\frac{\partial H}{\partial x_i}(t, \psi, x^*(t), u^*(t)), \quad (i = 1, \ldots, n).$$

2.The transversality conditions:

$\psi_0 \geq 0$ the $(n + 1)$-dimensional vector

$$\left\{\psi_1(T) - \psi_0 \frac{\partial F}{\partial x_1}(T, x^*(T)), \ldots., \psi_n(T) = \psi_0 \frac{\partial F}{\partial x_n}(T, x^*(T)), \times - H(T, \psi(T), x^*(T), u^*(T)) - \psi_0 \frac{\partial F}{\partial T}(T, x^*(T))\right\}$$

is orthogonal to the manifold M at the point $(T,x^*(T))$

3.The maximum condition:

$$\max_{u \in U} H(t, \psi(t), x^*(t), u) \\ = H(t, \psi(t), x^*(t), u^*(t)).$$

In the case of fixed time and free end, the transversality conditions reduce to

$$\psi_0 \geq 0, \quad \psi_i(T) \\ = \psi_0 \frac{\partial F}{\partial x_i}(t, x^*(T)), \quad (i = 1,\ldots,n)$$

(if $F = 0$, we have $\psi_i(T) = 0, (i = 1, \ldots, n)$). Let us remark that the vector ψ is defined up to multiplication by a positive constant, and in the case $\psi_0 \neq 0$ it can be normalized by dividing by ψ_0. As soon as the optimal value u^* at the point (t, x) depends only on that point, we can seek the optimal control as a feedback control, i.e. in the form $u^* = u^*(t, x)$. This function defines the optimal control at each point of the space (t, x), and thus it is called the optimal synthesis. The variables H and ψ can also regarded as functions of t and x. Let us denote the optimal value of the functional, corresponding to the initial point (t, x), by $x_0(t, x)$. This function is called Bellman's function.

The main idea of the economic interpretation of Pontryagin's maximum principle (which goes back to L.V. Kantorovich) is to consider the variables ψ_i as shadow prices. To explain, let us assume that the problem is regular ($\psi_0 \neq 0$), and that the optimal synthesis $u^*(t, x)$ and the dual variables $\psi(t, x)$ are smooth. In this case $x_0(t, x)$ is also smooth and Bellman's equation

$$\max_{u \in U} \left\{ \frac{\partial x_0}{\partial t}(t,x) + f(t,x,u) + \sum_{\alpha=1}^{n} \frac{\partial x_0}{\partial x_\alpha}(t,x)\varphi_\alpha(t,x) \right\} = 0$$

is fulfilled. The relationship between Bellman's equation and Pontryagin's maximum principle can be expressed by the equations

$$\frac{\partial x_0}{\partial x_i}(t,x) = \frac{\psi_i(t,x)}{\psi_0(t,x)}; \quad \frac{\partial x_0}{\partial t}(t,x) = -\frac{H(t,x)}{\psi_0(t,x)},$$

i.e. the normalized value of the dual variable ψ_i/ψ_0 is the marginal effect of the factor x_i on the optimal value of the functional x_0 and that is exactly the shadow price of x_i. The economic meaning of Pontryagin's maximum principle is as follows. For the optimal process $u^*(t)$, $x^*(t)$ there exist shadow prices ψ the adjoint equations and the transversality conditions being fulfilled, such that the optimal value of the control $u^*(t)$ at each moment t maximizes the flow of the profit, which is calculated in accordance with the shadow price. It is worth remembering, that in the irregular case ($\psi_0 = 0$), as well as in the case of discontinuous optimal synthesis $u^*(t,x)$ Bellman's function $x_0(t, x)$ is often nonsmooth, in spite of all the functions defining the statement of the problem being smooth. Bellman's equation breaks down, but Pontryagin's maximum principle is fulfilled. In that case the notion of 'prices' loses its natural meaning. The search for general enough conditions, guaranteeing the smoothness of Bellman's function, is a difficult and only partially explored mathematical problem.

The creation of Pontryagin's principle stimulated the two aforementioned lines of macroeconomics. Before listing the corresponding results, let us note some significant obstacles in the way of application of these optimizing methods to mathematical economics. To formulate an optimization problem, we have to choose a criterion. It is only natural to take as a criterion some function of the final state $x(T)$ or the profits over some interval of the time $[t_0, T]$. But the choice of the moment T (the horizon of the plan) is arbitrary from an economic point of view. Meanwhile it is highly desirable to define economically reasonable behaviour independently of such arbitrariness. Two approaches to overcome this obstacle are known–that of F.P. Ramsey (and his collaborator J.M. Keynes) and that of J. von Neumann.

Ramsey's approach is to take eternity as the horizon of the plan. He applied the calculus of variations, which can be regarded as a version of Pontryagin's maximum principle, to the problem of resource allocation between consumption and saving, aiming to maximize the benefits of society during the entire infinite period of its possible existence, and proved the Golden Rule of saving. From the mathematical point of view the problem is to minimize the integral over the half-open interval $[t_{0,\infty}]$ from the difference between absolute welfare (Bliss) and immediate welfare (the utility function), which tends to Bliss and depends on the solution of the differential equation containing the policy of saving as control. The principal part of the right-hand side of this equation is the production function. The naivety of this model lies in the conception of stationary and absolutely stable economic Universe, rather than in the assumption of the possibility of complete aggregation. I hope to be indulged in using such unusual (in economic context) terms as 'Universe'. But in fact we deal with the closed macroeconomic models, purporting to describe all basic economic phenomena, and in this sense the situation is closely related to that of physical models of the Universe; hence the reason for the proposed usage.

Later on there were attempts to modernize this model and to make it nonstationary. On the one hand, Hicks, Harrod and Solow among others varied the production function, aiming to include in it the effect of technical change. On the other hand, T.C. Koopmans broke off the relationship between the production and the utility functions (which was so essential in the views of Ramsey) and introduced a discounting factor in the integrand which guaranteed the convergence of the functional for any choice of control. The stationarity of Ramsey's economic Universe was slightly shaken.

The path of the Golden Rule in such models appears to be a singular path of Pontryagin's maximum principle. The path of the principle is called singular, if the maximum of the Pontryagin's function (3°) at all points of this path is attained at several distinct points of the set U. In the case of problems which are linear in the control the nonsingular (band-bang) control uses only the extreme points of the set U. Such a control corresponds to the economic policy with sharp changes (switches). The characteristic feature of bang-bang optimal control is instantaneous switches from one vertex of the polyhedron U onto another. On the contrary, the singular control, using the internal points of U, as a rule does not need switches and in this sense seems to be more acceptable than the bang-bang control from the economic point of view.

The application of Pontryagin's principle to such models calls for its generalization to the case of infinite time intervals. More precisely, the transversality conditions at infinity need generalization, and only those. But even that question turns out to be difficult enough. There were incorrect attempts to formulate these conditions in the form: $\psi(t) \to 0$ for $t \to \infty$. For the case of linear differential constraints Aubin and Clarke found out and proved a correct version of transversality conditions, which requires the convergence of the integral of $|\psi(t)|^q e^{\partial t}$ for some q and δ. A complete and correct solution of the problem of transversality conditions at infinity for nonlinear differential constraints is still absent.

Another line of evolution of macroeconomics begins with the work of von Neumann. He introduced a discrete model of the expansion of production, which was defined by two given matrices – that of input and that of output. Von Neumann seeks the balanced development of economics when the input vector is proportional to the output one. Among these rays he seeks those yielding maximal growth. He introduces dual variables – prices of the optimal plan – and gave optimality conditions in dual terms.

Later on it turned out (in accordance with the hypothesis of Samuelson) that the ray of maximal growth (now called) 'Neumann's ray' or 'the turnpike') plays the leading part in exploring the optimal paths of this model. The corresponding theorems (turnpike theorems) assert that this ray defines the asymptotic behaviour of the optimal paths, in the increase of the horizon of the plan (for $T \to \infty$), independently of the choice of terminal functional, and it is precisely this fact which makes it possible to overcome the aforementioned obstacle. Continuous versions of the turnpike theorems, which require Pontryagin's principle or the related methods for their proofs, were obtained by, among others, A.N. Ducalov, A.E. Ilutovich and L.F. Zelikina. Let us note that the turnpike in these models is the singular path of the principle. In the work of Zelikina, for certain optimal resource allocation problems, Neumann's concept of optimal policy, independent of the choice of functional, was brought to its logical conclusion. By constructing the optimal synthesis in n-dimensional space, it was shown that the shadow prices for increasing (with $T \to \infty$) initial segments of optimal paths are invariant relative to such a choice. The search for a complete system of invariants of optimal synthesis relative to a choice of functional (in some appropriate class of the latter) for the general economical optimizational problem still remains an open question.

A hint for an infinite-dimensional version of the theory of duality is contained in the formulation of Pontryagin's maximum principle itself. A.M. Ter-Krikorov (1977) introduces the dual problem to the linear optimizational problem, in which the dual variables ψ_i turn into the state variables and vice versa.

The techniques of turnpike theorems and Pontryagin's principle gives rise to a series of optimization models, which become more and more universal and finally develop into the concept of expanding economic Universe. The economic analogue of the physical concept of the oscillating Universe is yet developed only on the phenomenological level, in spite of the empirical evidence for the corresponding economic phenomenon. The reason for this fact is (as it seems) the lack of satisfactory optimization models taking into account the specific effect of money.

It is worth noting that, like the physical models of Universe, all these concepts of economic Universe are devoid of its substance – thought and ethics – which naturally bring the question out of the competence of pure economics. But without this substance, the economical Universe, as soon as it claims to be universal, cannot be explained in principle.

Poor Law, New

George R. Boyer

Abstract

The New Poor Law refers to the system of local public assistance in England and Wales initiated by the passage of the 1834 Poor Law Amendment Act. This act attempted to restrict relief outside of workhouses for the able-bodied, but was evaded for three decades. The Crusade against Outrelief of the 1870s marked a major shift in administration and the increased use of workhouse relief. Numbers on relief fell sharply thereafter, although the elderly continued to rely heavily on the Poor Law. The Liberal welfare reforms of 1906–11 paved the way for the 1948 abolition of the Poor Law.

The New Poor Law refers to the welfare policy in England and Wales initiated by the passage of the Poor Law Amendment Act in 1834. All destitute individuals were eligible for poor relief from their local Poor Law union. Those granted assistance were either given cash or in-kind payments in their homes (outdoor relief) or were relieved in workhouses (indoor relief). Although the Poor Law remained in existence until 1948, the Crusade against Outrelief in the 1870s and the adoption of the Liberal welfare reforms in the decade before the First World War significantly reduced its role as a safety net for the poor.

The Poor Law Amendment Act was an outgrowth of the Report of the Royal Commission to Investigate the Poor Laws (1834), which called for sweeping reforms to the existing system of poor relief, including the grouping of parishes into Poor Law unions, the abolition of relief for the able-bodied and their families outside workhouses, and the appointment of a centralized Poor Law Commission to direct the administration of relief. The Act implemented some of the report's recommendations, but left the regulation of outdoor relief to the Poor Law Commissioners.

By 1839 most rural parishes had been grouped into Poor Law unions, which had built or were building workhouses. However, the Poor Law Commission met with strong opposition when it attempted to set up unions in the industrial north, and the implementation of the New Poor Law was delayed in several industrial cities. The Commission and its 1847 replacement, the Poor Law Board, issued orders in 1842, 1844 and 1852 to restrict the payment of outdoor relief to able-bodied males, but these were evaded by both rural and urban unions. Thus, while real per capita relief expenditure fell by 43 per cent from 1831 to 1841, and remained at least 20 per cent below its 1831 level for the remainder of the 19th century (see Table 1), many Poor Law unions continued to grant outdoor relief to needy able-bodied males after 1834 (Rose 1970; Digby 1978). Data for three London parishes and six provincial towns in the years around 1850 indicate that large numbers of prime-age males continued to apply for relief, and that a majority of those assisted were granted outdoor relief (Lees 1998). The Poor Law played an important role in assisting the unemployed and their families in urban districts during cyclical downturns (Boot 1990; Boyer 2004). Moreover, the New Poor Law, like its predecessor, provided a major source of support for the non-able-bodied poor. From the 1840s to the 1860s, in much of rural England a large share of those aged 70 and over received regular poor relief payments, although these often did not provide full maintenance (Thomson 1984).

Data on the number of persons receiving poor relief are available for two days a year, 1 January and 1 July, beginning in 1849; the official estimates of the annual number relieved in Table 1 are the average of the number relieved on these two dates. Studies conducted by Poor Law administrators in 1892 and 1906–07 found that the day counts significantly underestimated the number assisted during the year. The 'revised' estimates in Table 1 are based on these studies, and assume that the ratio of actual to counted paupers was 2.24 for 1851–96 and 2.15 for 1901–11. These estimates indicate that from 1850 to 1870 about ten per cent of the population was assisted by the Poor Law each year. Lees (1998) contends that over a three-year period as much as 25 per cent of the population made use of the Poor Law.

Relief expenditures were financed by a local property tax, known as the poor rate. Up to 1865, each parish within a Poor Law union was responsible for relieving its own poor. As a result, tax rates were often significantly different across parishes within Poor Law unions, and were especially high in working-class districts. Economic crises put enormous financial strain on parishes that were already poor. The 'basic weaknesses' of the poor relief system were exposed in the 1860s, when the Poor Law 'was subjected to an almost continual series of shocks' (Rose 1981). The two major shocks of the decade were the Lancashire

Poor Law, New, Table 1 Relief expenditures and numbers on relief, 1831–1936

Year	Expenditures on Relief (1,000 £s)	Real expenditure per capita 1831 = 100	Number relieved (official) 1,000s	Share of population relieved (official)	Number relieved (revised) 1,000s	Share of population relieved (revised)	Share of paupers relieved indoors

cotton famine of 1862–4 and the East London crises of 1860–1 and 1867–9. The collapse of raw cotton imports from the United States during the American Civil War forced Lancashire cotton textile factories to shut down or severely curtail production. The resulting unemployment caused a huge increase in demand for relief, which the hardest-hit parishes were unable to meet, and led several Poor Law unions to appeal to private relief committees for charitable assistance. During the severe winters of 1860–1, 1867–8 and 1868–9, Poor Law unions in London's East End were also forced to turn to private charities for assistance in meeting the high demand for relief.

The problems associated with Poor Law finance led parliament to adopt the Union Chargeability Act in 1865, and similar acts relating to London in 1867, 1869 and 1870. These acts placed the cost of poor relief on the Poor Law union rather than on each parish within it, and thus shifted a large share of the cost of relief from working-class parishes (which had low tax bases and many paupers) to middle-class parishes (with higher tax bases and fewer paupers). The tax-shifting eased the financial burdens that had plagued the Poor Law, but also led to the revolt of middle- class taxpayers in many areas.

The Union Chargeability Act was one of the catalysts of the Crusade against Outrelief in the early 1870s. Encouraged by the Local Government Board (LGB), Poor Law unions throughout England and Wales curtailed outdoor relief for all types of paupers. In December 1871 the LGB issued a circular concluding that generous outdoor relief was destroying self-reliance among the poor. In the circular's words: ‘a certainty of obtaining outdoor relief in his own home whenever he may ask for it extinguishes in the mind of the labourer all motive for husbanding his resources, and induces him to rely exclusively upon the rates instead of upon his own savings for such relief as he may require' (quoted in Englander 1998, p. 107). The Charity Organization Society (COS), founded in 1869, aided the Board in convincing the public of the need for reform. It argued that most low-skilled workers earned enough to be able to set aside some income in anticipation of future interruptions in earnings caused by unemployment or sickness. The LGB and the COS maintained that the restriction of outdoor relief would improve the moral and economic condition of the poor in the long run. The COS also believed that most applicants for relief would refuse to enter workhouses and would remove themselves from relief roles, so that a shift from outdoor to workhouse relief would significantly reduce Poor Law expenditures. Most Poor Law unions found it difficult to resist a policy that promised to raise the morals of the poor *and* reduce taxes (MacKinnon 1987).

The effect of the Crusade against Outrelief can be seen in Table 1. Real per capita relief expenditures and the share of the population receiving relief both fell sharply from 1871 to 1876. The decline in numbers on relief was largely a result of the deterrent effect of the workhouse: as the COS predicted, many of those offered indoor relief refused it. From 1871 to 1881, the number of paupers receiving outdoor relief fell by 282,000 (a 33 per cent decline), while the number relieved in workhouses rose by only 21,000.

Real per capita relief expenditures increased after 1876, mainly because the Poor Law provided increasing amounts of medical care for the poor. Otherwise, the role played by the Poor Law declined in the last quarter of the 19th century. The share of the population receiving relief fell from seven per cent in 1876 (revised estimates) to 5.2 per cent in 1901. The decline was due in large part to improvements in living standards, which increased workers' ability to save and to join friendly societies – mutual help associations providing sickness, accident, death, and (sometimes) old age benefits. However, part of the decline in numbers on relief was a result of the Crusade against Outrelief and of a change in the attitude of the poor towards relief. Prior to 1870, a large share of the working class regarded access to public relief as an entitlement, although they rejected the workhouse as a form of relief. Partly as a result of COS propaganda, by the end of the century most within the working class viewed poor relief as stigmatizing, and went to great lengths to avoid applying for relief. Thus, the decline in the share of the population receiving poor relief from 1871 to 1901 overestimates the decline in the share living in poverty.

One section of the working class continued to rely heavily on the Poor Law – the elderly. Table 2 shows that, for the 12-month period from March 1891 to March 1892, 29.3 per cent of those aged 65 and over received poor relief, as compared with 5.1 per cent of children and 3.7 per cent of those aged 16–64. Most elderly paupers received only partial maintenance, which they combined with wage income, savings, friendly society or trade union benefits, and help from relatives or friends to achieve a subsistence income. The ability of the elderly to support themselves declined with age; Booth (1894) estimated that 40 per cent

Despite improvements in living standards, many manual workers still experienced 'acute financial' distress at some point in their lives (Johnson 1985). The inability of low-skilled workers to protect themselves from financial insecurity was the catalyst for the Liberal welfare reforms, several pieces of social welfare legislation adopted between 1906 and 1911. Acts of 1906 and 1907 provided free meals and medical inspections (later treatment) for needy schoolchildren. The 1908 Old Age Pension Act granted weekly pensions to persons aged 70 and over whose annual income was below a certain level, and the National Insurance Act of 1911 established compulsory systems of health insurance (covering all manual workers) and unemployment insurance (covering workers in a limited number of industries). The Liberal welfare reforms provided assistance to the working class that was outside the Poor Law and therefore did not involve 'the stigma of pauperism', and they paved the way for the eventual abolition of the Poor Law.

During the inter-war period the Poor Law served as a residual safety net, assisting those who fell through the cracks of existing social insurance policies. A large share of those on relief, especially in the mid-1920s, were unemployed workers who either did not qualify for unemployment benefits or had exhausted their benefits. The Local Government Act of 1929 abolished the Poor Law unions, and transferred the administration of poor relief to the counties and county boroughs. Finally, from 1945 to 1948, Parliament adopted a series of laws that together formed the basis for the welfare state, and made the Poor Law redundant. The National Assistance Act of 1948 officially repealed all existing Poor Law legislation.

Poor Law, old

George R. Boyer

Abstract

The Old Poor Law was the system of local public assistance that existed in England and Wales from 1597 until 1834. It provided an important safety net for labouring households that were unable to protect themselves against income loss, assisting the elderly, widows, children, the sick, and the unemployed. Relief expenditures increased sharply from 1750 to 1820, as did the share of paupers who were adult able-bodied males. Parliament responded to the increase in spending with the Poor Law Amendment Act (1834), which recommended that poor relief be granted to able-bodied males and their families only in workhouses.

The Old Poor Law was the system of public assistance in England and Wales from the Tudor era through the passage of the Poor Law Amendment Act in 1834. Parliamentary acts of 1597–98 and 1601 (43 Eliz. I c. 2) established a compulsory system of poor relief administered and financed at the parish (local) level. Overseers of the poor assessed a compulsory property tax, known as the poor rate, to assist those within the parish ‘having no means to maintain’ themselves. The overseers were to put the able-bodied poor to work, give apprenticeships to poor children, and provide ‘competent sums of money’ to relieve the aged or non-able-bodied.

The Elizabethan Poor Law was an attempt by Parliament both to prevent starvation and to ensure public order. It was adopted in response to a sharp deterioration in workers’ living standards in the 16th century, combined with a decline in traditional forms of charitable assistance. The dissolution of the monasteries, religious guilds, almshouses, and hospitals under Henry VIII had eliminated many of the traditional sources of charity for the poor.

The Settlement Act of 1662 stated that individuals were guaranteed relief only in their parish of settlement (typically their parish of birth). The act gave parishes the right to remove within 40 days of arrival any newcomer deemed ‘likely to be chargeable’ as well as any non-settled applicant for relief. Adam Smith believed that the Settlement Law put a serious brake on labour mobility, but available evidence suggests that parishes used it selectively, to keep out economically undesirable migrants such as single women, older workers and men with large families. The Removal Act of 1795 amended the Settlement Law so that no non-settled person could be removed from a parish unless he or she applied for relief.

The Old Poor Law constituted ‘a welfare state in miniature’, relieving the elderly, widows, children, the sick, the disabled, and the unemployed and underemployed (Blaug 1964). It provided an important safety net for labouring households who were unable to accumulate enough savings to protect themselves against income loss. While only a small share of the labouring population received relief at any point in time, the life-cycle nature of poverty meant that a much larger share required Poor Law assistance during their lifetimes. Slack (1990) estimates that in the late 18th century one-fifth or more of the inhabitants of a typical parish received poor relief over a five-year period.

In years of exceptionally high food prices, the share on relief could exceed 25 per cent.

During the 17th century the bulk of relief recipients were elderly, orphans, or widows with young children. In many parishes a majority of those collecting regular weekly pensions were aged 60 or older. Female pensioners far outnumbered males. On average, the payment of weekly pensions made up about two-thirds of relief spending; the remainder went to casual benefits, often to able-bodied males in need of short-term relief because of sickness or unemployment.

Growth in Relief Expenditures, 1750–1820
