The 18th century witnessed an explosion in relief expenditures, as can be seen from Table 1. Real per capita expenditures increased by 80 per cent from 1696 to 1748–50, more than doubled from 1750 to 1803, and then remained at a high level until the Poor Law was amended in 1834. Relief expenditures increased from 0.8 percent of GDP in 1696 to a peak of 2.7 per cent of GDP in 1818–20. The demographic characteristics of the 'pauper host' changed considerably in the late 18th and early 19th centuries, especially in the rural south and east of England. There was a sharp increase in numbers receiving casual benefits, as opposed to regular weekly pensions. The share of paupers aged 20–59 increased significantly, and the share aged 60 and over declined. Finally, the share of relief recipients in the south and east who were male increased from about a third in 1760 to nearly two-thirds in 1820. In the north and west there also were shifts toward prime-age males and casual relief, but the magnitude of these changes was far smaller than elsewhere.

Poor Law, old, Table 1 Poor relief expenditures 1696–1841

Year	Expenditures on relief (£1,000s)	Real expenditure per capita, 1803 = 100	Expenditures as % of GDP
1696	400	24.9	
1748–50	690	45.8	1.0
1776	1,530	64.0	1.6
1783–85	2,004	75.6	1.8
1803	4,268	100.0	2.2
1813	6,656	91.8	2.6
1818	7,871	116.8	
1821	6,959	113.6	2.7
1826	5,929	91.8	
1831	6,799	107.9	2.0
1836	4,718	81.1	
1841	4,761	61.8	1.1

Note: Relief expenditure data are for the year ended on 25 March. In calculations of real per capita expenditures, cost of living and population data for the previous year were used

What caused the sharp increase in the number of able-bodied males on relief? In the second half of the 18th century, a large share of rural households in southern England suffered significant declines in real income, resulting from the combination of a decline in agricultural labourers' real wage rates, an increase in seasonal unemployment, a decline in employment opportunities for women and children in cottage industry and, in some villages, the loss of access to land for growing food, grazing animals, and gathering fuel (common rights) as a result of enclosures. The situation was different in the north and midlands, where real wages of day labourers in agriculture increased from 1770 to 1820. Moreover, while some areas experienced a decline in cottage industry, in Lancashire and the West Riding of Yorkshire the concentration of textile production led to increased employment opportunities for women and children.

Forms of Relief and Regional Differences in Relief Spending

Relief for able-bodied males and their families took various forms, the most important of which were: allowances-in-aid-of-wages (the so-called Speenhamland system), child allowances for labourers with large families, and payments to seasonally unemployed agricultural labourers. Under the allowance system, a household head (whether employed or unemployed) was guaranteed a minimum weekly income, the level of which was determined by the price of bread and by the size of his or her family. The most famous allowance scale was that adopted by Berkshire magistrates at Speenhamland in May 1795. Such scales typically were instituted during years of high food prices, such as 1795–6 and 1800–1, and removed when prices declined. Child allowance payments were widespread in the rural south, which suggests that labourers' wages were too low to support large families. The typical parish paid a small weekly sum to labourers with four or more children under age 10 or 12. Seasonal unemployment had been a problem for agricultural labourers long before 1750, but the extent of seasonality increased in the second half of the 18th century as farmers in southern and eastern England responded to the sharp increase in grain prices by increasing their specialization in grain production. The increase in seasonal unemployment, combined with the decline in other sources of income, forced many agricultural labourers to apply for poor relief during the winter.

Table 2 reports data for 15 counties located throughout England on per capita relief expenditures for the years ending in March 1803, 1812 and 1831, and on relief recipients in 1802–3. Per capita expenditures were higher on average in agricultural counties than in more industrial counties, and were especially high in the grain-producing south-eastern counties. The share of the population receiving poor relief in 1802–3 varied significantly across counties, being 15–23 per cent in the grain-producing south and less than 10 per cent in the north. The demographic characteristics of those relieved also differed across regions. The share of relief recipients who were elderly or disabled was higher in the north and west than in the south, while the share who were able-bodied was higher in the south-east than

These regional differences in relief expenditures and numbers on relief largely were caused by differences in economic circumstances; poverty was more of a problem in the agricultural south and east than it was in the pastoral southwest or in the more industrial north (Blaug 1963; Boyer 1990). Recently, King (2000, pp. 267–8) has argued that the regional differences in poor relief were determined by 'very different welfare cultures on the part of both the poor and the poor law administrators'.

Political Economy of Poor Relief

From 1795 to 1834 relief expenditures as a share of national product were significantly higher in England than on the European continent. However, differences in spending between England and the continent were relatively small before 1795 and after 1834 (Lindert 1998). The increase in relief spending in late 18th and early 19th century England overstates the increase in poverty, because it was partly a result of politically dominant farmers taking advantage of the poor relief system to shift some of their labour costs onto other taxpayers (Boyer 1990). Most rural parish vestries were dominated by labour-hiring farmers as a result of the system of plural voting introduced by Gilbert's Act in 1782 and extended in 1818 by the Parish Vestry Act, which gave large property holders (typically labour-hiring farmers) up to six votes in local elections. Relief expenditures were financed by a tax levied on all parishioners whose property value exceeded some minimum level. A typical rural parish's taxpayers can be divided into two groups: labour-hiring farmers and non-labour- hiring taxpayers (tithe recipients, family farmers, shopkeepers, and artisans).

In grain-producing areas, where there were large seasonal variations in the demand for labour, labour-hiring farmers anxious to secure an adequate peak season labour force were able to reduce costs by laying off unneeded workers during slack seasons and having them collect poor relief. Tithe recipients and other non-labour-hiring taxpayers paid part of the relief benefits that went to seasonally unemployed labourers. Thus, some share of the increase in relief spending in the early 19th century represented a subsidy to labour-hiring farmers rather than a transfer from farmers and other taxpayers to agricultural labourers and their families. In pasture farming areas, where the demand for labour was fairly constant over the year, it was not in farmers' interests to shed labour during the winter, and the number of able-bodied labourers receiving casual relief was smaller.

Reform of the Poor Law

The sharp increase in relief spending after 1780 sparked a major debate on the Poor Laws. Most participants in the debate were critical of the granting of outdoor relief to able-bodied males, on the grounds that such aid created serious work disincentives. Among the sharpest critics was Thomas Malthus, who argued in *An Essay on the Principle of Population* (1798, pp. 40–1) that the Poor Laws, by guaranteeing parish assistance to able-bodied labourers, 'diminish both the power and the will to save among the common people, and thus . . . weaken one of the strongest incentives to sobriety and industry, and consequently to happiness'.

In 1832 the government appointed the Royal Commission to Investigate the Poor Laws to examine the operation of the Poor Law and suggest methods for improving the administration of relief. The commission's report (1834, pp. 261–3), written by economists Nassau Senior and Edwin Chadwick, called for sweeping reforms, including the abolition of outdoor relief for the able-bodied and their families. The report urged the adoption of a policy of 'less eligibility' whereby the condition of paupers would be worse than that of the lowest-paid independent labourers. To achieve this, Senior and Chadwick recommended that relief should be granted to able-bodied labourers and their families only in well-regulated workhouses; they predicted that the use of workhouses would restore the industry and 'frugal habits' of the poor, and improve their 'moral and social condition'.

The era of the Old Poor Law ended with the adoption of the Poor Law Amendment Act of 1834, which implemented many of the report's recommendations.

Population Ageing

David N. Weil

Abstract

Population ageing is primarily the result of past declines in fertility, which produced a decades-long period in which the ratio of dependents to working-age adults was reduced. Rising old-age dependency in many countries represents the inevitable passing of this 'demographic dividend'. Societies use three methods to transfer resources to people in dependent age groups: government, family, and personal saving. In developed countries, families are predominant in supporting children, while government is the main source of support for the elderly. The most important means by which ageing will affect aggregate output is the distortion from taxes to fund public pensions.

Population ageing is the shift in the distribution of a country's population towards older ages. An increase in the population's mean or median age, a decline in the fraction of the population composed of children, or a rise in the fraction of the population that is elderly are all aspects of population ageing.

Population ageing is occurring in most parts of the world, but is most advanced in the richest countries. Among the countries currently classified by the United Nations as more developed (which had a population of 1.2 billion in 2005), the median age of the population rose from 29.0 in 1950 to 37.3 in 2000, and is forecast to rise to 45.5 by 2050. The corresponding figures for the world as a whole are 23.9 for 1950, 26.8 for 2000, and 37.8 for 2050. In Japan, one of the fastest-ageing countries in the world, in 1950 there were 9.3 people younger than 20 for every person older than 65. By the year 2025, the ratio is forecast to be 0.59 people younger than 20 for every person older than 65 (United Nations 2004).

The sources of population ageing lie in two demographic phenomena: rising life expectancy and declining fertility. An increase in longevity raises the average age of the population by raising the number of years that each person is old relative to number of years in which he is young. A decline in fertility increases the average age of the population by changing the balance of people born recently (the young) to people born further in the past (the old). Of these two forces, it is declining fertility that is the dominant contributor to population ageing in the world today (Weil 1997). More specifically, it is the large decline in the total fertility rate since the 1950s that is primarily responsible for the population ageing that is taking place in the world's most developed countries. Because many developing countries are going through faster fertility transitions, they will experience even faster population ageing than the currently developed countries in the future.

While the economic underpinnings of the demographic processes that cause population ageing – in particular declining fertility – are interesting topics in and of themselves, this article instead concentrates on how ageing affects the economy.

The Economic Effects of Population Ageing

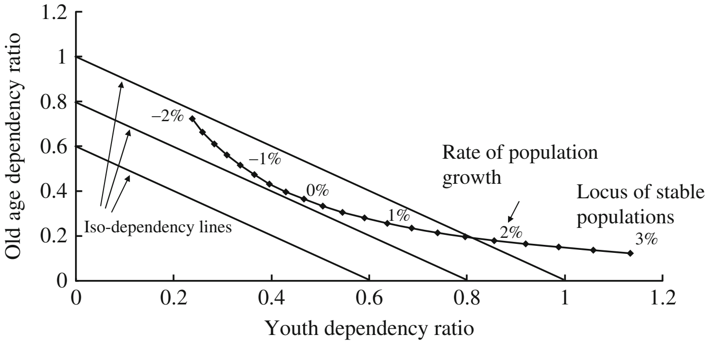
Population ageing has economic effects whenever some economic interaction (the sale of a good or service, the provision of a government benefit, and so on) brings together people whose participation is a function of their age. In such a situation, a change in the relative size of two age groups will require a change in behaviour by members of at least one group. For example, babies demand strollers, which are produced by working-age adults. Thus, a reduction in the ratio of babies to adults will mean more strollers per baby, fewer adults working in stroller production, or both. The changes in behaviour required to restore equilibrium in the face of demographic change are induced through either prices or institutions. If individuals on at least one side of the transaction respond elastically to price changes (as would be the case in getting working-age adults to move from stroller manufacture into the wheelchair business), then the effects of population ageing will be little worth commenting on. But when individuals on both sides of the interaction are not easily induced to change their behaviour, the economic effects of population ageing will be dramatic. Old-age pensions, child rearing, and the combining of old people's capital with young people's labour are all cases where a change in the relative numbers on either side of the equation will have important effects.

The simplest analysis of the economic effects of population ageing starts with the notion of age-based dependency: people of some ages produce less than they consume, and are dependent on the rest of society for their support. Consider a division of the population into three age groups: working age adults, dependent youths, and dependent elderly. We temporarily ignore the question of how resources are transferred from working-age adult to dependent children and elderly. For simplicity, we assume that people of all ages have the same consumption, although the analysis can easily be extended to allow for age-varying consumption needs (see Weil 1999). Finally, we assume that output is produced solely by the labour of working-age adults, with no additional factors of production such as capital.

P

The consumption possibilities of our idealized society can be analysed in a diagram like Fig. 1. The horizontal axis plots youth dependency ratio (population aged 0–19 divided by population aged 20–64); the vertical axis plots the old-age dependency ratio (population aged 65+ divided by population aged 20–64). A society's demographic structure is represented by a point in this space. For example, a newly planted colony might be represented by a point in the lower left-hand corner, with youth and old age dependency ratios of zero. For a normal society, however, the demographic processes of ageing, mortality and fertility will determine predictable movements of the age structure through the space of Fig. 1. A set of points of particular interest are what demographers call stable populations. These are populations in which age-specific mortality and

Population Ageing, Fig. 1 Stable populations and iso-dependency lines (*Source:* Author's calculations)



fertility rates have been constant for sufficient time that the relative number of people of each age is constant. Fig. 1 shows a typical locus of stable populations, generated using age-specific mortality rates for the United States in 2000 and varying the level of fertility. The labels show the population growth rate consistent with different points on the locus of stable populations.

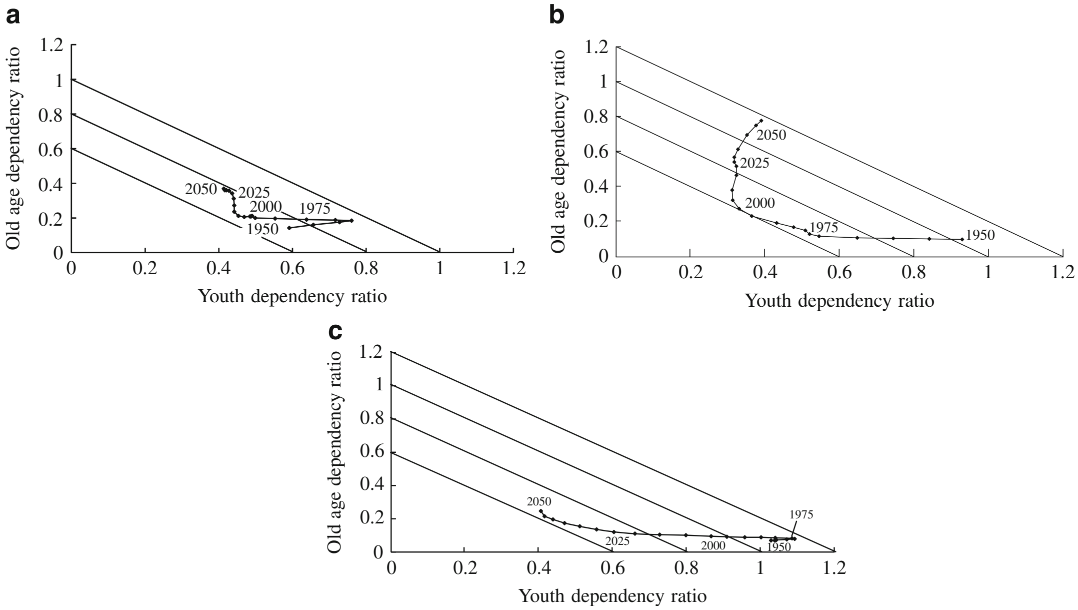
We can also represent in this space the effect of demographic structure on the consumption possibilities of the society through a series of iso-dependency lines. These are lines along which the sum of youth and old-age dependency is constant – in other words, combinations of old-age and youth dependency that yield constant levels of consumption per capita. Iso-dependency lines closer to the origin represent age structures which allow for higher consumption per capita. The tangency between the locus of stable populations and an iso-dependency line shows the stable population with the lowest dependency ratio.

Reductions in fertility will lead to clockwise movements of the point representing a country's demographic structure through the space of Fig. 1. Falling fertility reduces the youth dependency ratio immediately, and only raises the old age dependency ratio with a lag of several decades. For this reason, a country experiencing fertility transition will be able to move temporarily below the locus of stable populations.

FIgure 2a–c show data on population age structure for the United States, Japan, and India over the period 1950–2050. In all cases, the clockwise motion and period of temporarily low dependency due to fertility transition are visible, although the countries differ in how far along they are and how severe the process of ageing is forecast to be. In Japan, the total dependency ratio (youth plus old age) will rise from 0.64 to 1.17 over the period 2005–50, implying, *ceteris paribus,* that GDP per capita will grow 0.6 per cent per year more slowly than GDP per worker (see Weil 2005, ch. 5, for details of this calculation). By contrast, India, like many developing countries, is in the process of receiving a large 'demographic dividend' from reduced fertility (Bloom and Williamson 1998).

The lesson from this analysis of dependency is that, from the point of view of society as a whole, the period of rapid increase in old-age dependency that is in store for the world's richest countries is to a large extent simply the passing of the transitory benefit derived from a decrease in fertility. A second lesson is that any change in fertility that will in the long run undo the effects of population ageing will, in the short run, lead to an *increase* in total dependency by moving the point representing age structure above and to the right of the locus of stable populations.

The model discussed above ignores the means by which dependent members of society are supported. In practice, there are three mechanisms by which this takes place: through their own past savings; through institutions (primarily the government) that transfer resources between unrelated people of different ages; and through their own families. Lee (2002) refers to these various means by which resources are transferred among age groups as a 'reallocation system'. We shall see that the nature of the reallocation system affects the overall burden of ageing as well as the distribution of that burden.



Population Ageing, Fig. 2 (**a**) Demographic dynamics in the United States (Source: United Nations) (**b**) Demographic dynamics in Japan (Source: United Nations) (**c**) Demographic dynamics in India (Source: United Nations)

Ageing, Savings and Capital

Capital is important in analyses of population ageing for two reasons. First, accumulation of capital allows either individuals or society as a whole to break the temporal link between production and consumption: an individual, for example, can save some of her wages when she is working, and then use the accumulated capital to fund consumption during retirement. Second, as a factor of production complementary to labour, capital helps determine the quantity of output to be divided among workers and dependents. Analyses of ageing and capital accumulation proceed down both normative and positive channels.

The normative approach asks how society should respond to a looming change in demographics. Although there is in practice no social planner who makes saving decisions for society as a whole, the solution to the social planner's problem can inform the response of a government that influences national saving through fiscal policy and tax incentives. Common sense would suggest that a country that is undergoing population ageing should 'save for its old age', that is, accumulate extra capital during the period of low dependency in order to maintain a smooth path of consumption into the period of high dependency. As stressed by Cutler et al. (1990), however, there is a countervailing effect: population ageing due to lower fertility implies that the working-age population will grow more slowly, reducing the amount of investment required to supply new workers with capital. The flip side of this decrease in required investment is that, if a country did attempt to save sufficient capital to smooth consumption in the face of ageing, the result would be a rise in the capital–labour ratio, lowering the return on capital, which would lead households (or a social planner) to want to raise consumption. Elmendorf and Sheiner (2000) calculate that an optimizing social planner would want to make relatively small changes in saving rates in response to the population ageing currently forecast in the United States.

A positive alternative to the social planner approach is to consider the equilibrium of an economy in which consumers make privately optimal saving decisions taking as given the expected paths of interest rates and wages as well as taxes and government benefits. Forecasting the effects of demographic change on output or capital per worker, interest rates, and so on requires a fully articulated, rational expectations general equilibrium model. Kotlikoff et al. (2007) use such a model to analyse demographic change in the United States, under the assumption that the Social Security benefit regime does not change, and that payroll taxes adjust accordingly. They find that the capital deepening that would normally accompany a shift of the population into its peak asset-holding years is undone by rising payroll taxes. They forecast 'capital shallowing' that will raise the real return on capital by one percentage point by 2030 and a further two percentage points over the rest of the 21st century, as well as a dramatic slowing of real wage growth.

Rather than fitting an optimizing model of saving, another approach is to look empirically at the age pattern of actual behaviour. Poterba (2005) shows that individual net worth follows a hump-shaped path over the course of the lifetime, peaking between ages 65 and 69. Unlike the classical life-cycle model, however, the decline in average net worth is relatively slow, so that average net worth at death is significant. This life-cycle pattern of asset accumulation in turn implies that shifts in demography will shift asset demands and potentially asset prices. In particular, the movement of the baby-boom generation into its high accumulation years was widely cited as a potential explanation for the run-up in stock prices during the last decades of the 20th century (Abel 2003). Similarly, some analysts have suggested that, as the balance between age groups actively accumulating and running down wealth shifts in the period after 2010, there will be a corresponding meltdown of asset prices. However, Poterba (2005) finds little evidence of demographic effects on asset returns in time series data from the United States, Canada and the United Kingdom. Lim and Weil (2003) show that in a forward-looking asset pricing model it would require an unreasonably large adjustment cost for capital to produce a large asset price meltdown in response to projected population ageing. The shift in population towards the elderly will also lead to a significant increase in the flow of bequests relative to either income or wealth of the younger generation; Weil (1994) argues that this increased flow of bequests will reduce the saving of the receiving generation.

The above discussion implicitly considered the case of an economy closed to international capital flows. In an open economy, the mismatch between the demographically induced demand for asset holding and the capital requirements of the labour force can be channelled into capital flows abroad. For example, a country like India, where the working-age population is forecast to grow an annual rate of 1.8 per cent per year between 2000 and 2025, would be a natural recipient of investment from Japan, where the working-age population will shrink at an annual rate of 0.6 per cent per year over this period. In practice, however, net financial flows among countries tend to be far smaller than a model of perfectly open capital markets would imply, and movements in current accounts seem to bear little resemblance to those predicted by demographic change (see Brooks 2003).

Ageing and Government

In the developed countries that are ageing most rapidly, government transfer programmes are a major source of support for dependent elderly. In Germany, for example, transfers net of taxes and inclusive of public health benefits make up 65 per cent of the income of people aged 65 and older (Burtless 2006).

Correspondingly, one of the most important functions of government is transferring resources to elderly people. In 2005, US federal outlays were 18.9 per cent of GDP. Almost 60 per cent of that amount was spent on direct transfers attributable to specific age groups (Medicare for the elderly, unemployment insurance for working age, and so on). Of such transfers, 58 per cent (6.5 per cent of GDP) was directed toward those aged 65 and older. On a per person basis, the elderly received close to eight dollars in direct transfers for every dollar of transfers received by working-aged persons. In sharp contrast, children received just 35 cents per dollar of transfers awarded to workers. Assuming constant transfers per person by age group, a shift of ten per cent of the population out of the workforce and into retirement would increase federal transfer outlays by 4.7 per cent of GDP (calculations based on data underlying Gokhale and Smetters 2006). In addition to raising spending, population ageing also reduces government revenue. Putting these tax and spending effects together, Burtless (2006) calculates that the effect of population ageing would raise the tax rate required to pay for government transfers on a PAYGO basis in from 16 per cent in 2000 to 21 per cent in 2030 in the United States. In Germany, where transfers are larger and ageing more extreme, the increase in the tax rate would be from 28 per cent to 40 per cent. In the United States, the effect of ageing on the government budget is greatly exacerbated by the fact that the *price* of health care for the elderly is rising at the same time as the fraction of the population that is elderly (Elmendorf and Sheiner 2000).

One important way in which transfers to dependents (either children or elderly) that are channelled through the government differ from those mediated by either the family or through one's own saving is in how workers perceive the benefits resulting from their forgone consumption. People give money and other resources to their children or aged parents because they care about them. And when people save for their own old age, it is because they care about their future selves. But few people are so altruistic that they value the taxes that are taken from their pay in order to fund transfers to the elderly. For this reason, there is an efficiency loss associated with government support of the elderly that is not present in other forms of transfers to dependent age groups. Prescott (2004) argues that differences in marginal labour tax rates explain large cross-sectional differences and changes over time in labour supply among the G-7 countries. For example, in the early 1990s his calculations show the French average marginal tax rate (inclusive of consumption taxes) being 48 per cent larger than that in the United States; correspondingly, French adults aged 15–64 worked only 68 per cent as many hours as their US counterparts. The large elasticity of labour supply that Prescott estimates implies that deadweight losses will increase dramatically as populations age, as long as government old-age pensions continue to be funded through taxes that are largely divorced from the benefits that the individuals paying them will receive. Thus an economy that could function smoothly with a high level of youth dependency funded through family transfers, or a high level of old-age dependency funded through savings, might collapse if a similar level of old-age dependency were funded through taxes.

Because government transfers are so heavily weighted toward the elderly, the adjustment in government finances required to deal with population ageing will be proportionally much larger than the overall change in consumption in the economy as a whole. Roughly put, ageing is a much bigger problem for the government than for the economy as a whole. Most conceivable reforms in government old-age pensions will represent net losses to cohorts who are near or beyond retirement at the time of reform. Bohn (2005) calculates that, based on current participation rates, the fraction of voters aged 65 and over in the United States will rise from 19.8 per cent to 30.5 per cent between 2003 and 2030; over the same period the age of the median voter will rise from 47 to 52. Thus, as the fiscal strain from population ageing becomes acute it will be increasingly difficult for policymakers to solve their problems by reducing transfers to the elderly.

Ageing and Families

Transfers within families represent the final channel whereby dependents are supported. For the large majority of old people in developed countries, family transfers are the second or third most important source of support, behind their own past savings and/or transfers from the government. This is a relatively new pattern. Prior to the 20th century, the period of old-age dependency was much shorter, government transfers to the elderly were minimal, and cohabitation of elderly with their children was the norm. In the United States, for example, the fraction of elderly widows who lived with their adult children fell from 67 per cent in 1920 to 20 per cent in 1990 (McGarry and

Schoeni, 2002). Only 2.7 per cent of people aged 60 and over in the United States reported support from children as their main source of income in 2001. Even in Japan, where such transfers have traditionally played a much larger role, the fraction of people 60 and over reporting their children as their main source of support fell from 29.8 per cent to 12.0 per cent between 1981 and 2001 (United Nations 2005, Table I.2). In contrast to the elderly, the burden of supporting young dependents lies foremost on their own families. Mason et al. (2005) calculate that 57 per cent of consumption of people under 20 in the United States in 2000 was financed by transfers from family members. Thus, unlike governments, families headed by working-age adults find their budget constraints relaxed by the low fertility that causes population ageing.

An important distinction between support for elderly dependents and support for child dependents concerns the degree of choice that those doing the support enjoy. Working-age adults cannot choose how many siblings they share the burden of supporting their parents with, much less the size of the working-age cohort relative to the elderly population, which determines the level of taxation required to fund public pensions. But working-age adults *can* choose the number of children they produce and support, and their choices about fertility may respond to economic conditions. Of particular interest in the present context, population ageing itself may feed back to affect fertility. The best-known mechanism whereby population age structure affects fertility was identified by Easterlin (1987), who hypothesized that members of large birth cohorts would suffer from labour market crowding, earn wages that are low relative to the standard of living that they had grown up with, and would adjust fertility downward to partially restore their standard of living. The rise in taxes required to fund transfers to the elderly that will result from population ageing could have effects on after-tax income that are as large or larger than those from Easterlin-style generational crowding; thus, ageing could lead to lower fertility and, down the road, even more ageing (Hock and Weil 2006).

Population and Agricultural Growth

James Roumasset

Abstract

Thinking about population as a driver of agricultural development provides insights into induced technical and institutional change, whether it be Ester Boserup's declining fallow period, modern crop varieties, or the horizontal and vertical specialization that arise in labour-intensive agriculture. The non-convexities of research and development, infrastructure investments, and specialization imply that modest population pressure does not necessarily exert downward pressure on wages. As agricultural growth stimulates industrialization, the non-convexities of specialization become ever more compact. The combination of these and the increased demand for human capital, if not inhibited by policy failures, tends to promote a virtuous circle of human progress.

Q1

That economics became known as the ‘dismal science’ can largely be attributed to the theory of population and agricultural growth as developed by Malthus and Ricardo, notwithstanding the term's origin in another context. Starting from a point of relatively high wages, for example at the end of the Black Death in Europe, or after some exogenous technological improvement, population increases geometrically. The additional population is assimilated by agricultural growth at the extensive and intensive margins, both of which result in diminishing returns to labour. Extensive growth occurs through the expansion of cultivated land, which Ricardo (1817) presumed to be more distant from or of poorer quality than land already in use. Growth at the intensive margin likewise results in diminishing returns, due to the greater amount of labour and other inputs employed on the fixed quantity of previously cultivated land. As a consequence, Ricardo (1817) and Malthus (1798) theorized that wages would eventually decline towards a subsistence level, where population growth would cease due to ‘positive checks’ such as starvation and disease.

Modern economists still use this dismal theory to explain why growth in levels of living among the working classes was never sustained for long periods until the advent of the Industrial Revolution. Each technological improvement was subsequently ‘eaten up’ by population growth and the subsequent diminishing returns. The belief in this theory is so strong that Lucas (2002, ch. 3) wrote that he could look at a picture of a Korean peasant farm in an unknown century and confidently guess household income. Recent interest in ‘sustainable development’ has augmented resource pessimism. In this view, the conventional Malthusian vicious circle between population growth and poverty is exacerbated by resource depletion and environmental degradation. Expanding numbers of poor people in developing countries put more pressure on limited natural resources and fragile ecosystems, and the falling resource base makes the Malthusian circle even more vicious than with a fixed resource endowment.

Malthus famously argued that unchecked population growth is exponential while food production at best grows linearly, thus implying the inevitability – in the absence of sufficient *preventative* checks – of *positive* checks such as pestilence, plague, famine and war and of subsistence levels of income in the long run. Ironically, food supply has outstripped population growth ever since the publication of Malthus’s *Essay on the Principle of Population.* Technological and institutional change has been more rapid than he envisioned and preventative checks more robust.

Boserup Effects

Boserup (1965, 1981) takes a different tack by taking population growth as the exogenous variable and enquiring into the consequences thereof for agricultural technology and institutional change. I follow Boserup’s lead in most of what follows, eventually returning to a more integrated view. Boserup focused on the effects of physiological population density on an additional intensive margin – the fallow period. As population (and other demand factors) grow, the predominant agricultural system gradually transitions from long to short fallow to annual cropping to multiple cropping. Table 1 describes these systems and

Population and Agricultural Growth, Table 1 Boserup’s frequency of cropping by population density

System	Description of cropping system	Frequency of cropping	Person per km^2	Density
Hunting and gathering	Wild plants, roots, fruits and nuts are gathered	0%	0–2	Very sparse
Forest fallow (w/astoralism)	One or two crops followed by 15–25 years’ fallow	0–10%	1–4	Very sparse
Bush fallow (w/pastoralism)	Two or more crops followed by 8–10 years’ fallow	10–40%	4–64	Sparse to Medium
Short fallow (w/domestic animals)	One or two crops followed by one or	40–80%	16–64	Medium
	two years’ fallow			
Annual cropping (w/intensive animal husbandry)	One crop each year with only a few months’ fallow	80–100%	64–256	Dense
Multi-cropping	Two or more crops in the same fields each year without any fallow	200–300%	$ 256	Very dense

Source: Boserup (1981, pp. 9, 19 and 23) illustrates the rough correspondence between the frequency of cropping and population density in less developed economies. Other authors have extended the correlation between population density and cropping frequency to European countries, both over time and country.

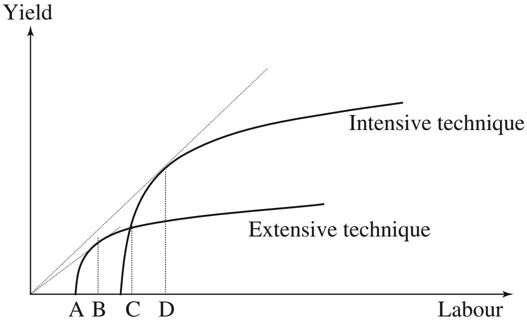
Boserup's insight can be partly understood from the perspective of *induced technical change* (Ahmad 1966). Absent industrial growth, population pressure makes land increasingly scarce relative to labour, thus inducing land-saving technical change. In the era of modern economic growth, the same tendency would influence whether capital was used to save labour or land. This was exemplified by labour- abundant Japan developing land-saving biological innovations and the United States developing labour-saving mechanical innovations (Hayami-Ruttan 1985). As represented with standard neoclassical analysis, however, induced innovation simply increases the elasticity of factor substitution (especially between land and labour). In the *very* long run, that is, allowing for induced technical change, the elasticity of substitution, such as between land and labour, is higher than without technical change.

Similarly, decreasing the fallow period allows the marginal product to decline more slowly than otherwise. For example, suppose that 100 workers cultivate 100 hectares with a 50 per cent cropping frequency (short fallow) and that the population doubles. Even though the additional labour can be productively employed, for instance by better weeding and more thorough land preparation, the marginal product of labour will suffer a large decline if the cropping frequency remains unchanged (perhaps by a half or more). By switching to annual cropping, however, it may be possible to accommodate the additional labour with only a small decline in its marginal product, even in the steady state. The optimal solution involves some conservation of soil fertility over time, for example through the use of animal manure and crop rotation (Barrett 1991).

Boserup contends that it is even possible that population pressure increases the productivity of agricultural labour. More intense farming systems require more fixed costs. For example, forest fallow systems require minimal land preparation. The slash and burn method leaves the land both fertile and weed-free. In the tropical African context that she describes, however, once the land has been burned and cropped, it is taken over by grasses and is no longer suitable for slash and burn agriculture until 20 or more years later, when the forest has returned. Consequently, land preparation requires time-intensive ploughing. Because of these fixed costs, the average product of labour rises over some range.

Other investments associated with intensification, such as irrigation and terracing, similarly increase labour productivity. This is illustrated in Fig. 1. Once population has reached point C, the average product of the extensive and intensive techniques is equalized and it becomes worthwhile to switch to the intensive method. As labour increases beyond C, the average product rises until D, where diminishing returns just offset the gains from spreading the fixed costs, and average product begins to decline. In this sense, population eventually overcomes the transitory gains from switching techniques and causes productivity to fall.

Innovation-through-intensification, as portrayed in Fig. 1, does not require invention. It is as if new techniques are taken 'off the shelf' when they are warranted by increased land scarcity. Genuinely new technology, developed through invention or imported from other areas, may provide additional positive effects. The same population increase that warrants the fixed cost of intensification also



Population and Agricultural Growth, Fig. 1 Average product of labour under different farming techniques (Source: Adapted from Krautkraemer (1994)) warrants increased expenditures on experimentation and research. This research shifts the *innovation possibility frontier* (IPC) between land and labour inwards. In modern settings, R&D becomes an important source of productivity growth.

For example, the high-yielding, or modern, wheat and rice varieties (MVs) developed in the 1960s were in large part induced by population pressure on increasingly scarce land. In the extensive phase of agricultural development, cultivated hectarage is increasing. Eventually, cultivated area reaches a maximum and declines as towns and industrial areas encroach on agricultural land. At this point, land scarcity is exacerbated by both rising food demand and falling land supply, and intensification accelerates.

One of the effects of intensification is to increase the demand for land-saving technology. According to the 'political Boserup effect' (Evenson 2004), increasing population densities induce countries to invest more in the genetic improvement of both crops and animals. By first characterizing existing technology by the unit requirements of land, labour, and capital, optimal investment by a country in new technology can be described by the amount of research and its factor-saving bias. In one version of this theory, a given research expenditure allows a country to pick any point on the IPC, the envelope of all unit isoquants in the land–labour plane, that said research expenditure affords. If it is assumed that the IPC shifts in a neutral fashion towards the ultimate IPC, wherein the marginal benefit of research is zero, then the factor-saving bias is in accordance with changes in relative factor prices. For example, if population growth results in a decrease in the wage rate and an increase in the land rental rate, both relative to the price of capital, then technical change will be land-saving and labour-using relative to capital (Binswanger and Ruttan 1978, chs 2 and 4).

In as much as the IPC shifts in a non-neutral fashion, however, these results will be modified. It is natural to assume, for example, that technical change is inherently capital-using, that the unit isoquant (net of capital costs) can be shifted inward more cheaply by increasing capital per unit of output than by increasing labour or land. Moreover, it may be that inventing technology that uses capital to save labour is cheaper than technology that saves on land. This may explain why the modern rice and wheat varieties have been found to be mildly labour-saving, in addition to being land-saving and capital-using (fertilizer responsive), even though their demand was created by falling wages relative to land rents. But even though labour per unit of output fell, output per hectare increased enough such that MVs had a positive effect on wages (for example, Evenson 1982). Overall, MVs have had a beneficial effect on poverty reduction by decreasing food prices and increasing wages relative to what they would have otherwise been given population growth and labour demand in other sectors.

Boserup's other 'secondary effects' of population growth may also cause productivity to rise, even in the absence of agricultural research. Among these are property rights, work habits, division of labour, education, and the infrastructure for transport and communication. Changing property rights exemplifies how institutions can change in response to population pressure and other changes in factor scarcities. This insight led to the theory of *induced institutional change* as a complement of the theory of induced technical change. For example, as population pressure increased the demand for land-saving investments, private property sometimes emerged as a more efficient substitute for top-down land management by community leaders or feudal lords (see, for example, North and Thomas 1973). Indeed, the first legal enforcement of the early English enclosures was effected by the Statute of Merton (1235), which noted the need to improve the land in order to generate greater rent. The subsequent waves of English enclosures beginning before the 17th and 19th centuries also appear to have followed increases in the rate of population growth, although the timing is not without dispute.

Population Induced Specialization in Agriculture

While population growth potentially augments the benefits of private property, potential efficiency gains do not automatically induce institutional change. In particular, rent seeking may lead to a ‘race’ such that private property is created before it actually increases efficiency (Lueck 1998). On the other hand, political costs may retard institutional change beyond the time that its benefits warrant. The advent of private property in Hawaii in 1848 was exceptional in two regards. First, the benefits of private property resulted from the increased profitability of sugar and pineapple production, even in the face of population decline. Second, the timing of private property accorded roughly with its efficiency benefits; the delaying effects of the political costs of change were offset by the expediency of governmental land sales.

A more profound institutional change that may be induced by population pressure and other sources of intensification is that of economic organization. The division of labour has fascinated economists since the time of Adam Smith, but was sidelined during the era of neoclassical economics. The theme of specialization has been resurrected, implicitly in endogenous growth theory and explicitly in the New Classical Economics (as in Yang 2003). In Yang’s model, population growth lowers the relative price of labour, thereby increasing the use and number of intermediate capital goods, which are produced with labour. This in turn increases production and the number of manufactured goods, and further bolsters the value of total output through learning-by-doing. In this model, agricultural growth is only indirectly stimulated, for example through the lower cost of manufactured fertilizer – a land- saving input.

Population growth can also facilitate specialization by lowering unit transaction costs. For example, the fixed costs of transport and communication infrastructure per capita may fall sufficiently to warrant additional infrastructure investment. Falling unit transaction costs, in turn, lower the friction that inhibits both horizontal and vertical specialization. In this case, learning-by-doing can directly bolster agricultural productivity.

A primary vehicle for increased specialization is hired labour. To see how population growth can induce hired labour, consider a hypothetical land-surplus economy wherein food is produced by family farms and where clearing costs are negligible. If we assume for the moment that output per hectare is a function of labour, farm size is efficiently determined where the marginal product of land is zero and the marginal product of labour is equal to the shadow price of household leisure. Once population growth brings lower quality, or sufficiently distant, land into production, intensification begins – lowering labour productivity. As the optimal land-to-labour ratio falls, the size of the average family farm declines. This process is efficiently halted, however, due to indivisibilities such as those associated with ploughs and draft animals. Eventually, farm size shrinks to a point where the economies of scale lost from further shrinkage are just offset by the transaction costs of hired labour. At this fundamental turning point, increases in labour per hectare induced by population growth are accommodated by hired labour instead of falling farm size. In this sense, the change in agricultural organization – known as the emergence of the rural proletariat – is not necessarily an indication of exploitation or inefficiency.

But hired labour is not a perfect substitute for family labour. Transaction costs are different, and, since hired labour is not necessarily tied to a particular farm, it can specialize in particular skills instead of adjusting to the attributes of that farm. In the common case where family labour has a higher shadow price of leisure, hired labour has a comparative advantage in arduous and well-defined tasks wherein transaction costs are manageable (for instance, because the results of the work are readily observable) and wherein speed and quality are enhanced by training and repetition. Family members have a comparative advantage in management-intensive tasks such as chemical applications that require knowledge of farm attributes and for which shirking is harder to control. The advent of hired labour stimulates horizontal specialization across tasks, as with men in the Philippines who specialize in transplanting rice and move from village to village to do so. The resultant learning- by-doing increases productivity – for example, in producing straighter rows of rice, which raise the productivity of workers through the use of rotary weeders. Vertical specialization also increases. For example, landowners may specialize in land improvements, such as irrigation, and employ tenants who specialize in management-intensive labour and who employ and monitor workers who specialize in arduous and more easily supervised tasks.

Further vertical and horizontal specialization is illustrated by the institution of piece-rate by teams. A team is hired to complete a task, such as transplanting, which is easily monitored by *ex post* inspection. In this sense, the task is equivalent to an intermediate good. The team may produce, for example, a stack of cane stalks that are of uniform length and ready for planting. Moreover, the team constitutes a separate firm. Its chief executive officer is the team manager, who contracts with the sugar grower and who bears the adverse reputational effects of any sub par performance. In this sense, the capacity for specialization in industry may be quantitatively greater than that of agriculture but not necessarily qualitatively different. Thus it is neither inevitable that population growth decreases or increases productivity in an agricultural economy.

The following stylized pattern of hired labour, based on Philippine rice farming in the 1960s to the 1980s, may serve to epitomize the evolution of specialization as labour intensification follows population growth. Once population density warrants clustered villages of farm families, the institution of exchange labour emerges for transplanting, harvesting, threshing, and often ploughing. Boserupian intensification increases the value of timeliness, and exchange labour allows these tasks to be completed in a day or less for one farm. The first widespread form of hired labour was for harvesting. Harvesters were paid a share of the harvest, typically one-sixth. This later evolved into the gama system, whereby a family or small group was assigned a portion of the farm to weed and later harvest, albeit for the same one- sixth share. This corresponded to a fall in wages relative to rents. In Java, Indonesia, where population pressure was even more intense, this same institution emerged – for the same one-sixth share – but the work requirement expanded even further, typically including transplanting.

When wage labour first appeared in Philippine rice farming, a given worker would typically perform a myriad of tasks over the cropping season. As intensification proceeded and the man-hours of hired labour increased, this undifferentiated wage-worker system was partially replaced by one involving specialized piece-rate workers who were paid according to their performance of a specific task. This evolved further into the piece-rate-by-team system described above. As per-hectare yields continued to increase, piece-rates were often converted back to wage contracts – due to the increased value of quality shirking – but task-by- task specialization was retained.

A common assertion in development economics is that large farms that rely primarily on hired labour are at a transaction-cost advantage relative to small, family farms. This view implicitly takes the distribution over farm size as exogenous, however. In the efficiency view sketched above, farm size is endogenous and responds to changes in population. Indeed, efficient farm size may actually increase as the increased incidence of hired labour warrants new contracting institutions that lower transaction costs. The transaction costs that remain are the necessary cost of retaining economies of scale and facilitating specialization. Whether productivity gains from specialization are enough to offset diminishing returns to more labour on a fixed amount of aggregate land cannot be determined a priori.

The view that share tenancy is inefficient is similarly incomplete. In the canonical view, share contracts are a pair-wise efficient institution for mitigating both the labour-shirking disadvantages of wage contracts and the risk-bearing disadvantages of rent contracts. Nonetheless, share tenancy is said to be socially inefficient because of the Marshallian labour shirking that remains under the common 50 per cent sharing. This view fails to explain how share tenancy fits into the evolution of agricultural organization in response to population pressure and other forces of intensification. Specialization is warranted by intensification and is facilitated by the evolution of contracts and other institutions. In particular, share tenancy facilitates vertical specialization between the landowner, the tenant, and the hired labour that the tenant supervises. It also facilitates the horizontal division of labour described above. On the other hand, share tenancy is primarily a type of family farm and may become less appropriate as agriculture becomes more capital-intensive. In any case, assessing the consequences of institutions without considering their causes, especially intensification, runs a risk of misplaced exogeneity.

A third example of questionable exogeneity concerns the view that the *modernization triad* – population pressure, technical change and commercialization – has inevitably immiserizing consequences. The case made against the new varieties of rice and wheat that emerged in the mid- to late 1960s is illustrative. Modern rice varieties are said to be most profitable on irrigated, highly productive land and for farmers facing relatively low shadow prices of credit and close connections with the money economy. These characteristics tend to favour wealthy landowners over small farm families. As the rich get richer, small farmers and tenants are allegedly disenfranchised, thus accelerating Ricardian forces of population and polarizing society into a class of landlords and the proletariat. Commercialization further augments proletariatization, breaking down safety-net customs such as gleaning rights for the poor, and setting the stage for violent conflict.

The Boserupian and induced innovation perspectives provide a compelling counterweight to the neo-Marxian view. Technical change induced by population growth is primarily land-saving and offsets downward wage pressure, whereas Marxian technical change is strongly labour-saving and exacerbates the downward effect of population. Like induced technical change, induced institutional change in the form of 'commercialization' has a positive effect on wages. The efficient emergence of landless workers helps to avoid the immiserizing effects that would occur from a growing population being accommodated by shrinking farm sizes. This class division in turn creates both a supply and a demand for hired labour. As labour markets emerge, new institutions such as piece-rate contracts and work teams with team leaders emerge to lower contracting costs, thereby lowering the transaction cost wedge between effective wage paid, including costs of recruitment, training and supervision, and effective wage received, net of the costs of search, required tools, and the journey to work. As the unit-transaction-cost wedge shrinks, workers move up their supply curves and employers down their demand curves for labour, resulting in more hired labour and increased net wages. From this perspective, induced innovation at least partially offsets the downward pressure that population pressure puts on wages.

These efficiency patterns are by no means inevitable, but serve to counter the view that the modernization triad is inevitably impoverishing. The efficiency view also provides a theoretical starting point for explaining agricultural growth or the lack thereof. Rent-seeking and policy distortions may induce arbitrary and inefficient patterns of ownership and farm size, thereby inhibiting the efficiency forces described. A challenge for economic historians and agricultural development theorists is to explain the political-economy forces that have facilitated induced innovation in some cases and inhibited it in others.

The positive Boserupian forces of induced innovation and specialization move in the opposite direction of the classical Malthusian effects. To summarize the above, even a small family farm can have four levels of vertical specialization – landowner, share-tenant farm manager, work team leader, and worker – as well as horizontal specialization across the array of farm tasks. The advent of each new form of specialization can be modelled along the lines of Fig. 1. Because of the non-convexity associated with the fixed cost of each advance in organizational complexity, population-induced specialization gives rise to increased labour productivity, but only over a limited range of additional labour. In the absence of other effects and changes, we would expect to see the marginal and average products of labour initially rising after each increase in specialization; then, as labour per hectare increases further, to a decline until the next innovation is made. Adding learning-by-doing to the picture increases the chances of sustained productivity gains. Nonetheless, the theory cannot tell us whether the positive forces will outweigh the negative Malthusian forces in the long run.

A Historical Perspective

The history of agricultural growth is informative. As documented by Evans (1998), the long-run rate of agricultural growth closely matched that of population until 1825, when world population reached one billion people. The corresponding increase in food production was almost entirely sourced in an increase in cultivated area, that is, it was *extensive* in nature. In contrast, since world population reached five billion late in the 20th century, the increase in food production has been almost entirely driven by increased productivity. During the intervening period, when world population increased by four billion, growth in food production was increasingly intensive in nature (due to increased inputs) with increased productivity becoming more important as the period progressed. That is, as intensification led to diminishing returns, increased productivity became increasingly important.

This broad-brush generalization about the nature of agricultural growth is consistent with the induced innovation perspective. As population growth increases land scarcity, the Ricardian gradient, which depicts the proportion of agricultural growth due to intensification, is monotonically rising. Intensification increases the relative scarcity of land further, relative to labour and capital, thus stimulating induced productivity increases, both from technical and institutional progress. Ironically, food supply has grown 'geometrically' since 1938 (averaging 2.2 per cent per year) and population has grown nearly 'arithmetically' since 1959 (with one billion being added to world population roughly every 13.3 years). Technological and institutional change has seemingly inverted Malthusian theory.

This does not imply that all technological change is demand-induced. Even the theory of induced innovation admits supply-side innovations. For example, knowledge capital produced in the defence industry may lead to better communications technology. Irrigation systems in ancient Mesopotamia and Egypt were presumably not induced by increasing land scarcity but because someone figured out how to produce more with less. Economic history in the United States suggests that demand was partly induced by labour scarcity, but, once certain types of farm equipment had been invented, they were adapted even in areas where land prices were increasing faster than labour prices. Kremer (1993) even suggests that until the late 18th century the Malthusian argument was so predominant that population could be viewed as a proxy for technological change.

On the other hand, the agricultural and industrial 'revolutions' are now viewed less as bursts in productivity spurred by invention and more as induced technical change. For example, the four-field system, whereby wheat, barley, turnips and clover were grown in separate fields and rotated the following year, was once viewed as an essential part of the English agricultural revolution during the 18th century. But the system was developed in land-scarce Flanders two centuries before and popularized in England only once it was warranted by sufficient population-induced land scarcity.

Even the mechanism of induced technical change is not entirely governed by factor prices, however. For example, the replacement of the fallow period in the medieval 'three field' rotation by beans or another leguminous crop appears to have been indirectly induced by the population decline in 14th-century western Europe. Higher wages and farm incomes, resulting from the lower population and decreased land scarcity, increased the demand for meat. Complemented with the Flemish demand for wool, this incentivized farmers to increase sheep production, and they responded by both converting some lands to pasture and growing legumes in place of fallow on much of the remaining lands.

The extent to which technical change in English agriculture was induced has been the subject of intense historical debate. Historians reporting that agricultural productivity increased rapidly, say in the late 18th and early 19th centuries, tend to see an agricultural revolution stimulated by exogenous technical change. Economic historians who estimate productivity increases to be quite gradual view changes in rotation and other innovations as induced. As suggested by the discussion of Fig. 1, induced changes do not by themselves reverse the price and income trends that induced them in the first place and therefore tend not to be associated with dramatic increases in productivity.

Sustainable Development

Resource depletion adds another negative dimension to the never ending debate between the development optimists and pessimists. Even before *sustainable development* became fashionable, neo-Malthusians argued that unbridled population growth in poor countries and economic growth in rich countries must inevitably cause severe pressure on the earth’s limited resources, resulting in burgeoning poverty and international conflict. The only solution was said to be the *steady state economy* with constant population, capital stock, and output.

After the Brundtland Commission’s 1987 report, resource depletion was broadened to include pollution and other environmental threats. Environmental degradation, including increasing water scarcity, soil erosion, deforestation, desertification, salinization, and global warming, as well as diminishing energy and marine resources, was viewed as exacerbating the Malthusian vicious circle. Accordingly, the Brundtland Commission called for a simultaneous assault on population growth, poverty and environmental degradation, thus giving rise to the modern movement for *sustainable development.* Economists have had limited success in modelling sustainable development, however. One notable review and synthesis (Arrow et al. 2004) was unable to settle on positive principles of sustainability and settled on the negative *sustainability criterion* – an injunction not to deplete the value of natural capital more than the additional value of produced capital.

Even if we abstract from technical change, expanding models of economic growth to include environmental degradation does not produce a necessarily dismal outlook, however. If we represent concern for future generations by *intergenerational neutrality* and assume that population grows exponentially at a constant rate, optimal per capita consumption grows to its *golden rule* level, under plausible assumptions about substitutability, both between renewable and non-renewable resources and between natural and produced capital. Adding technical change provides even rosier possibilities (Weitzman 1997). Whether these possibilities are realized depends largely on the effectiveness of private and public governance structures in facilitating specialization and exchange while guarding against unproductive rent seeking (Greif 2006).

The Co-evolution of Specialization and Governance

The economic history of Hawaii provides a relatively recent, pre-industrial example of how specialization and governance in agriculture co-evolve with changes in population. During the ‘colonization’ period AD 300–600, population growth, including further migration of Polynesian peoples, was slow. Agricultural expansion was extensive. The population began to increase more rapidly towards the latter part of the ‘development’ period (600–1100), and agriculture began to intensify with the advent of irrigation. There was little if any division of labour among the commoners. During the expansion period (1100–1650) population accelerated and intensification greatly increased with a decreased fallow period, a major expansion in irrigation and with the development of fishponds. Horizontal specialization among workers became commonplace, with fishing more of a distinct occupation. Evolving from a system of somewhat separate extended families units, social and production relations became increasingly stratified, eventually with a distinct hierarchy from local chief upwards to governor *(ali’i)* of the watershed to district head (see Kirch 1985).

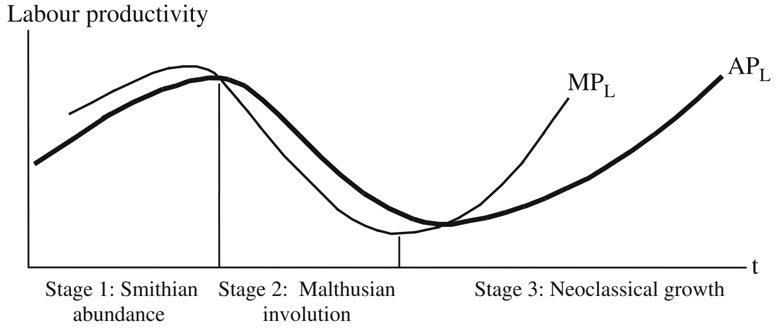
This stylized history is suggestive of a *governmental Kuznets curve.* During the extensive (pioneer) stage of development, family or extended family units are largely autonomous and decision-making is decentralized accordingly. During the intensive development stage, decision-making and governance are centralized at a higher, albeit intermediate level (for example, communal governance of the commons). As intensification and specialization continue, efficiency favours a further centralization of governance, at least for the minimal functions of defence and the justice system, but a decentralization of decision-making as facilitated by private property. This last stage occurred in Hawaii after Western contact in 1778. New trade opportunities raised the value of irrigation and other investments in plantation agriculture, initially for sugar and later pineapple. Private property provided the assurance that planters needed to commit to these investments and also facilitated specialization between districts that was warranted by international trading opportunities. Graphing this historical progression of increasing governmental centralization on the horizontal axis, and rising and then falling centralization of decision-making on the vertical axis, completes the governmental Kuznets curve. Viewing government intervention in these two dimensions provides a useful antidote to the misleading question of 'how much government' that sometimes arises in policy circles.

Smith to Malthus to Solow

A largely unexplored area of enquiry involves combining the theory of endogenous population growth with the theory of sustainable growth outlined above. Perhaps the simplest model of endogenous growth can be found in two-sector growth models of economic development wherein the birth rate is exogenous and the death rate declines to minimum as per capita income increases. The birth rate may also be made endogenous following the Chicago School's new household economics. The increased opportunity cost of child care is one pervasive cause of the decline in fertility with economic development. Moreover, as the capital intensity of the economy increases, the returns to human capital are raised, thus creating incentives for families (individually or collectively) to invest in human capital, a partial substitute for increased fertility.

Malthus's emphasis on the supply of food determining population and Boserup's focus on exogenous population growth increasing the demand for land and inducing supply side changes in agricultural production are clearly complementary. Focusing on one or the other is a device for dealing with the shortcomings of human imagination and the fact that models with both forces are indeterminate without further, possibly arbitrary, restrictions added to the model. Indeed, due to the endogeneity of population, enquiring into the impact of population levels involves something of a category mistake. In light of this, the World Bank statement (1984; see also Kelley 1988) that population growth in excess of two per cent per annum tends to have a negative impact on per capita income warrants reinterpretation. A more accurate statement would be that population growth in excess of two per cent tends to be associated with negative growth in per capita income after partially controlling for (imperfectly measured) positive effects. In particular, where high population growth occurs in the face of policy failures that cause an anti-labour bias, population growth tends to exacerbate the Brundtland vicious circle described above.

More generally, the effects of population growth on agricultural and economic development may be different depending on the population density and the stage of economic development, as illustrated in Fig. 2. For the early American frontier and for parts of Africa today, physiological population density may be sufficiently sparse for Smithian economies of specialization and Boserupian economies in infrastructure to afford increasing labour productivity, as shown by the rising segment of the average product of labour curve. There is no labour market, at least in the sense of a competitive spot market, in such economies because paying labour its marginal product would more than exhaust total output. When the extensive land frontier



Population and Agricultural Growth, Fig. 2 Stages of economic development the marginal product of labour begins to rise, causing wage rates to rise and pulling up average labour productivity soon thereafter. Accumulation of produced capital and the relative increase of the industrial sector generate the transition to modern economic growth

nears economic exhaustion, population density becomes high, and the economy is still dominated by agriculture (as on the Indonesian island of Java in the 1960s and early 1970s), real wages fall, along with the average product of labour. Once the 'structural transformation' takes place, such that the growth rate of the agricultural labour force (if any) is but a small fraction of that of the industrial labour force.

These stages are not inevitable forces of history. Some economies may be able to bypass the Malthusian stage altogether. For example, economic policies in Taiwan during the 1950s and 1960s encouraged labour intensity in agriculture. This and the investments in physical infrastructure, a gradual transition to processing and high value-added agricultural production and an efficient system of marketing cooperatives kept the demand for labour and wages rising. Hong Kong and Singapore were able to skip the Malthusian stage by early industrialization that relied on trade instead of the Johnston–Mellor linkages whereby agricultural development increases incomes (thus stimulating demand for industrial products), mobilizes savings for industrial investments, and provides a market for manufactured farm inputs (Johnston 1970). Korea was similarly able to bypass an extended Malthusian stage by allowing investment coordination through *chaebols* (business groups)and focusing on manufactured exports. In contrast, the negative force of policy failures can extend Malthusian involution and even prevent the transition to modern economic growth. Finally, because of policy failures and exogenous shocks, history may record more than two turning points. For example, after going through a Malthusian period during the 'long 16th century', wages in England rose between approximately 1640 and 1740, but then fell again before entering a 'Solovian' period of increase starting slightly after the advent of the 19th century and accelerating after the American Civil War.

Nonetheless, we may meaningfully enquire into the mechanics of the two turning points shown, after abstracting from policy failures and exogenous shocks. While the first turning point has clear Ricardian underpinnings, the second has generated substantial controversy. How does an economy go from 'Malthus to Solow?' Forward linkages from agriculture are important in explaining the relative growth of industry, but they do not, in and of themselves, explain the rapid and sustained growth in labour productivity during modern economic growth.

Note first that there is an implicit Kuznets curve corresponding to Fig. 2. During the Malthusian period, wages fall and Ricardian rents increase, worsening income distribution. Even as industrialization begins to pull up wages, income distribution may continue to worsen for some time as the total returns to capital increase faster than the wage bill. Eventually, as the returns to human capital induce the substitution of 'quality for quantity' in fertility decisions, widely distributed human capital accumulates and even produced capital becomes less concentrated. These forces cause a more equal income distribution in the model.

Were it only for Ricardian landlords accumulating an agricultural surplus and financing industrialization and the production of goods for a landed aristocracy, industrialization would have not have been as robust as that witnessed in modern economic growth. Indeed, increasing wages stifle the labour-intensive production that characterizes the early stages of industrialization, decrease the agricultural surplus, and detract from the rental incomes of capitalists and landlords that finance capital formation. What saves the day are the non-convexities inherent in industrialization.

While there are numerous possibilities for specialization and other non-convexities in agriculture, these are still few in comparison with those in industry. In industry, there is more horizontal specialization through proliferation in the number of products and more vertical specialization through multiple stages of intermediate production. In agriculture, the number of products is more limited, and vertical specialization without industry tends to be limited to separation of management and labour. With industry, agriculture can take advantage of land-saving intermediates such as fertilizer and tractors. Thus it is plausible that technological and institutional changes in agriculture have not been frequent enough to overcome the inexorable Malthusian force of increased food affording greater population growth.

In contrast, once industry becomes a major part of the economy, non-convexities may be sufficiently compact in the course of development to dominate the negative force of lower death rates. The resultant increase in per capita income in turn invokes a positive feedback mechanism whereby Engel effects increase the demand for manufactures, thus increasing capital formation and the returns to human capital, thereby contributing to the decline in the demand for child numbers described above. Greater product specialization and falling unit transport costs afford a further inducement to international trade, an additional positive feedback mechanism. This theory supports the revisionist interpretation that the agricultural and industrial 'revolutions' were misreadings of a gradual process of economic change (see Clark 2007).

The role of industrial development in sustaining increased wages and per capita incomes does not imply that the appropriate development policy requires pushing industrial development while 'squeezing' or neglecting the agricultural sector. Indeed, for countries with a preponderance of the labour force in agriculture, economic development can be sustained only by 'pushing' on the agricultural sector with R&D, infrastructure, and non-confiscatory prices (Pingali 2006). It does mean, however, that stimulating the agricultural sector alone – that is, relying on automatic linkages from the agricultural to the industrial sector – is not sufficient for sustained economic development. External economies of labour-market pooling, human capital, technological spillovers and other network externalities imply that there are aspects of investment coordination that are not internalized by spot markets. This leaves an important role for government in facilitating the requisite economic cooperation.

Population Dynamics

Ronald D. Lee

Abstract

Population dynamics are the patterns of change over time in populations. Populations fluctuate in response to fluctuating external forces, or because of the internal structure of the process of demographic renewal. Damped cycles one generation long may result from the interaction of random perturbation and the age distribution of reproduction. So-called Easterlin cycles two generations long, either damped or self-exciting, may arise from the lag between birth and labour force entry when fertility responds sensitively to labour market conditions. Longer-term dynamics arise from the interactions of population growth, capital, endogenous technology, and income.

Population dynamics are the patterns of change over time in populations, ranging from fluctuations to long-term trends, and the underlying principles that govern these changes.

Population Fluctuations

All human populations exhibit fluctuations in their vital rates and consequent irregularities in their age distributions to a greater or lesser degree. Analyses of such fluctuations are of interest for many reasons – for historical understanding, as a basis for forecasting, for a deeper understanding of underlying social processes – but perhaps most intriguing is the possibility that they may afford some insight into more fundamental aspects of population dynamics and may illuminate the very process of demographic renewal. More specifically, we may be able to learn from the occurrence or absence of longer cycles whether a population is subject to negative feedback of a Malthusian sort and perhaps to place bounds on its sensitivity if it occurs. To Malthus (1798) it seemed obvious that populations would perpetually oscillate about equilibrium. This notion is taken seriously as an interpretation of the long swings in the fertility of many contemporary developed countries, as we discuss in more detail below.

Fluctuations may come about in three ways (or through combinations of these ways). First, they may simply be imposed on a series of births or deaths by fluctuations in some driving force such as prices or the weather. In this case, both the amplitude and the period of the fluctuation depend entirely on the driving series. Second, damped fluctuations may be created by the internal structure of a demographic process, as it responds to random and non-cyclic external shocks; in this case the cycles will die out if the external disturbance stops. The period of such cycles depends entirely on the nature of the renewal process, not on the driving force; however, the amplitude of the cycles depends on the amplitude (variance) of the disturbing force.

The third possibility is that limit cycles occur. Like the aforementioned cycles, these are generated by the internal structure of the reproductive process, but unlike them they are self-sustaining or ‘self-exciting’ and would continue indefinitely even in the absence of outside shocks. In this case, both the amplitude and the period depend only on the reproductive process. When a dynamic equilibrium is unstable, such that trajectories tend to explode away from the equilibrium path, then one of three things may happen: explosive fluctuations may lead to extinction; the non-repeating fluctuations of chaos cycles may occur; or the system may settle down to a limiting pattern of cycles, called limit cycles. There are many examples of animal populations exhibiting such behaviour. In human demography, it is a matter of controversy whether such cycles have ever actually occurred, but if they have it is presumably through the kind of mechanism proposed by Easterlin (1968), a sort of Malthusian cycle about equilibrium.

Imposed Cycles

There are well known non-seasonal cycles in fertility and mortality at or below the annual frequency (obstetricians avoid deliveries on Sundays; people have lower mortality just before elections, compensated for by increased mortality thereafter). Seasonality is strong in fertility, mortality, nuptiality and migration, particularly in traditional agricultural societies and in those less insulated by their dwellings from the variations of climate (in the extreme case of Bangladesh in the 1970s, for example, the seasonal peak in fertility was two to three times the seasonal trough). In the case of mortality, nuptiality and migration the causes of seasonal variation are fairly well understood to be rooted in identifiable biological, institutional and economic influences. In the case of fertility, the causes of seasonality are much less well understood.

There are also somewhat longer fluctuations in vital rates, in the range of 2–15 years. These have been quite thoroughly studied and found to be associated with business cycle indicators in the developed world and with the harvest cycle in preindustrial conditions. Lower agricultural prices and less unemployment are associated with higher fertility and nuptiality and with lower mortality, with lag patterns of response indicating that much of the variation is confined to changes in the timing of events. Fluctuations in temperature also are important, with colder winters and hotter summers raising mortality and reducing fertility, with an appropriate lag. In the case of mortality, exogenous epidemiological variation historically played a larger role (Wrigley and Schofield 1981). These relationships have continued to hold at least until a few decades ago in the developed countries and are still evident in the Third World countries where they have been investigated.

Much longer fluctuations in population variables are also visible in the historical record. Kuznets cycles, of 15–25 years, include a procyclical response of migration, both internal and international. Some of the birth-rate series of 19th century Europe show signs of the Kondratieff cycle. But most striking are the waves lasting two or three centuries in the demography of Europe and of China, from at least the 12th century up to the 18th (Wrigley and Schofield 1981). These are evident in population growth rates and in mortality; their existence in fertility is problematic. The cause of these very long waves is not clear, although a case can be made for the influence of climatic variation and for the effects of intercontinental exchange of diseases through conquest or trade. Whatever their cause, such demographic fluctuations played a critical role in economic history, driving rents, wages and other relative prices, and possibly inflation. It is possible that such fluctuations were generated internally by the economic demographic system as Malthusian fluctuations about equilibrium; in the present state of knowledge, however, it appears more likely that the cycles were imposed.

Cycles Arising from the Internal Age and Temporal Structure of Reproduction

A characteristic pattern of delay between an event and its recurrence can act as a filter which creates quasi-cyclic behaviour in the series of events when the timing is subject to continual random perturbation. In this way, the typical spacing of a mother's births two to three years apart tends to generate cycles of this length, as was first pointed out by Yule (1906). Such cycles are visually discernible in many birth and fertility series and show up in the empirical power spectra.

More importantly, the typical delay between a woman's own birth and the time she herself gives birth to female children leads to cycles of 25–35 years, or the approximate length of a generation, when fertility is randomly perturbed (see Coale 1972; Lee 1974). This may be shown as follows. Let B(t) be the number of births in year t, and let $\varphi(a)$ be the expected number of births to each of these births at age a, net of mortality ($\varphi(a)$ is known as the 'net maternity function'). $\varphi(a)$ typically rises from zero at an age around 15 years to a peak in the twenties and declines again to zero at around age 45; its mean, μ, is the mean age at child-bearing and falls between 25 and 35 years depending on the population. The renewal process is written:

$$B(t) = \sum \varphi(a) B(t-a) \qquad (1)$$

where the sum is taken over the reproductive years. Such a process will settle down to a stable exponential growth path if the characteristic roots of φ lie within the unit circle. But as the B series converges to this growth path from an irregular past, it will fluctuate, and the fluctuations can be characterized by further examination of the characteristic roots of φ. There will generally be one real root, describing the steady state growth rate, and the others will come in pairs of complex conjugates. The pair with the largest modulus is the only one of substantive interest; it will describe a damped oscillation with length roughly equal to the mean age of child-bearing, μ. Any initially distorted age distribution, if subsequently subjected to fixed vital rates described by ϕ, will generate a birth sequence which moves in waves one generation long as it converges towards exponential growth.

The argument can easily be generalized to cover the case of a population whose net maternity function is subject to constant stochastic disturbance of any autocovariance structure; the age structure of reproduction, described by the mean values of φ, will amplify variation in the neighbourhood of frequencies corresponding to cycle length μ, leave them unchanged at higher frequencies, and attenuate them in the neighbourhood of cycle length 2μ. Thus, a population in a random environment will tend to exhibit cycles one generation long or to superimpose these on whatever pattern of variation is forced on it by the environment. The birth series of many pre-industrial populations, particularly at the parish level, indeed do reveal such waves; whether the mechanism described above suffices to account for them has not yet been established empirically.

Some scholars have seen a major economic influence in such population waves, but this view now appears exaggerated; waves generated in this way are generally quite mild; they have low amplitude, and they damp fairly rapidly following an identifiable disturbance.

Cycles Arising from Economic-Demographic Interaction

Interest in dynamic economic–demographic models of population renewal, stressing fluctuations arising from age distributions, was prompted by the long 'cycle' in US fertility, with a trough in the 1930s, a peak in the late 1950s, and a trough in the 1970s. A number of scholars, most notably Easterlin, suggested around 1960 that the fertility fluctuations might reflect the economic conditions faced by young labour market entrants, conditions which in turn were worse for large cohorts and better for smaller ones. This insight led them to forecast correctly the sharp decline in fertility occurring in the 1960s, as larger cohorts aged into the labour market. Easterlin (1968) developed a detailed theory, buttressed by extensive empirical investigation, leading to a tentative prediction of self-generating demographic cycles two generations long, as small birth cohorts had high fertility and gave birth to large cohorts, who in turn reared small cohorts, and so on. Such cycles are known as 'Easterlin cycles'. A considerable empirical literature has since appeared on the subject, lending considerable support at the aggregate time series level in the United States and some other countries, but very little at the micro level.

I now briefly review the theoretical literature on economic–demographic cycles. The account of the renewal process given above implicitly assumed that net maternity at time t, $\varphi(a, t)$, was independent of the population age distribution at time t, or equivalently of the preceding series of births. But it is entirely possible that this is not so. Suppose, for example, that a Malthusian model is appropriate, such that fluctuations in labour supply lead to inverse fluctuations in wages, and that fertility depends positively on the wage level. This leads to different dynamic possibilities and a modified renewal equation.

Suppose that the net maternity function, $\varphi(a)$, depends on some set of economic variables, let us say wages for concreteness. Suppose that these in turn depend on some set of economic variables, Z, which are independent of age distribution, as well as on the current population age distribution, which thus in conjunction with Z determines wages. If mortality is constant and the population closed to migration, as we here assume, then the current age distribution is completely determined by past births. We can then write:

$$B(t) = \sum \varphi^{*}[B(t), Z(t)]\, B(t-a), \qquad (2)$$

where $B(t)$ denotes the vector of past births; this replaces the purely demographic renewal eq. (1) introduced above (Lee 1974).

The renewal process will have an exponential equilibrium growth path, $B^{*}(t) = B\, exp(nt)$, which satisfies (2) for all t. For simplicity, suppose that Z is such that $n = 0$, so that the equilibrium path is stationary. It is helpful to consider the process of proportional deviations about this equilibrium path, denoted $b(t)$. Let $\varphi(a)$ be the value of $\varphi^{*}[\ ]$ evaluated at equilibrium. In this case, the sum of $\varphi(a)$ over all a, known as the net reproduction rate or NRR, is unity when evaluated at the equilibrium age distribution. Let $\Gamma(a)$ be the elasticity of the NRR with respect to the size of age group a, or equivalently with respect to births a years previously, $B\ (t\ -\ a)$; these elasticities are readily derived from the original function φ. Then the renewal process for fluctuations about the equilibrium growth path of births is simply:

$$b(t) = \sum [\varphi(a) + \Gamma(a)]b(t-a). \qquad (3)$$

The smaller the effect of the current age distribution on fertility (Γ), the more the population renewal process resembles the purely demographic version of (1). In any event, exactly the same procedures can be used to study the dynamic behaviour of birth fluctuations in this model as were used previously.

The first step is to check the characteristic roots to assess stability. If the oscillations of the process tend to explode away from the equilibrium growth path, then a different kind of analysis, discussed below, is called for. If the roots indicate that oscillations are damped, then the analysis of dynamic behaviour in the neighbourhood of equilibrium will be informative.

We can now consider specifications of the model which have been proposed in the literature. The first is the simplest Malthusian model, in which all age groups in the labour force are assumed to be perfect substitutes in production, and fertility at each age is assumed to be negatively related to the size of the potential labour force, through an hypothesized effect on wages. In this case, $\Gamma(\alpha) = \beta\, k(a)$, where β is independent of age, and expresses the sensitivity of response (elasticity of the net reproduction rate with respect to labour force size at equilibrium), while the $k(a)$ depend only on mortality conditions and equilibrium age specific labour supply and are therefore easily calculated from data at hand. Depending on values of β, this model will generate cycles ranging from one generation (as in the purely demographic model) to a century and a half or more. For $\beta = 7.5$, which is the empirical estimate from US data, 1917–1973, a cycle corresponding to the observed time path of births may be produced (Lee 1974; Wachter 1991).

Another model which is often used makes the fertility of a birth cohort depend only on the size of the cohort and makes it independent of all other age group sizes. The simplest form of this specification leads to:

$$b(t) = (1-\alpha) \sum \varphi(a)\, b(t-a), \qquad (4)$$

where α is the elasticity of each age's fertility with respect to cohort size. For α less than 1, there is a generation-long cycle; for α greater than 1 but less than 2, there is a damped two-generation cycle, and for α greater than 2 an explosive two-generation cycle occurs.

Specifications reflecting other degrees of substitutability of age groups of labour could of course be tried. Easterlin typically has used a ratio of younger to older workers to drive fertility (this could be derived from a CES model with two age groups of labour as separate factors, for example). The general expression can be used to explore dynamics under a wider variety of specifications. For example, the burden of supporting the elderly retired population might lead to a reduction in fertility; this would be expressed as a suitable negative $\Gamma(\alpha)$ for $a =$ 65 and over. If couples were led to desire larger families when they observed other couples' children, then $\Gamma(\alpha)$ would be positive for ages zero to ten.

When the cyclic behaviour near equilibrium is found to be explosive, then we need to consider behaviour further from equilibrium, at which point nonlinearities become important (unless, of course, the behaviour is truly linear, in which case population extinction results). Dynamic behaviour can be 'chaotic', an endless series of non-repeating fluctuations; for many models, however, limit cycles will occur, with amplitude and period determined not by the pattern of disturbances but rather by the functional relations themselves. Such cycles are observed in animal populations in laboratories and occasionally in the wild; in human populations their occurrence is conjectural: Samuelson (1976) considered a particular three-age group model leading to limit cycles.

Long-Term Population Trends and Economic Growth

Longer-term trends in population have also been viewed in the context of processes related to economic growth. Solow (1956) studied the behaviour of a population whose growth varied first positively and then negatively with respect to per capita income. Combining this study with his neoclassical growth model, he showed there was a stable low-level equilibrium at which per capita income was constant and population grew at the rate of technological progress, but also a second equilibrium at a high per capita income which was unstable. If the capital–labour ratio could be raised slightly above this equilibrium level, then per capita income would rise without limit while the population growth rate fell lower and lower.

In Solow's approach, as in Malthus's, technological progress was taken as exogenous. Boserup (1981) and others have suggested that larger denser populations would be more likely to experience technological progress in the long run, for reasons related to both the supply of innovations and the demand for them. She suggested that, combined with a Malthusian endogenous response of population growth to economic progress, an upward spiral of population growth and technological progress might occur, with positive feedback. A number of scholars have developed formal models of this process (Lee 1986; Kremer 1993), in a literature that overlaps slightly with the endogenous growth literature (Jones 2003).

Population Health, Economic Implications of

David Canning and David E. Bloom

Abstract

Population health is not only a consequence but also a cause of a high level of income. Healthier people are more productive in work. Healthy children have better school attendance and cognitive development, while longer prospective working lifespans encourage investments in education. Longer lifespans can also increase saving and wealth accumulation as an extended retirement becomes more likely. The beneficial effects of population health can be seen both at the individual and macroeconomic levels, while the continuing high burden of disease in sub-Saharan Africa poses a substantial challenge to its economic development.

Population health and a high level of income go hand in hand. Higher incomes promote better health through improved nutrition, better access to safe water and sanitation, and increased ability to purchase more and better quality health care. There is also, however, an effect of health on income. This can work through several mechanisms (Bloom and Canning 2000). The first is the role of health in labour productivity. Healthy workers lose less time from work due to ill health and are more productive when working. The second is the effect of health on education. Childhood health can have a direct effect on cognitive development and the ability to learn. In addition, because adult mortality and morbidity (sickness) can lower the prospective returns to investments in schooling, improving adult health can raise the incentives to invest in education. The third is the effect of health on savings. A longer prospective lifespan can increase the incentive to save for retirement, generating higher levels of saving and wealth, and a healthy workforce can increase the incentives for business investment. We examine the evidence for these mechanisms and find that there are potentially large effects of health on economic outcomes at both individual and macroeconomic levels.

Improved population health has a large impact on population numbers and age structure, and we examine the economic implications of this induced demographic change. The global population explosion of the nineteenth and twentieth centuries was caused not by a rise in fertility but by a fall in mortality. Lower mortality and improved survival rates increased population numbers, but also led to significant increases in the number of young people since the largest improvements in mortality are initially in infant mortality rates. In the long run, reductions in infant mortality lead to a fall in desired fertility, creating a one-time baby-boom cohort. As this large cohort ages, the resultant changes in population age structure can have significant economic implications.

The issue of population health and economic outcomes is particularly acute in sub-Saharan Africa. This region has a high burden of tropical and other infectious disease, such as malaria, tuberculosis, and intestinal worms, and it also suffers from the HIV/AIDS pandemic. We examine the impact of this disease burden on the prospects for economic development in sub-Saharan Africa.

Although we focus on the economic implications of population health, there is clearly two-way causality as health is partly a consequence of income levels. Preston (1975) demonstrated a positive correlation between national income levels and life expectancy. One reason for this link is that higher income levels allow greater access to inputs that improve health, such as food, clean water and sanitation, education, and medical care. Fogel (2004) emphasizes the role of access to food while Deaton (2006) puts more weight on public health measures such as clean water and sanitation (see Cutler and Miller 2005). Cutler and McClellan (2001) examine the increasing contribution of medical care to health outcomes. Pritchett and Summers (1996) use the relationship between income levels and health to argue for an emphasis on economic growth in poor countries as a method of increasing population health. However, the findings of Easterly (1999) weaken this argument. Easterly finds that, although income levels and population health are closely related, the effect of changes in income on population health over reasonable time spans appears to be quite weak. By contrast, relatively inexpensive public health interventions and policies can have remarkable impacts on population health even in very poor countries. In practice, the major force behind health improvements has been improvements in health technologies and public health measures that prevent the spread of infectious disease, and not higher incomes (Cutler et al. 2006).

We examine the role of health as an instrument to generate economic wellbeing. However, any reasonable view of the contribution of health to human welfare would also include the direct welfare benefits of a long lifespan and good health. Estimates of the monetary value of life (as measured by the willingness to pay to avoid a small risk of death) are often very large (Viscusi and Aldy 2003). We can use these estimates of the value of life to compare the welfare improvements that have come about due to improvements in population health and the improvements due to economic growth and higher incomes. Such comparisons suggest that in many countries the value of health gains has been comparable to, or has even surpassed, the value of income gains (Nordhaus 2003; Becker et al. 2005).

Health as Human Capital

The idea of health as a form of human capital has a long history (for example, see Mushkin 1962). Grossman (1972) develops a model in which illness prevents work so that the cost of ill health is lost labour time. However, there may also be an effect of ill health on worker productivity in employment. A major difficulty in measuring the economic effect of health is the two-way causality between wealth and health (Smith 1999). Another difficulty is the lack of consensus on what is meant by health. Different studies use different health measures: self-assessments of health, biomarkers, medical records, limitations on physical functioning, and anthropometric measurements have all been used as health indicators. Each of these approaches may fail to provide a complete picture of an individual's health status, giving rise to a problem of measurement error. In addition, it is necessary to separate out the effect of investments in health from the effect of natural or genetic variation in health (Schultz 2005).

One solution to these problems in measuring the effect of health on worker productivity is to establish the causal paths in panel data through the use of timing of health shocks and income or wealth responses (for example, Adams et al. 2003). Case et al. (2005), controlling for parental influences and education, find that childhood health has a significant impact on adult health and earnings. Yet another approach to establishing causality is to use instrumental variables. For example, Schultz (2002) instruments adult height with childhood health and nutrition to argue that each centimeter gain in height due to improved inputs as a child in Ghana and Brazil leads to a wage increase of between 8 and 10% (Strauss and Thomas 1998, provide a survey of studies in this area).

Thomas and Frankenberg (2002) caution against drawing inferences from observational studies and instead advocate an experimental approach. A randomized experiment using iron supplementation to reduce iron deficiency anemia led to sizeable effects on worker productivity in Indonesia (Basta et al. 1979). Quasi-experiments can be used where it is possible to treat changes to health as if such changes were randomly generated. Bleakley (2003) considers the effects of the eradication of hookworm and malaria in the United States in the 1910s and 1920s. These diseases were pandemic in many counties of the American South prior to eradication. Bleakley, controlling for normal wage gains in areas that were not infected, shows that children not exposed to these diseases due to their eradication had improved incomes as adults relative to those born before eradication.

This body of research on health and human capital generally supports the idea that health affects worker productivity. However, it lacks a good appreciation of which types of health intervention are most important and what rate of return can be achieved by investing in health as a form of human capital. In many developing countries, relatively inexpensive activities designed to prevent the spread of infectious disease (for example, vaccination) can increase population health at low cost, suggesting that even modest income gains from health will generate very high rates of return. By comparison, treating chronic non-infectious disease in developed countries is often costly. There is evidence that susceptibility to chronic disease in later life is determined by health and nutrition as a fetus and in infancy (Barker 1992; Behrman and Rosenzweig 2004), suggesting that early health investments are crucial for adult productivity.

Health and Education

Education is widely agreed to affect economic outcomes, and health affects education through two mechanisms. The first is the effect of better child health on school attendance, cognitive ability, and learning. Bleakley (2003) finds that deworming of children in the American South had an effect on their educational achievements while in school. Miguel and Kremer (2004) find that deworming of children in Kenya increased school attendance.

The second mechanism is the effect of lower mortality and a longer prospective lifespan on increasing incentives to invest in human capital. This effect occurs for the individual for whom the benefits of education are now greater (Kalemli-Ozcan et al. 2000). In addition, lower infant mortality may encourage parents to invest more resources in fewer children, leading to low fertility but high levels of human capital investment in each child (Kalemli-Ozcan 2002). Evidence for this effect is limited, though Bils and Klenow (2000) do find an effect of life expectancy on investments in education at the national level.

Health and Saving

Poor health affects both the ability to save and the impetus to save. Sickness can have a large effect on out-of-pocket medical expenses, which can reduce current and accumulated household savings. This occurs in developed countries (Smith 1999) but is of particular concern in developing countries where families may be thrown into poverty if productive assets such as land or animals must be sold to pay for medical expenses.

Because poor health tends to be associated with a short lifespan, increasing population health and expected longevity will have an effect on the planning horizon and will influence life-cycle behaviour. With a fixed retirement age, a longer lifespan elicits greater savings for retirement. Blanchard (1985) considers the theoretical effect of a longer lifespan in a macroeconomic model. Hurd et al. (1998) find that increased expectation of longevity leads to greater wealth-holding at the household level in the United States. Bloom et al. (2003) find an effect of life expectancy on national savings, using cross-country data. Lee et al. (2000) argue that rising life expectancy can account for the boom in savings in Taiwan since the 1960s. But the effect of a longer lifespan need not be increased saving for retirement; people could instead choose to work longer. The behavioural response to longer lifespans depends on social security arrangements and retirement incentives (Bloom et al. 2007).

In a life-cycle model with a stable age structure and no population growth or economic growth, the dissaving of the old will exactly match the saving of the young at any level of life expectancy. This suggests that the aggregate effect of longer lifespans on savings is temporary and occurs when life expectancy rises. In the long run, the high savings rates of the working age population will be off set by the dissaving of a large cohort of elderly.

An effect on saving may lead to higher investment if capital markets are not perfectly open. In addition, a healthy population and workforce may increase productivity and encourage foreign direct investment (Alsan et al. 2006).

Health and Demography

Improvements in health and decreases in mortality rates can catalyse a transition from high to low rates of fertility and mortality – the 'demographic transition' (Lee 2003). Population growth is the difference between birth and death rates (ignoring migration) and the global population explosion in the twentieth century is attributable to improvements in health and falling death rates. In developing countries, health advances tend to lower infant and child mortality rates, leading initially to a surge in the number of children. Reduced infant mortality, increased numbers of surviving children, and rising wages for women can lower desired fertility (see Schultz 1997) leading to smaller cohorts of children in future generations. Better access to family planning can also help couples achieve match more closely their fertility desires and realizations. This process creates a 'baby boom' generation that is larger than both preceding and succeeding cohorts. Subsequent health improvements tend primarily to affect the elderly, reducing old-age mortality and lengthening the lifespan.

In many theoretical models a population explosion reduces income per capita by putting pressure on scarce resources and by diluting the capital–labour ratio. In these models population declines spur economic growth in per capita terms. For example, the very high death rates, and decline in population, due to the Black Death in fourteenth century Europe appear to have caused a shortage of labour, leading to a rise in wages and the breakdown of the feudal labour system (Herlihy 1997). However, in modern populations there appears to be little connection between overall population growth and economic growth; indeed the twentieth century saw both a population explosion and substantial rises in income levels.

Although it is difficult to find significant effects of overall population growth on economic growth, it is possible to consider the components of population growth separately. High birth and low death rates both generate population growth, but seem to have quite different effects on economic growth (Bloom and Freeman 1988; Kelley and Schmidt 1995). This may be because, while both forces increase population numbers, they affect the age structure quite differently. The effect of changing age structure due to a baby boom has large effects as the baby boomers enter the workforce and then as they eventually retire. While the baby boomers are of working age, economic growth may be spurred by a 'demographic dividend' if the baby boom generation can be productively employed. Bloom et al. (2004) find that the demographic dividend increases the potential labour supply but its effect on economic growth depends on the policy environment.

There is a worry that health improvements and population aging will lead to high dependency rates and a slowdown in economic growth. In addition to longer lifespans, however, we are seeing a compression of morbidity; the period of sickness towards the end of life is falling as a proportion of overall lifespan (Fries 1980, 2003). The idea that old-age dependency starts at 65 is essentially a result of social security retirement arrangements (Gruber and Wise 1998) and healthy aging means that physical dependency now often occurs at much later ages.

Health and Economic Growth

In growth models, population health is usually taken to be life expectancy, or some other mortality measure, as opposed to the morbidity measured used at the individual level. This disjunction can be bridged by assuming a one-to-one relationship between mortality and morbidity rates in a population; however it is not clear that such a relationship holds, making comparison of the macroeconomic relationship and microeconomic relationships difficult. In addition, calculating life expectancy requires age-specific mortality rates that are unavailable for many developing countries and published life-expectancy figures from the World Bank and United Nations are often constructed from quite incomplete raw data (Bos et al. 1992). There is a need to improve our measures of population health and to expand them to measures that correspond to morbidity and not just mortality.

The effect of health on individual productivity implies a relationship between population health and aggregate output. Shastry and Weil (2003) calibrate a production function model of aggregate output using microeconomic estimates of the return to health. They find that cross-country gaps in income levels can be explained in part by differential levels of physical capital, education, and health, with these three factors being roughly equal in terms of their contribution to differences in income levels. (A little over half of cross-country income gaps are explained by these factors; the remainder of the gap is ascribed to differences in total factor productivity.)

Another approach estimates the effect of population health on economic growth. Estimating the effect of the current level of population health on current income levels is subject to the problem of reverse causality; income also affects health. One way around this problem is to look at the effect of population health on subsequent economic growth, arguing that the timing can determine the direction of causality. This requires the absence of reverse causality through an expectation effect (so that current health is not caused by expected future economic growth).

Growth regressions show that the initial levels of population health are a significant predictor of future economic growth (Bloom et al. 2004, provide a survey of this literature). Sala-i-Martin et al. (2004) find that the predictive power of health (as measured by life expectancy and malaria prevalence) is robust to the specification of the growth regression. Bhargava et al. (2001) argue that the effect of health on economic growth is larger in developing countries than in developed countries.

While population health measures are highly predictive of future economic growth, there is a debate about how to interpret the link. The health effect could be interpreted as the macroeconomic counterpart of the worker productivity effect found in individuals. However, Acemoglu et al. (2003) argue that health differences are not large enough to account for much of the cross-country difference in incomes, and that the variations in political, economic and social institutions are more central factors. They argue that health does not have a direct effect on growth, but serves in growth regressions as a proxy for the pattern of European settlement, which was more successful in countries with a low burden of infectious disease.

Even if a causal interpretation of the effect of health on individual productivity and economic growth is accepted, the argument for using health as an input depends on there being low-cost health interventions that can increase population health without first having a high income level. There are, however, a large number of such interventions that can be implanted (Commission on Macroeconomics and Health 2001).

Tropical Disease and HIV/AIDS

Sub-Saharan Africa suffers from poor health due to the widespread presence of tropical disease. Malaria and tuberculosis cause high illness and death rates, while parasitic diseases such as schistosomiasis and intestinal worms can cause anemia and reduced energy levels and productivity. In addition to these tropical diseases, the high prevalence of HIV/AIDS is causing life expectancy to decline dramatically in many countries in the region. Poor health status is one cause of sub-Saharan Africa's economic stagnation (Bloom and Sachs 1998). Malaria appears to have an effect on economic growth over and above that created through higher mortality, suggesting that its effects on productivity with a given mortality burden are greater than other diseases (Gallup and Sachs 2001).

Although HIV/AIDS has increased mortality rates dramatically, its impact on income per capita is unclear. HIV/AIDS is associated with high mortality but the period of sickness before death is relatively short. This mutes the worker productivity effects of the disease. Bloom and Mahal (1997) find that HIV/AIDS does not seem to lower the growth rate of income per capita; lower output is matched by lower population numbers due to high death rates. Young (2005) goes further and argues that AIDS mortality reduces fertility significantly, and that this will lower population pressure and increase the income per capita of the survivors of the pandemic in South Africa.

Many authors, however, argue that AIDS mortality has significant indirect effects that will reduce economic growth in the long term. Deaths from HIV/AIDS are concentrated among young adult men and women, leading to a higher dependency ratio. Bell et al. (2004) argue that the creation of a generation of AIDS orphans may lead to lack of care and education for children and to low productivity in the future. This effect may be compounded by fatalism induced by high AIDS mortality and shortened expected lifespan, which reduce the return to education. The high level of stigma associated with HIV/AIDS can reduce trust in the community, while high mortality and the strains imposed by extreme ill health before death can weaken families, community groups, firms, and government agencies, with long-term consequences for social capital (Haacker 2004).

It is important to remember that income per capita is not a complete measure of welfare. Resources devoted to preventing and treating HIV/AIDS are part of measured income but reduce consumption of other goods, reducing welfare even as measured GDP per capita may remain steady (Canning 2006). A more comprehensive welfare measure that included the welfare gain derived from a long lifespan, as well as annual income, would show a large welfare reduction due to HIV/AIDS (Crafts and Haacker 2004). The main welfare effect of HIV/AIDS is the sickness and death of its victims and the impact of these on the victims' families; the effect on the average income level of the survivors is decidedly secondary.

Portfolio Analysis

Nils H. Hakansson

Many observers trace the beginnings of modern financial investment theory to the pioneering article of Markowitz (1952), published only a third of a century ago. This is not surprising in view of the dominant position that the mean-variance approach to portfolio choice analysed by Markowitz has attained in the last two decades, particularly in empirical studies. Financial investment theory under uncertainty goes well beyond this particular model, however, and somewhat further back in time as well. This entry will first examine the pure portfolio model, both the single-period and the intertemporal varieties. It will then turn to consumptioninvestment formulations.

Pure Portfolio Analysis

Single-Period Models

Even though the mean-variance model 'dominates' single-period analysis, it will be expedient to begin with the approach which is a direct application of the theory of rational choice, also known as expected utility portfolio models.

The Expected Utility Approach

The investor, starting the period with initial capital $w_0 > 0$, is assumed to have preferences that are rational (in the von Neumann and Morgenstern (1944) sense) with respect to end-of-period distributions of wealth and therefore representable by a utility function, u, defined on end-ofperiod wealth w. Thus, the investor's problem is to maximize $E[u(w)]$, where E denotes the expectation operator. Letting r_i denote the (generally random) return per unit of investment in opportunity i and z_i the amount (to be) invested in opportunity (asset, security) i, $i = 1, \ldots, m$, we obtain

$$w = \sum_i z_i(1 + r_i), \qquad \sum_i z_i = w_0,$$

where the second expression is the budget constraint. Solving the second expression for z_1 and inserting the result in the first equality, the investor's problem becomes

$$\text{P1}: \max_{z_2, \ldots, z_m} E\left\{ u\left[\sum_{i=2}^{m} (r_i - r_1) z_i + w_0(1 + r_1) \right] \right\} \tag{1}$$

subject to

$$\text{miscellaneous constraints.} \tag{2}$$

At this point, several remarks are in order. First, in our expression for w we have implicitly assumed a perfect market, that is an absence of transaction costs and taxes, perfect divisibility, a competitive securities market, constant returns to scale, and that the investor has full use of the proceeds from short sales (negative holdings). These assumptions are standard and will be maintained throughout. Second, when some security is risk-free over the holding period, it carries the subscript $i = 1$ above; in this case, the first $m - 1$ terms in (1) represents the excess earned (over and above what an entirely risk-free portfolio would have provided) on the risky holdings (this excess may of course be negative). Third, it is usually assumed (quite innocuously from an empirical viewpoint) that the investor prefers more to less and is averse to risk, that is that

$$u' > 0, u'' < 0. \tag{3}$$

Finally, the constraints (2) usually represent institutional and/or self-imposed barriers on borrowing (e.g. margin requirements), on short positions, and on solvency (such as $\Pr\{w > 0\} = 1$).

The solution to P1 is usually denoted $z^*(w_0) = z_2^*(w_0), \ldots, Z_m^*(w_0)$. It exists under various innocent conditions: one set imposes bounded returns on the available securities, 'no-easymoney', and a solvency constraint. The no-arbitrage or no-easy-money condition precludes both a payoff $w \geq 0$, where $\Pr\{w > 0\} > 0$, from a nonpositive net investment, as well as a payoff $w = 0$ from a negative net investment. Given existence, the second part of (3) (strict concavity of u) implies that the optimal payoff distribution w^* (though not necessarily the optimal portfolio z^*) will be unique.

Define $a(w)$ (the absolute risk aversion function) and $r(w)$ (the relative risk aversion function) by

$$a(w) \equiv -u''(w)/u'(w), \qquad r(w) \equiv wa(w).$$

Arrow (1965) demonstrated that if $E[r_2] > r$,

$$a'(w) \gtreqless 0 \Rightarrow \frac{dz_2^*}{dw_0} \lesseqgtr 0$$

when there are only two assets available, one risky and one risk-free. While the result does not extend in general to the case of many risky assets (Cass and Stiglitz 1972), the empirical observation that a given portfolio of risky assets is overwhelmingly treated as a normal (as opposed to inferior) good lends strong support to the notion that the preferences of the great majority of investors have the property

$$a'(w) < 0 \tag{4}$$

in addition to those given in (3). Beyond this, however, we have little to say about investors' preference functions with respect to wealth.

Since properties (3) and (4) leave much room for individuality, there is rather little one can say in general about the solution to P1 – except that the optimal portfolio will be well diversified. This observation was probably first made in a scholarly context by Bernoulli (1738) in his advocacy of the logarithmic measure of welfare.

There are, however, two cases of special interest. One is the case in which the optimal investment policy is *proportional* to initial capital. This occurs if and only if utility is a member of the family of power functions (the isoelastic family), that is

$$u(w) = \begin{cases} -w^\gamma, & \gamma < 0 \\ \ln w, & (\gamma = 0) \\ w^\gamma, & 0 < \gamma < 1 \end{cases}, \tag{5}$$

which in turn implies, and is implied by, constant relative risk aversion. [For the family above, $r(w) = 1 - \gamma$.] The optimal policy is now of the form

$$z_i^*(w_0) = x_{iy}^* w_0, \qquad \text{all } i, \gamma, \tag{6}$$

where the x_{iy}^* are constants corresponding to the proportions to be invested in the various assets.

A second special case is that of *linear* optimal investment policies (of which (6) is obviously a special case). This occurs, *assuming a risk-free asset or portfolio is available*, if and only if preferences exhibit linear risk tolerance $[a(w)^{-1}$ is linear] or, equivalently, hyperbolic absolute risk aversion, that is

$$u(w) = \begin{cases} \gamma^{-1}(w+\phi)^\gamma & \gamma < 1 & a' < 0 & \text{(7a)} \\ -(\phi - w)^\gamma & \gamma > 0, \ \phi \text{large} & a' > 0 & \text{(7b)} \\ -\exp\{\phi w\} & \phi < 0 & a = 0. & \text{(7c)} \end{cases}$$

The optimal policies are given, in the three cases, by

$$z_i^*(w_0) = \begin{cases} x_{iy}^*\left(w_0 + \dfrac{\phi}{1+r_1}\right) & & \text{(8a)} \\ x_{iy}^*\left(\dfrac{\phi}{1+r_1} - w_0\right) & i = 2, \ldots, m & \text{(8b)} \\ \text{a constant } (\phi) & & \text{(8c)} \end{cases}$$

and are said to exhibit the *separation* property. This name derives from the fact that the *mix* of risky assets (the ratio of $Z_i^*(w_0)/z_j^*(w_0)$ any i, j $\geq$ 2) is independent of initial wealth w_0 (it is also independent of the preference parameter ϕ). *In the absence of a risk-free asset or portfolio*, separation obtains only for quadratic utility, or when $\gamma = 2$ in (7b). Thus we have the remarkable observation that, for arbitrary return distributions, two individuals of differing initial wealth levels would be willing to delegate the choice of risky asset proportions to the same mutual fund only if they share probability beliefs *and either* a risk-free portfolio is available and both individuals' preference functions belong to either (7a) or (7b) with a common γ or to (7c), *or* both investors have quadratic utility. When it comes to risky investments, individuality runs strong indeed!

Separation based on return distributions rather than preferences can also occur but only under highly restrictive assumptions (Ross 1978). The most noteworthy case is when returns are normally distributed, which is discussed in the next section.

The Mean-Variance Approach

The essence of the mean variance model is that more expected return is preferred to less and that less variance of return is preferred to more, *ceteris paribus*. In addition, it is usually assumed that indifference curves in standard deviation-mean space are convex. Since the return r on a portfolio is $w/w_0 - 1$, we obtain, defining x_i as the fraction of w_0 invested in opportunity i or $x_{\mathrm{i}} \equiv z_{\mathrm{i}}/w_0$ and using (1),

$$r(x) = \sum_{i=2}^{m} (r_i - r_1)x_i + 1 + r_1.$$

More formally, the mean-variance approach can thus be viewed as postulating a preference function $f(E[r], V[r])$, where $V[r]$ is the variance of r, such that

$$\frac{\partial f}{\partial E} > 0, \qquad \frac{\partial f}{\partial V} < 0, \qquad \left.\frac{\mathrm{d}^2 E}{\mathrm{d}\left(\sqrt{V}\right)^2}\right|_{f=f_0} > 0. \quad (9)$$

The first two properties of (7) provide the basis for the central notion of mean-variance dominance: return distribution r_i is said to MV-dominate distribution r_k if and only if

$$E_i \geq E_k, \qquad V_i \leq V_k$$

and at least one inequality is strict. Given the set of feasible portfolios, dominated portfolios are referred to as *inefficient* and nondominated portfolios as *efficient*. The first two properties of (7) thus generate a partial ordering of payoff distributions in a manner similar to that of the various stochastic dominance criteria.

In the absence of a risk-free asset or portfolio, $E[r]$ is (except in pathological cases) a strictly concave function of $\sigma[r](= \sqrt{V[r]})$ for the set of efficient portfolios. In the presence of a risk-free asset, the expected return of any efficient portfolios p is given by the linear equation

$$E\left[r_p\right] = r_1 + \frac{E[A] - r_1}{\sigma[A]}\sigma\left[r_p\right],$$

where A is the one portfolio composed solely of risky assets that is efficient. In other words, all efficient portfolios are combinations of the risk-free asset and portfolio A, that is the separation property holds.

As noted, Markowitz is viewed as the originator of mean-variance portfolio theory, although Tobin (1958) also made important early contributions. However, the mean variance approach itself has three other independent and rather interesting origins. Marschak (1951), using a Taylor series expansion as an approximation to the expected utility of return, obtained, on the basis of the first three terms, the expression

$$E[r] - b(E[r])^2 - bV[r], \qquad b > 0,$$

which is an eligible form of the mean-variance function $f(E, V)$. Roy (1952) argued for maximizing the probability of exceeding some disaster level d, or the criterion

$$\max \Pr\{r > d\}.$$

Applying Chebychev's inequality, he obtained the operational expression

$$\max_x \frac{E[r(x)] - d}{\sigma[r(x)]}.$$

which clearly captures the essence of the mean variance framework. Finally, Freund (1956), assuming negative exponential utility [see 7(c)] and normally distributed returns, obtained

$$E[u(w)] = -\exp\left\{k\left(E[w] + \frac{k}{2}V[w]\right)\right\}, k < 0,$$

where, upon optimization, each permissible value of k implies a mean-variance efficient solution.

The mean-variance model is consistent with the expected utility criterion in two principal cases. First, under arbitrary return distributions, utility must be quadratic [$u(w) = w - bw^2, b > 0$], which unfortunately implies $u' \leqslant 0$ for $w \geqslant b/2$ and that risky assets are inferior goods (see 8b). Second, when returns are normally distributed, consistency occurs for that subset of preferences for which the expected utility integral exists (a necessary condition for this is that $u(w)$ is defined on the whole real line – this excludes the family (7a), for example).

Although normally distributed returns are a poor approximation of actual returns in a world of limited liability, and quadratic utility leaves much to be desired, the mean-variance model is by far the most widely used. This appears to be attributable to three principal properties. First, MV-efficient portfolios are (like the portfolios of risk averse expected utility maximizers) well diversified. Second, the MV-model makes more modest input demands and is computationally much simpler than the (non-quadratic) expected utility models. (What business person would appreciate the advice that (s)he maximize expected utility?) Finally, the normality assumption appears to provide a reasonable approximation of the returns for well diversified portfolios in many cases, and the quadratic function, over a limited range, is often a satisfactory approximation to an arbitrary utility function.

Multi-Period Models

This section addresses the type of models in which a large number of sequential portfolio choices is of the essence. We shall therefore employ the subscript t to denote period t; w_t represents wealth at the end of period t. The returns r_{it} will be assumed to be independent with respect to t (but not i).

The Long-Run Growth Model

Let $R_t(xt) \equiv 1 + r_t(x_t)$; R_t is now called the wealth relative for period t. Thus, under full reinvestment of the previous period's payoffs.

$$\begin{aligned} w_t &= w_0 R_1(x_1)\ldots R_t(x_t) \\ &= w_0 \exp\left\{\sum_{n=1}^{t} \ln R_n(x_n)\right\}, \end{aligned}$$

where we assume that $R_t(x_t) \geq 0$, all t. Letting

$$G_t(\langle w_t \rangle) \equiv \sum_{n=1}^{t} \ln R_n(x_n)/t \qquad (10)$$

and observing that the variates $1\text{n}\ R_1$, $1\text{n}\ R_2$, ... (under mild restrictions) obey the law of large numbers, we obtain

$$w_t \to \begin{cases} 0 & \text{if } E[G_t] \leqslant \delta < 0 \\ \infty & \text{if } E[G_t] \geqslant \delta > 0 \end{cases} \quad t \geqslant T, T \text{ large.} \qquad (11)$$

Thus, it is the expectations of the logs of the wealth relatives which are the principal determinants of what happens to your capital over the long haul.

In view of (9), it is natural to think of maximizing the expectation of G since this almost surely leads to more capital in the long run than any other (significantly different) strategy. To do this, it is necessary and sufficient to

$$\max_{x_t} E[\ln R_t(x_t)], \quad \text{each } t, \qquad (12)$$

that is to solve (10) one period at a time. Note that (10) is equivalent to maximizing the geometric mean of Rt in each period. This model appears to have been independently discovered by Williams (1936), Kelly (1956), Latané (1959), and Breiman (1960).

The long-run growth model has several noteworthy properties. First, the decision rule (10) implies, and is implied by, logarithmic utility of wealth in each period. Thus, it is inconsistent with all (significantly) different preferences (including the mean-variance model). In other words, almost surely having more capital does not imply higher expected utility (or conversely). Various writers have on occasion been confused on this point.

Second, the ‘growth-optimal’ investment policy is not only proportional to initial wealth but (10) implies that it is *myopic*, that is independent of the return distributions beyond the current period (this is true even under returns that are weakly dependent over time). Finally, with relative risk aversion equal to 1, the model tells us that to do well in the long run in terms of capital accumulation, one must be averse to risk; furthermore, both greater and smaller risk aversion almost surely leave one with less capital than logarithmic risk aversion.

Terminal Utility Models

Now consider the case in which the investor’s preferences for wealth w at some (distant) terminal point in time h are represented by the utility function $U_h(w_h)$. Letting w_n be the investor’s wealth with n periods to go, we obtain, under full reinvestment of each period’s proceeds,

$$w_{n-1}(z_n) = \sum_{i=2}^{m} (r_{in} - r_{1n})z_{in} + w_n(1 + r_{1n}),\quad n = 1, 2, \ldots$$

where, for convenience, we set $h = 0$. Defining $U_n(w_n)$ as the maximum expected utility obtainable with w_n, we obtain the recursive equation

$$U_n(w_n) \equiv \max_{z_n} E\{U_{n-1}[w_{n-1}(z_n)]\},\quad n = 1, 2, \ldots \tag{13}$$

Consequently, $U_n(w_n)$ is the derived or induced utility of wealth with n periods to go.

The conditions for the existence of a solution to system (11) are the same as for the singleperiod model; when U_0 has properties (3), so do the induced functions $U_1, \ldots, U_n$. In general, $U_n(w_n)$ depends on all of the inputs: U_0, the joint distribution functions $F_1(r_1), \ldots, F_n(r_n)$, and the interest rates $r_{11}, \ldots, r_{1n}$. There are, however, two special cases. First, when $U_0(w_0)$ belongs to class (5), U_n becomes a positive linear transformation of U_0 so that in effect

$$U_n(w) = U_0(w),\quad n = 1, 2, \ldots$$

Consequently, the optimal investment policy $z_n^*(w_n)$ depends in this case only on the current periods inputs, $F_n(r_n)$ and r_{1n}, and is thus *myopic*. This was first shown by Mossin (1968).

The second special case occurs when interest rates follow a deterministic process. Then, when U_0 belongs to class (7a) with $\phi \leq 0$. U_n depends only on U_0 and $r_{11}, \ldots, r_{1n}$, which is called *partial myopia.* U_n and z_n^* are now given by

$$\begin{aligned} U_n(w_n) &= \gamma^{-1}(w_n + A_n)^\gamma, && \gamma < 1 \\ z_{in}^*(w_n) &= x_{in\gamma}^*(w_n + A_n), && i = 2, \ldots, m, \end{aligned}$$

where $A_n = \phi[(1 + r_{11})\ldots(1 + r_{1n})]^{-1}$. In the other cases of family (7), partial myopia occurs locally, that is for w_n greater than or equal to a (positive) lower bound.

The most interesting aspect of the terminal utility model, however, is a strong set of convergence results (see e.g. Hakansson 1974). Under very general conditions, we obtain from (11) that U_n converges to a member of the isoelastic family (5), that is

$$U_n(w_n) \to \frac{1}{\gamma} w_n^\gamma,\quad \text{some } \gamma < 1.$$

In addition,

$$z_n^*(w_n) \to x_{n\gamma}^* w_n.$$

Thus, we have the remarkable result that reinvesting individuals with distant horizons should follow an isoelastic investment policy independently of their terminal preferences as long as their horizon remains distant.

The Continuous-Time Model

Since transaction costs are zero under the perfect market assumption, it is natural to consider shorter and shorter periods between reinvestment decisions. In the limit, reinvestment takes place continuously. Assuming that the returns on risky assets can be described by diffusion processes, we obtain that optimal portfolios are mean-variance efficient in that the instantaneous variance is minimized for a given instantaneous expected return. The intuitive reason for this is that as the trading interval is shortened, the first two moments of the change in a security's price become more and more dominant (see Samuelson 1970). The optimal portfolios also exhibit the separation property – as if returns over very short periods were normally distributed. Over any fixed interval, however, payoff distributions are, due to the compounding effect, usually lognormal.

Consumption-Investment Analysis

In consumption-investment models, investment is merely a means to an end – future consumption and bequests. Thus, preferences are defined on consumption and bequest programmes, c_1, c_2, $\ldots$, c_n, b_n, where c_t is the *level* of consumption in period t and b_n the bequest at the end of the last period, assuming death occurs in period n. The utility of wealth is therefore not a primitive but must be induced or derived. Preferences may of course be conditional on n and depend on the environment s, in which case they may be written

$$U_{ns}(c_1 \ldots, c_n, b_n), \tag{14}$$

where it is usually assumed that the functions U_{ns} reflect a preference for more to less and are strictly concave. Commonly studied forms of (12) are those in which (12) is additive or multiplicative. When additive and state-independent, (12) may be written

$$u_1(c_1) + u_2(c_2) + \ldots + u_n(c_n) + g_n(b_n).$$

Wealth is now governed by the difference equation

$$\begin{aligned} w_{t+1} = {} & \sum_{i=2}^{m} (r_{its} - r_{1ts}) z_{it} \\ & + (w_t - c_t)(1 + r_{1ts}) + y_{ts}, \end{aligned}$$

where y_{ts} is employment income.

The simplest consumption–investment model is based on just two periods and can profitably be used to study such questions as, 'How does the investor respond to increasing investment risk?' Answer: any which way – see e.g. Rothschild and Stiglitz (1971). In multiperiod formulations, additional issues that must be addressed are the probabilistic nature of the investor's lifespan and the stochastic process obeyed by returns. Dynamic programming formulations of this problem become rather lengthy (see e.g. Hakansson 1970, 1971). The most general models posit a state-contingent opportunity set where the states obey a Markov process.

When preferences are either additive or multiplicative and $u_t(c_t)$ belongs to the family (7a) with $\phi \leq 0$, the separation property is preserved; when $\phi < 0$, $-\phi$ assumes the role of subsistence level. For the family (7b) and (7c), on the other hand, the non-negativity constraint on consumption is generally binding and poses insurmountable problems for the mean-variance model. However, as in the pure reinvestment model, mean-variance efficiency is restored by moving to a continuous-time formulation (Merton 1971).

Portugal, Economics in

António Almodovar and José Luís Cardoso

Abstract

The development of economics in Portugal has been marked by intellectual curiosity coupled with pragmatism. Both characteristics are explained by the long-standing feeling that, although Portugal was lagging in terms of social and economic development, the situation could be overcome by means of an appropriate economic policy. This feeling motivated a continuing effort to find answers to economic and financial problems by careful analysis of other countries' experiences – both the principles discussed by economists and the policies eventually implemented by governments. Portuguese experience thus well illustrates the international diffusion of the ideas associated with different schools of economic thought.

Mercantilism

The first interesting examples of a concern to establish first principles to explain economic reality emerged in Portugal in the 16th century. Extending the spirit of the Discoveries by the early Portuguese explorers to the scantily studied areas of economic knowledge, Portuguese authors showed a certain pioneering spirit. In contrast with former prejudices about the harmfulness of trade, commerce began to be considered as the principal cause of the wealth: commerce dynamically connected the different sectors of economic activity and brought individuals and communities together.

Portuguese economic literature of the second half of the 16th century exhibits innovative analyses with regard to: (*a*) an abstract conceptualization of the market as a space wherein to promote individual and public interests, and as a mechanism to reveal the value of goods exchanged; (*b*) a comparison of the advantages and disadvantages of a monopolistic organization of trading circuits; (*c*) the link between the real and the monetary spheres of the economy and an early version of a quantity theory of money; and *(d)* the doctrinal legitimization of individual gains arising from mercantile activity, for example in the case of exchange and insurance contracts. Handling such different subjects required new ways of thinking. However, in this literature, produced by merchants, theologians and court counsellors, there was no change in the theological and ethical foundations or the method on which the new elements were based. Despite the adaptations needed to interpret the new realities presented by the Discoveries, Portuguese thought continued to rest on moral and religious ideas.

During the period of the dynastic union that for 60 years (1580–1640) kept Portugal under the direct control of the Spanish crown, economic ideas started to be based on the standards of the so-called bullionist literature. However, the political restoration movement that started in 1640 initiated a search for economic strategies for consolidating independence and political sovereignty.

The tactics recommended were varied. Some favoured aiming for either balanced trade or a surplus, others favoured the introduction of monetary regulation (considering an intuitive approach to the relationship between money flows and prices), while yet others favoured the growth of the population to ensure an increase in output and tax revenues. Portuguese authors managed to receive and disseminate, almost simultaneously, different types of foreign contemporary economic literature. They adapted and used analytical constructs and economic policy proposals provided not just by Spanish but also by Italian mercantilists (particularly their proposals regarding population as a means to increase wealth), the English (the balance of trade doctrine and proposals to set up regulated companies for foreign commerce) and the French (manufacturing policy). The policy of protection for manufacturing proposed by Duarte Ribeiro de Macedo (1675), adopted at the close of the 17th century, clearly illustrates this process of assimilating ideas and economic guidelines into a national economic development strategy.

The new commercial framework imposed by the Methuen Treaty with England in 1703 did not silence supporters of this strategy. Protectionism continued to attract support, and contributed to the shaping of an entrenched tradition. During the government of Marquis of Pombal (1750–77), a protectionist economic policy was extensively applied, especially through the establishment of monopolistic companies in both commercial and productive economic activities.

Enlightened Political Economy

From the late 18th century, the development of political economy reflects the wave of economic, social, cultural and political transformations taking place throughout Europe, known as the Enlightenment. During this period, the discourse of Portuguese economists – particularly that represented by the publications of the Royal Academy of Sciences of Lisbon (Cardoso 1990–91) – reveals some familiarity with Physiocratic doctrines and principles. The primary aim of these discourses, which helped create a climate receptive to laissez-faire ideology, was the abolition of the internal barriers and excessive regulations of the *ancien régime,* which were considered as obstacles to the smooth working of the domestic market.

The dissemination of Smithian political economy was furthered by the same concerns, particularly after 1803. The ideas of both Smith and the French Physiocrats were valued as possible guidelines for a successful state-led process of social and economic change; for this reason, the reading that was made of Smith's works in Portugal by J.J. Rodrigues de Brito (1803–1805) and José da Silva Lisboa (1804) focused mainly upon the feasibility of the systems of political economy that were encouraged by François Quesnay and by the *Wealth of Nations.* Aided by Jean- Baptiste Say, Adam Smith was rapidly acknowledged as the true founder of modern political economy.

Notwithstanding the unanimous acknowledgement of the importance of Smith's economic thought in the subsequent spread of classical political economy, which led to its eventual institutionalization as a separate area of study, the English classical school did not have a significant effect on Portuguese economics. As English economic success was undeniable, and as England continued to be Portugal's principal commercial, political and military ally, the lack of a marked preference for English economics may, at first sight, seem strange. However, several factors explain it. Portugal's problematic political and diplomatic circumstances, after the first signs of the Brazilian desire for independence (1814), made it clear that England's support for free trade could be harmful. After this date, a compromise was gradually established regarding the appropriateness of the principles supported by English political economists: Acúrsio das Neves (1814–1817) made a clear distinction between the virtues of domestic liberalization and the need for prudence at the international level. On the other hand, the need to simplify and popularize political economy was seemingly better fulfilled through Continental political economy. Although some French, German and Italian works might be less vigorous analytically, they provided both an explanation and a critical assessment of many of the English school's doctrines.

Given that Continental political economists were as concerned as the Portuguese with the consequences of the English system, it was only natural that they eventually had a greater impact in Portugal than the more specific, abstract ideas of Ricardo and his followers. This is particularly evident in the first discussions regarding the choice of a political economy handbook, for no one suggested the use of an English author. The first attempts to write a Portuguese text were based either on Say's work (Manuel de Almeida) or on Storch's *Treatise* (José Ferreira Borges). In the 1840s, Forjaz de Sampaio (1841) was to write a handbook inspired by the approach developed by Karl Friderich Rau, while Marnoco e Sousa (1910), the most celebrated early 20th-century professor at the University of Coimbra, came under the spell of E.R.A. Seligman.

Establishing a Canon

The overthrow of the *ancien régime* in 1820 in a liberal revolution did not change the previous misgivings about some aspects of classical political economy, particularly those regarding international free trade.

Concern with national economic development, coupled with a suspicion that English political economy was biased in favour of English interests, led to the prevalence of an approach that was quite similar to the one that was later to be developed in Friedrich List's national system of political economy. Between 1820 and 1850, a significant number of Portuguese authors insisted that several principles of classical economic theory and policy were abstruse and therefore inappropriate for steering the development of their own country. As a result, not just the doctrine of free trade but also the theories of population, rent, diminishing returns and the stationary state were dismissed either as wrong or as being solely applicable to the more advanced English circumstances.

When, in 1836, political economy was eventually accepted as an academic discipline, and situated within legal studies, the critical stance regarding the selection of both authors and doctrines to be taught was reinforced. On the one hand, since political economy was mainly taught for the benefit of lawyers, teachers were naturally expected to emphasize the relations between economic laws and legislative action. On the other hand, since they were scholars and not pamphleteers, teachers were meant to adopt an unbiased approach to political economy, not supporting any single school of economic thought. The ensuing eclecticism had the beneficial consequence of allowing for a continuous updating process, teachers such as Adrião Forjaz de Sampaio (between the late 1830s and the early 1870s) or Marnoco e Sousa (between 1900 and 1916) always being ready to mention each and every new school of economic thought that came to their knowledge. This same concern eventually led to significant space being allotted in Portuguese law schools to the study of the history of economic thought.

When coupled with a constant awareness of the national conditions that could make some of the doctrines of political economy unworkable, and a mistrust regarding excessively abstract formulae, this eclecticism also helps us to explain why marginalism and neoclassical economics had less impact than the sociological and historical schools of the second half of 19th century.

The Rejection of Mainstream Economics

At the start of the 20th century, investment in the development of theoretical abstractions was still generally deemed by Portuguese authors not to be an essential part of their role as economists, for they thought that they should concentrate on the task of identifying and solving present economic and social problems. Therefore, even if the conceptual advances made by the marginalist revolution and the theoretical apparatus developed by neoclassical economists both in Europe and in the United States of America did have repercussions, these did not lead to any effort towards furthering economic analysis per se. Jevons was partly translated, and the doctrines of the Manchester, Austrian and Lausanne schools were closely summarized and scrutinized (either approvingly or disapprovingly). But on most occasions, these foundations of the modern canon of economic analysis were laid in Portugal in an eclectic manner, devoid of any noticeable tendency to claim that there were undisputable economic principles (see Almodovar and Cardoso 2001).

In the rare cases where this attitude did not prevail, the reaction was quite vigorous. António Horta Osório (1911) aimed to establish the importance of the mathematical method in political economy in the context of the development of the general equilibrium theory of the Lausanne School.

The Paretian distinction between utility and ophelimity was used by Osório as the foundation of his view of economic science: economics was defined as a disciplinary field restricted to the study of a small part of human behaviour, while psychology was portrayed as the global science pertaining to the study of human action. Consequently, economics would be no more than one of the branches of the general study of mankind. For him, pure economics was an abstract and experimental science which had to evaluate its scientific character, like all the exact sciences, not through the practical utility of its conclusions but chiefly by establishing the exactness of its formal internal logic.

When Osório was writing, the comprehensibility of this methodological attitude was problematic, even for those learned in economic matters, not to mention the fact that general equilibrium in exchange was far from being acknowledged by mainstream economics – something that happened only in the 1930s with the neoclassical synthesis.

In an environment that was clearly unsympathetic both to pure theory, and to any claims for the supremacy of one school, Osório was condemned to oblivion and his book was dismissed. Such an outcome symbolized the reiteration by early 20th century Portuguese economists of traditional views regarding the usefulness and role of political economy. At a time when economics was moving decisively towards establishing itself as a science, Portuguese authors stood aloof from that process. At a time when Portugal's political situation was characterized by a fair degree of cosmopolitanism, economic discourse remained focused on its own political implications, musing on topics of an ideological nature.

From Corporatism to Keynesianism

The traditional Portuguese unwillingness to abide by any single school of economic thought faded away only when faced with the ambitious state-driven project of building up a new type of political economy, that of the corporatist state (see Almodovar and Cardoso 2005).

The political and economic experiment of corporatism represents one of the most interesting stages in the study of the historical evolution of economic thought in Portugal. The corporatist movement in itself is part of the broader movement of authoritarian experiments that took place on the European and international political scene, especially after the First World War. The restlessness of many social and political sectors, which were discontented with the performance of liberal and socialist regimes, paved the way for a search for an alternative to both capitalism and socialism.

Corporatism was therefore offered as a third way between existing regimes, and its supporters claimed that it provided the sole reliable answer to the ongoing social, political and economic turmoil. Portuguese authors like Pires Cardoso and Marcelo Caetano joined their French and Italian counterparts in the effort to develop an economic point of view that could match the ethical and philosophical base provided by the philosophy of Thomas Aquinas. The final outcome was an economic doctrine openly against utilitarianism and in favour of the gradual establishment of a new type of economic agent – the so-called *homo corporativus* – that would be capable of re-embedding social values and aims into its own scale of preferences. This quest did not stop the reception of Keynes, and particularly those ideas that could be seen as a critique of the idea of a self-regulated market and as an appeal to some state intervention in favour of a more socialized economy. Keynes was fairly well-known in Portugal from the mid-1920s onwards. However, the reception and assimilation of the *General Theory* occurred more than ten years after its publication, when Fernando Pinto Loureiro (1948) and Luis Simões de Abreu (1949) published the first extended reviews and digests of J.M. Keynes's major work. Therefore, it was only after 1950, under the impulse provided by the works of António Pinto Barbosa (1950), Jacinto Nunes (1956) and F. Pereira de Moura (1964), that Keynesian concepts began to play a significant role in newly established courses on macroeconomics, public finance, development economics and econometrics.

Despite this process, the reception given to the propositions of the *General Theory* at the political level was ambiguous and much less enthusiastic. One of the most notable aspects of the economic strategy followed in Portugal throughout the 1930s and 1940s was the enactment of legislation to set up industrial companies and to control industrial activity. The basic aim was not just to prevent Portuguese industry from being disturbed by internal or external competition but to keep in check and organize industrial growth and the overall process of economic development. In such a context, where the pace of development was restricted and a balanced budget and the preservation of the country's gold reserves were praised, Keynesian economics could hardly figure prominently.

This vision of economic life was shared by the various political assemblies and executive bodies responsible for directing economic and financial policy. As a result, whenever they incorporated Keynesian ideas, they did so in a watered-down and superficial manner. In fact, it can be said that in the post-war period no type of short- run macroeconomic policy was ever developed: the factors which would normally justify it – such as unemployment and external disequilibrium – did not represent real problems for the Portuguese economy. Something similar occurred in relation to long-run economic policy. The first five-year development plan (1953) was totally insensitive to the assessment of its impact in macroeconomic terms. The second plan in 1958 contained, in the explanation given for its design, projections based on a Harrod–Domar growth model, but this was no more than a rhetorical device.

Throughout the period that we have been considering here, Portuguese economic policy remained faithful to corporatist principles, coupled with a traditional model of empirical, and essentially descriptive, economic studies, without any visible influence of Keynesian concepts.

Concluding Remarks

The first Portuguese university institution created specifically for the teaching of economics was formally founded in 1933. A profound reform of its curricular and pedagogical structure took place in 1949, involving the replacement of essentially technical courses in the fields of commerce, bookkeeping, accounting, customs and diplomatic services with more general courses in economics and finance. Only after that did the full incorporation of a neoclassical approach begin to take place, in the form of a synthesis with Keynesian thought. However, integration into the international mainstream was held back by the resilience of the traditional Portuguese attitude regarding economic knowledge, which was to try to take over the doctrinal and political ingredients that best fitted the search for a specifically Portuguese route to economic development. At all of the most significant moments in the evolution of economic thought in Portugal, we find this attempt to select and adapt existing economic ideas to Portuguese circumstances. Inquisitiveness regarding alternative routes to economic progress, coupled with a pragmatic view regarding economic policy guidelines, favoured a continuous oscillation between schools of economic thought and the emergence of eclecticism. As a consequence, Portuguese economic thinking retained its links with law, ethics, politics, and sociology; and it took a long time to accept the autonomy and analytical competence of economics (see Almodovar and Cardoso 1998).

A further example of the tendency to eclecticism prevalent among Portuguese economists was the impact of the structuralist and developmentalist economic ideas in the 1960s and in the 1970s, through the influence of the Latin American economists concerned with the problems of underdevelopment and with the political responses to overcome it. However, this influence was superseded by the process of harmonization resulting from the democratic revolution of 1974 and Portugal's integration into the European economy in 1986. The considerable institutional changes that then occurred have largely contributed to the smooth reception and institutionalization of both macroeconomic and microeconomic principles and applications. As a result of this integration process, eclecticism has gradually given way to approaches that conform much more closely with the international mainstream.

Positive Economics

Richard G. Lipsey

Abstract

'Positive economics' refers to the view that economic theories consistent with all conceivable observations are empirically empty and that empirically useful theories need to be consistent with existing observations (thus passing the 'sunrise test') and predict something new. It is neither logical positivist, nor operationalist, nor naïve falsificationist; nor is it based on strict dichotomies between positive and normative statements and between positive analysis and normative advice. It rejects the views that theories can assist understanding the world without making refutable statements about it; that theories can be criticized only on their own terms; and that all distinctions inhibit useful discourse.

The term 'positive economics' refers to some specific views about what makes economics a science. According to some of the most influential 19th century English economists, positive economics consisted of propositions or 'laws' concerning real-world events that were derived from intuitively self-evident assumptions. Facts were to be used, therefore, as illustrations of theories, not as tests. To give policy advice, the propositions of positive economics had to be combined with value judgements. An elegant 20th century statement of this view of 'scientific economics' was given by Robbins (1935). Not surprisingly, these economists were, as Blaug (1992) has argued, 'verificationists' who shielded their theories from empirical refutation.

The term was used by such 20th century writers as Friedman (1953) and Lipsey (1963) to refer to what they regarded as scientific economics: non-normative theories whose assumptions were not necessarily self-evident and whose implications were to be judged by empirical observations. Karl Popper provided the methodological underpinning of these works, underpinnings that were either implicit (as in Friedman's case) or explicit (as with most other writers). Terence Hutchison (1938) was the first to introduce Popper's ideas to economists, although he did not describe his work as positive economics. Blaug (1992) and Hutchison (1992) provide excellent formulations of the main tenets of modern positive economics, along with criticisms of both its main detractors and advocates of other views.

Friedman (1953, pp. 7–8) stated the sense in which he understood the term 'positive' when he wrote: 'The ultimate goal of positive science is the development of a "theory" or "hypothesis" that yields valid and meaningful (i.e., not truistic) predictions about phenomena not yet observed. . . .

only factual evidence can show whether it is . . . tentatively "accepted" as valid or "rejected" '. Shortly after my textbook appeared, I wrote:

> I tried to break away from the treatment of economic theory as revealed truth and to emphasize from the outset the very tentative nature of much of our economics . . . to say . . . to the student 'you cannot have both certainty and empirical relevance'.. . . The adjective 'positive' in the title of the book was [partly an allusion to the positive–-normative distinction and] partly an allusion to the distinction between positive (i.e., empirical) Versus a priori methods of judging between theories. (Lipsey 1964, pp. 370–1)

To this end, the concluding chapters in several parts of my textbook discussed 'measurement', 'tests', and 'criticisms' of the theories already presented.

Some Criticisms and Misunderstandings

The history of positive economics at the London School of Economics' Staff Seminar on Methodology, Measurement, and Testing (M^2T seminar) has been well described by de Marchi (1988) – although I disagree with most of his conclusions on pages 162–3. Ours was a crusade for making economic theories empirically relevant and for rejecting intuition as the test of validity, replacing it with empirical testing. Positive economics, as we conceived it, had two main messages. First, if an economic theory is to be about the real world, it must be possible to imagine observations that would be conflict with it. If conflicting observations cannot even be imagined, the theory is compatible with all states of the world and hence empirically empty. A great advance in making theory more relevant would be achieved if today's editors insisted that each author state what factual observations would conflict with his or her theory, and, if there were none, to state the theory's purpose. Second, a new theory should be compatible with ('explain') some existing facts and suggest some new one(s).

We were subject to misunderstandings, as well as to criticisms, from those who disagreed with our main message. Here are some of the most influential.

1. Its philosophical base was thought by many critics to be logical positivism, which we rejected in favour of Popper's methodology.
2. Samuelson (1948) was partly responsible for another confusion when he stated a similar view on testability but espoused a version of operationalism. We never took an operationalist position, arguing only that *all* those parts of a theory that did say something empirically should be open to empirical testing. Subsequently, Wong (1978) argued – correctly in our view – that, since even such simple 'entities' as prices and quantities are theoretical concepts that do not exactly correspond to real-world entities, theories cannot be expressed solely in operational terms.
3. Friedman set off a long debate on the testability of assumptions that helped to discredit positive economics to many. We disagreed with Friedman, arguing that, if empirically correct predictions were deduced from a set of empirically false assumptions, this called for further serious study, not complacency. See Blaug (1992, pp. 91–7) for a full discussion.
4. Contrary to the tenets of positive economics, Friedman used his essay on methodology to dismiss monopolistic competition as adding nothing that could not be learned from a judicious combination of perfect competition and monopoly. That this was not our position was shown when this, and similar arguments of others in the Chicago school, were criticized by members of the M^2T seminar (Klappholz and Agassi 1959; Archibald 1961).
5. We were accused of being naive falsificationists. Although we may have been at the outset, we soon refined our position as a result of experience and accepted that 'we cannot get a categorical disproof of an hypothesis' (Lipsey 1975, p. 46), which statement was followed by a long passage on what can be learned from apparent refutations. Another member of the M^2T seminar, Archibald (1967), argued that empirical testing could at best establish the balance of probabilities between two conflicting theories rather than refuting either categorically. We did not, however, as implied by de Marchi (1988, p. 162)

P

give up on positive economics just because we abandoned naive falsification; indeed, many of us went on to do significant empirical work.

6. Some critics argued that positive economics was merely what Mark Blaug calls 'conformatism', asking only that a theory be consistent with known facts. From the very outset we accepted Popper's criticism that theories that explained only already known facts were being subjected to a 'sunrise test' from which we could only learn that the theorist was ingenious enough to build a theory that jumped through predetermined hoops.
7. Others argued that we naively accepted the earlier economists' strict dichotomy between positive and normative statements. We quickly discarded this view. Lipsey (1963, p. 4, n. 1) introduces a discussion of this matter thus: 'Philosopher friends have persuaded me that when pushed to its limits, the distinction between positive and normative becomes blurred or breaks down completely.' However, the blurring did not stop us from arguing that the ability to distinguish what one thinks is true from what one would like to be true is critical to all science.
8. In a similar but not identical vein, yet others argued that we naively accepted the strict division that the earlier economists had made between positive economic analysis and normative advice. My first exposure to policy advising in 1962 disabused me of that idea. As I later put it: 'The economic adviser and the policy-maker are involved in a complex human relationship, entangled in various uncertainties and communicating with each other through an inevitable haze of emotional reactions. Economists may strive towards an ideal of communicating their knowledge as objectively as possible, but objectivity remains an ideal that guides their actions, not a reality that fully describes them' (Lipsey 1981, p. 35). For detailed discussions of the history of the distinction.

We rejected many other methodological approaches that were either implicit or explicit criticisms of positive economics, of which the following are examples. First was the view of many pure theorists, such as Hahn (1984, pp. 44–5), criticized by Blaug (1992, pp. 164–5) and Hutchison (1992, p. 43), that theories can somehow add to our understanding of the world without making testable statements about it. Second, there was the view subsequently articulated by Caldwell (1982) that falsification is too strong and that we can criticize each school of thought only on its own terms. As Hutchison pointed out, this amounts to rejecting in principle any method of discriminating between alternative theories. Third, in reaction to the view that all distinctions inhibit full discourse, we maintained that distinctions help to structure arguments and, without them, there is anarchy of discourse.

Positive Economics Today

What is the fate of positive economics today? While many economists pay lip service to the view that economic theories should make testable predictions about the world and that the ultimate arbiter of different theories is empirical evidence, many research programmes do not show this as their revealed preference. Theoretical articles that do no more than state and pass sunrise tests abound.

The modern version of industrial organization has had most of its empirical content eliminated. Students who used to learn institutional material about such 'practical' matters as competition policy, and who studied empirical information about scale effects and entry barriers, often today know little more than game theory. (See Lipsey 2001, for full discussion.)

The new formalism has given rise to the belief among some theorists (although not typically among those who do game theory) that the more general a theory is, the better it must be. But this assumption ignores the fact that the more general a theory is, the less empirical content it is likely to have since, by ignoring the specific context in which many problems arise, it becomes impossible to analyse them in depth. (See Hodgson 2001, for a full discussion.) One set of examples, criticized at length in Lipsey et al. (2005, pp. 466–7), is found in those modern growth theories that use an aggregate production function devoid of institutions or anything that distinguishes economies with various degrees of development.

Not a few theories are devoted to explaining mere possibilities. Typically someone develops a simple ‘Mark I model’ on some matter such as the effects of rent controls and draws strong policy conclusions from it; someone else comes along with a Mark II model saying ‘if I add some not implausible complexity, the model’s predictions and policy conclusions are altered’. Then someone does the same to the Mark II model, and so on. (For a case study see Lind 2007.) Although it is possible to learn something from all exercises, this sort of research programme tells us little more than that very simple and more complex theories on the same issue do not usually have identical predictions.

Many research programmes are ‘internally driven’, by which I mean that they are driven by their own internal logic. Investigators seek to understand problems created by the models that they are using rather than deriving their problems from observations. In contrast, an ‘externally driven research program’ (EDRP) is one that is driven and constrained by observed facts. A perusal of the literature will show IDRPs to be at least as common as EDRPs. (For examples, see Lipsey 2001.)

On a personal level, the revolution that I tried to create in textbook writing through *An Introduction to Positive Economics* has slowly dwindled – in spite of its being the dominant text book in the UK for decades, being widely used throughout the Commonwealth, and having significant sales in its US adaptation, initially co-authored with Peter Steiner. As a result of constant criticism from teachers who wanted to present only mainline economics, the criticism and testing chapters were slowly eroded – much faster in the US editions than in the UK ones. Today, all too many modern theory textbooks at all levels, from basic to advanced, present current economic theories as if they were revealed truth, paying little attention to controversies and alternative theories.

Finally, I ask what the real successes of positive economics are. As already mentioned, most economists pay a least lip service to the ideal that economic theories are meant to tell us something about the real world through potentially testable hypotheses. The journals are full of empirical observations, many of which are extremely useful – although many others are used in the non-informative types of theory mentioned earlier. In some empirically oriented fields, such as economic history and labour economics, the ideal of positive economics does come close to realization. For example, much work in labour economics seeks to establish empirical relations, such as those between the characteristics of a person’s schooling and his or her lifetime earnings. It is a matter of taste whether one interprets these studies as hypothesis testing or just establishing statistical relations, but either way they are important.

So the ideas of positive economics are still present – more strongly in some fields than in others – though many economists reject them, as shown either explicitly by their methodological pronouncements or implicitly by their research practices.

Positivism

Bruce Caldwell

Abstract

The article identifies the major tenets of logical positivism and its successor, logical empiricism, two important movements within 20th-century philosophy of science. It then documents some of the arguments that led to the decline of positivism in the latter half of the 20th century. The impact of positivist ideas on the work of economists writing about economic methodology is examined in a final section.

Positivism and the Philosophy of Science

The term 'positivism' was coined in the second quarter of the nineteenth century by one of the founders of sociology, Auguste Comte. Comte believed that human reasoning passes through three distinct historical stages: the theological, the metaphysical, and the scientific. In the theological stage, natural and social phenomena are explained by reference to spiritual forces. In the metaphysical stage, 'ultimate causes' are sought to explain such phenomena. In the scientific stage, attempts to explain phenomena are abandoned, and scientists seek instead to discover correlations among phenomena (Comte 1830–1842). Another important figure in the development of *classical positivism* was the physicist Ernst Mach (1886), who propounded a 'fictionalist' view of theories. Scientific theories are useful mnemonic devices, but progress in science occurs only when such useful fictions are replaced by statements which contain only observation terms. Though both Comte and Mach had some influence on the writings of economists (Comte influenced J.S. Mill and Pareto, Mach was mentioned in passing by Samuelson and Machlup), their primary influence was on the ideas of certain twentieth century philosophers of science, the logical positivists.

Logical Positivism

The major tenets of *logical positivism* were developed in the 1920s by Moritz Schlick, Herbert Feigl, Kurt Gödel, Hans Hahn, Otto Neurath, Friedrich Waismann, Rudolf Carnap and other members of the famous Vienna Circle. Logical positivism was a radically empiricist philosophical position, and its founders believed it marked a new beginning for philosophical inquiry. The goal of all philosophical analysis was henceforth to be the logical analysis of the knowledge claims of the positive, or empirical, sciences: hence the label 'logical positivism'.

The first task facing the logical positivists was to define what constitutes a knowledge claim. Their solution was to analyse the logical form of statements. Only statements that are either analytic (such as definitions) or synthetic (testable statements of fact) qualify as cognitively significant, or meaningful. All other statements lack cognitive significance: they are meaningless, metaphysical, non-scientific. Analyses that make use of such statements may express emotional stances, or 'general attitudes towards life', or moral valuations, but they do *not* express knowledge claims.

To put their programme into operation, the logical positivists needed an objective criterion of cognitive significance which could be used to distinguish synthetic statements from meaningless ones. One early solution was the principle of verifiability: a synthetic statement has meaning only if it is verifiable. Unfortunately, statements of universal form (for example, 'all ravens are black'), which are frequently encountered in science, are unverifiable. Other criteria included falsifiability, Ayer's weak verifiability, Carnap's translatability into an empiricist language, and confirmability. None of these was able to resolve the problem conclusively, however. Another dilemma was posed by the presence of theoretical terms in statements made by scientists. Some positivists followed Mach in insisting that they should be eliminated from science, while others argued that such statements should be retained. A final element of the logical positivist programme was an emphasis on the unity of science, variously defined as meaning that all true sciences share a common method, that the results of all sciences should ultimately be expressible in a common physicalist language, or that the results of the various sciences should be integrated, better to assist the scientific planning of society.

Logical Empiricism

Hahn died in 1934, and Schlick was murdered in 1936 by an insane student. But it was Hitler's rise to power, and the subsequent flight of intellectuals, that primarily caused the disintegration of the Vienna Circle in the 1930s. Logical positivism was modified and ultimately replaced over the next two decades by a more analytically austere form of positivist thought, *logical empiricism.* Though differences exist in their analyses, philosophers who have contributed to this later tradition include Carnap, Ernest Nagel, Carl Hempel and Richard Braithwaite.

There were six major tenets of the logical empiricist programme. First, the *unity of science thesis* was narrowed to mean only a unity of scientific methods. The next three had to do with the structure and appraisal of theories. The *hypothetico-deductive model of theory structure* states that all sciences employ theories, which may be represented formally as axiomatic, hypothetico-deductive structures. Such structures have no empirical import until some of their elements (usually the deduced theorems, or predictions of the theories) are given an empirical interpretation via the use of correspondence rules. Not every statement will have an empirical interpretation. Those containing theoretical terms, in particular, will not be interpretable. Are such sentences then meaningless? Not at all; according to the *indirect testability thesis* such sentences gain cognitive significance indirectly when the theories in which they are embedded are confirmed. Finally, concerning the questions of demarcation and theory assessment, logical empiricists settled on *confirmationism* as their primary criterion of theory appraisal. A theory is scientific if it is testable; test instances confirm or disconfirm the theory; the acceptability of the theory depends on its degree of confirmation. Degree of confirmation is measured by such things as the quantity and precision of favourable test outcomes, the precision of procedures of observation and measurement, the variety of supporting evidence, and whether new test situations support the hypothesis. Additional non-empirical criteria of appraisal (for example, simplicity, elegance, fruitfulness, generality, extensibility) may also be invoked if theory choice on empirical grounds yields no preferred theory. The last two tenets of logical empiricism concerned the logic of scientific explanation. All explanations in science must be expressible in the form of a deductive argument in which an explanandum, a sentence describing the event to be explained, is logically deduced from an explanans. The explanans contains a group of sentences, some of which express initial conditions, and at least one of which states either a general or a statistical law. The *deductive-nomological* and *inductive-probabilistic covering law models of scientific explanation* take their names, then, from the types of laws (general or statistical) used in the explanations. Additionally, logical empiricists believed in the *symmetry thesis*: explanation and prediction are structurally symmetrical, the only difference between them being one of temporality. In the case of an explanation the phenomenon described in the explanandum has already taken place, whereas in the case of a prediction it has not yet occurred.

As documented in Suppe (1977), logical empiricist ideas (sometimes dubbed 'the received view') came under heavy attack in the mid-twentieth century. The viability of both the hypothetico-deductive model of theory structure and the indirect testability thesis depended on one's ability to draw a clear distinction between observational terms (terms that refer to observables, to 'brute, atomic facts') and non-observational, theoretical terms. Unfortunately, in many sciences there are degrees of observability, and no hard division can be drawn between theoretical terms that refer to non-observables and non-theoretical terms that refer to observables. Furthermore, because observation itself is not a neutral activity but requires both data selection and interpretation, it was argued (by critics like Karl Popper and Norwood Hanson) that all observation is theory-dependent. Regarding confirmationism, the failure to solve Hume's problem of induction and a number of paradoxes of confirmation undercut attempts to construct an inductive logic of confirmation. In addition, Popper (1959) challenged the desirability of making statements that have a high inductive probability. Finally, many explanations in a variety of sciences could not be reconciled with the two covering law models of scientific explanation.

The Naturalistic Turn

The influence of positivism within the philosophy of science declined considerably through the 1960s and 1970s. As noted by Hands (2001), its apparent successor has been dubbed the *naturalistic turn,* an approach that, rather than laying out a priori criteria for identifying appropriate scientific practice, instead employs the tools of the sciences themselves to investigate scientific practice. There are, of course, many different scientific disciplines from which to draw such tools; some that have been used are cognitive psychology, evolutionary biology, sociology, and economics. Depending on which scientific practice is analysed, reflexivity issues may appear (for example, in using economic analysis to explain the development of economics and the behaviour of economists). Other important issues facing the naturalistic turn are choosing among the various tools on offer, and deciding whether the ensuing analysis has prescriptive implications in addition to descriptive merits. Another movement that has had less impact in philosophy of science proper, but great influence in a number of sciences including economics, derives from the work of Karl Popper. A critic of inductivism and confirmationism, the father of falsifiability and of critical rationalism, Popper had sufficient insight, foresight and longevity to influence a number of generations of philosophers of science, among them J. Agassi, W.W. Bartley III, P.K. Feyerabend and Imre Lakatos. Within economics, the work of T.W. Hutchison (for example, 1997), Mark Blaug (1992) and Lawrence Boland (2003) most directly reflect Popper's influence, while that of Wade Hands (1993) and Bruce Caldwell (1991) reflect a critical reappraisal.

In the 1990s an historical dehomogenization of the writings of the logical positivists of the Vienna Circle began. A rehabilitation of Otto Neurath, whose anti-foundationalism, advocacy of pluralism, and emphasis on scientific practice led many to see him as a precursor of the naturalistic turn, was the most notable result (Uebel 1991). Some historians and philosophers also praised his willingness to advocate the scientific planning of society and of science, to employ the philosophy of science as a tool in the restructuring of society. For these interpreters, the emergence of a more austere logical empiricism in the 1950s represented not a scientific advance but a retreat to more neutral formalism in response to the ideological pressures of McCarthyism and the cold war (for example, Reisch 2005). This interpretation parallels Philip Mirowski's (2002) historical account of the development of formalism in economics during the same period.

Positivism and Economics

There are various ways to describe the influence of positivist thought in economics.

If one focuses on the period in which positivist philosophy of science was invoked by economists, the positivist epoch spanned roughly 40 years, from the late 1930s to the late 1970s. This is not to say that during this period economists self-consciously adopted the philosophical positions outlined above. As shown in Caldwell (1994), what in fact occurred was that certain economists writing about methodology borrowed, usually somewhat haphazardly, from the language of positivism, while others invoked various positivist positions to defend or to criticize theories and practices in economics.

Four economists from this period whose writings most reflect the influence of positivism are T.W. Hutchison, Fritz Machlup, Paul Samuelson, and Milton Friedman. In the 1938 book, *The Significance and Basic Postulates of Economic Theory*, Hutchison launched an empiricist attack on the pure logic of choice, a doctrine that had been espoused and defended by Lionel Robbins 6 years earlier in his *The Nature and Significance of Economic Science* (1932). For more than 50 years, Hutchison was to continue to criticize all forms of economics that were based on untestable foundations, his targets ranging from the apriorism of Ludwig von Mises to the elaborate mathematical models of general equilibrium theory. Fritz Machlup offered one response to Hutchison with his 1955 paper, 'On the problem of verification in economics', where he invoked the indirect testability thesis to defend the use of theoretical constructs in economics against what he dubbed Hutchison's 'ultra-empiricism.' In the Introduction of his *Foundations of Economic Analysis,* Paul Samuelson (1947) borrowed from the work of physicist Percy Bridgman when he insisted that economists search for operationally meaningful theorems. The intent of Samuelson's revealed preference approach to demand theory was to place consumer theory on an observational basis. Finally, Milton Friedman's influential 1953 piece 'The methodology of positive economics' contained the famous argument that the realism of the assumptions of a theory is irrelevant; what counts in the assessment of a theory is its relative predictive adequacy and its simplicity. Though Friedman's unique brand of instrumentalist methodology owes more to the American pragmatists than to positivism, his approach came to be viewed as synonymous with positivism through the 1950s and 1960s.

Though economists today rarely invoke positivist philosophy of science in defending their preferred practices, there is plentiful evidence of its continued influence, mostly in terms of what is considered to be 'appropriate' or 'legitimate' practice, with 'positivist' often being equated with 'truly scientific'. Thus, important areas like game theory and transactions cost analysis initially encountered substantial opposition from mainstream economists because such analyses, though rich in terms of explaining diverse economic phenomena, often did not produce the sort of testable hypotheses demanded by positivist doctrine. (Strangely, during its period of dominance, general equilibrium theory was much less affected by such critiques.) Similarly, the positivist belief in the cumulative development of science tends to render less important both heterodox approaches to the discipline and the study of doctrinal history. Finally, the insistence on defining progress in terms of 'the discovery of law-like relationships' or 'better predictive ability' has fuelled a sustained growth in data collection and in computing power, the development of new econometric techniques, and a staggering increase in empirical studies. That all this has resulted in at best meagre progress (see Backhouse 1997) in establishing robust economic 'laws' and in improving forecasting power has typically engendered not a reassessment of the goals but a redoubling of resources committed to reaching them, with the attendant opportunity costs. It will be interesting to see what the entry on 'positivism' in the third edition of *The New Palgrave* reveals about its legacy in economics.

Post Keynesian Economics

J. E. King

Abstract

Post Keynesian economics is a dissident school in macroeconomics based on a particular interpretation of Keynes. A brief intellectual history of Post Keynesian ideas is provided, along with a discussion of some important methodological questions. Three short-period macro models are outlined: Paul Davidson's aggregate supply–aggregate demand model, Michal Kalecki's two-class model, and Hyman Minsky's financial instability hypothesis. The Post Keynesian approach to economic growth is shown to focus on the expansion of aggregate demand, with a distinctive approach to monetary, fiscal and other dimensions of macroeconomic policy. In conclusion the future prospects of Post Keynesian economics are assessed.

Post Keynesian economics is a dissident school of macroeconomic thought based on a particular interpretation of John Maynard Keynes's *General Theory of Employment, Interest and Money* (1936).

Post Keynesian economics developed in the 1950s and 1960s in Cambridge (UK) and in the United States in the course of a critique of the so-called 'neoclassical synthesis' (sometimes also described as Old or Bastard Keynesianism). It represents both a recovery and an extension of Keynes's ideas (Palley 1996): a recovery, because Post Keynesians believe that the neoclassical interpretation of Keynes is profoundly misleading, and an extension, since they deal with important questions that Keynes neglected or ignored, including income distribution, social conflict, economic growth and inflation. Post Keynesian economics involves a distinctive approach to methodology, theory and policy (Holt and Pressman 2001; King 2003).

At the heart of Post Keynesian theory is the principle of effective demand, according to which output and employment are generally demand-constrained rather than supply-constrained. Post Keynesians claim to take the principle of effective demand more seriously do than mainstream macroeconomists, even those who describe themselves as 'Keynesians'. For Post Keynesians, demand constraints upon output and employment are not restricted to short period and are not the result of market imperfections or wage and price rigidities, but must be explained instead in terms of the characteristics of money and the pervasive influence of fundamental uncertainty. The six central messages of Keynes's vision may be summarized as follows. First, output and employment are determined in the product market, not in the labour market. Second, involuntary unemployment exists. Third, an increase in savings does not automatically generate an equivalent increase in investment. Fourth, a monetary economy is fundamentally different from a barter economy. Fifth, the quantity theory of money holds only under full employment, but cost-push forces may generate inflation well before this point is reached. Sixth, capitalist economies are driven by the 'animal spirits' of entrepreneurs, which determine the decision to invest (Thirlwall 1993).

It follows that Say's Law is false, and capitalism will normally not achieve or sustain full employment without government intervention. Post Keynesians therefore advocate the systematic use of fiscal and monetary policy to regulate aggregate demand, and deny the policy ineffectiveness propositions of mainstream macroeconomics. They advocate prices and incomes policies, rather than restrictive monetary policy, to control inflation.

A Brief Intellectual History

The origins of Post Keynesian economics may be traced back to the publication of the *General Theory* in 1936, since Keynes's masterpiece was open from the outset to alternative interpretations (King 2002). One of them, the IS–LM model developed by J. R. Hicks, James Meade and others, subsequently formed the core of the neoclassical synthesis model of output and employment in the short run. However, the Cambridge (UK) Post Keynesians, including Richard Kahn, Nicholas Kaldor, Joan Robinson and Piero Sraffa, directed their early criticisms against the long-run component of the neoclassical synthesis, the Solow growth model, in which full employment was ensured by capital–labour substitution along a well-behaved aggregate production function. The 'Cambridge capital controversies' of the late 1950s and early 1960s demonstrated the analytical failure of neoclassical growth theory, and were an important episode in the emergence of the Post Keynesian school (Mata 2004). Subsequently Robinson, Kaldor and the American Sidney Weintraub attacked the monetarist theory of inflation, emphasizing the causal role of the rate of change of money wages and arguing that monetary growth was the effect of inflation, not its cause. Kaldor, Weintraub and another American, Paul Davidson, were early advocates of the theory of endogenous money (Kaldor 1970).

Robinson conducted a lengthy correspondence with yet another American dissident, Alfred Eichner (Lee 2000). When, in December 1971, she gave the keynote Richard T. Ely lecture at the American Economic Association meeting in New Orleans to a large and enthusiastic audience, the defeat of the orthodox paradigm seemed to be only a matter of time (Robinson 1972). By the mid-1970s the term 'Post Keynesian' was widely used to describe the emerging school of thought (Eichner and Kregel 1975), which had broadened to include a systematic critique of the neoclassical synthesis. The IS–LM model was rejected, since uncertainty and animal spirits rendered the IS curve unstable, and endogenous money undermined the LM function. The Phillips curve model of wage inflation was rejected in favour of a socio-political analysis of distributional conflict and its resolution in a class society where capitalists enjoyed product market power and workers were highly unionized. And the marginal productivity theory of income distribution, discredited in the capital controversies, was replaced by a macroeconomic model that focused on the different savings propensities of capitalists and workers, or companies and households.

The critique of Chicago School monetarism was soon extended to New Classical Economics ('monetarism Mark II'). Post Keynesians objected to the principle of rational expectations, since it ignored the existence of fundamental uncertainty, and they denied the claim of Lucas and his associates that fiscal and monetary policy could have no effect on output or employment. They saw only slightly more merit in New Keynesian

Economics, with its emphasis on market imperfections as the source of all macroeconomic problems. More was involved than disagreements on economic theory; important methodological and policy issues were also at the heart of these criticisms.

The mainstream never accepted the Post Keynesian critique. Orthodox Keynesian macroeconomists like Robert Solow accused the Post Keynesians of incoherence; they were united, he suggested, only by what they were against. Insiders distinguished three Post Keynesian schools, the Kaleckians, the Sraffians and the 'fundamentalist Keynesians', with a number of prominent individualists who belonged to none of them (Harcourt 1987; Hamouda and Harcourt 1988). Divisions remain on the respective virtues of a 'big tent' and a 'small tent' definition of Post Keynesianism.

In 2006 Post Keynesians were a small, embattled minority, strongest in France, Italy and a few institutions in the United States (especially the University of Missouri at Kansas City), with outposts in Britain and Australia. They published in a range of heterodox journals, especially in the *Journal of Post Keynesian Economics*, founded by Davidson and Weintraub in 1977, in the *Cambridge Journal of Economics, Journal of Economic Issues and Review of Political Economy.*

Methodology

As is common with dissenting schools of thought, Post Keynesians have always recognized the importance of methodology. They have been strongly influenced by Keynes's philosophical writings (O'Donnell 1989), identifying with his insistence on 'open-system thinking' and organic rather than atomistic models of human behaviour, his distrust of formalism (and of econometric modelling in particular), and his belief that economics was nothing if not a policy science – or an art, perhaps.

On many specific methodological questions, Post Keynesians stress their differences with the mainstream (Dow 1996). They doubt the relevance of equilibrium models, which fail to allow for cumulative causation, the role of history or the importance of hysteresis. Their emphasis on uncertainty leads them to reject the 'rational expectations' principle and to assert the importance of habit, convention and social institutions in the formation of business expectations. Post Keynesians criticize the mainstream insistence that 'microfoundations' must always be provided for macroeconomic theory, because this denies the existence of emergent properties of macro systems that cannot be inferred from their micro components, and thus involves a fallacy of composition. Microeconomic theory needs *macrofoundations*, they maintain. Finally, Post Keynesians take a quite distinctive approach to long-run theory. Since the principle of effective demand applies in the long run, no less than in the short run, Post Keynesian growth theory stresses the role of demand as a determinant of economic growth, and does not impose a condition that resources (including labour) are always fully employed, and output constrained solely by supply, in the long run.

Many (though not all) Post Keynesians are attracted by *critical realism* as a unifying methodological position (Lawson 2003). There are many points of contact, including the critical realists' endorsement of open-system thinking; their denial of 'event regularities' of the type needed if standard econometric estimation techniques are to be generally reliable; and their stress on the importance of ontology and the identification of causal processes and mechanisms as the key to explanation in social science. Critical realism has become a significant point of contact between Post Keynesians and other schools of heterodox economic thought.

Macroeconomic Theory: The Short Period

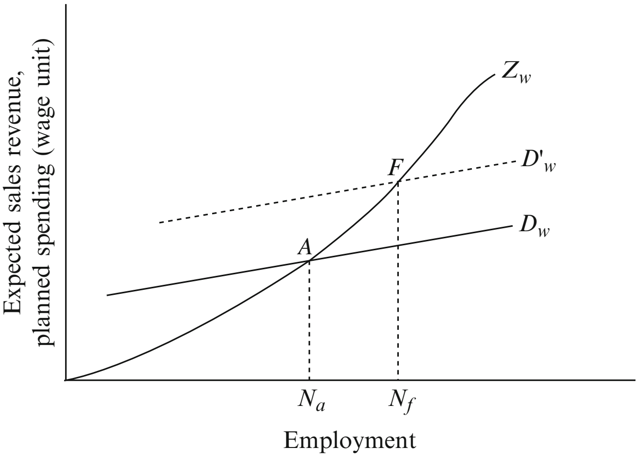
The short-period theory of output and employment is the core of Post Keynesian macroeconomics. In the short period, the capital stock is held constant. This is done purely for analytical convenience; there is no presumption that the theory of effective demand is irrelevant to the long period, when the accumulation of capital is brought into the analysis. Thus the Post Keynesian treatment of the short and long periods must be distinguished from the neoclassical analysis of the 'short run' (in which demand matters) and the 'long run' (when it does not).

There is no single canonical short-period Post Keynesian model. The three most influential models are those of Paul Davidson, Michal Kalecki and Hyman Minsky, which differ in some important respects. They are not, however, entirely incompatible. All agree on the central role of the principle of effective demand; the defects of the IS-LM model; the importance of uncertainty, money and finance (this is largely implicit in the Kalecki version, and quite explicit in the other two); the consequent repudiation of rational expectations; and the policy implications, which include the need for government intervention to stabilize the economy and to maintain full employment. They differ on some questions of microeconomics (there is no question of providing microfoundations), on the detailed treatment of money and finance, and most obviously on the social and political context, above all on the class-driven or class-blind nature of the analysis.

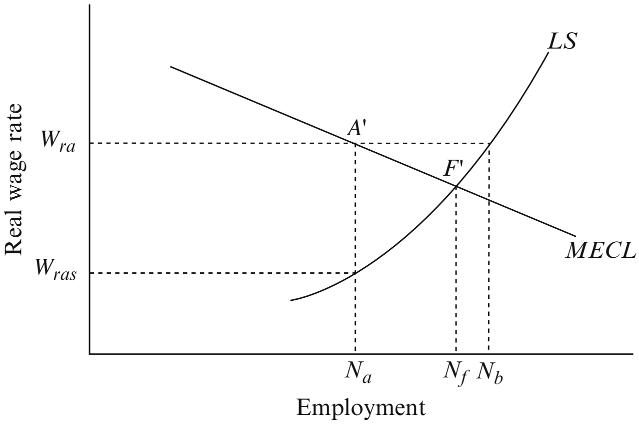
The Fundamentalist Keynesian Model

This is an elaboration of the aggregate supply-aggregate demand model set out by Keynes himself in the early chapters of the *General Theory* (Keynes 1936, ch. 3). (Note that this is emphatically *not* the textbook model in price level/real output space, which is a teaching version of the neoclassical synthesis and would be repudiated by all Post Keynesians.) Originating in the 1950s with Weintraub, it has been propagated tirelessly over several decades by Davidson in a series of books beginning with *Money and the Real World* in 1973 and culminating in *Financial Markets, Money and the Real World* (Davidson 2002). In Fig. 1 the aggregate supply function Z_w links total employment to total expected sales; it slopes upwards since total costs of production (including gross profits) increase as employment rises. The aggregate demand function D_w does not coincide with Z_w, as it would in an economy where Say's Law prevails. It, too, slopes upwards, as planned spending also rises with employment. The point of effective demand is A, where the two curves intersect, and aggregate employment is given by N_a. The labour market implications are illustrated in Fig. 2 (which, like Fig. 1, comes from Davidson 1999, not directly from Keynes). Employment is determined in the product market, in Fig. 1. The real wage can be established from the market equilibrium curve of labour-hire (MECL) in Fig. 2; it is W_{ra}. Davidson emphasizes that MECL is *not* the labour demand curve; employment depends on aggregate demand and is therefore determined in the product market, not the labour market. Involuntary unemployment is N_aN_b; it is not due to (real or money) wage rigidity, but to deficient effective demand.

Post Keynesian Economics, Fig. 1 Aggregate supply and demand (*Source:* Davidson (1999, p. 582))



Post Keynesian Economics, Fig. 2 Wages and employment (*Source:* Davidson (1999, p. 582))



For full employment to be achieved, the aggregate demand curve would need to shift to D'_w, increasing employment to N_f, with a movement from A to F in Fig. 1 and a corresponding move from A' to F in Fig. 2. Without such a shift there will be no increase in employment, no matter how willing workers might be to accept a cut in either money or real wages. In fact Fig. 2 reveals that W_{ras} is the reservation wage of the marginal unemployed worker, but in the absence of an adequate level of effective demand this is simply not relevant.

Underlying Keynes's model, Davidson argues, is a rejection of the three fundamental axioms of mainstream macroeconomics. The *axiom of ergodicity* asserts that the future can be reliably inferred from the past. The *axiom of gross substitution* asserts that flexibility in relative prices will ensure that all markets clear. The *neutral money axiom* ensures that changes in the stock of money have no permanent effects on real output or employment. Non-ergodicity creates radical uncertainty, which induces people to hold money; since goods are not perfect substitutes for money, money is not neutral, even in the long run, and Say's Law is false. The non-neutrality of money does not require 'money illusion' on the part of any agent. Involuntary unemployment is not the result of wage or price rigidity, and can be eliminated only by increases in effective demand. Wage reductions will prove futile, or even counter-productive (since deflation depresses business and household confidence and increases real interest rates).

The Kaleckian Model

Michal Kalecki discovered the principle of effective demand in the 1930s independently of Keynes under the influence of Rosa Luxemburg and, through her, of Karl Marx. The class distinction between capitalists and workers, which is only implicit in the *General Theory,* occupies centre stage in Kalecki's analysis. In place of a single consumption function, there are two. Workers save nothing from their wages, while capitalists save a constant proportion of their profit income. Kalecki's famous aphorism that 'capitalists get what they spend, while workers spend what they get', can be derived from the simple income-expenditure model set out in his 1939 *Essays in the Theory of Economic Fluctuations* (1990, pp. 233–318), itself an elaboration of his 1933 model of the business cycle (1990, pp. 65–108). In the simplest case, if we neglect both the government and the foreign sector, total wage (W) and profit (P) income is equal to the sum of consumption expenditure by workers (C_w) and capitalists (C_c) plus investment spending (I):

$$W + P = C_w + C_c + I. \tag{1}$$

Since $W = C_w$ by assumption, it follows that

$$P = C_c + I, \tag{2}$$

so that profits are equal to the sum of capitalists' consumption and investment expenditure. If investment is a positive function of expected profits, which are themselves closely related to recent past profits, this leads directly to a demand-driven model of the trade cycle. If we incorporate the government and overseas sectors, eq. (1) can be replaced with

$$W + P + T + M = C_w + C_c + I + G + X \quad (3)$$

where taxes (T) and imports (M) are added to the income side of the equation and government expenditure (G) and exports (X) to the expenditure side. It follows that

$$\mathrm{P} = C_c + I + (G - T) + (X - M), \quad (4)$$

so that capitalists profit from both government deficits ($G – T$) and trade surpluses ($X – M$).

Unlike Keynes, Kalecki had no time for the marginal productivity theory of distribution. In his model the share of profits in total output is determined by the degree of monopoly in the product market. Outside agriculture, oligopoly rather than perfect competition is the rule. Firms set prices by marking up their average variable costs of production, the markup varying inversely with the degree of competition that they face. This, Kalecki argues, establishes a strong tendency for a chronic deficiency in effective demand, since the wage share will normally be too small (and the profit share too high) to generate enough consumption expenditure to maintain full employment. This aspect of Kalecki's analysis was emphasized by 'left Keynesians' like Josef Steindl and the neo-Marxists Paul Baran and Paul Sweezy in their work on *monopoly capital.*

Kalecki also highlights the class nature of capitalist society in the context of macroeconomic policy. Capitalists will resist deficit-financed spending by the government, even though it might be expected to increase total profits. This is only partly due to an unthinking attachment (encouraged by orthodox economists) to the principles of sound finance. It has more rational roots in their concern to avoid competition from state-owned enterprises, and more especially in their well-founded fear that full employment will prove inconsistent with 'discipline in the factories'. As early as 1943 Kalecki was predicting the emergence of a *political business cycle,* in which fiscal and monetary policy is repeatedly eased before elections and tightened (under pressure from business interests) soon afterwards (Kalecki 1990, pp. 347–56). In the 1950s, viewing the Cold War from his native Poland, he criticized the 'military Keynesianism' of Western governments – capitalists had welcomed demand-boosting armaments spending while resisting more socially useful civilian expenditures.

The Financial Instability Hypothesis

The Kaleckian model is characterized by a relative neglect of money and finance. Hyman Minsky's version of the short-period Post Keynesian model quite explicitly aimed to put finance back into business cycle theory (Minsky 1986). His 'Wall Street vision' of capitalism focuses on the relationship between investment bankers and their customers, by contrast with the 'village fair' conception of exchange between individual small producers that underpins mainstream theory. Like Davidson and Kalecki, Minsky sees fluctuations in investment expenditure as the principal cause of economic fluctuations. The investment decisions of capitalists are constrained by their ability to pay for them, and this is conditioned by lenders' estimates of their ability to repay. Minsky distinguishes three phases of the cycle. In the immediate aftermath of a crisis lenders are very cautious, and accommodate only those borrowers who can demonstrate an ability to service their loans and repay the principal on time; this is the phase of *hedge finance.* As the upswing gathers pace, and memories of previous difficulties begin to fade, it becomes possible to borrow for more questionable projects, where interest payments are covered by expected profits, but not repayments of principal; this is the phase of *speculative finance.* In the final stages of the boom caution is thrown to the winds and lenders now provide *Ponzi finance* (the term is derived from a notorious early 20th-century swindler): new borrowing is now required to enable borrowers to make interest payments on previous loans. When lenders' confidence collapses, borrowers are unable to obtain refinance and are forced to sell securities and other assets at 'fire sale' prices. In the ensuing financial crisis, real investment falls and the economy moves into recession. The early stages of recovery are again characterized by the provision of hedge finance, and so the cycle repeats itself, over and over again. Memories are short, and expectations are far from rational.

Rather late in his career Minsky discovered Kalecki, and added the Kaleckian theory of profits to his own model. This gave him a theory of firms' financial resources to set against his original analysis of their financial commitments, and reinforced the policy implications that he had drawn from the financial instability hypothesis. It can be seen from eq. (4) that aggregate profits are increased by higher budget deficits, and reduced by fiscal conservatism. Deficits, then, are good for business. There is a stock dimension as well as a flow dimension to this conclusion. The United States financial system was much less fragile after 1945 than it had been in 1929, Minsky argued, in large part because of the cumulative impact of wartime and post-war deficits. The huge growth in the federal government debt had provided the private sector with massive quantities of risk-free government securities, thereby rendering their asset portfolios much more robust than they had previously been. Minsky was therefore a supporter of big government. He also advocated tight and intrusive regulation of financial markets, and argued that central banks should recognize their duty to act as lender of last resort to Wall Street, no matter how much this increased the dangers of moral hazard. But he doubted whether the inherent instability of the capitalist economy could ever be completely overcome.

Some Comparisons

The similarities between these three models are much more important than their differences, especially when they are contrasted with the 'new consensus' model of mainstream macroeconomics. There are no 'microfoundations', and certainly no attempt is made to ground the analysis in any form of multi-period utility-maximizing model of general equilibrium under rational expectations. This is ruled out by the non-ergodicity axiom in the Fundamentalist Keynesian model, and by the cyclical myopia of borrowers and lending institutions that is central to the financial instability hypothesis (Kalecki's analysis of 'lender's risk' and 'borrower's risk' has affinities both with Minsky and with Keynes's treatment of fundamental uncertainty). There are no 'representative agents': capitalists and workers in Kalecki, borrowers and lenders in Minsky (and bulls and bears in Keynes's analysis of liquidity preference) are structurally and behaviourally heterogeneous. Deflation is viewed as part of the problem – a very important part, at least for Minsky – not as the solution to macroeconomic difficulties. Cyclical fluctuations originate in the private sector, due to the volatility of business investment decisions, not in the policy errors of the public sector. And government intervention is essential to 'stabilize an unstable economy', to paraphrase the title of Minsky's last (1986) book – though neither he nor Kalecki minimized the obstacles that it would encounter.

These are not the only short-period Post Keynesian models, though they remain the most influential. They are, it must be repeated, all inconsistent with the 'new consensus' in macroeconomics, which can be encapsulated in three equations. Post Keynesians dispute all three. They reject the aggregate demand curve, on the grounds that interest rates are less important, and uncertainty-induced shifts in the curve much more important, than the mainstream is willing to admit. They are equally critical of the Phillips curve, since it neglects socio-political institutions and denies any role for class conflict over income distribution. And they criticize the Taylor rule that underpins the monetary policy response function, as it uses a single instrument (the short-term interest rate) instead of many to influence the wrong objective (output price inflation instead of employment, neglecting asset price inflation). More will be said about Post Keynesian thinking on money and inflation in a later section.

Macroeconomic Theory: The Long Period

In the *General Theory* Keynes analysed the effects of investment in a short-period model in which, by definition and purely as a simplifying assumption, the capital stock was held constant. 'Generalising the *General Theory*' to the long period, Post Keynesian theories of capital accumulation take as their starting point the Harrod–Domar growth model (which Kalecki extended further to apply to socialist economies). There is no requirement that capital or labour are fully employed or that the growth path will be stable; this can be expected, as Robinson put it in her *Accumulation of Capital* (1956), only in a mythical 'golden age'. The Cambridge capital controversies demonstrated that the neoclassical adjustment mechanism – capital–labour substitution in response to changes in relative factor prices – is not in general a reliable one. Differences between the actual, equilibrium (or 'warranted') and maximum possible (or 'natural') rates of growth might be eliminated through changes in the average propensity to save induced by changes in income distribution. But, Post Keynesians maintain, there are no grounds for supposing that effective demand is unimportant in the long period, or for the neoclassical belief that economic growth is entirely supply-determined.

There are a number of Post Keynesian models of demand-driven growth (Setterfield 2002). All of them invoke 'Say's Law in reverse', according to which aggregate supply (and potential output) responds to the growth of aggregate demand (and actual output). *Kaldorian* models treat exports as the only truly exogenous source of demand and highlight the balance of payments constraint on economic growth, which is especially (but not exclusively) relevant to developing economies. *Kaleckian* models focus on the connection between wages, consumption and aggregate demand, adding to the familiar *paradox of thrift* (in which an increased propensity to save reduces income and keeps the volume of saving unchanged) a *paradox of costs,* in which an increase in the real wage increases workers' consumption, raises the level of capacity utilization and thereby leads to a higher rate of profit. Finally, there are models of *transformational growth* associated with Luigi Pasinetti and Edward Nell, in which capital accumulation is inextricably linked to structural change. Once again attention is concentrated on demand conditions; this time, however, it is investment demand that plays the crucial role.

These Post Keynesian growth models are all radically different from neoclassical theories, including both the canonical Solow model and the more recent 'New' or 'endogenous growth' models (though they share with the latter a denial of diminishing returns in the manufacturing and advanced service sectors). The Post Keynesians assert the continuing importance of the principle of effective demand and the irrelevance or reversal of Say's Law, since in the long period demand tends to create its own supply. They have no truck with marginal productivity theory or with the use of aggregate production functions of any description.

There are connections between Post Keynesian growth theory and the treatment of capital accumulation in other heterodox traditions, especially the radical-Marxian focus upon the class nature of capitalist society, the critical role of the profit rate and the instability of the capitalist growth path. Equally, the emphasis placed in evolutionary and Schumpeterian theory on the role of entrepreneurs, the importance of finance and the cyclical nature of growth is fully consistent with the Post Keynesian approach.

Post Keynesian Microeconomics

Post Keynesian microeconomics is relatively underdeveloped. There are methodological reasons for this, since (as we have seen) Post Keynesians reject the neoclassical requirement that rigorous microfoundations be provided for macroeconomic theory. Although microeconomics is not needed as the basis for serious macroeconomic thinking, Post Keynesians are nevertheless highly critical of many aspects of mainstream microeconomic analysis, including the modelling of equilibrium, the elimination of uncertainty by expressing all relevant magnitudes in certainty-equivalents, and the reliance on identical or 'representative' rather than heterogeneous agents.

As in macroeconomics, in their microeconomics Post Keynesians are concerned with the real world, and insist that formal models must bear a close relation to the 'stylized facts' of modern capitalism. Thus Post Keynesian pricing theory (Lee 1998) addresses itself to the large oligopolistic corporation, not to an imaginary world of perfect competitors. Drawing on the work of Kalecki, Philip Andrews, Gardiner Means, Paolo Sylos-Labini and Alfred Eichner, it models the formation of *administered prices,* with firms first adding a markup to their variable costs of production and then selling as much as they can given the prevailing demand conditions. Prices increase only if costs rise, or under quite exceptional demand pressure. This also provides a Post Keynesian theory of income distribution, since the average degree of monopoly, which determines markups, is the most important determinant of the income shares of wages and profits. Changes in the degree of monopoly have other macroeconomic consequences, for both inflation and aggregate demand.

Post Keynesian consumer theory is still in its infancy. It places more emphasis on income effects than on substitution effects and replaces the neoclassical axioms of rational choice with a theory of lexicographic preferences where habit, custom and social convention are important constraints on individual behaviour (Lavoie 1992, pp. 61–92). The full implications for labour supply decisions have yet to be fully worked out. In their microeconomics Post Keynesians have drawn heavily on insights from other more or less heterodox schools of thought, especially institutional and evolutionary economics. Much remains to be done to extend and deepen Keynes's early exploration of the role of habit, conventions, bounded rationality and rules of thumb in individual and corporate decision-making. The lack of a distinctive Post Keynesian welfare economics is a particularly important weakness, which has hindered the emergence of a coherent approach to environmental issues (Winnett 2003).

Economic Policy

There is, however, a very clear Post Keynesian position on matters of macroeconomic policy. Since Say's Law is rejected, in both the short period and the long period, the principle of effective demand is the foundation for monetary and fiscal policy. This leads Post Keynesians to a broadly social democratic position, not far removed from that of the Old Keynesian advocates of the 1950s–1960s neoclassical synthesis. Thus they favour big government, since it is more likely than small government to be able to stabilize the level of economic activity and achieve full employment. Post Keynesians worry much less about state failure than about market failure. Unlike both Old and New Keynesians, however, they are very clear that market imperfections, and the associated wage and price rigidities, are not at the root of macroeconomic problems. There is no point in using an imaginary world of perfect competition as a reference point. Deflation, even if it were practicable, would be undesirable and counter-productive. Increased inequality is also likely to have adverse macroeconomic consequences, notably if the Kaleckian 'paradox of costs' applies, so that stabilization policy need not conflict with the imperatives of social justice. Post Keynesian rejection of neoliberal policies carries over to a comprehensive critique of the 'Washington Consensus' on policy for developing countries. At the same time Post Keynesians are not Stalinists; they aim to make markets work better, not to eliminate them. This, they argue, requires wide-ranging government intervention, with a number of macroeconomic targets and a variety of instruments.

Monetary Policy

Post Keynesian thinking on monetary policy developed out of opposition to monetarism in the early 1970s and to the policy prescriptions of New Classical macroeconomics in later years. Post Keynesians insisted that, since money was endogenous, the stock of money was not a control variable or a feasible policy instrument. Thus monetary policy must necessarily operate via central bank control over the (short-term) rate of interest, and would inevitably have consequences for output and employment as well as for the inflation rate. In this they were proved to be entirely correct, and they are entitled to view the treatment of monetary policy in the 'new consensus' as a vindication of the Post Keynesian critique. However, they also criticize the Taylor rule on the grounds that it is aimed at the wrong target and relies upon a single, very blunt instrument. There is a strong case, they argue, for reviving prices and incomes policy to combat the danger of inflation, using monetary policy to target and output and employment, asset price inflation and financial fragility. Post Keynesians regard stock market and housing bubbles, and rising levels of household and corporate debt, as serious problems that need policy solutions. No single-instrument approach to these problems will succeed. Alternative instruments include the (re)introduction of direct controls over lending, the tightening of financial regulations, and more market-friendly measures such as asset-based reserve requirements that would operate as a tax on types of lending that the authorities wished to discourage. Post Keynesians have been particularly critical of the highinterest policy adopted by the European Central Bank and the apparent absence of a lender of last resort within the Eurozone.

Fiscal Policy

Post Keynesians are no less critical of recent mainstream thinking on fiscal policy. Here the Old Keynesian principle of *functional finance* has given way to the pre-Keynesian principle of *sound finance,* which is invariably interpreted as requiring balanced budgets in the short run and fiscal consolidation (budget surpluses, and a reduction in government debt) in the long run. For Post Keynesians, the principle of effective demand should govern fiscal policy, and governments should run deficits, or surpluses, or (exceptionally) balanced budgets, depending solely on the macroeconomic requirement of achieving full employment with an acceptably low inflation rate. Some would go further in the direction of 'unsound finance', since in the Kaleckian short-period model permanent deficits mean permanently higher business profits and hence higher – not lower – levels of investment expenditure; private spending is *crowded in* by government spending, not crowded out. Hyman Minsky added a stock dimension to this argument: the government debt accumulated as the sum of past deficits serves to render private sector balance sheets more robust and thus to reduce the danger of financial instability. The European Union's 'Stability and Growth pact' is in fact a recipe, Post Keynesians argue, for stagnation and instability.

Prices and Incomes Policy

Post Keynesians deplore the way in which one entire area of macroeconomic policy has disappeared completely from the mainstream agenda: prices and incomes policy is no longer taken seriously as an anti-inflationary instrument, and indeed is rarely discussed. In the 1960s and 1970s Post Keynesians led the way in proposing innovative alternatives to deflationary monetary and fiscal policies, including the tax-based incomes policy proposed by Wallich and Weintraub (1971) and more centralized neocorporatist social agreements that worked well for many years in much of northern Europe (Cornwall and Cornwall 2003). Weaker unions, reduced levels of industrial conflict and much lower rates of wage and price inflation have reduced the attraction of measures such as these, but Post Keynesians regard them as a valuable policy resource should the inflation dragon once more rear its ugly head.

Other Policy Issues

On questions of international economic policy Post Keynesians tend to be sceptical of the benefits of unregulated free trade and free capital movements (Blecker 2003). Many regard floating exchange rates as a major source of macroeconomic instability, urging instead a reconsideration of Keynes's ambitious plans for an International Clearing Union (Davidson 2002; Milberg 2003; Vernengo 2003). For the long period they focus on demand-side policies for economic growth and criticize the deflationary bias of the structural adjustment programmes imposed on developing countries by the international financial institutions. As already noted, there is no specifically Post Keynesian welfare economics, so that there is also no genuinely distinctive position on most microeconomic issues (including environmental questions, industry policy, labour market regulation and antitrust). However, their social democratic sympathies do tend to bring Post Keynesians close to the institutionalist or 'left neoclassical' position on many of these questions.

Assessment and Prospects

In the 1970s many Post Keynesians believed that mainstream economics was in a state of Kuhnian crisis, with the very real prospect of a paradigm shift in their favour. This confidence proved to be misplaced, and by the first decade of the 21st century Post Keynesian economics had been thoroughly marginalized. This had something to be with the sociology of the profession, which displayed an increasing intolerance of alternative perspectives and methods of research. Some Post Keynesians suspected that they had to share part of the blame, since there was some truth in the accusation that the Post Keynesian church had become too broad, with a message that was lacking in coherence. Part of the problem was that the mainstream itself had changed, with the New Keynesians adopting some Post Keynesian positions (for example on endogenous money and the consequent rejection of the LM schedule) while rejecting many others. New Keynesian economics offered a rather less clear target for Post Keynesian criticism than the neoclassical synthesis, or monetarism, or New Classical economics. Subsequent developments in 'behavioural macroeconomics' and 'post-Walrasian theory' confused the picture still further, making the oppositional character of Post Keynesian economics less easy to define. The future relationship between Post Keynesianism and heterodox economics more generally was also unclear, with familiar fault lines developing here, too, between sectarians and pluralists. For all that, Thirlwall's (1993) six propositions with which this entry began are clear enough, and important enough, to provide a secure intellectual future for this unusually persistent and perceptive dissenting minority.

B31

M.M. Postan, who was born in Tighina, Bessarabia, in 1899 and who died in Cambridge in 1981, was one of most distinguished economic historians of the 20th century. After briefly studying natural sciences and sociology at the University of St Petersburg he moved on to study law and economics at the University of Odessa, and then at the University of Kiev. He came to England in 1920 and between 1921 and 1926 took his first degree, his MA, and his Ph.D. at the London School of Economics. Between 1927 and 1937 he held lectureships, successively, at University College, London, at the London School of Economics, and at Cambridge University. In 1938 he was appointed to succeed Sir John Clapham in the chair of economic history at Cambridge, a position he retained until his retirement.

A specialist in medieval economic history, Postan originally made his reputation during the late 1920s and early 1930s on the basis of his studies on medieval trade and finance. His joint volume, with Eileen Power, Studies in English Trade in the Fifteenth Century (1933), became a standard work. He also published such seminal articles as ‘Credit in Medieval Trade’ (1928) and ‘Recent Trends in the Accumulation of Capital’ (1935).

From the later 1930s, Postan began to present his own distinctive interpretation of long-term trends in the medieval economy. In ‘The Chronology of Labour Services’ (1937) and ‘The Rise of the Money Economy' (1944) Postan advanced devastating critiques of the hitherto-dominant unilineal evolutionist interpretation of pre-industrial European economic development, as advanced by distinguished medievalists such as Henri Pirenne. According to that view, it was the more or less steady expansion of commerce which drove the European economy forward, leading first to the decline of serfdom, next to the differentiation of the peasantry and the rise of agrarian capitalism, and ultimately to the growth of manufacturing and modern industry. Postan showed, in contrast, that trade, in itself, could as easily lead to the strengthening of the old, pre-capitalist forms as to their dissolution. He illustrated his point with a detailed discussion of the fluctuations of labour services in medieval England, showing that they rose and fell in direct proportion to lordly demands for labour and, in particular, that demesne production grew, serfdom was intensified and labour services increased in precisely those areas of the country which were most commercialized and most exposed to the London market. Postan also pointed out that the spectacular rise of serfdom in late medieval and early modern Europe took place in large part in response to the rise of the international grain market.

In his 1950 report to the Ninth Congress of Historical Sciences, Postan put forward the initial version of his own population-centred interpretation of medieval economic history as an alternative to the trade-centred interpretation. In this and later work, Postan demonstrated that the pre-industrial economy of Europe was marked by a succession of long cycles of demographically driven expansions and contractions, following a basically Malthusian dynamic. He then went on to argue, in Ricardian fashion, that during the up phase of these cycles declining returns in agriculture (declining productivity) determined rising rents, falling wages, and terms of trade running in favour of agricultural and against industrial goods, while in the down phase, rising returns in agriculture determined just the opposite trends. Postan's interpretation followed lines which had begun to be sketched by the German demographic historian Wilhelm Abel and it influenced, in turn, the work of the French agrarian historian of the early modern period, Emmanuel Le Roy Ladurie. By the later 1950s, Postan's demographic view already had been so widely accepted as the key to the interpretation of pre-industrial economic change, that H.J. Habakkuk could reasonably conclude, in a synthetic essay on 'The Economic History of Modern Britain' for the *Journal of Economic History* in 1958, that

> For those who care for the overmastering pattern, the elements are evidently there for a heroically simplified version of English history before the nineteenth century in which the long-term movements in prices, in income distribution, in real wages, and in migration are dominated by changes in the growth of population.

Postan further developed his interpretation in a long series of specialized studies on all aspects of the medieval economy – agricultural technique, agricultural investment, the legal status of the peasantry, and so on – as well as in a number of major syntheses. In all these works, he remained guided by the conviction that the best results would come by linking, as closely as possible, generalizations derived from economic theory with the results of exhaustive primary research.

Postlethwayt, Malachy (1707–1767)

William Darity Jr.

Malachy Postlethwayt gave vent to the most comprehensive expression of mercantilist thought on behalf of British imperial interests. Fay (1934, p. 3) justifiably called Postlethwayt, alongside Joshua Gee, a major 'spokesman' for 18th-century England. Postlethwayt's mercantilist vision emphasized (1) the slave trade to Africa and slavery in the Caribbean as vital stimuli to development of British manufactures; (2) the Royal African Company as an instrument of management of 'the African trade'; (3) the necessity of competition with France for control of the slave trade; and (4) the general principle that government must promote trade and industry.

His monumental *Universal Dictionary of Trade and Commerce*, 20 years in the making before its first edition was published in instalments over the interval 1751–55, included an entry entitled 'Africa', summarizing his views on the relationship between African slavery and British industry. Despite acknowledging the brutality of the trade and allusion to some future date when a 'Christian spirit' might be moved to end the trade, Postlethwayt was wholly pragmatic. After all, he concluded, the gains for Britain from the slave trade were substantial – being a 'trade (that) is . . . all profit' and a trade that 'occasionally gives so prodigious employment to our people both by sea and land'.

This perspective resonated throughout Postlethwayt's pamphlets (see his *Selected Works*). Sir James Steuart may have been the 'last' British mercantilist, but he certainly was not the purest. For that we must turn to Postlethwayt, whose vision was undiluted by vestiges of humanitarism.

Although foreign trade, with the slave trade as a key component, was Britain's engine of growth for Postlethwayt, there was great breadth in the matters he viewed as relevant to British economic development. Scientific and technical advances, maintenance of low or zero interest rates (see Viner, 1937, p. 47), sport and leisure (Dorfman, 1971, p. 7), the public debt (Johnson, 1937, pp. 190–5), agricultural policy (Johnson, 1937, pp. 196–201), maintenance of low wages, and development of securities markets were among the many factors he identified as influences on the rate of economic expansion. Nevertheless, the overseas 'plantations' or 'colonies' lay at the heart of Postlethwayt's mercantile system, and, for Postlethwayt, full development of the plantations required slaves. Indeed, Postlethwayt's writings provided compelling evidence for Eric Williams's view in *Capitalism and Slavery* (1944) that British mercantile strategists were aware of slave-trading and slavery's ramifications as a spur to British industrialization.

Postlethwayt's *Universal Dictionary* (4th edn, 1774) purported to be a translation of Jacques Savary's *Dictionnaire universal du commerce*, but as Schumpeter (1954, pp. 156–7) noted, it was really much more. Nevertheless Schumpeter (p. 372, n.15) viewed Postlethwayt as a writer whose name survived despite 'substandard performance'. Schumpeter added that E.A.J. Johnson's careful bibliographic efforts 'reduced to its proper proportions the charge of plagiarism that has been frequently leveled against Postlethwayt, though the case remains bad enough' (Schumpeter, 1954, pp. 156–7). But Johnson himself concluded that his efforts 'relieve[d] Postlethwayt, at least partially, from an ill-founded charge' (Johnson, 1937, p. 405). Nonetheless, substantial portions of Richard Cantillon's *Essai* first appeared in English in Postlethwayt's *Dictionary* (Higgs, 1905, pp. ix–xiii) without acknowledgement.

Postlethwayt apparently sought, with mixed results, to become a well-heeled sycophant to British royalty through his work (Johnson, 1937, pp. 186–7). Johnson even speculated that Postlethwayt may have been a paid agent of the Royal African Company. He died abruptly in relative poverty in 1767 and was buried in Old Street churchyard in the Clerkenwell section of London. It is probable that he was the brother of James Postlethwayt, author of a major history of British public revenue.

Postmodernism

M. Klaes

Abstract

Postmodernism resists encyclopaedic definition. On the level of economic phenomena, debates have centred on postmodernity as a separate historiographic period. On the conceptual level, the work of prominent economists has been argued to resonate with postmodernist themes. Certain parts of behavioural and experimental economics have begun to display key postmodernist features. A small selfconsciously postmodernist literature draws from economics, literary criticism, and Continental philosophical traditions in its analysis of economic phenomena.

Keywords

Animal spirits; Choice theory; Computational functionalism; Critical rationalism; Economic modernism; Enlightenment; Experimental economics; Keynes, J. M.; Postmodernism; Rhetoric of economics; Becker, G. S.; Rhetoric of economics; Methodology of economics; Relativism

JEL Classifications

B4

Postmodernism is a concept that escapes encyclopedic definition, to the extent that mischievous commentators have described postmodernists as a club of individuals who tacitly collude in a refusal to collectively define what postmodernism is about. This should strike a chord with any economists: who have been accused of leaving central notions such as market, firm, competition or equilibrium ill-defined (for example, Coase 1937; Clower 1995), despite having good grounds for doing so (compare Popper 1945: p. 18).

On the level of economic phenomena, debates have centred on whether or not one can consistently speak of postmodernity as a separate historiographic period. Advocates of postmodernity in this epochal sense assume that profound changes in the constitution of contemporary society have brought an end to the modern period, the close of which has variously been located from the last quarter of the 19th century to the last quarter of the 20th century. On the conceptual level, it has been argued that the work of several prominent economists, including Keynes (1936) and Becker (1976) for example, resonates with postmodernist themes. Broader strands of research in economics have begun to display key postmodernist features, most notably as a result of critical examination of the notion of the rationally unified individual. A small, selfconsciously postmodernist literature draws from economics, literary criticism, and Continental philosophical traditions in its analysis of economic phenomena.

Postmodernity

The postmodern found its initial motivation in postmodernity viewed as a historiographic category, commonly attributed to Arnold Toynbee (for example 1954, pp. 234–8). Toynbee suggested that the modern period in Western history, as the period immediately following the Middle Ages, had come to an end by the 1870s. He associated modernity with social stability, Enlightenment rationalism and progress. A 'post-Modern' period in turn was characterized by social unrest and the collapse of rationalism. This cultural pessimism in regard to the advent of the postmodern propagated by Toynbee and others contrasts with positive assessments of the move from industrialization to a post-industrial knowledge economy, where new technologies would replace ideology as key drivers of social change (for example, Toffler 1970). Both the culturally pessimistic and optimistic views share the acceptance of postmodernity as a particular historical phase with a distinct set of postmodern or 'late capitalist' socioeconomic features, a perspective which has found its apex in neo-Marxist stage theories of capitalist development (Mandel 1975; Jameson 1991).

The postmodern as a historiographic category rests on an epochal interpretation of history, which assumes that historic junctures separate adjacent periods. Many historians are not prepared to accept that modernity has been superseded by a qualitatively different period however. Interpreting the postmodern as 'post modernity' suffers here from the limitations that plague epochal categorization in general. To the extent that sceptics of postmodernity are not in fact sceptics regarding epochal categories and historiographies, they face a dilemma. They can either argue that modernity is the end of history (Fukuyama 1992), or propose an alternative successor to it. But how can one conceive of such alternatives as anything else than a particular interpretation of 'post modernity'?

Postmodern authors seek to avoid being trapped in binary oppositions of this kind. The work of Jean-François Lyotard, for example, has served as a prominent point of reference. His *Postmodern Condition* (1979) defined modernity in terms of a style of thought or epistemological outlook characterized by grand 'meta-narratives' centred on the ideas of scientific progress and individual emancipation, or the rationalist Enlightenment project *tout court*. Inverting these characteristics, Lyotard associated the postmodern with fragmented personal identities and a pervasive heterogeneity and indeterminacy of knowledge. But by doing so, he in fact affirmed the ahistorical dimensions of an ultimately bimodal categorization of contemporary society. The 'postmodern' turns thus into the less well-recognized face of the modern: '[p]ostmodernity is not a new age, but the rewriting of some of the features claimed by modernity . . . [T]hat rewriting has been at work, for a long time now, in modernity itself' (Lyotard 1987, p. 34).

Postmodernist Economics

In contrast to other social sciences, the notion of a postmodernist kind of economics has only relatively recently begun to gain currency, both as a label for the work of several prominent economists, including Keynes (1936) and Becker (1976) for example, and in terms of methodological features displayed in several strands of current research. To speak of postmodernist economics along these lines requires a concept of economic modernism to begin with. Largely unrecognized, two different understandings of economic modernism have sprung up, with different implications for the understanding of postmodernism in economics.

Economic modernism has been understood either as the manifestation in economics of modernism more generally understood as a widely recognized 20th-century socio-cultural style, or as the methodological face of modernity epochally conceived (see above). As a socio-cultural style, modernism is commonly thought to have flourished in the early 20th century, although, depending on the particular context, its influence may be traced from the late 19th century to the first decade of the 21st century and quite likely beyond it (compare Weston 1996). Across fields as diverse as literature, painting, music, architecture and design, proponents of modernism have questioned individual identity, displayed profound scepticism towards realist accounts of the world, and embraced dissonance and uncertainty as defining aspects of social life, developing ever more sophisticated forms of representation and a display of formal technique. What the many guises of modernism share is a profound reaction to the conditions of modernity.

In contrast to this avant-garde notion of modernism as the pursuit and transcendence of the limits of modernity, the concept of modernism first entered economics in a more restricted and conservative way, encapsulating a rejection of the methodological face of modernity. Economists by and large see themselves as adhering to the broad outlines of a critical rationalist methodology. This 'official' methodology of economics has been characterized by some methodologists as 'modernist', in the sense that it is committed to a belief in scientific progress through the formulation and empirical testing of hypotheses, to the rational actor paradigm, and to mathematical formalism (McCloskey 1983; Dow 1991).

Most economists will, of course, find these assumptions innocuous. It is thus no coincidence that economic modernism, in the sense described, is typically employed by authors who dissent from the 20th-century neoclassical tradition in economics. Samuelson's (1939) article on the multiplier–accelerator model, itself a central contribution to Keynesian business cycle theory, has been cited as a *pièce de résistance* in this regard, illustrating the modernist spirit underlying the neoclassical school (Klamer 1995). The article covers barely four journal pages. Packed with mathematical notation, tables and graphs it keeps discursive elements to a minimum. Compared with Samuelson's treatment of the business cycle, Keynes's (1936) original analysis engages in an exuberance of narrative in his explanation of the business cycle, coming to a head in the well-known passages of Chap. 22 of the *General Theory.* Keynes's portrayal there of the uncertainties of the world of markets as being beyond the reach of rational analysis and containable only within a domain of 'animal spirits' (though channelled by social conventions) has prompted some authors to regard these aspects of his work as indicative of important postmodernist currents in 20th-century economics (in particular Ruccio and Amariglio 2003, Chap. 2), which reflect concerns comparable to the appreciation of the heterogeneity and indeterminacy of knowledge as it can be found in the work of Lyotard (1979), for example.

Reading the work of the mature Keynes as an expression of postmodern currents in the economics of the 1930s requires us to regard the neoclassical orthodoxy of that time as the prime manifestation of economic modernism, thereby allowing a rapprochement between dissenting schools of thought and a postmodern kind of economics. Not all who have identified postmodern aspects in economics have found compelling the association of economic postmodernism with dissenting, and of economic modernism with consenting, approaches vis-à-vis a putative mainstream, however. Characterizing Keynes's work as postmodernist can be challenged on historiographic grounds along the lines discussed above in the context of epochal interpretations of the postmodern. Moreover, this characterization rests on interpreting economic modernism as the methodological face of modernity. If modernism is instead understood as a broadly based early 20th-century socio-cultural style, there are good grounds for regarding the *General Theory* and other works of Keynes as a prime expression of economic modernism (Klaes 2006).

Rather than depicting it as a caricature of orthodox approaches in economics, the appreciation of an economic modernism in its own right may help to account for a range of departures from the neoclassical tradition in early 20th-century economics, including both Keynes's *General Theory* and the work of Samuelson and others who were at the forefront of the formalist turn in economics. Conversely, postmodernist dimensions in economics may be sought not only in dissenting approaches, a point most prominently expressed by Jameson (1991, pp. 263–71), who argues that Becker's (1976) work, in its treatment of children, companionship and health as conventional commodities, displays a deep affinity with the postmodernist notion of consumption as an all pervasive cultural pattern, sharing the ambition of reducing all human interaction to market exchange.

Decentred Economic Selves

As an illustration of how close contemporary theorizing in economics has come to key postmodernist concerns, let us consider how individuals are portrayed in economics. According to Davis (2003), there no longer exists a coherent account of the individual in contemporary economics following its de-psychologization and reduction to a rational preference ordering. With no concept of the individual beyond this ordering, choice theory has become equally applicable to individual persons and supra-person individuals like firms. Increasingly, however, economists also entertain the possibility of multiple sub-person objectives, with fascinating challenges to the notion of a unified economic self (for example, Schelling 1984).

Ever since the publication of Berle and Means (1932), economists have been attuned to the split personality of multi-person individuals. Senior management follow their own objectives that do not necessarily coincide with the objective function of the corporation. A similar line of argument can be applied to the notion of a coherent self. At the sub-person level we may well consist of a range of competing selves. The de-psychologization of the individual in economics leads therefore to a postmodern critique of integrated individual identities.

Economists have begun exploring the implications of a decentred economic self (Kavka 1991; Steedman and Krause 1986), which rests on the proposition that the market without is matched by a market within. Warding off a postmodernist disintegration of the unified self amounts to solving the internal 'social choice' problem through the imposition of a dictator. To the extent that the internal and external worlds of choice are formally equivalent however, this literature has revealed a curious asymmetry whereby the desirability of dictatorial solutions to the internal choice problem is taken for granted in the same vein as its undesirability regarding the external choice problem is taken for granted in economics.

Upon closer inspection, choice theory exhibits further postmodernist dimensions. Pursuing his basic argument from another angle, Davis (2003) suggests that economics, in its rejection of early neoclassical subjectivism, has subscribed to computational functionalism in its conception of the abstract individual. Computational functionalism, as a theory of mind, holds that brain states are computational states of mental algorithms, and that two individuals share the same type of mental state if they function in a causally equivalent way in respect of their physical environment. The abstract individual is therefore a preference computing algorithm, boundedly rational or not, that can be implemented in different entities without prejudice as to whether these entities are individual human beings, particular 'modules' within a human brain, economic institutions such as firms and markets, or non-humans (animals, machines and other 'aliens').

Mirowski (2002) has cast this ontological indifference of the economic individual in respect of its range of potential actualizations (human decision-makers, various subsets of brain tissue, animals, computers, and so forth) into the postmodern motif of the cyborg, a cyber organism that is half man and half machine. Recent work in experimental economics has unwittingly come up with an interesting illustration of this proximity between man and machine: on the level of convergence and efficiency, double auction behaviour of experimental subjects and computational agents programmed as random number generators turns out to be rather similar (Gode and Sunder 1993). The cognitive capacities of market participants matter much less than the market algorithm itself. This allows the provocative suggestion that markets use us simply as pawns to further their algorithmic life, with the possibility of endogenous evolution of cyborg-like market automata in a decidedly post-humanist and thereby postmodernist fashion.

While postmodernist dimensions become apparent in a range of current strands of research in economics once they are read with an eye sensitive to debates in other social sciences and the humanities, self-consciously postmodernist work in economics has remained relegated to its fringes (see the collections by Woodmansee and Osteen 1999; Cullenberg et al. 2001; and Zein-Elabdin and Charusheela 2004). Its most influential impetus has come from the rhetoric of economics tradition. Initially concerned with the rhetoric found in the texts of academic economists, rhetoricians of economics have generalized their approach to include economic conversation more generally conceived (McCloskey 1994, pp. 367–78). Prices are carriers of information only because they are part of a conversation. Entrepreneurs succeed only if they can persuade others to provide the capital necessary for turning their inventions into marketable products, which only sell if consumers can be persuaded to buy them. Stock markets epitomize this conversational feature of economic life (see Shiller 1989, p. 56, 387).

The resulting suggestion, of reading the economy as a text (Brown 1994), leads to the prospect of a postmodernist economics that approaches the economy on the premise that all economic texts should be treated alike in this ongoing overarching conversation by which resources are allocated, be they authored by Nobel Laureates or the man or woman on the street. Opinion is divided even among rhetoricians regarding the merit of so radical a revision of the traditional hierarchy between economic analyst and agent (Mehta 1999; McCloskey 1999). It points to the implied relativism present in most postmodernist perspectives as a major and recurring point of contention (see Backhouse 1998), although relativism as such, though not popular among practitioners and methodologists alike, is not the unanimously discredited philosophical position that some make it out to be (Kusch 2002).

Poverty

A. B. Atkinson

JEL Classifications
D6

Concern for poverty has been expressed over the centuries, even if its priority on the agenda for political action has not always been high. Its different meanings and manifestations have been the subject of study by historians, sociologists and economists. Its causes have been identified in a wide variety of sources, ranging from deficiencies in the administration of income support to the injustice of the economic and social system. The relief, or abolition, of poverty has been sought in the reform of social security, in intervention in the labour market, and in major changes in the form of economic organization.

Poverty today is most obvious – and has the most pressing claim on our attention – on a world scale. The unequal distribution of income between countries, and the disparities within countries, mean that there are large numbers of people in Africa, Asia and Latin America whose standard of living would be agreed by everyone to be poor. The World Bank has suggested that there is 'a global total of close to 1 billion people living in absolute poverty' (World Bank 1982, p. 78), of whom about 400 million are thought live in South Asia, about 150 million in China, and some 100 million in East/South-East Asia and Sub-Saharan Africa. At such levels of living, the risks of death through hunger or cold, and vulnerability to disease, are of a quite different order from those in advanced countries. This has manifested itself most urgently in the occurrence of famine. Whatever the immediate cause of such disasters, whether inadequate total supply of food or whether unequal distribution, the severity of the situation in areas such as the Sahel and Ethiopia is an indicator of the precariousness of survival in many low income countries.

Such mass poverty in poor countries is quite different from poverty in advanced countries. The target of the American War on Poverty, launched in 1964, was the minority of Americans with incomes below a poverty line of $3000 a year for a family of four (in 1962 prices), which was many times the average income of India. The basis for the US official poverty line is to be found in a food consumption standard (the Department of Agriculture economy food plan), but its level reflects the prevailing living conditions in that society. It might well be argued that concern with poverty in advanced countries, at a time when other countries face disaster, is unjustified and that the term 'poverty' cannot legitimately be applied. The parallel may be drawn with rearranging the deckchairs on the *Titanic* as the ship goes down. This does not, however, seem fully apposite. A closer parallel is with the position of those on ships steaming to the aid of the stricken vessel. The overriding objective should be to get to the rescue as rapidly as possible, but those on the rescuing ships should also be concerned that their steerage passengers do not die of exposure on the way. The relief of famine, and the redistribution of income to alleviate poverty on a world scale, should have priority, but the problem of poverty in advanced countries, defined in their terms, may legitimately come next on the list of concerns.

The fact that the term 'poverty' is being used in different senses highlights the need to clarify the underlying concept and the discussion so far has touched on several aspects which need to be elaborated. After a brief historical review of studies of poverty in section "Historical Review of Studies of Poverty", we examine some key conceptual issues. What is the indicator of resources which should be employed in measuring poverty? What is the underlying notion of poverty and how is it related to inequality? These issues are discussed in section "Poverty: Living Standards and Rights". The determination of the poverty standard is a crucial question. Here we need to consider approaches based on such 'absolute' concepts as food requirements and those poverty scales which are explicitly) 'relative'. We must consider the treatment of families with differing needs. These topics are the subject of section "Setting the Poverty Line". Once we have established the extent of poverty, its causes become a central concern. Here we are led first to ask 'who are the poor?' This is examined in section "The Composition of the Poor". Is poverty concentrated in particular classes or particular sections of society? How far is it associated with particular stages of the life-cycle? The composition of the poor provides in turn a starting point for the investigation of the underlying causes of poverty, and an analysis of policies to combat poverty. These are the subject of section "Causes and Policies".

Historical Review of Studies of Poverty

The scientific study of poverty in the Anglo-Saxon world is usually taken to date from the investigations of Booth and Rowntree at the end of the 19th century. In Britain it is true that King and others had given estimates of the number of paupers; and that *The State of the Poor* by Eden (1797) contained a great deal of material collected from over 100 parishes and giving details of family budgets. Engels and Mayhew provided insight into the condition of the poor in urban England. But it was Booth's *Life and Labour* (1892–7) survey of London, started in the East End in the 1880s, that combined the elements of first-hand observation with a systematic attempt to measure the extent of the problem. Taking the street as his unit of analysis, he drew up his celebrated map of poverty in London.

The study of Rowntree (1901) was intended to compare the situation in York, as a typical provincial town, with that found by Booth in London, but his method represented a significant departure in that it was concerned with individual family incomes and in that he developed a poverty standard based on estimates of nutritional and other requirements. The development of survey methods was taken further by Bowley (1912–13) who pioneered the use of sampling in his 1 in 20 random sample of working-class households in Reading. A great many local studies were subsequently conducted, including Bowley's Five Towns survey in 1915, replicated in the early 1920s, and the new Survey of London Life and Labour published in the early 1930s. Rowntree himself repeated his survey of York in 1936 and 1950. The latter became the standard source of information as to the effectiveness of the post-1948 welfare state, with most commentators concluding that poverty had been effectively abolished in Britain by the combination of full employment and the new social benefits. Doubt began to be cast on this conclusion by the work of empirical sociologists and came to the fore with the publication of *The Poor and the Poorest* by Abel-Smith and Townsend (1965). This showed, using secondary analysis of a national survey, that in 1960 about two million people fell below the social security safety net level. This finding was confirmed in official estimates which began to be published by the Department of Health and Social Security in the 1970s, and by Townsend's own major survey (1979).

As in many fields, the United States entered later and has taken the subject further. The definition of a poverty line was attempted by Hunter in 1904 and this was developed in a series of studies, such as the 'minimum comfort' and other budgets produced for New York City. There was the 1949 report on low income families by the Joint Committee on the Economic Report. It was not however until the 1960s that the problem of poverty received systematic study, with a few notable exceptions such as the work of Lampman (1959). *The Other America* by Harrington (1962) and *The Affluent Society* by Galbraith (1958) did much to arouse the attention of the public, politicians and academics. The 1964 report of the Council of Economic Advisers set out the $3000 poverty level, drawing heavily on the research of Orshansky (1965), and this was subsequently refined to form the official poverty line, which has been applied since that date (with modifications, such as the addition of alternative measures including the value of transfers in kind).

Similar studies have been carried out in many countries, and researchers have become increasingly interested in cross-country comparisons. The OECD made an early attempt at such comparisons and a more extensive exercise is being carried out in the Luxembourg Income Study. Any assessment of world poverty depends on the availability of information about the distribution of living standards within individual countries; and here both the World Bank and the International Labour Organization have made significant contributions. In some low income countries, there has been extensive research on poverty, India being an example, where there has been a great deal of discussion as to whether poverty has increased or decreased over time. The ILO and the World Bank have also been influential in the widespread interest, reflected in the Brandt Report (1980), in the concept of 'basic needs', or a minimum set of specific goods and environmental conditions.

Poverty: Living Standards and Rights

Concern about poverty may take the form of concern about such basic needs: for example, food, housing and clothing. In this case, we can identify clearly the items of consumption in which we are interested. This approach leads to poverty being measured in a multidimensional way, where a family may be deprived in one but not other respects, although particularly serious will be situations where families suffer deprivation in several dimensions, or what is referred to typically as 'multiple deprivation'.

This approach is concerned with specific deprivation, but we may also seek to record disadvantage in a single index of living standards, such as total expenditure, a household being said to be in poverty if it has total expenditure below a specified amount. This is not however the approach followed in most studies of poverty in advanced countries, which record poverty on the basis of total *income*. Income may *understate* the level of living. A family may be able to dissave or to borrow, in which case its current level of living is not constrained by current income and expenditure may be the more appropriate index. (Although in the short run there may be a divergence between *consumption* and *expenditure*, as families use up stocks of goods, etc.) The level of living may exceed that permitted by income where the family is able to share in the consumption of others. An elderly person living with his or her children may benefit from their expenditure. Income may, conversely, *overstate* the level of living. This may happen where money alone is not sufficient to buy the necessary goods: where there is rationing, or unavailability of goods. It is also possible that people choose a low level of consumption. This latter reason has led to its being argued that income *should* be the indicator of poverty, since it is a measure of the opportunities open to a family and is not influenced by the consumption decisions made.

In considering the choice between income and expenditure, it is helpful to distinguish two rather different conceptions of poverty: that concerned with *standards of living* and that concerned with *minimum rights* to resources. On the former approach, the goal is that people attain a specified level of consumption (or consumption of specific goods); on the latter approach, people are seen as entitled, as citizens, to a minimum income, the disposal of which is a matter for them. In practice, the two notions are often confounded, but the distinction is important, and it has obvious implications for the choice of poverty indicator. Income is the focus of the rights approach, but its use on a standard of living approach must be seen as a proxy for consumption.

The reference to 'rights' raises the question of the relation between poverty and inequality. Here four different schools of thought may be distinguished. There are those who are concerned only with poverty, attaching no weight to income inequalities above the poverty line. There are those who attach weight to the reduction of inequality as a goal of policy but give priority to the elimination of poverty, so that we have a lexicographic objective function. There are those who are concerned about both goals and who are willing to trade gains in one direction against losses in the other. Finally, there are those who attach no especial significance to poverty, simply regarding it as a component of the wider cost of inequality.

In this context, reference should be made to the choice of *poverty measures.* Where poverty puts survival in doubt, it is natural to take as one's measure the proportion of the population at risk. Concern for minimum rights may also make the 'head count' the most relevant measure. But we may also be concerned, particularly on a standard of living approach, with the severity of poverty, in which case measures such as the poverty deficit (the total shortfall from the poverty line) may be more appropriate. One can indeed go further, as proposed by Sen (1976), and take account of the distribution of income within the poor population: for example, with the poverty index depending on the Gini coefficient for this distribution.

Setting the Poverty Line

The most straightforward approach to the determination of the poverty line is to specify a basket of goods, denoted by the vector $\mathbf{x}^*$, purchasable at prices $\mathbf{p}$, and to set the poverty standard as:

$$(1+h)\mathbf{p}\cdot\mathbf{x}^*$$

where h is a provision for inefficient expenditure or waste, or a provision for items not included in the list $\mathbf{x}$*. This was in effect the method adopted by Rowntree, whose diet for Tuesdays was porridge for breakfast, bread and cheese for lunch, and vegetable broth for dinner. It was the method followed by Orshansky, where $\mathbf{x}^*$ represented food requirements and h (=2) made allowance for spending on other goods. This approach is often referred to as an 'absolute' poverty standard, and contrasted with a 'relative' approach that relates the poverty line to contemporary levels of living: for example the proposal of Fuchs in the United States that the poverty line should be one-half the median family income. It is sometimes suggested that the absolute standard is less problematic than the relative approach and less dependant on value judgements.

The term 'absolute' can, however, scarcely be used in the same sense as in the physical sciences and there is scope for a great deal of disagreement about where the line should be drawn. This is most evident in the case of the rights approach, where the determination of the minimum level of income is explicitly a social judgement, but it applies also to the standard of living approach. In the case of food requirements, where a physiological basis may appear to provide a firm starting point, it is in fact difficult to determine $\mathbf{x}^*$ with any precision. There is no one level of food intake required to survive, but rather a broad range where physical efficiency declines with a falling intake of calories and protein. Nutritional needs depend on where people live and on what they are doing. They vary from person to person, so that any statement can only be probabilistic: at a certain level of consumption there is a certain probability that the person is inadequately fed. Even if these problems could be resolved, there is the difficulty of the disparity between expert recommendations and actual consumption behaviour. The factor h is intended to allow for this, but the precise allowance will depend on the judgement of the investigator. Rowntree, for example, included an allowance for tea, which has little or no nutritional value but which formed a staple item of consumption.

In the case of non-food items, there is even greater scope for judgement. This applies whether we seek to include the goods in the vector $\mathbf{x}^*$ or whether we allow for non-food items via the multiplier h. For example, the procedure of Orshansky has been criticized as under-stating the proportion of income spent on food and hence overstating the value of h. More fundamentally, the role of goods in the determination of the poverty line needs reconsideration. The literature on 'household production' has pointed to the role of goods as an input into household activities, with the level of activities being our main concern rather than the purchase of goods as such. On this basis, if we denote the target level of activities by $\mathbf{z}^*$, and if there is an input–output matrix A, relating goods inputs to activity levels, then the necessary level of expenditure becomes:

$$Y=(1+h)\mathbf{p}A\mathbf{z}^*$$

The significance of this view is that poverty may be measured in absolute terms, in the sense that the vector $\mathbf{z}^*$is fixed, but the required bundle of goods may be changing because the input-output matrix is affected by developments in the particular society. If the activity is 'attending school', then the demands in terms of clothing, books and equipment are quite different today from those of a century ago. This does not mean that there is no distinction between absolute and relative concepts. There is a clear difference in principle between taking the vector $\mathbf{z}^*$ as fixed and allowing it to be influenced by the living patterns of the rest of society, as in the work of Townsend (1979), who is concerned with the extent to which families can participate in the 'community's style of living'.

The notion of a fixed absolute poverty standard, applicable to all societies and at all times, is therefore a chimera. Nor is it evident that a poverty standard, once set, can be compared across time by simply adjusting by an index of consumer prices. In the case of both absolute and relative approaches, we have to face the problems of judgement. Here several lines of attack may be discerned. There are studies which take the *official* poverty standards as embodying social values, which seems natural on the minimum rights approach and which at least provides a measure of governmental performance. There are studies which base the poverty line on the views expressed in surveys of the population as a whole. In the United States, the Gallup Poll has regularly asked the question: 'What is the smallest amount of money a family of four needs to get along in this community?' These, and other approaches, will produce a range of poverty lines, and it seems unlikely that we can reach universal agreement. There are therefore strong reasons for recognizing such differences of view explicitly and using a *range* of poverty lines. This means that we may not be able to reach unambiguous conclusions – it may be that poverty will be shown to have increased according to one line but not according to another – but it will avoid a total impasse. In the same way, when making a comparison over time, we may want to compare 1950 with two alternative lines for 1980, one updated by the price index and the other adjusted to allow for rising real incomes, thus generating a 'confidence interval' around the 1980 estimate.

To this point, the poverty line has been discussed as though it were a single number, but families of different types and different sizes will receive different treatment. In Britain, for example, the social security safety net is typically some 60 per cent higher for a couple than for a single person. The relationship between the poverty lines for different family types is usually referred to as an *equivalence scale.* However, a prior question before the equivalence scales are determined is the choice of the *unit of analysis.* Here the distinction between the standard of living and rights approaches is important. In the latter case, the notion of rights must be essentially individualistic. The case for considering a wider unit must rest on there being within- family transfers which cannot be adequately observed. The family is taken when measuring poverty because we do not accept that a large number of those with zero recorded cash income are in fact without resources. At the same time, little is known about the distribution of income within the family. Certainly, it would be quite wrong to treat all married couples as having equal rights to the joint income. On a standard of living approach, the logical unit is that which shares consumption; and we may wish to go beyond the inner family to the household as a whole. This would take account of the fact that items of expenditure may have 'public good' characteristics for the family members. Again, however, it may be that there are unequal living standards within the household.

Several approaches have been adopted to the determination of the equivalence scales for different-sized units. Survey information about individual assessments of what is needed 'to get along' has been used for this purpose. More commonly, the basis has been sought for observation of actual behaviour. One of the early methods provides an illustration. By taking a commodity consumed only by adults (e.g. men's clothing), one can observe the level of income at which a family with one child, say, can attain the same level of consumption of that commodity as a family with no children. This method, and other more sophisticated implementations of the idea, have been the subject of considerable debate. The underlying difficulty is that one is assuming, in the example given, that preferences for the commodity are independent of family composition: the arrival of the child may mean that the couple go out less and spend less on clothing. With other methods based on observed consumption behaviour, identifying restrictions are similarly needed. At a more fundamental level, the ethical status of such scales is far from transparent. Not only is it impossible to draw conclusions about welfare levels with different family compositions, but also society may wish to modify the implied judgements: for example, to vary the parental evaluation to take account of the interests of the children.

The Composition of the Poor

One of the main aims of those investigating poverty has been to establish who the poor are. Popular opinion is often coloured by vivid, but not necessarily representative, accounts of life below the poverty line. For this reason, the Council of Economic Advisers stressed at the start of the War on Poverty in the US that poverty should not be seen as a minority phenomenon: 'Some believe that most of the poor are found in the slums of the central city, while others believe that they are concentrated in areas of rural blight. Some have been impressed by poverty among the elderly, while others are convinced that it is primarily a problem of minority racial and ethnic groups. But objective evidence indicates that poverty is pervasive. . .the poor are found among all major groups in the population and in all parts of the country' (1964, pp. 61–2).

Poverty in advanced countries affects a minority in terms of numbers but it is not confined to specific marginal groups. At the same time, certain groups are much more at risk. In 1983, the poverty rate for blacks in the United States was nearly three times that for whites, and that for Hispanics was more than twice. Compared with the average, the rate for families with children is nearly double, and that for families with a female head is much higher. The evidence for other countries equally shows large differences in the incidence of poverty between groups: for instance, in Malaysia, recorded poverty among Malays is much higher than among the Indian or Chinese ethnic groups. The World Bank has argued that poverty in low income countries is very much a rural problem; and the evidence from India shows poverty to be much higher in rural than urban areas.

If we seek to probe further into the composition of the poor, then the dynamics of poverty must be taken into account. Is poverty a largely transitory phenomenon, in that the families poor today will quite probably be above the poverty line next year? Is poverty associated with particular periods of the life cycle? Transitory poverty may occur for a variety of reasons. Income may be temporarily reduced because of ill-health or unemployment or because wages are cut. It may be a bad harvest. Families may split up, leaving one parent with the family responsibilities but inadequate income. The evidence from panel surveys, where the same families are interviewed on a continuing basis (as, for example, in the Michigan Panel Study of Income Dynamics), has shown the extent of mobility in the incomes and circumstances of the poor. A sizeable fraction of those recorded as poor in one year are above the poverty line next year. This does not mean that their poverty is not a matter for concern, since low current incomes may impose severe hardship, but it means that these people do not constitute a permanent 'under class'.

Such mobility does however require careful interpretation. It may arise on account of the life cycle. In Rowntree's 1899 survey he found that the life of the labourer was marked by 'five alternating periods of want and comparative plenty', the periods of want being childhood, when he himself had children, and old age. The impact of such life-cycle factors depends on the extent to which income support is provided by state or private transfers. In this respect the situation in Britain has changed dramatically since 1899, with the introduction of state pensions, a large increase in private pensions, and the payment of child and other benefits. In other countries too there has been major growth in transfers: between 1960 and 1981 social expenditure as a percentage of GDP rose in the United States from 7 per cent to 15 per cent, in West Germany from 18 per cent to 27 per cent, and in Japan from 4 to 14 per cent (Institute for Research on Poverty 1985). Transfers, and other programmes, such as health care, must have reduced the extent of life-cycle poverty. The incomes of the elderly in the United States, for example, are considered to have risen relative to those of the population as a whole. But there remains concern about certain stages of the life cycle, particularly among families with children; and while the poverty rate among the elderly in the US has fallen, that among the non-elderly has risen.

To the extent that poverty is a life-cycle phenomenon, this means that more people experience poverty at some point in their lives but that its duration is limited. At the same time, poverty at one stage of the life cycle may lead to poverty at a subsequent stage. Those who are hard-pressed when they are bringing up children may have little savings on which to draw in retirement. Those who grow up in low- income families may themselves be more likely to be below the poverty line, as was found in the follow-up in the 1970s of the children of the families interviewed by Rowntree in 1950 (Atkinson et al. 1983). Moreover, we should not however lose sight of the fact that for some people poverty persists. Agricultural labourers, or farmers with small plots, may be in poverty even in 'good' years. Among industrial workers, there are those whose earnings are inadequate to support even themselves; there may be a problem of low *pay.* And the low paid may be more vulnerable to the transitory factors such as ill-health and unemployment.

Causes and Policies

In 1913, R.H. Tawney argued for the restatement of the problem of poverty: 'the diversion to questions of social organization of much of the attention which, a generation ago, was spent on relief'. The problem of poverty, he said, was 'primarily an industrial one'. In terms of the composition of the poor described above, this means that the causes of poverty were sought not in the failure of income support but in the reasons why income was inadequate in the first place.

Tawney recognized the importance of personal factors in causing poverty, but laid principal stress on the position of groups and classes and their economic situation, factors which may equally be relevant today. Workers may be locked into low-paying industries where techniques and machinery need to be modernized; they may live in depressed regions to which private capital cannot be attracted. There may be a low level of unionization and employers may be able to hold wages down.

These aspects, which have been emphasized in theories of 'segmentation' in the labour market, point to the need for government intervention. This may take the form of minimum wage legislation, to guarantee minimum levels of earnings, coupled with measures to offset any adverse effect on employment and to modernize the sectors or regions concerned. At a macro-economic level, the government has an important responsibility. Studies in the United States have identified unemployment as a much more serious problem than inflation for low income groups. There can be little doubt, for example, that the recession of the 1980s has increased the incidence of poverty in advanced countries.

The counterpart of this structural explanation in the context of less developed, primarily agricultural economies is to be found in the role of land tenure and its distribution and in the nature of labour and capital markets. Rural poverty is high among landless labourers and those farmers with small or unproductive holdings. Their difficulties may be intensified by the terms on which they have to borrow or purchase intermediate goods. Here too policy requires government intervention, whether to redistribute land holdings, or to facilitate the introduction of new methods, or to eliminate extortionate lending practices, or to provide non-farm employment. Measures such as land reform raise major political issues, and in both developing and advanced countries it can be argued that basic changes in the form of economic system are necessary to eradicate poverty. The World Bank has noted, for example, the role played by the Chinese food security policy in the reduction of poverty and the way in which it is tied into China's collective system.

The industrial explanation of poverty may be contrasted with the 'supply side' explanation which has seen low pay as attributable to workers lacking productive skills, because they have been unable to complete education or training. This 'human capital' interpretation leads in turn to the policy recommendation that training and educational programmes should be expanded, a proposal that is congruent with the goal of reducing inequality of opportunity. Education and training had a central role in the United States War on Poverty, with schemes such as the Job Corps and the Neighborhood Youth Corps. A characteristic of individual workers also identified in the United States is that of race. Discrimination may lead to otherwise equally qualified workers receiving lower pay, as where black workers were prevented from entering certain occupations. The civil rights legislation and the operations of the Equal Employment Opportunity Commission may have reduced the direct effect of discrimination (as well as the indirect effect via unequal opportunities in education, etc.), but although the policy implications are clear in principle, experience suggests that they are not easily made effective.

Policies to improve job and earnings prospects must be central to the elimination of poverty, but they cannot succeed without complementary income maintenance provisions. The growth of transfers has not succeeded in providing a completely effective income guarantee for those without incomes from work or with additional needs. This is because of incomplete coverage, particularly where new needs develop, because of the inadequate levels of benefits (for example, those paid to people with poor employment records) and the incomplete take-up of income-tested benefits. In the last case, there is evidence that complexity or stigma deters families from claiming the transfers to which they are entitled, and hence they fall through the safety net.

To this end, proposals have been made for major reform of the transfer systems in advanced countries. One front-runner for many years in the United States has been the 'negative income tax', which would pay an income-related supplement using the income tax machinery. There are those reformers who would like to integrate fully the income tax and social security systems, as with the basic income guarantee scheme, where everyone receives a basic income and is then taxed on all income. Such a reform would mean that income maintenance largely ceased to be categorical: for example, there would not be separate treatment for the unemployed or the sick. An alternative would be to preserve the categorical nature of social insurance but to make the insurance benefits more extensive in their coverage and sufficient to avoid the necessity to depend on public assistance or other forms of means-tested benefits. In considering the feasibility of such reforms, one must have regard both to the arithmetic of the redistribution and to the reasons why they have not been enacted in the past. As the 'public choice' school of public finance economists has stressed, the actions of the government are themselves to be explained by economic and other motives. The reasons why governments have failed to enact successful anti-poverty policies is a subject of great importance.

The policies discussed in this section are solely concerned with the poverty *within* countries, and would do nothing to redistribute between countries. Indeed, some of the policies designed to help the low paid in advanced countries may actually have adverse consequences for low income countries. The income transfers which rich countries have so far made are of minuscule size when viewed against the magnitude of the problem of world poverty, and there can be little doubt that redistribution on a world scale is of the highest priority.

Poverty Alleviation Programmes

Martin Ravallion

Abstract

This article reviews the issues and evidence concerning a class of policies that aim to reduce poverty by providing direct current relief to those in need and/or by compensating for market and governmental failures that help perpetuate poverty. The article focuses on programmes found in developing countries. Poverty proxies or self-targeting mechanisms are typically used and the specific policies discussed include contingent transfers, community-based programmes, social funds and workfare programmes.

Keywords

Affirmative action; Agency costs; Conditional transfers; Deadweight losses; Equity–efficiency trade-off; Factor mobility; Indicator-based targeting; Intrahousehold welfare; Learning-by-doing; Poverty alleviation programmes; Poverty proxies; Poverty traps; Programme evaluation; Redistribution of income; Workfare

Rapid poverty reduction is widely seen to call for a combination of policies that on the one hand promote economic growth and on the other help poor people share in, and contribute to, the opportunities of a growing economy. There is wide agreement that the latter set of policies should include universal provision of adequate basic health care and schooling. There is less agreement on the scope for 'poverty alleviation programmes,' typically entailing transfers in cash or kind targeted to poor people. This article provides an overview of such programmes. First their objectives and the factors constraining their performance are discussed. Then the focus turns to the types of programmes found in developing countries.

Objectives and Constraints

The generally agreed objective of this class of policies is to increase the standard of living of those with low levels of living, that is, to reduce 'absolute poverty'. While recognizing that high levels of inequality can impede prospects for reducing poverty, the objective of this class of policies is poverty reduction, not redistribution per se. Trade-offs underlie this objective. Inequality-reducing interventions can come at a cost to efficiency, such as through effects on the work effort or savings of beneficiaries. While these costs can be serious for specific programmes in specific contexts, it should not be presumed that there will necessarily be an equity–efficiency trade-off. In a world of market failures and 'poverty traps' direct interventions against poverty can also promote aggregate efficiency and (hence) growth. (On how there can be too much inequality and risk from the point of view of aggregate output see, *inter alia,* Bénabou 1996; Aghion et al. 1999; and Bardhan et al. 2000. On poverty traps, see, *inter alia,* Dasgupta 1993; Banerjee and Newman 1994; and Hoff 2001. Policy implications are examined in Ravallion 2005a; World Bank 2001, 2006.) For example, credit constraints leave unexploited investment opportunities, notably for the poor (who have little or no collateral). Agency costs are probably also borne more heavily by the poor. (Agency costs arise when an agent, such as a worker or tenant farmer, makes key decisions relevant to a principal – the capitalist or land owner – who faces high supervision costs. Such models can generate efficient redistributions, from principal to agent; see Bowles and Gintis 1996.)

There can be other trade-offs. The programmes that are best for reducing current poverty need not coincide with those that are best for reducing future poverty; examples will be given later. And the policies that are good for reducing chronic poverty (such as promoting the adoption of new farming technologies) may matter little to, or even exacerbate, transient poverty (by exposing poor farmers to greater downside risk).

There are a number of constraints in formulating effective anti-poverty programmes. Governmental budgets figure prominently. Interventions in the name of poor people that require less public spending on other things that matter to their welfare, or are financed in distortionary or inflationary ways that reduce growth, may well increase poverty. The political economy will also constrain the feasible set of anti-poverty policies. What is feasible in practice will of course depend on the specific context.

The scope for these policies is naturally constrained by the information available and administrative capabilities for acting on that information. Problems of information and incentives are at the heart of programme design. Addressing these problems can increase administrative costs, depleting the net resource transfer to the poor. Informational constraints are particularly relevant in the rural and urban informal sectors of developing countries, where policies such as a progressive income tax are seldom feasible (though such policies are themselves second-best responses to information constraints even in rich countries).

Programmes differ in the emphasis given to enhancing the assets of poor people as opposed to raising their current incomes. In principle, poverty-creating inefficiencies due to credit market failures or agency costs can be ameliorated by asset redistributions. However, governments face political-economy constraints on their ability to redistribute wealth. Certain asset-based interventions tend to be more feasible than others. Reducing inequalities of opportunity by improving the schooling and health of children from poor families is often politically easier than reducing inequalities in the ownership of non-human capital or land. And even when asset redistribution is feasible, state-contingent income transfers may also be needed to help address failures in the provision of private insurance. It is likely that antipoverty policy will continue to call for a mix of efforts to redress inequalities of opportunity (probably emphasizing human resource development) and specific transfers in cash or kind.

Another issue is how finely targeted antipoverty programmes should be. Policy discussions often call for better 'targeting' – a higher share of total spending going to the poor. However, the most finely targeted programme need not be the one with the greatest impact on poverty. Fine targeting can increase administrative costs, yield deadweight losses (as will be illustrated later) and undermine political support for the programme. (On the political economy of targeting see Gelbach and Pritchett 2000. On deadweight losses see Ravallion and Datt 1995. On administrative costs see Grosh 1995. More general discussions of these issues can be found in Besley and Kanbur 1993; van de Walle 1998.) Uncertainties about the measures used in practice to identify the poor can also lead one to question the benefits of fine targeting.

Reliable monitoring and *ex post* evaluation is crucial. Our knowledge about the performance of these programmes has traditionally been poor, but this is changing as more resources and better data and methods go into impact evaluations. (An impact evaluation measures impacts on outcomes relative to explicit counterfactuals.

Ravallion 2005b, reviews methods and results on the impact evaluation of this class of policies.) These have revealed both successes and failures, often depending crucially on the context; the same type of programme can achieve very different outcomes in different settings including at different scales of operation. (Theory and evidence indicating that targeting performance tends to improve as a programme expands can be found in Ravallion 2005c.) Thus greater emphasis is now given to adapting programmes to their context – 'learning-by-doing' – as well as to broader reforms in governance and new, more pro-poor, institutions that can help assure better policy-making and implementation.

The following discussion briefly examines the main types of programmes found in practice, which will illustrate some of the generic points above. While 'targeting' per se is not the objective, existing programmes can usefully be classified according to the way they try to target the poor. The focus is on programmes that rely on transfers in cash or kind. (Lipton and Ravallion 1995, review the full range of antipoverty policies found in practice, which, in addition to transfers, include various forms of direct support to smallholders, better instruments for credit and insurance, tenancy reforms and titling programmes to enhance security of access to land, and removing biases against the poor in taxation, spending and regulatory – including migration – policies.)

Indicator Targeting

The problems of observing incomes and the incentive effects of means-testing have led to various schemes that make transfers in cash or kind according to 'poverty proxies' such as living in a poor area, age (both children and the elderly) and rural landlessness. Everyone with the same value of the indicator (or some combination) is treated the same way. Tools exist for finding optimal allocations to minimize a poverty index based on poverty proxies and for measuring the impact on poverty (Ravallion 1993). Naturally, the more information that is available, the better indicator targeting works. Significant advances have been made in our ability to exploit sample survey information for the purposes of informing policy-making. For example, reasonably reliable and quite detailed 'poverty maps' can now be formed by combining sample survey data with census data; see, for example, Elbers et al. (2003).

Policy-makers have often been overly optimistic about how well they can reach the poor based on readily observable indicators. Here there are some sobering lessons from empirical research. Even using comprehensive, high-quality household sample surveys we have rather modest ability to account for differences in the levels of measured consumption or incomes in terms of the sorts of readily observed covariates that are typically used for targeting. There appears to be sizable heterogeneity in living standards within target groups identified by poverty proxies. Further sources of targeting errors arise from the fact that one must base actual policies on data for the whole population (not just a sample survey) and that respondents will naturally face incentives to distort the data when it is known why it is being collected. Thus, one can expect (possibly large) errors in practice when using indicator targeting to fight poverty.

Performance in reaching the transiently poor through indicator-based targeting appears to be generally worse than performance in reaching the chronically poor (see Ravallion et al. 1995; Lokshin and Ravallion 2000; van de Walle 2004). This is not too surprising given that widely used poverty proxies have even less ability to explain changes over time in levels of living (with the use of panel data in which the same households are interviewed over time). And stakeholders naturally resist changes to a programme's allocations. Despite the potential in theory, targeted transfers in practice have not responded rapidly to changing household circumstances, as would be required for effective insurance.

Such observations have prompted efforts to find 'smart policies' that rely more on incentives in their design and can adapt more rapidly, and on institutional changes that can help assure that poor people are better represented in decision-making; examples are given below.

There are also reasons for thinking that the benefits of indicator targeting are sometimes underestimated. Policy discussions have typically viewed targeting in a static non-behavioural way; location or ethnicity are simply poverty proxies. Recent research has offered a new perspective, pointing to the potential for efficiency gains from targeting groups being locked out of economic opportunities by market or political mechanisms. For example, residential stratification in the presence of externalities can generate persistent inequality (Bénabou 1993; Durlauf 1996). There is evidence of 'geographic poverty traps' in underdeveloped rural economies, such that living in a poorly endowed area reduces prospects of escaping poverty at given individual (non-geographic) characteristics; see Jalan and Ravallion (2002), who use data for China. Poor-area development programmes in such a setting can thus secure long-term gains (Jalan and Ravallion 1998). There is also evidence that the political economy can generate biases against specific groups defined by location or ethnicity and that affirmative actions favouring these groups can enhance the impact of an anti-poverty programme (Besley et al. 2004). Specific demographic groups (both children and the elderly) have also been targeted, given the evidence of strong demographic correlates of poverty found in household survey data, though the robustness of these empirical findings to measurement assumptions is questionable. (Allowing for scale economies in consumption can readily reverse the common finding that larger households tend to be poorer based on consumption or income per person; Lanjouw and Ravallion 1995.) Here too there can be efficiency gains. South Africa has a pension scheme that gives cash transfers to the elderly; Duflo (2003) reports that these pensions have positive external benefits for child health within recipient families. The upshot of these findings is that targeting certain groups can have a greater long-term impact on poverty than suggested by a purely statistical poverty profile.

Finding that transfers based on indicators of current poverty can bring long-term benefits (given factor market imperfections) does not, however, mean that they are the best policy option for this purpose. Policies to increase factor mobility can also have a role. Incentives to attract private capital into poorly endowed areas or to encourage labour migration out of them could well be more poverty reducing than transfers targeted to those areas. There has been very little work on these policy choices, and one often hears unsubstantiated claims by advocates.

Securing the efficiency gains from targeted transfers will often require complementary programmes or reforms. This has been emphasized in the context of redistributive land reforms, where impediments in access to credit and technologies can greatly attenuate the efficiency gains (Binswanger et al. 1995; World Bank 2003). Recognition of the need to combine transfers (of specific assets or incomes) with other initiatives to help foster the productivity of the poor has prompted recent interest in a class of conditional transfers that we now turn to.

Conditional Transfers

Many anti-poverty programmes impose conditions on recipients that attempt to change their behaviour. The (more or less explicit) rationale is that some form of market failure has entailed that current behaviours are not socially optimal. (On the efficiency arguments for conditionality requirements on transfer schemes see Das et al. 2004.) In the 1990s, a number of new conditional transfer programmes emerged that required recipients to satisfy schooling (and sometimes child health-care) requirements. An example is Bangladesh's Food-for-Education (FFE) programme, which relies on community-based targeting of food transfers that aim to create an incentive for reducing the costs to the poor of market failures. Other examples are PROGRESA (renamed Oportunidades) in Mexico and Bolsa Escola in Brazil; in these programmes cash transfers are targeted to certain demographic groups in poor areas, conditional on regular school attendance and visits to health centres.

If one was concerned solely with current income gains to participants then one would not want to make transfers conditional on school attendance, which imposes a cost on poor families by inducing them to withdraw children from the labour force, thus reducing the (net) income gain to the poor from the programme. Rather, this type of programme is aiming to balance a current poverty reduction objective against an objective of reducing future poverty. Given the credit market failure, the incentive effect on labour supply of the programme (often seen as an adverse outcome of transfers) is now judged to be a benefit – to the extent that a well-targeted transfer allows poor families to keep the kids in school rather than sending them to work. Notice too that concerns about distribution *within* the household often underlie the motivation for such programmes; the programme conditionality makes it likely that relatively more of the gains accrue to children. This can also be interpreted as a policy response to the deficiency of traditional poverty proxies in reflecting distribution within the household.

There is evidence of significant gains from Bangladesh's FFE programme in terms of school attendance, with only modest income forgone through displaced child labour (Ravallion and Wodon 2000). The programme was able to appreciably increase schooling, at modest cost to the current incomes of poor families. Mexico's PROGRESA programme has also been found to increase schooling, though the gains appear to be lower than for FFE (Behrman et al. 2002; Schultz 2004; Skoufias 2005). This is probably because primary schooling rates are higher in Mexico, implying less value-added over the (counterfactual) schooling levels that would obtain otherwise. Sadoulet and de Janvry (2002) argue that there would be greater efficiency gains (through higher schooling) from PROGRESA if the programme had concentrated on children less likely to attend school in the absence of the programme, notably by focusing on the transition to secondary school. However, the policy choice will depend critically on the weight one attaches to current income gains for the poor as against future gains through schooling.

Community-Based Programmes

In recent times, community participation in programme design and implementation has been advocated as an institutional change that can help relieve informational constraints, and possibly tilt the balance of power toward the poor. A common form of this idea in practice is that the central government sets up a 'social fund' that provides financial support to a potentially wide range of community-based projects, with strong emphasis on local participation in proposing and implementing the specific projects. Community (governmental or non-governmental) organizations are assumed to be better informed about what is needed. The centre retains control over how much goes to each locality. A useful overview of what is known about this class of programs can be found in Mansuri and Rao (2004).

While 'empowerment' of the poor has motivated such community-based efforts, capture by local elites has been a continuing concern. Reliable generalizations are as yet elusive. There are reasons to expect heterogeneity across communities in the impacts of the same programme. Relevant sources of heterogeneity identified in the literature include local asset inequality (Bardhan and Mookherjee 2000; Galasso and Ravallion 2005) and the extent of interlinkage in local social networks (Spagnolo 1999).

In the design of Bangladesh's FFE programme, economically backward areas were supposed to be chosen by the centre, leaving community groups – exploiting idiosyncratic local information – to select participants within those areas. Galasso and Ravallion (2005) use survey data to assess FFE incidence within and between villages. They found that targeting performance – measured by the difference between the realized per capita allocation to the poor and the non-poor – varied greatly between villages. Higher allocations from the centre to a village tended to yield better targeting performance, but there was no sign that poorer villages were any better or worse at targeting their poor.

The results also point to the role played by antecedent inequalities within villages in determining the relative power of the poor in local decision-making. Galasso and Ravallion found that more unequal villages are worse at targeting the poor – consistent with the view that greater land inequality comes with less power for the poor in village decision-making. (This echoes the view that inequalities can persist through their influence on the institutions that develop. For example, Engerman and Sokoloff 2005, argue that this is why high initial inequality persisted in colonized countries. Also see World Bank 2006.) This suggests a mechanism whereby inequality is perpetuated through the local political economy; the more unequal the initial distribution of assets, the better placed the non-poor will be to capture the benefits of external efforts to help the poor.

Self-Targeting

The informational constraints on anti-poverty programmes have strengthened arguments for using self-targeting mechanisms. There are numerous ways to use incentives in programme design to assure self-targeting of the poor. For example, the rationing of food or health subsidies by queuing can be self-targeting (Alderman 1987), as can subsidizing inferior food staples or packaging in ways that are unappealing to the non-poor. However, the classic example of a self-targeted anti-poverty programme is a workfare programme, in which work requirements are imposed on welfare recipients with the aim of creating incentives to encourage participation only by the poor and to reduce dependency on the programme. (Besley and Coate 1992, provide a formal model of the incentive arguments.)

An example is the famous Employment Guarantee Scheme (EGS) in Maharashtra, India. This aims to assure income support in rural areas by providing unskilled manual labour at low wages to anyone who wants it. The scheme is financed domestically, largely from taxes on the relatively well-off segments of Maharashtra's urban populations. The employment guarantee helps support the insurance function, and is also seen to help empower poor people. In practice, however, most workfare schemes have entailed some administrative rationing of the available work, often in combination with geographic targeting.

Workfare schemes generally have a good record in screening the poor from the non-poor, and providing effective insurance against both covariate and idiosyncratic shocks. (For evidence on this point see Ravallion and Datt 1995; Subbarao 1997; Jalan and Ravallion 2003; Coady et al. 2004.) They have provided protection when there is a threat of famine (Drèze and Sen 1989) or in the wake of a macroeconomic crisis (see, for example, Pritchett et al. 2003, for Indonesia's crisis in 1998, and Galasso and Ravallion 2004, for Argentina's crisis in 2002). Design features are crucial, notably that the wage rate is not set too high. For example, Ravallion et al. (1993) provide evidence on how the EGS responds to aggregate shocks, and on how its ability to insure the poor was jeopardized by a sharp increase in the wage rate. Low-wage workfare schemes have been advocated as a core element of a 'permanent safety net' for risk-prone economies (Ravallion 2005c).

Self-targeted schemes face a trade-off between targeting performance (meaning their ability to concentrate benefits on the poor) and net income gains to participants, given that these programmes work by deliberately imposing costs on participants. Self-targeting requires that the cost of participation is higher for the non-poor than the poor (so that it is the poor who tend to participate), but it may not be inconsequential for the poor.

A potentially important cost to workfare participants is forgone income. This is unlikely to be zero; the poor can rarely afford to be idle. An estimate for two villages in Maharashtra, India, found that the forgone income from employment on the EGS was quite low – around one quarter of gross wage earnings; most of the time displaced was in domestic labour, leisure and unemployment (Datt and Ravallion 1994). By contrast, for Argentina's Trabajar Program (a combination of workfare and social fund), it was estimated that about one half of gross wage earnings was taken up by forgone incomes (Jalan and Ravallion 2003; Ravallion et al. 2005).

Workfare schemes also illustrate the potential trade-off in policy design between short-term income gains to the poor and longer-term gains through asset creation. Workfare programmes have not traditionally emphasized the value to the poor of the assets created, which appear often to mainly benefit the non-poor or to be of remarkably little value to anyone (see, for example, Gaiha 1996, writing about Maharashtra's EGS.) The Trabajar Program illustrates the scope for a new wave of workfare programmes that emphasize asset creation in poor communities.

The programme's design gave explicit incentives (through the *ex ante* project selection process) for targeting the asset creation to poor areas, again compensating for the market failures that help create poor areas in the first place. There is typically much useful work to do in poor neighbourhoods – work that would probably not get financed otherwise.

The choice between the goal of raising current incomes of the poor and reducing future poverty will never be a straightforward. The choice will naturally depend on circumstances. For example, in macroeconomic or agro-climatic crises it is to be expected that the emphasis will shift to current income gains, away from asset creation – implying, for example, more labour-intensive sub-projects on workfare programmes.

Poverty Lines

Martin Ravallion

Abstract

The article provides welfare-economic definitions of poverty lines and critically assesses the main methods of setting poverty lines found in practice. These can be interpreted as ways of expanding the information set used in applied work to address some long-standing problems in measuring welfare. Objective methods draw on information from outside economics on the commodities needed for normative activity levels. Subjective methods extend the information base by drawing on selfreported perceptions of consumption adequacy, allowing estimation of an endogenous social subjective poverty line.

Knowing how many people live in households with income or consumption expenditure below the ‘poverty line’ has helped focus attention on the extent of poverty and has informed policymaking for fighting poverty. But how are poverty lines defined and calculated? This article first provides a theoretical definition, and then describes the main methods found in practice.

Poverty Lines in Theory

People in different circumstances – with different household sizes or demographic compositions or living in different places – naturally have different levels of economic welfare at the same level of income. They have different needs. A poverty line should reflect these differences. But how should that be done? To answer this question we must first define the conceptual ideal against which the methods found in practice are to be judged.

The poverty line for a given individual can be defined as the money the individual needs to achieve the minimum level of ‘welfare’ to not be deemed ‘poor’, given its circumstances. Everyone at the poverty line is taken to be equally badly off, and all those below the line are worse off than all above it. The next question is: what concept of ‘welfare’ should serve as the anchor for the poverty line? For economists the obvious answer is ‘utility’. A justification for utility-consistent poverty lines can be found by applying standard welfare-economic principles to poverty measurement (Ravallion 1994). These principles are that assessments of social welfare should depend solely on utilities, that people with the same initial utility should be treated the same way, and that social welfare should not be decreasing in any utility.

To formalize this definition, consider individual i with characteristics x_i (a vector). The interpersonally comparable utility function is $u(q_i,x_i)$. The quantity vector q_i is utility maximizing, giving demand functions $q(p_i,y_i, x_i)$ at total expenditure y_i and corresponding utility maximum, $v(p_i,y_i, x_i)$. The utility-consistent poverty line is the point on the consumer’s expenditure function corresponding to a common reference utility level. (As always, the monetary measurement of welfare requires a reference utility level.) The consumer’s expenditure function is $e(p_i, x_i, u)$, giving the minimum cost of utility u when facing the price vector p_i. Let u_z denote the minimum utility deemed necessary to escape poverty. Consistency requires that this is a constant across all i. The money metric of u_z defines the *utility-consistent poverty lines:*

$$z_i^u = e(p_i, x_i, u_z) \text{ for all } i = 1, \dots n \qquad (1)$$

This is closely related to a number of other economic concepts. Eq. (1) is ‘money-metric utility’ at a specific reference utility, interpretable as the poverty line in utility space. (Textbook treatments of money-metric utility functions – sometimes called ‘equivalent income functions’ – can be found in Varian 1978, and Deaton and Muellbauer 1980.) The value of $z_i^u/e(p_r, x_r, u_z)$ for reference individual r gives the ‘true cost-of-living index’ (see, for example, Deaton and Muellbauer 1980). The value of y_i/z_i^u is the 'welfare ratio' (Blackorby and Donaldson, 1987). On exploiting the properties of the expenditure function, Eq. (1) can be written in a more instructive form:

$$z_i^u = p_i q(p_i, x_i, u_z) \tag{2}$$

Thus, the poverty line is the cost of a bundle of goods, namely, the vector of utility-compensated (Hicksian) demands, $q(p_i, x_i, u_z)$. This bundle can be interpreted as 'basic consumption needs'.

Note that an absolute poverty line in terms of utility can have the properties of a *relative poverty line* in the income space, in that it rises with the mean income of a relevant reference group. This is possible if individual utility depends on both 'own income' and income relative to others in that reference group. In other words, the indirect utility function has the form, $v\left(p_i, y_i, y_i/\overline{y}_i^r, x_i\right)$ where $\overline{y}_i^r$ is the mean income of the reference group(s); the poverty line takes the form $z_i = z\left(p_i, \overline{y}_i^r, x_i, u_z\right)$ (which solves $u_z = v\left(p_i, z_i, z_i/\overline{y}_i^r, x_i\right)$). Thus, we can view poverty as absolute in the space of welfare, but relative in the space of commodities (paraphrasing Sen 1983). However, the extreme case in which the poverty line is a constant proportion of the mean (as used by poverty measures derived by Eurostat, for the European Commission) requires the seemingly implausible assumption that utility depends *solely* on relative income, given by the ratio of own income to the mean. By this measure, if all incomes increase by the same multiplicative factor then the proportion of people living below the poverty line will be unchanged. Cross-country comparisons of poverty lines suggest that relative income is valued more highly as mean income rises; in the poorest countries, absolute income levels are the dominant consideration, so then the poverty lines tend to have a low elasticity to the mean (Ravallion 1994, 1998). There is micro empirical evidence supporting this view, based on self-assessed welfare (Ravallion and Lokshin 2005).

For economists, utility is the obvious anchor for setting poverty lines, but it is not the only approach. Functioning-based concepts of welfare offer an alternative foundation for poverty lines. The approach can be characterized in the terms of Sen's (1985) argument that 'well-being' should be thought of in terms of a person's capabilities, that is, the functionings ('beings and doings') that a person is able to achieve. On this view, poverty means not having an income sufficient to support specific normative functionings. Utility – as the attainment of personal satisfaction – can be viewed as one such functioning relevant to well-being (Sen 1992, ch. 3). But it is possibly only one of the functionings that matter. Independently of utility, one might say that a person is better off if she is able to participate fully in social and economic activity.

From this starting point, a more general theoretical formalization of the definition of a poverty line can be proposed as follows. Let a person's functionings be determined by the goods she consumes and her characteristics, giving the vector of functionings:

$$f_i = f(q_i, x_i) \tag{3}$$

where f is a vector-valued function. One can postulate that a person derives utility directly from her functionings. We can then interpret $u(q_i, x_i)$ as a derived utility function, obtained by substituting (3) into the (primal) utility function defined over functionings.

Functioning consistency for a set of poverty lines requires that certain normative functionings are reached at the poverty line. Let f_z denote the vector of critical functionings needed to not be deemed poor. These are normative judgements, just as u_z is a normative judgment. Assume that there is a bundle q_i^c such that no functioning is below its critical value:

$$f_z \leq f\left(q_i^c, x_i\right) \tag{4}$$

This yields the poverty lines: $z_i^c = p_i q_i^c$. There can be multiple solutions for q_i^c. Two ways to pick a unique poverty line can be identified. The first is to define z_i^c as the minimum y such that (4) holds. Notice that one (or more) specific functionings will be decisive; that is, the functioning that is the last to reach its critical value as income rises. In this sense, the lowest priority functioning for the individual will be decisive. The alternative approach is to treat attainments as a random variable (that is, with a probability distribution) and take a mean conditional on income and other identified covariates, including group membership. Then poverty lines are deemed to be functioning consistent if f_z is reached in expectation.

Implementing these concepts empirically requires that we solve two problems. The first can be called the *referencing problem:* what is the reference level of utility that anchors the poverty line (u_z in Eq. 1)? It is tempting to say this choice is arbitrary, and to hope that it is innocuous. But the choice of the reference is far from arbitrary, and (in general) it affects the resulting poverty measure. This speaks to the importance of testing the sensitivity of poverty comparisons (such as between groups or over time) to the choice of reference, as it determines the level of the poverty line. Tests exist for the robustness of ordinal comparisons using stochastic dominance criteria; on this approach see Atkinson (1987) and Ravallion (1994).

The second problem is the *identification problem.* Even if we can readily agree on what the poverty line is in welfare space, there is a further problem in identifying the expenditure function in Eq. (1). Standard practice is to calibrate the parameters of the cost function from consumer demand behaviour. The problem is that individuals vary in characteristics, such as their size and demographic composition, which influence welfare in ways that may not be evident in consumer demand behaviour. Then there is a fundamental problem of identification (Pollak and Wales 1979; Pollak 1991).

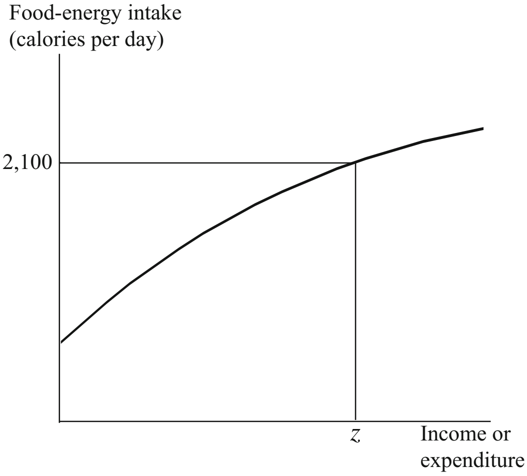
Poverty Lines in Practice

The methods of setting poverty lines found in practice fall under two headings: objective poverty lines and subjective poverty lines.

Objective Poverty Lines

The main methods found in practice are the food-energy-intake (FEI) method and the cost-of-basic-needs (CBN) method. It is known that these methods give radically different results; using data for Indonesia, Ravallion and Bidani (1994) found virtually zero correlation between the regional poverty profiles (given the poverty rates across geographic areas) produced by these two methods. Since policy choices (such as in regional targeting) could depend critically on which method is used, it is important to probe carefully into the choice.

The FEI method can be interpreted as a special case of the functioning-based approach described above. The specialization is to focus on just one functioning, namely food-energy intake. The method finds the consumption expenditure or income level at which food-energy intake is just sufficient to meet predetermined food-energy requirements for good health and normal activity levels. (Such caloric requirements are given in WHO 1985, for example.) To deal with the fact that food-energy intakes naturally vary at a given income level, the FEI method typically calculates an expected value of intake at given income. Figure 1 illustrates the method. The vertical axis is food-energy intake, plotted against income (or expenditure) on the horizontal axis. A line of ‘best fit’ is indicated; this is the expected value of caloric intake at given income (that is, the non-linear regression function). By simply inverting this line, one finds the income z at which a person typically attains the stipulated food-energy requirement. This method, or something similar,



Poverty Lines, Fig. 1 The food-energy intake method of setting poverty lines has been used often, including by Dandekar and Rath (1971), Osmani (1982), Greer and Thorbecke (1986), and Paul (1989), and by numerous governmental statistics offices. It is often found in practice in developing countries.

One concern about this method is that the resulting poverty lines need not be consistent in terms of utility or capabilities more generally (Ravallion 1994; Ravallion and Lokshin 2006). Consider first how FEI poverty lines respond to differences in relative prices, which can of course differ across the subgroups (such as regions) being compared in the poverty profile and over time. For example, the prices of many non-food goods relative to food are likely to be lower in urban than in rural areas. This will probably mean that the demand for food and (hence) food-energy intake will be lower in urban than in rural areas, at any given real income.But this does not, of course, mean that urban households are poorer. The relationship between food-energy intake and income will shift according to differences in tastes, activity levels and publicly provided goods. There is nothing in the FEI method to guarantee that these differences are ones that would normally be considered relevant to assessing welfare. Indeed, it is quite possible to find that the 'richer' sector (by the agreed metric of utility) tends to spend so much more on each calorie that it is deemed to be the 'poorer' sector. That has been found to be the case in studies of the properties of FEI poverty profiles for Indonesia (Ravallion and Bidani 1994) and Bangladesh (Ravallion and Sen 1996; Wodon 1997).

Problems also arise in comparisons over time. Suppose that all prices increase, so the cost of a given utility must rise. There is nothing to guarantee that the FEI-based poverty line will increase. That will depend on how relative prices and tastes change; the price changes may well encourage people to consume cheaper calories, and so the FEI poverty line will fall. Wodon (1997) gives an example of this problem in data for Bangladesh. The FEI poverty line fell over time even though prices generally increased. The potential utility inconsistencies in FEI poverty lines are worrying when there is mobility across the subgroups of the poverty profile, such as due to inter-regional migration. For example, it is possible that a process of economic development through urban sector enlargement, in which none of the poor are any worse off and at least some are better off, would result in a measured *increase* in poverty.

The CBN method stipulates a consumption bundle deemed to be adequate for 'basic consumption needs', and then estimates its cost for each of the subgroups being compared in the poverty profile. This is the approach of Rowntree (1901) in his seminal study of poverty in York, England, in 1899, and there have been numerous examples since, including the official poverty lines for the United States (Orshansky 1963; also see Citro and Michael 1995). Some form of functioning consistency is assured by construction, since various valued functionings are essentially the starting point for defining 'basic consumption needs'. The poverty bundle is typically anchored to food-energy requirements consistent with common diets in the specific context. However, allowances for non-food goods are also included, to assure that basic non-nutritional functionings are assured.

The CBN method is utility consistent *if* the right bundle is used, corresponding to the relevant points on the utility-compensated demand functions (Eq. 2). However, there is nothing to guarantee that the bundles of goods built into CBN poverty lines lie on the compensated demand functions, at the (common) reference level of utility. Thus it is important to have some way of assessing a set of CBN poverty bundles. Ravallion and Lokshin (2006) propose an approach to testing the utility consistency of CBN poverty lines across households with common preferences using Samuelson's (1938) theory of revealed preference. However, this can be applied only within subgroups deemed to have common preferences. In practice utility functions can vary, due to differences in climate, for example.

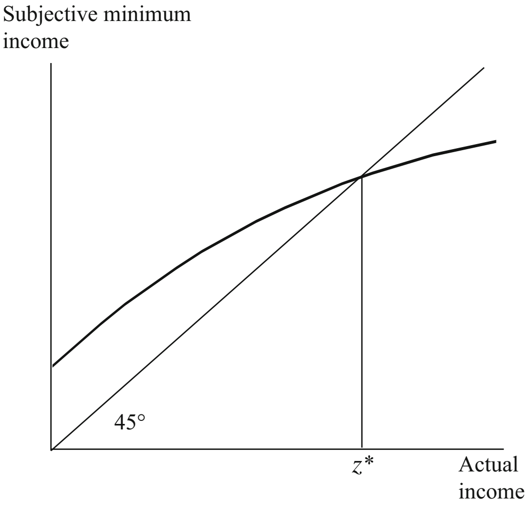
In some cases a complete vector of normative (food and non-food) goods is set, as in Russia's poverty lines (Ravallion and Loskhin 2006). However, it is more often the case that only food needs are set, based on nutritional requirements. To include an allowance for non-food needs, a common practice is to divide the food poverty line by some budget share for food. For example, the US poverty line assumes a food share of one third, so the total poverty line is three times the food line (Orshansky 1963). However, the basis for setting a food share is rarely transparent. Why use the average share, as in the US line? Whose food share should be used?

Arguably, a more appealing approach is to set an allowance for non-food goods that is consistent with demand behaviour at (or in a region of) the food poverty line. Ravallion (1994) proposes two methods. The first divides the food component of the poverty line by the mean food share of households whose actual food spending is in a neighbourhood of the food poverty line. The second method uses mean non-food spending of households whose total sending is in a neighbourhood of the food poverty line. Ravallion argues the first method gives a reasonable upper bound to the allowance for non-food needs while the second gives a lower bound.

Subjective Poverty Lines

There is an inherent subjectivity and social specificity to any notion of 'basic needs', including nutritional requirements. Psychologists, sociologists and others have argued that the circumstances of the individual relative to others influence perceptions of well-being at any given level of individual command over commodities. (Runciman 1966, provided an influential exposition, and supportive evidence. Also see the discussions in Easterlin 1995, and Oswald 1997.) By this view, 'the dividing line . . . between necessities and luxuries turns out to be not objective and immutable, but socially determined and ever changing' (Scitovsky 1978, p. 108).

Subjective poverty lines have been based on answers to the 'minimum income question' (MIQ), such as the following (paraphrased from Kapteyn et al. 1988): 'What income level do you personally consider to be absolutely minimal? That is to say that with less you could not make ends meet.' (This can be thought of as a special case of Van Praag's 1968, 'income evaluation question', which asks what income is considered 'very bad', 'bad', 'not good', not bad', 'good', 'very good'.) One might define as poor all whose actual income is less than the amount they give as an answer to this question. However, this would almost certainly lead to inconsistencies in the resulting poverty measures, in that people with the same income, or some other agreed measure of economic welfare, will be treated differently. Clearly an allowance must be made for heterogeneity, such that people at the same standard of living may well give different answers to the MIQ, but must be considered equally 'poor' for consistency. Past empirical work has found that the expected value of the answer to the MIQ conditional on actual income tends to be an increasing function of actual income. (Contributions include Groedhart et al.1977; Danziger et al.1984; and Kapteyn et al.1988.) Furthermore, past studies have tended to find a relationship such as that depicted in Fig. 2, which gives a stylized representation of the regression function on income for answers to the MIQ. The point z^* in the figure is an obvious candidate for a poverty line; people with income above z^* tend to feel that their income is adequate, while those below z^* tend to feel that it is not. We can call z^* the 'social subjective poverty line' (SSPL).



Poverty Lines, Fig. 2 The social subjective poverty line (z^*)

It is recognized in the literature that there are other determinants of economic welfare which should shift the SSPL, such as family size and demographic composition. Indeed, the answers to the MIQ are interpretable as points on the consumer's expenditure function at a point of minimum utility (Eq. 1). Under this interpretation, subjective welfare assessments provide a means of overcoming the well-known problem of identifying utility from demand behavior alone when household attributes vary (Kapteyn 1994).

While the MIQ has been applied in a number of OECD countries, there have been few attempts to apply it in a developing country. There are a number of potential pitfalls. 'Income' is not a well-defined concept in most developing countries, particularly (but not only) in rural areas. It is not at all clear whether one could get sensible answers to the MIQ. The qualitative idea of the 'adequacy' of consumption is a more promising one in a developing-country setting, and (arguably) many developed counties.

Pradhan and Ravallion (2000) propose a method for estimating the SSPL based on qualitative data on consumption adequacy, as given by responses to appropriate survey questions. Instead of asking respondents what the precise minimum consumption is that they need, one simply asks whether their current consumptions are adequate. This provides a multidimensional extension to the one-dimensional MIQ. The SSPL is the level of total spending above which respondents say (on average) that their expenditures are adequate for their needs. For empirical implementation, the probability that a sampled household will respond that its actual consumption of each type of commodity is adequate can be modelled as a probit regression. Under certain technical conditions, a unique solution for the subjective poverty line can then be obtained from the estimated parameters of the probit regressions for consumption adequacy. Pradhan and Ravallion provide empirical examples for Jamaica and Nepal; the SSPL gave a similar overall poverty rate to preexisting objective poverty lines for both countries, though the structure of the poverty profile was different in some respects: for example, while the objective poverty lines implied that larger households tended to be poorer, this was not the case with the subjective approach.

Subjective data also offer a test of objective poverty lines, by regressing selfrated welfare on income normalized by the poverty line *plus* the variables that went into the construction of the poverty line, which should be jointly insignificant if those lines accord with subjective welfare. This approach is outlined in Ravallion and Lokshin (2002) and illustrated using Russia's poverty lines.

Poverty Traps

Kiminori Matsuyama

Abstract

A poverty trap is a self-perpetuating condition, in which an economy suffers from persistent underdevelopment, vicious circle of poverty, created by circular causation due to the presence of some external economies and/or strategic complementarities. We discuss the concept in a dynamic setting, and review some models of poverty traps in the literature. The policy prescriptions of such models should be treated with caution, since each model identifies one cause; but as many causes are likely to coexist, attempts to pull an economy out of one trap may push it into another.

A poverty trap is a self-perpetuating condition whereby an economy, caught in a vicious circle, suffers from persistent underdevelopment. Although it is often modelled as a low-level equilibrium in a static model of coordination failures, we discuss the concept in a dynamic setting. This is because, in a static setting, we would be unable to distinguish poverty traps from (possibly temporary) bad market outcomes, such as recessions and financial crises, that are also often modelled as low-level equilibriums in a static model of coordination failures.

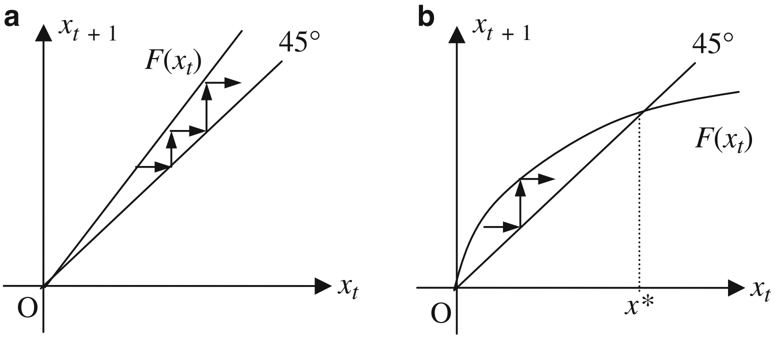
On the Mechanics of Poverty Traps

Imagine that the state of the economy in period t is represented by a single variable, x_t, where a higher x means that the economy is more developed, and that the equilibrium path follows a deterministic one-dimensional difference equation, $x_{t+1} = F(x_t)$. Once the initial condition, x_0, is given, this law of motion can be applied iteratively to obtain the entire trajectory of the economy.

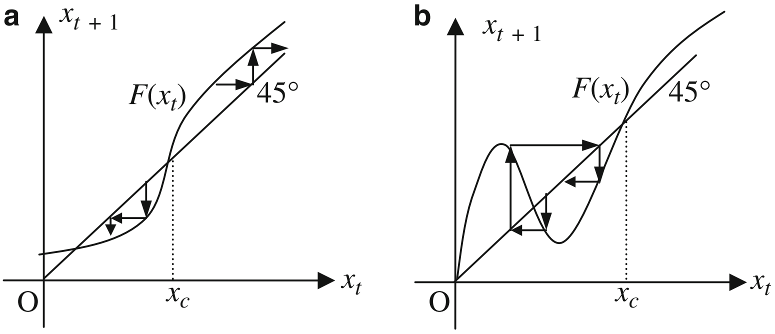
In Fig. 1a, $F(x)$, stays above the 45° line everywhere, hence the economy grows forever (as in the endogenous growth models). In Fig. 1b, for any x_0, the economy converges to x^* (as in the Solow growth model). In either case there is no poverty trap, since the long-run performance of the economy is independent of the initial condition, no matter how underdeveloped the economy is initially. (Confusion sometime occurs because a few authors use the term 'trap' to describe the situation depicted in Fig. 1b, in the sense that growth is not sustainable. However, this should more appropriately be called 'the limit to growth'. This limit is not caused by the initial poverty of the economy.)

In Fig. 2a and b, on the other hand, the long-run performance depends on the initial condition. When the economy starts above x_c, it will stay above x_c and may either grow forever or reach a higher stationary state. However, if it starts below x_c, it will be trapped forever below x_c. In this sense, both figures exhibit a poverty trap in its strong form. In Fig. 2a, the economy caught in the trap will converge to the low-level stationary state. In Fig. 2b, it will fluctuate below x_c. In both cases, the economy will remain poor only because it is poor. Thus, the poverty becomes its own cause. It is this self-perpetuating nature that sets 'the poverty trap' apart from 'the limit to growth'.

Both Fig. 2a and b project the very stark view that the economy can never escape from the poverty trap. This should not be taken too literally.



Poverty Traps, Fig. 1



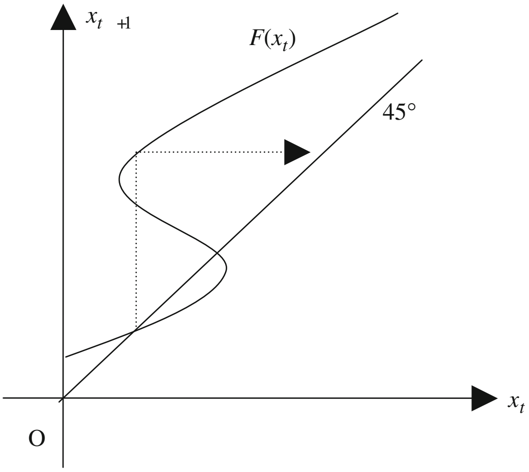
Poverty Traps, Fig. 2

The essential message of poverty traps is that poverty tends to persist, and that it is difficult, but not necessarily impossible, for the economy to escape from it. Poverty traps in their weak form are depicted in Fig. 3a and b. In Fig. 3a, the economy has to experience stagnation for long time as it travels through the 'narrow corridor' between $F(\cdot)$ and the 45° line, before eventually succeeding in taking off. In Fig. 3b, the economy may or may not manage to escape the trap after experiencing (possibly many) periods of volatility. For all practical purposes, the situations depicted in Fig. 2a and b and Fig. 3a and b are difficult to separate, but the message is the same: the self-perpetuating nature of poverty.

The above analysis can be extended in many directions. First, one could add stochastic shocks to the system, as $x_{t+1} = F(x_t, \xi_{t+1})$. Such shocks perturb the map, which may switch the graph back and forth between Figs. 2a (or 2b) and Figs. 3a (or 3b). This can be viewed as a jump in the state variable in the case of the additive shocks, $x_{t+1} = F(x_t) + \xi_{t+1}$. (For example, natural disasters, plagues and wars could cause the capital–labour ratio to jump up and down.) In the presence of such stochastic shocks, the economy may occasionally and recurrently escape or fall into the trap. Hence, the analysis has to be described in terms of the stochastic kernel; see Azariadis and Stachurski (2005) for a detailed discussion of stochastic poverty trap models.

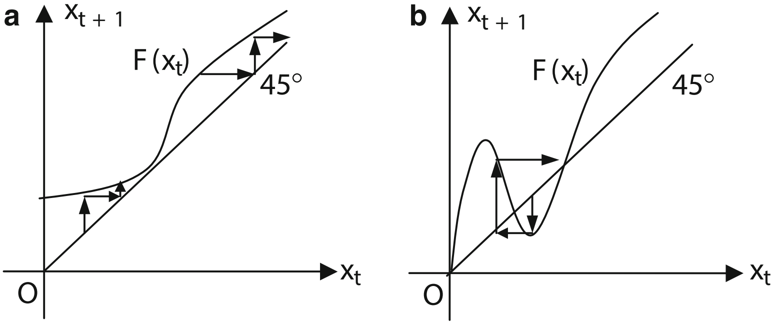
Second, the above analysis assumes that x_{t+1} is uniquely determined as a function of x_t. If the underlying economic models permit multiple equilibria, as often is the case with models of external economies and strategic complementarity, then $F(\cdot)$ becomes a correspondence, and the (deterministic) equilibrium path follows the difference inclusion, $x_{t+1} \in F(x_t)$. See Matsuyama (1997) for some examples. Figure 4 depicts one possibility, suggesting that the economy is stuck in a low-level stationary state, in part due to coordination failures. In this case, the economy could escape the poverty trap if it succeeded in coordinating on a higher equilibrium, as indicated by the dotted arrow. (If such coordination takes place through a realization of some coordination devices, 'sunspots', it can be viewed as a model of endogenous stochastic shocks.)

Third, the underlying economic model may imply that the law of motion be described in a multi-dimensional system. For example, the state space may be two-dimensional, $(x; q)$, where x is



Poverty Traps, Fig. 4

Poverty Traps, Fig. 3



the state (or backward-looking) variable, such as the capital stock, and q is the co-state (or forward-looking) variable, such as the asset price or consumption, and the law of motion is given by a two-dimensional difference equation, $(x_{t+1}, q_{t+1}) = F(x_t, q_t)$. In this case, for a given initial condition, x_0, the equilibrium condition may not uniquely pin down the initial value, q_0. That is, there may be multiple equilibrium paths, with self-fulfilling expectations, which suggests another way in which the economy may escape from the poverty trap; see Matsuyama (1991). Or the dimensionality of the state space may be equal to the number of industries in a multi-industry model, or to the number of countries in a multi-country world economy model. In such a high-dimensional system, one could encounter a much richer set of dynamics, where the long-run behaviour can depend on the initial condition in a much more complex manner.

Some Models of Poverty Trap

Many (dynamic) models of poverty traps have been proposed in the literature. The common feature of these models is the presence of some external economies or strategic complementarities that give rise to the circular causation. Here is a highly selective list.

Learning-by-Doing Externalities

The infant industry argument for protection (see Corden 1977, for a synopsis) is a classic example. When firms are inexperienced and unproductive, they cannot offer wages high enough to attract workers from other sectors, and hence are not able to accumulate experience. Temporary protection has been suggested as a way to break the vicious circle. Helping some industries accumulate experience to escape from a poverty trap, however, may end up pushing the economy into another poverty trap, as it could prevent other (new and possibly more promising) industries from growing. If the scope of productivity improvement in any industry is limited, then the only way of avoiding poverty traps and achieving sustainable growth is to keep the delicate balance so that production will shift constantly from one industry to another, as existing industries become mature and new industries are born; see Stokey (1988); Brezis et al. (1993); Matsuyama (2002).

Search Externalities

The difficulty of finding business partners can discourage many from entering an industry, which in turn makes it even harder for others to find business partners. See Diamond (1982).

Human Capital Externalities

Following the Lucas (1988) model of endogenous growth based on human capital accumulation, Azariadis and Drazen (1990) showed how it could lead to the existence of poverty traps, when human capital is subject to threshold externalities.

Market Size and Division of Labour

Adam Smith argued that 'the division of labour is limited by the extent of the market'. Young (1928) argued that the extent of the market is also limited by the division of labour. That is, economic growth can be achieved by means of greater specialization, which was formalized by Romer (1987) and others. Building on this body of work, Ciccone and Matsuyama (1996) showed how the economy can be caught in a poverty trap. The basic mechanism is that advanced technologies require the use of highly specialized equipment and producer services. In the underdeveloped economy, the limited availability of specialized inputs forces downstream industries to rely on less advanced technologies, which do not require the use of specialized inputs. This in turn leads to a small market size for specialized firms in upstream industries. Hence, the economy is caught in the vicious circle of limited market size and limited division of labour.

Financial Developments

In countries with limited opportunities to diversify risk, entrepreneurs are discouraged from making productive but risky investments. This in turn leads to a limited set of traded financial assets, which reduces the opportunity to diversify risk. See Saint-Paul (1992) and Acemoglu and Zilibotti (1997).

Low Wealth/Low Investment

When external finance is more costly than internal finance, a decline in borrower net worth leads to a higher investment distortion. In Bernanke and Gertler (1989), this leads to a decline in the investment, which in turn leads to a decline in the net worth of the next generation of entrepreneurs, hence generating persistence in the aggregate investment dynamics. In Matsuyama (2004), the same mechanism could make some (but not all) countries in the world caught in the vicious circle of low net worth–low investment. Matsuyama (2007) showed how the trap can sometimes take the form of greater volatility (as shown in Fig. 2b). In a set-up that allows for wealth distribution to evolve over time, Banerjee and Newman (1993) suggested that greater initial wealth inequality, to the extent that it increases the number of entrepreneurs rich enough to finance their investments, can lead to a higher aggregate investment, which in turn could help the poor in the long run, thereby breaking the vicious circle.

Demographic Trap

Nelson (1956) is among the first to argue that underdeveloped countries are caught in the vicious circle of high population growth and low per capita income. Becker et al. (1990) showed how the economy may be caught in the vicious circle of high fertility–low human capital. Basu (1999) and Doepke and Zilibotti (2005) discussed child labour traps. In Matsuyama (2000), intergenerational persistence of a high labour force participation rate by the elderly could lead to a poverty trap.

Contagious Social Norms

Tirole (1996) showed how corruption or other unethical behaviour can be contagious and persistent. He considered the setting where, in the presence of imperfect information, the reputation of a member of the group (say, a firm in the industry) depends not only on his own past behaviour, but also on the past behaviour of other group members. Then, when the group has the reputation of being dishonest, it would be difficult for the member to establish a reputation for honesty. This induces him to behave dishonestly, thereby contributing to the bad reputation of the group.

Modelling Inertia

Underdevelopment is often modelled as a Pareto-dominated equilibrium in a static game of strategic complementarities. Murphy et al. (1989) is the best-known example. By adding some inertia, which restricts the ability of the players to switch their strategies, one can convert virtually any static game of strategic complementarities into a dynamic model of poverty traps, where both the initial condition and expectations can play a role in determining the long-run performance of the economy. See the techniques developed by Matsuyama (1991) and Matsui and Matsuyama (1995).

Some Cautionary Remarks on Interpretations

The poverty trap is often interpreted as an explanation for *cross-country* income difference. As such, it is frequently viewed as an *alternative* to the models that attribute *cross-country* income difference to the *cross-country* difference in, say, TFP and/or investment distortions. This is a misinterpretation. First, the message of poverty trap models is the self-perpetuating nature of poverty. It suggests that the long-run performance of an economy could be much better if its initial condition were better. It does *not* mean that the cross-country difference in the long-run performance is due mostly to the difference in their initial conditions. Second, the notion of poverty trap does not contradict the observation that low income is often associated with low TFP and/or high investment distortions. Indeed, many poverty trap models attempt to explain the two-way causality between low-income and low TFP and/or high investment distortions. By endogenizing TFP and/or investment distortions, these poverty trap models go one step further than the models that treat these variables as exogenously given.

Many calls for foreign assistance for underdeveloped countries can be understood using the notion of poverty trap; see, for example, Sachs et al. (2004). Indeed, the poverty trap is often viewed as a powerful case for policy activism. However, one should be careful when using any particular model of the poverty trap to make policy proposals. It is important to keep in mind that each model of the poverty trap is designed to highlight one particular feedback mechanism behind the vicious circle. To this end, other sources of the poverty trap are deliberately assumed away. In reality, of course, many sources of the poverty trap are likely to coexist. If there is one important lesson from the literature reviewed above, it should be that there are hundreds of traps that the economy can fall into, and any policy intervention that attempts to pull the economy out of one trap may end up pushing it into another. As we know, any attempt to solve a problem can often become a source of another, even bigger problem. For more on this issue, see Matsuyama (1996), which discusses economic development as 'complex' coordination problems.

Power

Samuel Bowles and Herbert Gintis

Abstract

We consider the exercise of power in competitive markets for goods, labour and credit. We offer a definition of power and show that if contracts are incomplete it may be exercised either in Pareto-improving ways or to the disadvantage of those without power. Contrasting conceptions of power including bargaining power, market power, and consumer sovereignty are considered. Because the exercise of power may alter prices and other aspects of exchanges, abstracting from power may miss essential aspects of an economy. The political aspect of private exchanges challenges conventional ideas about the appropriate roles of market and political competition in ensuring the efficiency and accountability of economic decisions.

Power is exercised in the competitive markets for goods, labour and credit. We consider this aspect of economic power, setting aside the widely recognized exercise of power by members of governments and other coercive bodies and the influence of economic groups on governmental policy.

Background

'An economic transaction is a solved political problem.…', wrote Abba Lerner (1972, p. 259)'. . .economics has gained the title Queen of the Social Sciences by choosing solved political problems as its domain'. Prior to the development of modern contract theory, the standard approach to power among economists was aptly summed up by Paul Samuelson (1957, p. 894), 'Remember that in a perfectly competitive market, it really does not matter who hires whom; so have labor hire capital'. As if responding to Samuelson, John Kenneth Galbraith (1967, p. 47), chided economists for not having asked 'why power is associated with some factors [of production] and not with others?' But with some notable exceptions (for example, Zeuthen 1930; Shapley and Shubik 1967; Samuels 1973; Lindblom 1977; Basu 1986; Takada 1995; Hirshleifer 1991; Chichilnisky and Heal 1984; Lundberg and Pollak 1994; Rotemberg 1993; Pagano 1999; Bardhan 2005; Aghion and Tirole 1997) economists have treated power as the concern of other disciplines and extraneous to economic explanation. The term does not appear among the 1,300 or so index entries of the leading graduate microeconomics text (Mas-Colell et al. 1995).

The reason is that Samuelson's claim is true in the Walrasian model: if contracts are complete, 'hiring' simply means 'buying'.'What does it mean', Oliver Hart (1995) asked, 'to put someone "in charge" of an action or decision if all actions can be specified in a contract?' But as an empirical matter, as Marx (1867), Coase (1937), Simon (1951) and others have stressed, the firm is a political institution in the sense that some members of the firm routinely give commands while others are constrained by the threat of sanctions to obey. To say that the manager has the right to decide what the worker will do means only that he has the legitimate authority to do this, not the power to secure compliance. Given that in a liberal economy management is sharply restricted in the kinds of punishment they can inflict, and given that the employee is free to leave, the fact that orders are typically obeyed is a puzzle. Why, in Coase's initial formulation, is the command of the manager (to move ‘from department Y to department X’) obeyed (Coase 1937)?

Noticing the lack of a good answer, Alchian and Demsetz (1972) challenged the Coasean idea that the firm is a mini ‘command economy’, suggesting that the employment contract is no different in this respect from other contracts.

> The firm. . .has no power of fiat, no authority, no disciplinary action any different in the slightest degree from ordinary market contracting between any two people. . .Wherein then is the relationship between a grocer and his employee different from that between a grocer and his customer? (1972, p. 777)

Hart (1989, p. 1771) offered the following response to Alchian and Demsetz:

> . . .the reason that an employee is likely to be more responsive to what his employer wants than a grocer is that the employer. . .can deprive the employee of the assets he works with and hire another employee to work with these assets, while the customer can only deprive the grocer of his customer and as long as the customer is small, it is presumably not very difficult for the grocer to find another customer.

Hart motivates the difference between the grocer and the employer by the assumption that the employee needs access not just to a job (and hence *some* assets) but *to this particular employer’s assets*. This might be the case due to a complementarity between the two (the employee may have made an investment in training which is of value only when combined with this particular asset, for example). Other less obvious (and probably more important) examples come to mind. Excluding an employee from access to a particular asset may require the employee to relocate, disrupting family and friendships. The loss of a job may also harm the employee’s reputation.

While transaction-specific investments of this type undoubtedly explain some authority relationships – in company towns, and for some professional jobs and managers, for example – the explanation seems insufficiently general to provide an adequate explanation of the entire authority structure of the firm, especially in large urban labour markets and for non-professional employees. We thus need a complementary explanation based on the fact that the employee excluded from access to *her current employer’s asset* may not find access to *any asset* even in a competitive economy in which transaction-specific assets are absent. This will require clarity about what we mean by power.

Power as a Political Means to Gain Economic Advantage in Private Exchange

Because of its close connection to value-laden words such as ‘coercion’ and ‘freedom’ the term itself has proven to be controversial among philosophers and political theorists (Nozick 1969; Lukes 1974; Bachrach and Baratz 1962; Barry 1976; Taylor 1982). Nonetheless, common usage suggests several characteristics that must be present when power is said to be exercised. First, power is *interpersonal*, an aspect of a relationship among people, not a characteristic of a solitary individual. Second, the exercise of power involves the *threat and use of sanctions*. Indeed, many political theorists regard sanctions as the defining characteristic of power.

Lasswell and Kaplan (1950, p. 75) make the use of ‘severe sanctions. . .to sustain a policy against opposition’ a defining characteristic of a power relationship, and Parsons (1967, p. 308) regards ‘the presumption of enforcement by negative sanctions in the case of recalcitrance’ a necessary condition for the exercise of power. Third, the concept of power should be *normatively indeterminate*, allowing for Pareto-improving outcomes (as has been stressed by students of power from Hobbes to Parsons), but also susceptible to abuse in ways that harm others in violation of ethical principles. Finally, power must be *sustainable as a Nash equilibrium* of an appropriately defined game. Power may be exercised in disequilibrium situations, of course, but, as an enduring aspect of social structure, it should be a characteristic of an equilibrium.

The following sufficient condition for the exercise of power captures these four desiderata: *For B to have power over A, it sufficient that, by imposing or threatening to impose sanctions* *on A, B is capable of affecting A's actions in ways that further B's interests, while A lacks this capacity with respect to B* (Bowles and Gintis 1992).

The fact that sanctions are essential to the exercise of power in our sense makes it distinct from other means of influencing the behaviour of others that may operate even in the complete absence of strategic interaction, as in a Walrasian market setting. Consider, for example, the standard definition due to Robert Dahl (1957, pp. 202–3): 'A has power over B to the extent that he can get B to do something that B would not otherwise do.' But one can affect the behaviour of another in ways that do not involve power in the usual sense of that term. If we buy a commodity, there will be a whole series of market effects through the economy which entail others doing things they would not otherwise have done. But to say that our purchase of bread is an exercise of power over some unknown wheat farmer with whom we do not interact strategically is to expand the concept of power beyond recognition. By making the threat of sanctions a necessary aspect of power we also exclude forms of interpersonal influence such as persuasion and the provision of information.

Short-Side Power in Labour, Credit and Goods Markets

The power that may be exercised by an economic actor depends on the actor's position in the institutions of society. Power may be exercised by economic actors who are on the short side of a non-clearing market, namely, the side of the market on which the number of desired transactions is less, that is, employers in a labour market with unemployment, lenders in a loan market with borrowers facing credit constraints, and so on. Because those holding power in these cases are those on the short side of the market, we term this 'short-side power'. This clarifies the difference between the employer and the grocer in Hart's response to Alchian and Demsetz: the sanctions imposed on the employee by depriving him of access to the capital good are severe because, in a labour market with perpetual excess supply of labour, finding another job will be difficult, while the costs imposed on the grocer by the departing customer are negligible or zero. The reason why the consumer, in switching to another seller, does not impose a sanction on the grocer is that the grocer (in competitive equilibrium) was maximizing profits by selecting a level of sales that equates marginal cost to the exogenously given price, and, this being the case, a small variation in sales has only a second-order effect on profits.

Let us check to see that this conception of power applies to the employment relationship in which transaction specificity is absent. We know that in a standard labour-discipline model (Gintis 1976; Shapiro and Stiglitz 1984; Bowles 1985), in equilibrium the worker receives a rent: the present value of the job exceeds her next-best alternative (job search) and, because she fears losing his job, she works harder than she would have in the absence of the employer's incentive strategy. These results together imply that the employer has caused the worker to act in the employer's interest by credibly threatening to sanction the worker. The employee lacks this capacity with respect to the employer for, were the employee to threaten the employer with a sanction should he not raise the wage (to damage his machinery or beat him up or simply to work less hard), the threat would not be credible. The employer would simply refuse to respond, knowing that it would not be in the interest of the employee to carry out the threat.

Note that the exercise of power allows a Pareto improvement over a counterfactual condition in which power cannot be exercised, namely, that the worker is hired at her reservation wage and works at the reservation effort level. This follows directly as we know from the fact that the worker receives an equilibrium rent at the wage offered by the employer. Both expected worker lifetime utility and firm profits are higher in equilibrium (with power being exercised) than at the (power-absent) reservation position. This is yet another example of a situation in which the exercise of power helps to address coordination failures, albeit sometimes with objectionable consequences those without power. An example from Bowles (2004) follows.

Suppose the employer determines (in addition to the wage) some aspect of the job affecting workplace amenities, including not only such innocuous things as the quality of the music on the office sound system but also management practices affecting the employee's dignity, such as not being subjected to racial insults, sexual harassment or other on-the-job indignities. If the firm sets these amenities to maximize profits, it follows that the employer can inflict first-order costs on the worker (by reducing the amenity a small amount) at second-order cost to himself (the costs are second-order because due to profit maximization the derivative of profits with respect to the level of amenities is zero). Thus the competitive equilibrium in an employment relationship gives the employer the capacity not only to exercise power to attenuate coordination problems but also to exercise power arbitrarily, that is, to inflict costs on another at virtually no cost to himself. When this power is exercised in unethical ways it may be termed coercive.

Thus the strategic interaction between the employer and employee allows the exercise of power in a manner conforming to the four desiderata outlined above: sanctions are credibly threatened (and used) in a strategic interaction describing a Nash equilibrium, and the resulting exercise of power is Pareto-improving over a reasonable counterfactual but may also be used coercively.

It is easy to check that power in the sense defined may be exercised in the standard principal–agent model of the credit market as well. The lender offers the borrower terms that are preferred to the borrower's reservation position, promising to make additional loans in the future if the borrower repays the loan. In this contingent renewal model, the borrower pursues a less risky strategy than would have been the case had the lender not offered a rent. Where the borrower's participation constraint holds as an equality, power in the sense defined cannot be exercised for the simple reason that the borrower is indifferent between the current transaction and the next-best alternative, so the only sanction permitted in a liberal economy – termination of the contract – has no force.

Short-side power may be contrasted with the 'markets and hierarchies' approach pioneered by Oliver Williamson (1985). Rather than seeing firms simply as 'islands of conscious power in this ocean of unconscious cooperation', in Robertson's (1923, p. 85) apt words, the incomplete contracts approach traces the exercise of power to both the structure of markets and the structure of firms. The firm is an important venue in which power is exercised, but, as the credit market model makes clear, power may be exercised in the absence of firms or indeed any organizational structure whatsoever. Short-side power is exercised *in* markets, not simply outside markets or despite markets.

Wealth, Power and 'Consumer Sovereignty'

Thus an agent's location in the economic structure of a society – on the short side of a non clearing market – may make it possible for him to exercise power over others. How are agents assigned to these positions of short-side power? Given that employing others requires capital and that borrowing substantial amounts typically requires that the borrower have sufficient wealth to invest in the project or to provide collateral, an important determinant of an individual's assignment to a position of short-side power is the individual's wealth. The wealthy may exercise power over those to whom they lend, who in turn may exercise power over those (managers or other employees) whom they hire. As a result, power cascades downward from the loan market to the market for managers to the market for non-managerial employees (Bowles 2004).

A less obvious case concerns the power of the consumer, sometimes summarized by the term 'consumer sovereignty'. Consider a principal–agent model involving difficult-to-measure product quality (Klein and Leffler 1981; Gintis 1976). In equilibrium, the buyer pays the seller a price exceeding the seller's next-best alternative and promises continued purchases contingent on the seller providing high-quality goods. The seller's prospect of losing the resulting rent conferred by the buyer induces the seller to provide higher quality than would have been provided in the absence of the threatened sanction. Thus the buyer has exercised power over the seller in the sense just defined.

As the example suggests, buyers may exercise power over sellers whenever the buyer's threat to switch to an alternative seller is credible and inflicts a cost on the seller. Consider two monopolistically competitive sellers (that is, firms facing downward-sloping demand functions) and a consumer who is indifferent between purchasing from one or the other. Both sellers have chosen a level of output to maximize profits, setting marginal cost equal to marginal revenue (which is less than the price because the demand curve is downward sloping). For both sellers, price thus exceeds marginal cost, and as a result the consumer's choice confers a rent on one and deprives the other of the rent. The reader may wonder how the rent can arise if the firm has chosen the output level to maximize profits, each setting the derivative of profits with respect to sales equal to zero. But the buyer's switch from one to the other seller is not a movement *along* a demand function (the basis of the firm's output choice), but rather is a horizontal *shift* in the demand function (inwards for the firm the consumer rejected, outwards for the firm to which he switched). As a result of the switch, for the fortunate firm it is profit maximizing to sell one more unit at the going price.

Ironically, the idealized Walrasian conditions under which consumer sovereignty is said to hold give the consumer no power in the sense defined here, while deviations from the canonical competitive assumption that price equals marginal cost (because firms face downward sloping demand functions) create an environment in which the consumer may exercise power. Of course, the strategic position of the consumer as one of many principals facing a single agent is quite unlike that of the employer facing many potential employees or the lender facing many potential borrowers. As Hart observed about the consumer and the grocer, a single consumer will not generally be in a position to command the supplier to improve the product quality and expect the supplier to obey. The power of consumers is thus limited by the difficulties the many principals face in acting in a coordinated fashion.

Non-clearing Markets and Inefficient Competitive Equilibria

Where power is exercised by a principal who confers a rent on an agent and monitors the agent's actions – as in the markets for labour, credit and goods just analysed – the equilibrium allocation will generally be neither Pareto-efficient nor technically efficient. The reason for the first is that the principal is constrained not by the agent's reservation utility but by the agent's best-response function. As a result, small changes in the instruments controlled by the principal – the wage, the rate of interest or the price – incur only second-order costs or benefits for the principal but first-order benefits and costs for the agent. For the actions controlled by the agent the reverse is true. Therefore, there must exist some set of small variations away from the equilibrium allocation that improve the utility of both principal and agent. A labour market example of such a Pareto improvement is a small increase in the wage accompanied by a small increase in worker effort.

The allocation will be technically inefficient because the principal chooses the enforcement strategy with respect to the private costs (the costs of both the rent conferred on the agent and the monitoring) while there is no social cost associated with the rent (because, unlike the monitoring costs, it is a pure transfer and is not resource using). From the equilibrium allocation, therefore, there must exist a technical efficiency-improving increase in the agent's rent and a reduction in monitoring.

Exploiting these potential efficiency gains requires changes in the information and incentive structure of the interaction, for example by making the agent the residual claimant on his or her non-contractible actions, if this is possible.

The three cases for which we have analysed the exercise of power – by the buyer over the seller, the lender over the borrower, and the employer over the employee – are members of a generic class of power relationships which are sustainable in the equilibrium of a system of voluntary competitive exchanges. In all three, those with power are transacting with agents who receive rents and hence are not indifferent between the current transaction and their next-best alternative. This being the case, there must exist other identical agents who are quantity constrained, namely, the unemployed, those excluded from the loan market or restricted in the amount they can borrow, and sellers who fail to make a sale. For this situation to characterize an equilibrium it must be that markets do not clear, which, as we have seen will be the case.

Power as we have defined it can be exercised in other ways, even when markets clear. An interesting (if perhaps not empirically important) example is provided by the case of optimal job fees, in which the fee eliminates the job rent *ex ante* so the market clears, the worker being indifferent between taking the job and paying the fee or not. But an *ex post* rent nonetheless exists, giving the employer the ability to sanction the employee. A job fee of this type is a pure case of an employee's transaction-specific investment, and the basis of the power of the employer in this case is an example of Hart's reasoning, above.

All three of those exercising power in the above examples – buyer, lender, employer – have in common that the party that contributes money to the transaction – the buyer's purchase price, the lender's loan, the employer's wage offer – is the one exercising power. This may seem an analytical foundation for the familiar adage that 'money talks', but the conclusion is misleading. Recall that in the centrally planned Communist economies it was generally the case that consumer durables (and many other consumer goods) sold below market-clearing prices. The resulting excess demand was allocated through a process of queuing and by other means (Kornai 1980). In this case the producers (sellers) were on the short side of the market, and those bringing money to the transaction – the buyers – were the long-siders, some of whom failed to make a trade. The notorious inferiority in the quality of consumer goods in centrally planned economies to those in capitalist economies may be explained in part by the fact that consumers were long-siders in the former and shortsiders in the latter. Or, to put it more graphically, one reason why Fords were better cars than their Cold War era Russian equivalents is that in Russia customers waited in line to purchase Volgas while in the United States Ford salesmen lined up to sell customers cars. Another reason is that in the United States workers waited in line to get jobs at Ford.

Other Conceptions of Power

Other uses of the term 'power' are common in economics. (We do not address the concept of 'coalitional power' advanced by Shapley and Shubik 1954, as it has found application primarily in the analysis of committees voting and other arenas addressed by political scientists.) 'Purchasing power' is just another word for the position of one's budget constraint (or wealth), and it does not concern the exercise of sanctions or indeed any strategic interaction at all. 'Market power' arises in thin markets in which an actor can benefit by varying a price. In the standard monopolistic competition case the seller is said to have market power. The seller is less constrained in the sense that he faces a downward sloping demand rather than horizontal demand function, while the consumer is more constrained in that there may be less choice among suppliers. But we have just seen that in this case the consumer who switches from one seller to another confers a rent on his favoured firm. (This why Ford salesmen line up to sell you cars.) Thus, if the buyer can credibly threaten to withdraw the rent he may be able to exercise short-side power over the seller. It thus is not clear how to reconcile usual notions of power – the use of sanctions to gain advantage – with the statement that the monopolist has power over the consumer.

Finally, there is 'bargaining power', typically meaning the share of the joint surplus which a party gains in a bargain (Binmore et al. 1986). Reflecting this usage, the exponents used in the

'Nash product' to solve the generalized Nash bargaining model are said to refer to the bargaining power of the two parties. Used this way, bargaining power refers to outcomes – to how much advantage one may gain – rather than to any particular means of attaining it (for example by threatening a sanction). If the bargaining problem is embedded in an ongoing interaction, then bargaining power and short-side power appear not only unrelated but even opposed. In the competitive equilibrium of the standard principal–agent model of the labour market, for example, the principal receives his reservation return (given by the zero profit condition) while the agent receives a rent. Therefore, the bargaining-power perspective would say that the employee has *all* the bargaining power. But the short-side power perspective would conclude that, far from a sign that the employee is powerful, the rent conferred on the employee as a profit-maximizing choice of the employer is the reason why the employer has power over the employee. The employee receives the rent because his services cannot be costlessly contracted for, and the employer profits in this case by paying to exercise power over the employee.

The fact that the exercise of power is ubiquitous in private exchange shows that it is mistaken to think of society as composed of a political sphere, meaning governments and other bodies with formal powers of coercion, and a private economic sphere in which the exercise of power is absent. The rejection of this public–private division raises important issues concerning the appropriate scope of for democratic political competition (in addition to market competition) as a guarantor of accountability in the economy (Dahl 1977; Bowles and Gintis 1993).

Power Laws

Xavier Gabaix

Abstract

A power law is the form taken by a remarkable number of regularities in economics, and is a relation of the type $Y = kX^{\alpha}$, where Y and X are variables of interest, α is called the power law exponent, and k is a constant. Many economic laws take the form of power laws, in particular macroeconomic scaling laws, the distribution of income, wealth, size of cities and firms, and the distribution of financial variables such as returns and trading volume. This article surveys the empirical evidence and the theoretical explanations for the occurrence of power laws.

A power law (PL), also known as a scaling law, is the form taken by a remarkable number of regularities or 'laws' in economics, and is a relation of the type $Y = kX^{\alpha}$, where Y and X are variables of interest, α is called the power law exponent, and k is a typically unremarkable constant.

A special type is the distributional PL, also called a Pareto law. For instance, the probability that a firm has more than x employees is proportional to $1/x^{\zeta}$, for some positive number ζ: $P(S > x) = k/x^{\zeta}$, for some k, at least in the upper tail or most of it. The exponent ζ is independent of the units in which the law is expressed. A special case is Zipf's law, which is a Pareto law with $\zeta \simeq 1$.

Understanding what gives rise to the scaling law, and explaining the precise value of the exponent (for example, why it is equal to 1 rather than any other number) is a challenge that has fascinated successive generations. Schumpeter (1949, p. 155) wrote: ‘Few if any economists seem to have realized the possibilities that such invariants hold for the future of our science. In particular, nobody seems to have realized that the hunt for, and the interpretation of, invariants of this type might lay the foundations for an entirely novel type of theory.’ Champernowne (1953) and Simon (1955) made great strides towards realizing Schumpeter’s vision, and the quest continues.

Power laws are also of great interest outside of economics. Understanding PLs is a large part of the theory of critical phenomena, in which many materials behave identically around phase transitions – a phenomenon physicists call ‘universality’, and which is still only partially understood. Power laws have proven useful for describing and understanding networks. Biology has also many scaling regularities; for example, the daily energy intake of an animal of mass M is proportional to the $M^{3/4}$. This regularity was explained (Brown and West 2000) via simple physical reasoning, which eschews the need to talk about the feathers and the hair of animals. Simpler and deeper principles underlie the regularities instead. The same holds for economic laws. Power laws give the hope of robust, detail-independent economic laws.

Theory: Forces That Generate Power Laws

Proportional Random Growth

Getting a power law To explain distributional PLs, a central mechanism is proportional random growth (Sornette 2001). The process was developed in economics by Champernowne (1953) and Simon (1955). Things are more tractable in continuous time (see Gabaix 1999).

Take the example of cities in an economy with a constant number of cities and a fixed total population. When the system grows, the same reasoning applies after normalization – S is the normalized size of a city, for example as a multiple of the median city population. Suppose that each city i has a population S_t^i and, between t and $t+1$, increases by a growth rate γ_{t+1}^i:

$$\mathrm{S}_{t+1}^i = \gamma_{t+1}^i \mathrm{S}_t^i \qquad (1)$$

and suppose that the γ_{t+1}^i are identically and independently distributed, with density $f(\gamma)$, at least in the upper tail. Call $G_t(x) = P\left(\mathrm{S}_t^i > x\right)$ the counter-cumulative distribution function. The equation of motion of G is:

$$\begin{aligned} G_{t+1}(x) &= P\left(S_{t+1}^i > x\right) = P\left(S_t^i > x/\gamma_{it}\right) \\ &= E[G_t\left(x/\gamma_{it}\right)]. \end{aligned}$$

Hence:

$$G_{t+1}(S) = \int_0^\infty G_t\left(\frac{S}{\gamma}\right) f(\gamma) d\gamma.$$

Its steady state distribution G, if it exists, satisfies

$$G(S) = \int_0^\infty G\left(\frac{S}{\gamma}\right) f(\gamma) d\gamma. \qquad (2)$$

One can try the functional form $G(S) = a/S^\zeta$, where a is a constant. Plugging it in Eq. (2) gives: $1 = \int_0^\infty \gamma^\zeta f(\gamma) d\gamma$, that is

$$E\left[\gamma^\zeta\right] = 1. \qquad (3)$$

The steady state distribution is (in the upper tail) Pareto, with an exponent ζ that satisfies Eq. (3).

To make sure that the steady state distribution exists, one needs some friction, for example a force that prevents small cities from becoming too small.

Getting a Zipf’s law We see that proportional random growth leads to a PL. Why should the exponent $\zeta = 1$ appear in so many economic systems? An answer is the following (see Gabaix

1999; Luttmer 2007; Rossi-Hansberg and Wright 2007). Suppose that the random growth process Eq. (1) holds through most of the distribution, and that the system has constant size. Then, $E[S_{t+1}] = E[\gamma]E[S_t]$. As the system has constant size, then we need $E[S_{t+1}] = E[S_t]$, hence $E[\gamma]= 1$. That means that $\zeta = 1$ is a solution of Eq. (3). In other words, to get Zipf's law we need a random growth process with small frictions.

In sum, proportional random growth with frictions leads to PLs, and proportional random growth with small frictions leads to a special type of PL, namely Zipf's law.

Inheritance Via Algebraic Transformation

Power laws have excellent inheritance and aggregation properties. The property of being distributed according to a PL is conserved under addition, multiplication, power transformation, min, and max. The general rule is that, when we combine two PL variables, the fatter-tailed (that is, the one with the smaller exponent) dominates. Call ζ_X the PL exponent of X, with $\zeta_X = +\infty$ if X is thinner than any PL, for example is a Gaussian. For X and Y independent random variables, and $\beta > 0$ a constant, we have: $\zeta_{X+Y} = \zeta_{X\cdot Y} = \zeta_{\max(X;Y)} = \min(\zeta_X\,;\zeta_Y)$, $\zeta_{\min(X;Y)} = \zeta_X + \zeta_Y$, $\zeta_{\alpha X} = \zeta_X, \zeta_X{}^{\alpha}/\zeta_X = \alpha$ (see Jessen and Mikosch 2006). Those properties generate new PLs from old ones. For instance, if mutual funds are PL distributed, then many of their actions (for example, trading volumes, or the price movements they create) will be PL distributed (Gabaix et al. 2006).

Equilibrium Economic Mechanisms

Optimization with PL objective function The early example is the Allais–Baumol–Tobin model of demand for money (see also Mulligan and Shleifer 2005; Gabaix et al. 2003). Costs and benefits are power functions of the variables of interest, so that maximization also yields a PL – there, money demand is proportional to the interest rate to the power $-1/2$. PL in, PL out.

Matching talents in the upper tail Another way to generate PLs is in matching the talent of individuals with large firms or audiences. For instance, Gabaix and Landier (2008) study the market for executives. They derive that, in the upper tail of all well-behaved distributions, if $T(x)$ is the talent of an individual in the x upper quantile, then $T'(x)$ is approximately a power function x^{α}. As a result, the competitive matching process generates a PL relation between CEO pay and firm size, and a PL of the pay distribution. Huge differences in pay reward minuscule differences in talent. The PL form of T' is likely to be useful in other superstars markets.

Empirics: The Main Power Laws of Economics

Old Macroeconomic Scaling Laws

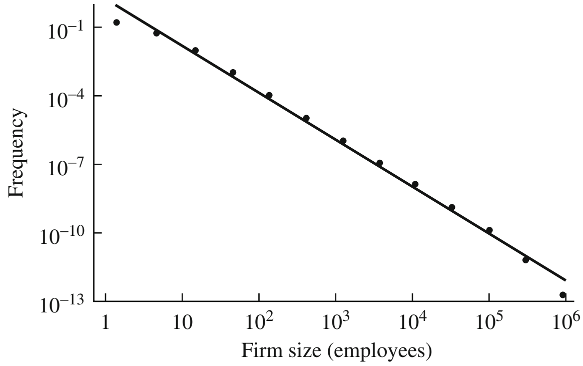
The first quantitative law of economics is probably the quantity theory of money, which, not coincidentally, is a scaling relation. It states that the price level P is proportional to the mass of money in circulation M, divided by the gross domestic product Y, times a pre-factor V: $P = VM\ /Y$. If the money supply doubles while GDP remains constant, prices double – a nice scaling law, relevant to policy.

More modern, we have Kaldor's stylized facts on economic growth: with K the capital stock, Y GDP, L population, r the interest rate, K/Y, wL/Y, and r, are roughly constant across time and countries. Explaining these facts led Solow to his growth model.

Reasonably Old and Well-Established Laws

Income and wealth The first PL is the Pareto law of income or wealth, which states that the tail distribution of income (or, respectively, wealth), is PL. The tail exponent of income seems to vary between 1.5 and 3, while the tail exponent of wealth is more stable. While, starting with Champernowne (1953), many models have been proposed to explain it (mainly along the lines of random growth), it is intriguingly unclear why the exponent is rather stable across economies.

Firm sizes The bulk of the distribution of firm sizes is well described by a Zipf's law (Fig. 1). This severely constrains models of firm growth,



Power Laws, Fig. 1 Note: Log frequency ln $f(S)$ vs. log size ln S of US firm sizes for 1997. OLS fit gives a slope of $1 + \zeta = 2{:}059$(s.e. $= 0.054$; $R^2 = 0.992$). This corresponds to a frequency $f(S) = kS^{-2{:}059}$, that is, a power law distribution with exponent $\zeta = 1{:}059$. Indeed, if $P(\text{Size} > S) = kS^{-}\zeta$ the density is $f(S) = k\zeta S^{-(\zeta+1)}$. This is very close to Zipf's law, which says that $\zeta = 1$ (Source: Reprinted with permission in Fig. 1 from Robert L. Axtel, *Science* 293, 1818–1820 (7 September 2001)

and means that idiosyncratic shocks of large firms may affect GDP (Gabaix 2006). Zipf's law holds for different measures of firm sizes and countries (Axtell 2001; Fujiwara et al. 2004; Gabaix and Landier 2008).

City sizes In the upper tail, Zipf's law holds generally well across times and countries (Gabaix and Ioannides 2004).

Gibrat's law for the growth rate of cities is shown in the United States by Ioannides and Overman (2003).

Roberts's law for executive compensation Across times and countries, an executive heading a firm of size S earns an amount proportional to S^{κ}, for a κ around 1=3. Superstars models explain the presence of this scaling (Gabaix and Landier 2006), but the reason for the 1/3 value remains a mystery.

More Recently Proposed Laws

Power law of stock market activity: returns, trading volume and trading frequency Following Mandelbrot, the following regularities have been found. Stock market returns (over one minute to one week) have PL tails, with an exponent around three (Gopikrishnan et al. 1999). Individual trades have a PL exponent around 1.5 (Gopikrishnan et al. 2000). The number of trades executed over a short horizon has an exponent close to three (Plerou et al. 2000). There is no consensus about the origins for those regularities. The fat tails of the returns might come from GARCH effects. One view (Gabaix et al. 2003, 2006) attributes it to the trades of large institutional investors in relatively illiquid markets, which creates spikes in returns and volume, and generates empirically found exponents.

Supply of regulations Mulligan and Shleifer (2005) establish another candidate law. In US states, the quantity of regulation is a PL of population.

Estimation of Power Laws

How does one estimate a distributional PL? We take the example of n cities in the upper tail, ordering them by size, $S_{(1)} \geq \cdots \geq S_{(n)}$. One method is Hill's estimator:

$$\hat{\zeta}^{Hill} = (n-1)/\sum_{i=1}^{n-1}\left(\ln S_{(i)} - \ln S_{(n)}\right)$$

which has a standard error $\hat{\zeta}^{Hill} n^{-1/2}$. The second method is a 'log rank log size regression', where $\hat{\zeta}$ is the slope in the regression of the log rank i on the log size:

$$\ln(i - s) = \text{constant} - \hat{\zeta}^{OLS} \ln S_{(i)} + \text{noise}$$

which has a standard error of $\hat{\zeta}^{OLS} \cdot (n/2)^{1/2} \cdot s$ is a shift, $s = 0$ is typical, but $s = 1/2$ is optimal (Gabaix and Ibragimov 2006). Both methods have pitfalls, as true errors are often larger than nominal standard errors (Embrechts et al. 1997; Gabaix and Ioannides 2004).

Power, Eileen Edna (1889–1940)

Phyllis Deane

Eileen Power's undergraduate years were spent at Girton College, Cambridge, where she was a teaching fellow in history for some years. Having little patience, however, with the medieval treatment Cambridge University meted out to female scholars, she was glad to escape first to the Sorbonne, then to the London School of Economics as a research student (1911–13) and finally on a travelling fellowship to the Far East in 1920–21. In 1921 she returned to the LSE, where she was rapidly promoted to Reader and in 1931 to Professor. There at least she did not have to fight for the privilege of giving her immensely popular lectures in a university lecture room.

The most distinctive feature of Eileen Power's contributions to economic history was her ability to distil from a pyramid of dusty manuscripts an account of human and institutional behaviour which was at once coherent, clear, comprehensive and lively. Her *Medieval English Nunneries* (1922) and *Medieval People* (1924) attracted a wide audience. Her posthumously published *Wool Trade in English Medieval History* (1941) synthesized two decades of patient detective work in contemporary records and literary sources and told the story of the medieval woollen industry from the pasture to the loom, the counting house and the ports. The detailed statistical research into the voluminous English trade records which she stimulated the members of her LSE seminars to exploit led to the pathbreaking *Studies in English Trade in the Fifteenth Century* (1933) which she edited with the young Michael Postan, her closest collaborator from 1926, when he became her research assistant, and her husband from 1937.

But it was through the stimulus of her imaginative scholarship on other economic historians that Eileen Power made her strongest impact on the study of economic history. It was said of her when she was being presented for an honorary degree at Manchester that she combined the graces of a butterfly with the sober industry of the bee. She was one of the founder members of the Economic History Society and the wide range of her international professional friendships made her an invaluable member of the Editorial Board of the *Economic History Review.*

Pownall, Thomas (1722–1805)

Henry W. Spiegel

English colonial administrator and Governor of Massachusetts, Pownall was an early critic of Adam Smith's *Wealth of Nations.* He published his criticism under the title *A Letter from Governor Pownall to Adam Smith* in 48 large quarto pages late in 1776. Smith acknowledged it in a polite letter early in 1777. There is a further reference to the matter in Smith's correspondence with Andreas Holt of 26 October 1780.

In the *Letter,* Pownall expresses his admiration for Smith's work as a whole, which, if properly corrected, should serve as the basis of lectures at the universities. He finds fault, however, with a number of Smith's ideas. He opposes Smith's view of the propensity to barter as a cause of the division of labour. To him, the latter stems from differences in men's natural endowment. He has doubts about Smith's distinction between natural and market price, the latter being the only 'real' price, and about the search for a real measure of value. He does not accept the view that relative prices are measured by labour; in his opinion they reflect the bargaining power of the parties. He defends the monopoly of colonial trade, bounties on exports and restraints on imports, and has much praise for metallic money, which is a national asset and not merely a medium of exchange. He takes Smith to task for underestimating the economic and military value of the North American colonies and for proposing the dismemberment of the empire. Some of Pownall's critical points are informed by his experience as a colonial administrator. His criticism, on the whole, reflects a late flowering of mercantilist views and demonstrates that Smith's ideas did not altogether go unchallenged by exponents of the old order.

Pownall's *Letter* was only a passing episode in a life filled with accomplishments in public service, and he was the author of *The Administration of the Colonies,* first published in 1764 and frequently reprinted, in which he proposes a commonwealth-type colonial reorganization.

Prebisch, Raúl (1901–1986)

José Gabriel Palma

Abstract

Prebisch was concerned with four stylized facts of commodity-exporting middle- income countries: (*a*) failure to 'catch-up'; (*b*) recurrent balance of payments disequilibrium; (*c*) unstable and deteriorating terms of trade; and (*d*) persistent unemployment. At the core of Prebisch's analysis lies his differentiation of the economic and export structures of the centre and periphery. Those of the centre were seen as *homogeneous* and *diversified,* those of the periphery as *heterogeneous* and *over-specialized.* Prebisch associates the second and third problems above primarily with export over-specialization (too few homogeneous, unbranded and price-volatile commodities), and the first and fourth with structural heterogeneity (which hindered industrialization).

Prebisch was born on 17 April 1901 in Tucumán, Argentina, and died at the age of 84 in Santiago de Chile. He graduated in Economics at the University of Buenos Aires in 1923 having already published six papers in academic journals.

He was Professor of Political Economy at the University of Buenos Aires from 1925 to 1948. In 1930 he became Under-Secretary of Finance at the age of 29, and soon afterwards the first Director General of the Argentine Central Bank (1935–43). He then moved to the United Nations, being appointed Executive Secretary of the Economic Commission for Latin America and the Caribbean (ECLAC) in 1950. In 1963 he moved to the United Nations Conference on Trade and Development (UNCTAD) as its first Secretary General.

Although his main intellectual concern was always the understanding of the specific development obstacles facing commodity-exporting, middle-income, peripheral countries, he always acknowledged that early in his career he had viewed them from a mainstream perspective. His approach only changed when he witnessed the Great Depression (including the heterodox response to it of many industrialized countries) and read the *General Theory.* After writing several articles and an influential book on Keynes, in the 1950s he led his ECLAC team (which eventually included Fernando Henrique Cardoso, Enso

Faletto, Celso Furtado, Aníbal Pinto and Osvaldo Sunkel) in the formulation of the 'structuralist approach' (see dependency; Furtado, Celso; structuralism).

In this approach, Prebisch was basically concerned with four stylized facts of commodity-exporting, middle-income countries: (*a*) their growing income gap with industrialized countries (failure to 'catch up'); (*b*) their recurrent balance of payments disequilibrium; (*c*) the instability and the tendency to deterioration of their terms of trade; and (*d*) their persistent unemployment (often coexisting with inflationary pressures). At the core of Prebisch's analysis lies his differentiation of the economic and export structures of the centre and the periphery. Those of the centre were seen as *homogeneous* and *diversified,* those of the periphery as *heterogeneous* and *over-specialized*. Heterogeneous because economic activities with remarkably different productivity-growth dynamics existed side by side – namely, a modern export sector coexisting with a backward agriculture and an undersized manufacturing sector. Over-specialized because the range of exports was limited to just a few (homogenous, unbranded and price-volatile) commodities, and their process of production had very limited backward- and forward-linkages with the rest of the economy (see structuralism).

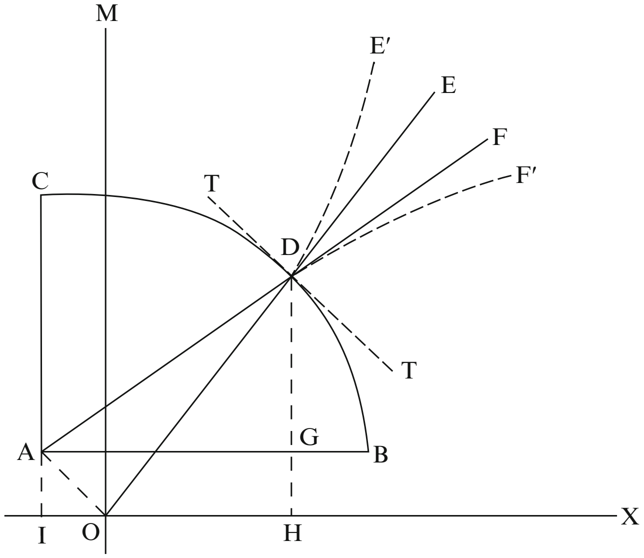
The recurrent cyclical problems of the balance of payments and the instability and the tendency to deterioration of the terms of trade are associated primarily with an excessive degree of export specialization (due to a narrow Ricardian understanding of comparative advantage); the problems of slow growth (and failure to 'catch up' with industrialized countries) and persistent unemployment with the constraints created by structural heterogeneity interacting with export overspecialization (which, among other things, hindered industrialization and created inflationary pressures).

His best-known thesis is the tendency to deterioration in the terms of trade of the periphery, the development of which coincided with (and owed much to) Hans Singer's work (1950). It is not clear whether he saw this as his most important contribution (or even as the most significant problem of a commodity-exporting country), but by its own nature the 'Prebisch–Singer' thesis was a seductive empirical challenge to that part of the academic world which is ever anxious for onedimensional hypotheses referring to clearly established variables. Prebisch was in fact much more concerned with the lack of impetus for industrialization resulting from a narrow and static Ricardian integration into the world economy. His main hypothesis is that there are reinforcing elements that – left to unregulated markets – would tend to work against the periphery's growth and welfare.

The tendency towards deterioration in the terms of trade of the periphery could be synthesized as in Fig. 1.

From the point of view of the periphery's consumption path, the Prebisch-Singer hypothesis is that the income elasticity of the periphery's imports from the centre (manufactures) is not only greater than 1 but also much greater than that of the centre for products of the periphery (commodities). Therefore, left to unregulated markets the long-term trend of the periphery's consumption path would be biased towards trade with the centre (say, ODE′ instead of the 'trade-neutral' ODE); that is, as incomes grow the proportion of importables (from the centre) in the periphery's consumption would increase. This would not be the case for the centre in terms of the share of its commodity imports from the periphery in total consumption (their income and price elasticities for commodities are low).

The same long-term trade bias would tend to happen in the production path – the periphery would tend to move along the ADF′ path instead of the 'trade-neutral' ADF one. That is, as output grows the share of (low price- and low income-elasticity) commodities for export in total output would increase, not least because of the additional foreign exchange needed to finance the trade-biased consumption path (something that often turns out to be a self-defeating endeavour). Therefore, vis-à-vis each other's products, the periphery would tend to have a more trade-biased path than the centre in terms of both consumption and production. There would consequently be a tendency for an excess demand from the periphery for imported manufactures from the centre, and an



Prebisch, Raúl (1901–1986), Fig. 1 X = exportable of the periphery (Primary commodity); M = importable of the periphery (manufacturing good); ABC = transformation curve of the periphery; ODE = the periphery's 'neutral' consumption path; ODE' = its 'biased-for-trade' consumption path; ADF = the periphery's 'neutral' production path; ADF' = its 'biased-for-trade' production path. For the periphery, at point D, OA = TT = terms of trade, DH = consumption of M, DG = local production of M, GH = AI = imports of M, IH = production of X, OH = local consumption of X; and IO = exports of X

excess supply of commodities, resulting in a tendency towards a deterioration of the terms of trade.

This tendency would be reinforced because of a similarity and a difference in productivity growth between commodities and manufactures. The similarity is that productivity growth can be relatively high in both types of products (commodities and manufactures, although is likely to be faster in the latter). The difference is that productivity increases in the centre's manufacturing do not tend to be transferred into lower prices as much as those of (homogenous and unbranded) primary production in the periphery (due to market imperfections in the centre's product and labour markets, mainly oligopolistic firms operating in product-differentiated markets and strong unions).

The end result would be that, if both poles were to grow at the same rate of per capita income, the periphery's more trade-biased path in both consumption and production (vis-à-vis each other's products) would tend to generate a deficit in its trade balance with the centre. Therefore, a long-term equilibrium in their balance of payments would require the income per capita of the periphery to grow systematically at a lower rate than that of the centre (the opposite of a 'catching up' scenario).

Further, Prebisch adds that this growth asymmetry would be reinforced by the fact that productivity growth in manufactures tends to have higher positive externalities and spillover effects, stronger linkages with the domestic economy, steeper technology ladders, and so on. Within this context, Prebisch argues that (for reasons of supply and demand) the periphery could achieve a higher sustainable growth path only by substituting highly income-elastic manufacturing imports with domestic production, and diversifying its exports towards more income- and price- elastic, productivity-enhancing products – that is, if it were to embark on a deeper and faster process of industrialization than one that would 'spontaneously' emerge from a Ricardian integration into the world economy.

Therefore, Prebisch's arguments for forcing the pace of industrialization are not only based on differences in income elasticities of demand for imports and in price elasticities of demand for exports (arguments at the level of the circulation of commodities), but are also due to the growth-enhancing nature of manufacturing activities (an argument at the level of production; see Kaldor, Nicholas).

Prebisch’s theory challenges Ricardo’s comparative advantage premises – in fact, for Prebisch the higher the rate of growth of productivity in the periphery’s primary commodity export sector, the greater the need for import-substituting industrialization (1983, p. 1082). It also challenges the classical terms-of-trade approach – for example, Mill (1848) and Keynes (1920) – which argued that in the long term they are bound to move in favour of commodities (mainly due to hypothetical diminishing returns in commodity production). Prebisch’s logic would later influence Joan Robinson (1979) when she argued that in Ricardo’s example Portugal ends up with a low rate of accumulation, and having destroyed its promising textile industry, while England in contrast had an industrial revolution (see Robinson, Joan Violet). It would also influence Kaldor’s arguments in favour of manufacturing-led growth (1967), Pasinetti’s multi-sector macro-dynamics framework (1983), Ajit Singh’s concept of an optimal degree of industrialization (1977), Rowthorn and Wells’ seminal work on de-industrialization (1987), and Thirlwall’s balance-of-payments-constrained growth multiplier (2003).

For criticisms of Prebisch’s ideas, see structuralism and dependency. Some additional issues to which the literature on Prebisch has not given due consideration are as follows:

1. Although there is no evidence that this was Prebisch’s intention, for many years his ideas led in many intellectual and policymaking circles to a strong bias against commodity production per se.
2. The asymmetric trade liberalization that has taken place since globalization (the periphery opening up to manufacturing imports, but the centre not reciprocating for commodities) has deepened the problems identified by Prebisch.
3. Prebisch’s Argentinian background is undoubtedly responsible for his focusing mainly on the relative decline of middle-income, commodity-rich countries, and for his scepticism regarding the role of an inelastic supply of agricultural products in explaining the regions’ persistent inflationary pressures (Argentina simply did not fit the pattern of the structuralist theories of inflation developed by many of his colleagues at ECLAC; see structuralism).
4. The recent remarkable export drive of basic (homogenous and unbranded) manufacturing products in some developing countries has led to their ‘price commoditization’ , leading to a similar terms of trade problem vis-à-vis their imports of more technologically advanced manufactures (see Palma 2005).
5. There are significant fallacy-of-composition issues among commodity-exporting countries (for example, actual price elasticity of demand crucially depends on market shares), making cooperative games among producers difficult.
6. Probably because of his own ‘institutional constraints’ (inevitable when working in international organizations), Prebisch never addressed properly some crucial institutional issues associated with the often poor macroeconomic performance of many mineral-exporting economies – such as those analysed (not always successfully) by the ‘resource course’ literature (see de-industrialization, ‘premature’ de-industrialization and the Dutch Disease).
7. Prebisch’s preferences for a ‘stage’ approach (first an import-substituting phase, then a manufacturing export-oriented one towards a regional custom union, then one to the rest of the world) did not account for institutional and political path- dependency inertias that would create almost insurmountable hurdles for the transition even to the second stage; East Asia’s ‘simultaneous’ approach was far more successful (Palma 2007).
8. Finally (and crucially), the contrasting experiences of Latin America and East Asia show that, while it is one thing to use trade and industrial policies to create incentives (rents)

to divert resources towards more 'dynamic' products (that is, income- and price-elastic manufacturing products, with deeper linkages, higher productivity growth potential, stronger externalities and spillover effects, useful for technology ladders, and so on), it is quite another to have the institutional capabilities necessary to ensure that the capitalist elite uses those rents effectively (Khan 2000).

Precautionary Principle

Christian Gollier and Nicolas Treich

Abstract

The precautionary principle (PP), as it appears in international treaties or in some countries' legal systems, suggests that the prospect of scientific progress should not justify the delay of preventive measures. Three effects identified in the economics literature – the irreversibility, the precautionary and the ambiguity aversion effects – may be consistent with the normative content of the PP. A difficult question is how then the PP can be implemented. Several social actors may want to take advantage of a current lack of scientific evidence to promote their own interests. The PP can also be misused, for example, for demagogy or protectionism.

The precautionary principle (PP) is a recent notion. It has its roots, some believe, in the early 1970s as the German principle of *Vorsorge,* or foresight (see, for example, O'Riordan and Cameron 1994; Morris 2000; Sunstein 2005). It is often said that the PP was first introduced in 1984 at the International Conference on Protection of the North Sea. Its popularity increased after the Conference of Rio in 1992; Principle 15 of the Rio Declaration states, 'Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation' (UNGA 1992).

Similar definitions have been proposed in international statements of policy, including the 1992 Convention on Climate Change, the 1992 Convention on Biological Diversity, the Maastricht Treaty in 1992/1993, and the 2000 Cartagena Protocol on Biosafety. The PP has also been enacted in the national law of several countries, especially in Europe.

The PP is the most notable anticipatory principle with special relevance for human-induced environmental problems under conditions of scientific uncertainty. Although devoid of practical content, the main message of the PP is conceptually clear: the prospect of anticipation of scientific progress should not justify the delay of measures preventing environmental degradation. In practice, its scope has became wider and there are reasonable grounds for applying it to regulate the protection of human, animal and plant health issues (see, for example, Commission of European Communities 2000).

The economic analysis of the PP has mostly studied the tension between two effects: (*a*) developing an economic activity that is profitable now but may pose risks to the society in the future, and (*b*) not developing this activity until conclusive scientific information is forthcoming about its harmlessness. The PP is said to be socially efficient if the benefit of postponing the risky activity is greater than its cost. To put it differently, the PP is efficient if the net social benefit of early prevention efforts is positive. The economic conditions for efficiency were first analysed in the 1970s in the literature on the 'irreversibility effect'.

The Irreversibility Effect

Let us consider a model of economic decisions represented by the following optimization program

$$\max_{x_1 \in D_1} E_{\tilde{y}} \max_{x_2 \in D(x_1)} E_{\tilde{\theta}/\tilde{y}}\ v\left(x_1, x_2, \tilde{\theta}\right) \tag{1}$$

The timing of the model is the following. At date 1, the decision-maker chooses x_1 in a set D_1. Between date 1 and date 2, he observes the realization of a signal y correlated to $\tilde{\theta}$. At date 2, before the realization of $\tilde{\theta}$, he chooses x_2 in a set $D(x_1)$. Finally $\tilde{\theta}$ is realized and the decision-maker gets a utility payoff $v(x_1; x_2, \theta)$. The problem is to determine the effect of a ‘better information structure’ $\tilde{y}$ on the optimal decision at date 1.

We first solve this problem when $v(x_1, x_2, \theta) = x_1 + x_2\theta$ with $D_1 = \{0, 1\}$ and $D(x_1) = \{x_1, 1\}$. This special case can be interpreted as a simple investment problem. The development of a ‘risky’ project – like the exploitation of a forest in which the value of biodiversity is unknown – is considered. If the project is implemented today ($x_1 = 1$), it yields a net benefit of 1 today and of $\tilde{\theta}$ in the future. The project is irreversible in the sense that once it is developed it cannot be stopped ($x_2 = 1$ if $x_1 = 1$). The stakeholders are assumed to be risk neutral.

Consider first the case in which no scientific progress is expected, that is, when $\tilde{y}$ is independent of $\tilde{\theta}$. In this case, program (1) becomes

$$\begin{aligned}&\max_{x_1 \in \{0,1\}, x_2 \in \{x_1, 1\}} E_{\tilde{\theta}}\left(x_1 + x_2\tilde{\theta}\right)\\ &= \max\left(1 + E_{\tilde{\theta}}\tilde{\theta}, 0\right)\end{aligned} \tag{2}$$

Either the project is implemented today if its expected net present value (ENPV) is positive, that is if $1 + E_{\tilde{\theta}}\tilde{\theta} \geq 0$, or it is never implemented. Consider alternatively the case of scientific progress that yields perfect information about $\tilde{\theta}$. This is equivalent to assuming perfect correlation between $\tilde{y}$ and $\tilde{\theta}$. In this case, program (1) becomes

$$\begin{aligned}&\max_{x_1 \in \{0,1\}} E_{\tilde{\theta}} \max_{x_2 \in \{x_1, 1\}}\left(x_1 + x_2\tilde{\theta}\right)\\ &= \max\left(1 + E_{\tilde{\theta}}\tilde{\theta}, E_{\tilde{\theta}}\max\left(0, \tilde{\theta}\right)\right)\end{aligned} \tag{3}$$

Viewed today, the ENPV of postponing the decision to develop the project equals $V = E_{\tilde{\theta}}\max\left(0, \tilde{\theta}\right)$. The project will be initiated today only if it yields a larger ENPV than that obtained if the decision is postponed to the future: $1 + E_{\tilde{\theta}}\tilde{\theta} \geq V$. The quantity V has been coined the (quasi-)option value (Arrow and Fischer 1974).

The comparison between (2) and (3) shows that scientific progress has the effect of increasing the ENPV of the best alternative option from 0 to $V \geq 0$. Consistent with the PP, this example shows that the prospect of scientific progress may lead to the postponement of the development of the risky project. The prospect of receiving information in the future increases the cost of choosing the irreversible decision today. This decision would prevent the decision maker from taking advantage of the information in the future. This is the ‘irreversibility effect’ (Henry 1974).

The literature has studied the generalization of this effect in several directions, including partial resolution of uncertainty, relative flexibility, continuous decision variables, non-separable preferences and risk aversion. This example relied on two extreme information structures: one structure gives no information and the other gives perfect information. The appropriate general notion of a ‘better information structure’ was introduced by Blackwell (1951). This general notion was used and developed in a systematic way by Epstein (1980) under some differentiability assumptions. Epstein then demonstrated that the irreversibility effect does not hold for most payoff functions $v(x_1; x_2, \theta)$. Jones and Ostroy (1984) have generalized Epstein’s result to non-differentiable problems and to a more general characterization of adjustment costs.

The Precautionary Effect

The subsequent literature has mostly used Epstein’s approach to examine the effect of better information for various payoff functions, on the assumption of continuous decisions, differentiability and that the conditions for optimization in (1) were satisfied. Ulph and Ulph (1997) consider a payoff function of the form $v(x_{1,} x_2, \theta) = u_1 (x_1) + u_2(x_2) - \theta d(\delta x_1 + x_2)$ and interpret x_t as the emissions of CO_2 in period t and $\theta d(.)$ as the uncertain climate damage that depends on the sum of emissions up to a decay parameter δ. They show that a better information structure may lead to an increase, not a decrease, in emissions at date 1. Gollier et al. (2000) analyse a similar model with monetary damages $v(x_1, x_2, \theta) = u_1 (x_1) + u_2(x_2 - \theta(\delta x_1 + x_2))$. They show that that emissions at date 1 decrease if and only if $u_2(.)$ has a constant relative risk aversion lower than 1, or a derivative 'sufficiently' convex. This latter condition suggests that the coefficient of prudence (Kimball 1990) is instrumental in signing the effect of a better information structure on x_1. This is not surprising since in this model x_1 affects future utility u_2, no longer by reducing the future set of choices but directly by changing the risk borne in the future $\theta(\delta x_1 + x_2)$. This is the 'precautionary effect'. Overall these results suggest that the qualitative effect of a better information structure strongly depends on functional forms, in particular on the risk attitude of the decision maker.

The Ambiguity Aversion Effect

The Ellsberg paradox tells us that many people do not behave according to the expected utility criterion when facing (scientific) uncertainty, contrary to what we assumed above. Gilboa and Schmeidler (1989) proposed an alternative decision criterion that performs better in this context. Under their model of ambiguity aversion, for each possible choice *ex ante,* the decision maker computes the expected utility conditional to each plausible scientific theory, and takes the minimum to evaluate the welfare generated by that choice. Agents who behave according to this maxmin model exhibit a form of choice-sensitive pessimism, which is called 'ambiguity aversion'. As shown for example by Chen and Epstein (2002) for financial markets, this ambiguity aversion reinforces risk aversion to induce people to adopt a more precautionary behaviour in the case of (scientific) uncertainty, as suggested by the PP.

Positive Aspects of the Precautionary Principle

The economic approach of the PP has been mostly normative so far. Under which conditions is the PP socially efficient? How should scientific uncertainty affect risk management? An equally important approach involves discussion on how the PP has been or should be implemented. We briefly turn to these more positive aspects.

A general argument is that scientific uncertainty may exacerbate, or even trigger, some market or regulatory failures (Gollier and Treich 2003). With a global pollution problem such as climate change, there are incentives for countries to free ride on other countries' reduction of emissions. Coalitions formations may reduce this inefficiency but coalitions are less likely to form if there is scientific progress (Na and Shin 1998). At a political level, an argument used by governments is that the problem is 'too uncertain' to abate emissions. Early commitments may help, but there are incentives for some governments, once information reveals low levels of damage in their own country, to refuse to abate emissions at a level announced by previous governments.

A difficult question is that of the most efficient policy to induce firms to internalize the risks they pose for the economy. In a market with imperfect legally enforceable property rights, firms may not take up the option of waiting for better information when high profits are guaranteed to first-movers. How to set binding legal incentives for firms' past actions made under conditions of scientific uncertainty is a big issue in law. This issue is augmented by the classical limited liability problem.

Another issue is that of international relations and the different approaches to safety and precaution across countries (Hammitt et al. 2005). One possibility is to leave states to decide how to account for scientific uncertainty in their safety policy. The problem is that such a discretionary power may be the source of disguised protectionism.

Scientific uncertainty may also increase the cognitive biases of the public in their perception of risks, like the standard 'availability heuristic'. Citizens often deem an event to be more probable when its occurrence can be easily recalled or visualized. As a result, they may overreact to highly publicized risks. Interest groups may exploit this bias, as well as politicians. A critical interpretation of the PP is to view it as a demagogic response to citizens' perceptions of risks (Sunstein 2005).

More generally, scientific uncertainty may favour, through the multiple channels of decision-making, opportunistic behaviours. Scientific uncertainty creates space for discretion in the risk regulatory process. Several social actors (entrepreneurs, lobbies, experts, politicians, media, and so on) may take advantage of the lack of scientific evidence to promote their own interests. The PP may be viewed as a soft safeguard against opportunistic behaviours in situations of asymmetric and evolving information. Yet designing stronger mechanisms needs a more detailed analysis of the sources of market failures, of risk management institutions and of citizens' behavioural responses. This may partly explain the existing voluminous literature on the PP in the social sciences, and may occupy economists in the future.

Precautionary Saving and Precautionary Wealth

Christopher D. Carroll and Miles S. Kimball

Abstract

Precautionary saving measures the consequences of uncertainty for the rate of change (and therefore the level) of wealth. The qualitative aspects of precautionary saving theory are now well established: an increase in uncertainty will increase the level of saving, but will reduce the marginal propensity to save. Quantitatively, theory combined with empirical estimates of risk aversion suggests that precautionary saving and precautionary wealth should be quite large. More direct empirical evidence on precautionary saving suggests that precautionary effects on saving are substantial, but the magnitude of the effects is disputed, and the different estimates are not all expressed in comparable units.

Precautionary saving is additional saving that results from the knowledge that the future is uncertain.

In principle, additional saving can be achieved either by consuming less or by working more; here, we follow most of the literature in neglecting the 'working more' channel by treating non-capital income as exogenous.

Before proceeding, a terminological clarification is in order. 'Precautionary saving' and 'precautionary savings' are often (understandably) confused. 'Precautionary saving' is a response of current spending to future risk, conditional on current circumstances. 'Precautionary savings' is the additional wealth owned at a given point in time as the result of past precautionary behaviour. That is, precautionary savings at any date is the stock of extra wealth that has resulted from the past flow of precautionary saving. To avoid confusion, we advocate use of the phrase 'precautionary wealth' in place of 'precautionary savings'.

Strength of the Precautionary Saving Motive

In the standard analysis, originally formulated in a two-period model by Leland (1968), and extended to the multi-period case by Sibley (1975) and Miller (1976), precautionary saving is modelled as the outcome of a consumer's optimizing choice of how to allocate existing resources between the present and the future. Additional interest in precautionary saving was stimulated by numerical solution of a benchmark model by Zeldes (1989) and the connection made in Barsky et al. (1986) between precautionary saving and the effects of government debt. (We assume time-invariant preferences in order to sidestep the important issues of time consistency recently explored by Laibson 1997, and others. That literature opens up a rich and interesting field of further behavioural possibilities beyond the basic logic outlined here.)

To clarify the theoretical issues, we break down the consumer's problem into two steps: the transition between periods, and the choice within the period. A consumer who ends period t with assets a_t receives capital income in period $t + 1$ of $a_t r$. The consumer's immediate resources ('cash-on-hand') in period $t + 1$ consist of such capital income, plus the assets that generated it, plus labour income y_{t+1}:

$$m_{t+1} = a_t r + a_t + y_{t+1} \tag{1}$$

$$= \underbrace{(1+r)}_{\equiv R} a_t + y_t + 1. \tag{2}$$

The simplest interpretation of m is as the contents of the consumer's bank account immediately after receipt of the paycheck and interest income ('cash-on-hand'). R is the real interest *factor*, as distinct from the real interest *rate*, lower case r. a_t reflects the consumer's accumulated assets at the end of period t, after the spending decision for period t has been made. The transition from the beginning to the end of period t reflects the fact that spending is paid for by drawing down m:

$$a_t = m_t - c_t. \tag{3}$$

To decide how to behave optimally in period t, the consumer must be able to judge the value of arriving in period $t + 1$ in any possible circumstance. This information is captured by the value function $v_{t+1}(m_{t+1})$. Here, we simply assume the existence of some well-behaved v_{t+1}; below we show how to construct v_{t+1}.

Standard practice assumes that consumers in period t weight future value by the factor β; if $\beta = 1$ the consumer today cares equally about current and future pleasure, while if $\beta < 1$ the consumer prefers present to future pleasure. Given β, and assuming that the consumer's period-t beliefs about future distribution of income are captured by the expectations operator E_t, we can define the value of ending period t with accumulated assets a_t as

$$\omega_t(a_t) = \beta E_t\left[v_{t+1}\left(Ra_t + \tilde{y}_{t+1}\right)\right], \tag{4}$$

where the ~ over the y indicates that period- $(t + 1)$ income is uncertain from the perspective of period t. Think of $\omega_t(a)$ as the end-of-period value function.

The consumer's goal is to optimally allocate beginning-of-period resources between current consumption and end-of-period assets; the value function for period t is defined as the function that yields the value associated with the optimal choice:

$$v_t(m_t) = \max_{c_t} \{u(c_t) + \omega_t(m_t - c_t)\}. \tag{5}$$

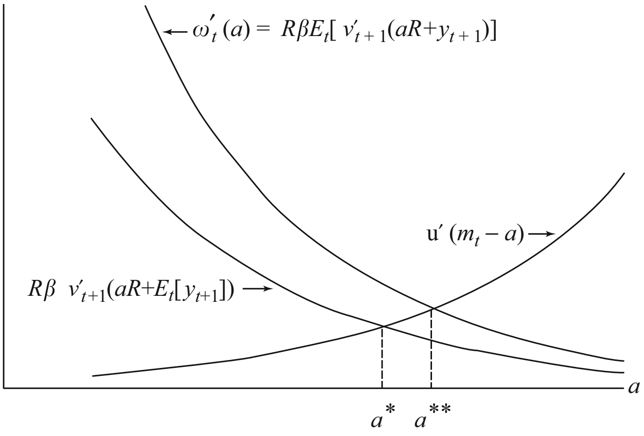
By definition, the optimal choice will be a level of c_t such that the consumer does not wish to change spending. Under standard assumptions, this implies that the marginal utility of consumption must be equal to the marginal value of assets:

$$u'\left(\overbrace{m_t - a_t}^{c_t}\right) = \omega_t'(a_t), \tag{6}$$

since if this were not true the consumer would be able to improve his well-being (value) by reallocating some resources between a and c.

Figure 1 depicts the consumer's problem graphically. For given initial m_t, the consumer's goal is to find the value of a such that Eq. (6)

Precautionary Saving and Precautionary Wealth, Fig. 1 Marginal utility of assets and of consumption



holds. The left-hand side of Eq. (6) is the upward-sloping locus. As for the two downward-sloping loci, the lower one reflects expected marginal value if the consumer is perfectly certain to receive the mean level of income $E_t\left[\tilde{y}_{t+1}\right]$, while the higher downward-sloping function corresponds to the case where income is uncertain.

When the risk is added, the optimal choice for end-of-period assets moves from a^* to a^{**}. Since $c_t = m_t - a_t$, the increase in a in response to risk corresponds to a reduction in consumption. This reduction in consumption is the precautionary saving induced by the risk.

For a given $v_{t+1}(m_{t+1})$, the exercise captured in the diagram can be conducted for every possible value of m_t, implicitly defining a consumption function $c_t(m_t)$.

Kimball (1990) shows that the index of absolute prudence $\frac{-v^m_{t+1}(m_{t+1})}{v^m_{t+1}(m_{t+1})}$ and the index of relative prudence $\frac{-v^m_{t+1}(m_{t+1})m_{t+1}}{v^m_{t+1}(m_{t+1})}$ are good measures of how much a risk of given size will shift the marginal value of assets curve $\omega'_t(a)$ to the right. For a constant relative risk aversion value function, relative prudence is equal to relative risk aversion plus 1. Kimball and Weil (2004) look at the strength of the precautionary saving motive when Kreps and Porteus (1978) preferences are used to break the usual equation $\varsigma = 1/\rho$ where ς is the elasticity of intertemporal substitution and ρ is relative risk aversion. In this more general case, the counterpart to relative prudence $\mathcal{P}$ is given by $\mathcal{P} = (1 + \varsigma\varepsilon)\rho$, where ε is the elasticity with which absolute risk aversion declines and absolute risk tolerance increases.

Note that, given the basic properties $\varsigma > 0$ and $\rho > 0$, a positive wealth elasticity of risk tolerance implies that $\mathcal{P} > \rho$. This is a special case of a much more general result first hinted at by Drèze and Modigliani (1972). Even for very exotic objective functions, the precautionary saving motive will always be stronger than risk aversion whenever ownership of more a_t due to a small forced reduction in consumption would lead an optimizing investor to bear more risk (a property that Drèze and Modigliani 1972 call ‘endogenously decreasing absolute risk aversion’). This general result holds because, if ownership of extra a_t due to a small forced reduction in consumption were to lead an optimizing investor to bear risks she was previously indifferent to, then reduced consumption must be complementary with bearing near-indifferent risks. The symmetry of complementarity then implies that, given a free choice of consumption levels, taking on an additional near-indifferent risk will lead an optimizing consumer to reduce consumption. For example, consider an agent with additive habit formation (as distinct from multiplicative habits, compare Carroll 2000), for whom reduced consumption not only increases assets but reduces the size of the consumption habit, and so unambiguously leads to more willingness to bear risks. Such an agent will want to reduce consumption if induced to take on an additional risk by a compensation that makes her indifferent to the risk. The size of the compensation is determined by risk aversion. Yet the compensation for the agent’s risk aversion is not enough to cancel out the precautionary saving effect of the risk.

Buffer Stock Wealth

The above discussion suggested that precautionary behaviour can be understood by considering a trade-off between the present (captured by $u(c_t)$) and the future (captured by $\omega_t(m_t - c_t)$).

That analysis was incomplete in a crucial respect: it took the initial level of resources, m_t, as given exogenously. But, arguably, the most important question about precautionary behaviour is how large an effect it has on the prevailing level of m. This cannot be answered using a framework that treats m as exogenous.

The framework can be extended to address this problem, by defining the problem in such a way that the functions v and ω reflect the discounted value of an infinite number of future periods. This is often accomplished by making assumptions under which optimal behaviour in every future period is identical to optimal behaviour in the current period; it is then possible to solve for a ‘consumption function’ that provides a complete characterization of the relationship between resources and spending.

The critical extra assumption is 'impatience', broadly construed as a condition on preferences that prevents wealth (or the wealth to income ratio) from growing to infinity. In the simplest version of the model where income does not grow, the required condition is $R\beta < 1$; for the appropriate condition in models with income growth, see Carroll (2004).

The exact nature of income risk turns out to be less important than the assumption of impatience. Here, we analyse a particularly simple case (which is an adaptation of a model by Toché 2005). There are two kinds of consumers: workers and retirees. Retirees have no labour income, and must live off their assets. Workers earn a fixed amount of labour income in each period, but face a constant danger of being exogenously forced into retirement. (Exogenous forced retirement is the sole source of risk in the model.)

Under these assumptions, if the utility function is of the standard constant relative risk aversion form $u(c) = c^{1-\rho}/(-\rho)$, optimal behaviour for retirees is very simple: they spend a constant fraction of m in each period, where the fraction depends on the degree of impatience and intertemporal substitution $(1/\rho)$.

The situation for workers is more interesting; it is depicted in Fig. 2. The simplest element of the figure is the line labelled 'Perm inc'. This shows, for any m, the level of spending that would leave expected m unchanged; it is equal to labour income plus the interest on capital income, and is upward sloping because a consumer with more m earns more capital income.

The assumption of impatience is reflected in the fact that the consumption function that would apply if uncertainty did not exist, $\overline{c}(m)$, is everywhere above the level of permanent income (income of the perfect-certainty consumer is adjusted downwards so that the reduction in unemployment risk does not cause an increase in mean income). In other words, an impatient consumer facing no uncertainty would choose to spend at a rate that cannot be sustained indefinitely.

The locus with arrows is the consumption function, which indicates the optimal level of spending (in the presence of uncertainty) for any given level of m. Since the difference between $c(m)$ and $\overline{c}(m)$ is purely the consequence of risk, that difference $\overline{c}(m) - c(m)$ constitutes the amount of precautionary saving associated with any specific m.

Standard assumptions about preferences and uncertainty imply that there will be an intersection between the permanent income locus and the consumption function. (For a proof that there will be only one intersection, see Carroll 2004.) The intersection defines a 'target' level for the buffer stock of wealth m: the level such that an employed consumer with this amount of resources today will end up with the same m next period. Dynamics are captured by the arrows, which indicate that, for initial values of m below the target, consumption is below permanent income, so m is increasing and consumption crawls upwards along the consumption function towards the target. For initial values of m above the target, consumption is above permanent income, so m is falling. The consumer holds a 'buffer stock' of wealth in an attempt to reach the 'target' level of wealth as defined above.

The existence of a target level of resources has many interesting implications. Perhaps the most surprising is that in long-run equilibrium the expected growth rate of consumption for employed consumers is unrelated to the interest rate or the degree of impatience.

To understand this point better, and to relate it to the literature, we restate it in a slightly more general form: The equilibrium expected growth rate of consumption for employed consumers is approximately equal to their predictable rate of income growth,

$$E_t\left[\Delta \log c^e_{t+1}\right] \approx g. \tag{7}$$

In many respects, the equilibrium equality of consumption growth and permanent income growth seems intuitive. However, it appears to conflict with a standard way of analysing consumption growth, which relies on the first-order condition from the optimization problem (the

'Euler equation'), which is often approximated by an equation of the form

$$E_t\left[\Delta \log c^e_{t+1}\right] \approx \rho^{-1}(r-\tau)+\varphi \tag{8}$$

where ρ is the coefficient of relative risk aversion and τ is the geometric rate at which future utility is discounted (related to the time preference factor β); φ is a term that reflects the contribution of precautionary motives to consumption growth.

The resolution of the apparent contradiction is that the precautionary component of consumption growth is endogenous; combining Eqs. (7) and (8) permits us to solve for the equilibrium value of the precautionary contribution to consumption growth:

$$\varphi \approx g-\rho^{-1}(r-\tau). \tag{9}$$

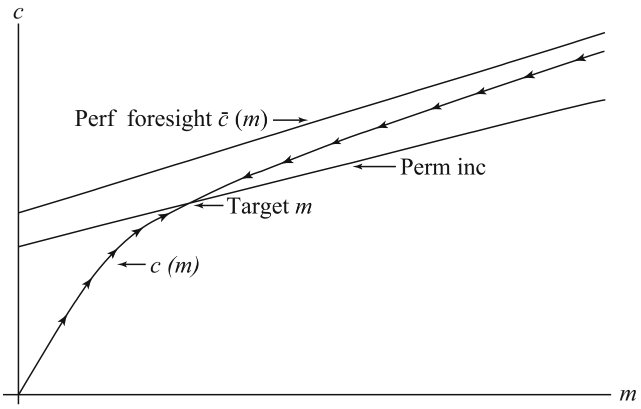
We return to this point below.

We can characterize the effect of uncertainty by noting three facts about Fig. 2: $c(m) < \bar{c}(m)$ (consumption is lower in the presence of uncertainty); $\lim_{m\to\infty}\bar{c}(m)c(m)=0$ (as wealth approaches infinity the effect of uncertainty in labour income vanishes); and $c(m)$ is strictly concave, so that the marginal propensity to consume out of a windfall increase in income, $c'(m)$, is greater for poor people than for rich people.

The concavity of the consumption function bears further comment. Intuitively, it can be understood in a similar light to the effect of liquidity constraints. A consumer who is subject to a currently binding liquidity constraint is someone for whom a marginal increase in cash will result in an immediate one-for-one increase in spending (a marginal propensity to consume, MPC, of 1). However, if the same consumer happened to have a large windfall transfer of cash (say, he wins the lottery), he would no longer be currently constrained, and his MPC would (presumably) be less than 1. In the case of precautionary saving, the ownership of an extra unit of wealth relaxes the suppression of consumption due to risk; this relaxation is more powerful for low-wealth consumers living on the edge of (precautionary) fear than for high-wealth consumers with plenty of resources. Thus, either liquidity constraints or precautionary motives or both will cause the consumption function to become concave (Carroll and Kimball 2005). Huggett (2004) shows that consumption concavity in turn implies greater equilibrium wealth.

Empirical evidence indicates that the wealth distribution is highly concentrated. This means that the owners of much of the aggregate capital stock probably inhabit the portion of the consumption function to the far right, where it approaches the linear consumption function that characterizes the perfect foresight solution. Note, however, that this does not necessarily imply that aggregate consumption behaviour will resemble that of a perfect foresight consumer, because a large proportion of aggregate consumption is accounted for by households with small amounts of market wealth. Spending of such households is probably determined much more by their permanent income than by their meagre wealth, and so it remains possible

Precautionary Saving and Precautionary Wealth, Fig. 2 The consumption function



that a high proportion of consumption is performed by households inhabiting the more nonlinear part of the consumption function.

Empirical Evidence

Euler Equation Methods

The early literature relevant to identifying the strength of precautionary motives tended to rely on Euler equation estimation (see Browning and Lusardi 1996 for a survey), often by estimating regression equations of the form

$$\Delta \log C_{t+1} = \alpha_0 + \alpha_1 E_t[r_{t+1}] \qquad (10)$$

and interpreting the coefficient on the interest rate term as an estimate of the inverse of the coefficient of relative risk aversion (CRAA) (which holds true under timeseparable CRRA utility, as in equation Eq. (8)). However, this analysis did not take into account the dependence of higher-order terms like φ on the independent variables (see Eq. (9)). Some papers like Dynan (1993) attempted to account for precautionary contributions to consumption growth; but see Carroll (2001) for a critique of the whole Euler equation literature (including the second-order approach).

Structural Estimation Using Micro Data

A new methodology for estimating the importance of precautionary motives was pioneered by Gourinchas and Parker (2002) and Cagetti (2003) (with a related earlier contribution by Palumbo 1999). Their idea was to calibrate an explicit life-cycle optimization problem using empirical data on the magnitude of household-level income shocks, and to search econometrically for the values of parameters such as the coefficient of relative risk aversion that maximized the model's ability to fit some measured feature of the empirical data. Gourinchas and Parker (2002) matched the profile of mean consumption over the lifetime; Cagetti (2003) matched the profile of median wealth. The intensity of the precautionary motive emerges, in each case, as an estimate of the coefficient of relative risk aversion, which Gourinchas and Parker (2002) put at about 1.4 and Cagetti (2003) finds to be somewhat larger (a value of 1 corresponds to logarithmic utility). One important caveat about these quantitative results is that the method's estimates of relative risk aversion depend on the model's assumption about the degree of risk households face. Recent work by Low, Meghir and Pistaferri (2005) that attempts to correct for measurement problems caused by job mobility suggest that the estimates of the magnitude of permanent shocks in Carroll and Samwick (1997) used for calibration by Gourinchas and Parker (2002) and Cagetti (2003) may be overstated by as much as 50 per cent. Re-estimation of the structural parameters using the Low et al. (2005) calibration would generate larger estimates of relative risk aversion.

Regression Evidence

A separate literature attempts direct empirical measurement of the relationship between uncertainty and wealth. To fix notation, index individual households by i and assume that uncertainty for household i in period t can be measured by some variable $\sigma_{t,i}$. Then in its simplest form the idea is to perform a regression of cash-on-hand on its determinants along the lines of

$$\log m_{t,i} = \sigma_{t,i}\gamma + Z_{t,i}\alpha + \varepsilon_{t,i} \qquad (11)$$

where Z is some set of variables that capture life cycle, time series, and other nonprecautionary effects. In principle, one can then calculate the predicted magnitude of m if everyone's uncertainty were set to zero (or some more sensible alternative like the minimum measured value of σ in the population).

This method permits the data to speak in a much less filtered way than the structural estimation approach. A drawback is that even if the magnitude of precautionary wealth could be estimated reliably and precisely, it would not be clear how to translate those estimates into a measure of relative risk aversion or some other set of behavioural parameters that could be used for analysing policy questions such as the optimal design of unemployment insurance or taxation.

A further disadvantage is that the method does not reliably yield the same answer in different data. Using a measure of subjective earnings uncertainty from a survey of Italian households, Guiso et al. (1992) estimate the precautionary component of wealth at only a few per cent, while Kazarosian (1997) and Carroll and Samwick (1998) estimate the precautionary component of wealth for typical US households to be in the range of 20–50 per cent. Hurst et al. (2005) argue that estimates of α are inordinately sensitive to whether business owners are included in the dataset; and work by Lusardi (1997, 1998) and Engen and Gruber (2001) implies much smaller precautionary wealth. Such large variation in empirical estimates is not plausibly attributable to actual behavioural differences across the various sample populations.

A problem that plagues all these efforts is identifying exogenous variations in uncertainty across households. The standard method has been to use patterns of variation across age, occupation, education, industry and other characteristics. This runs the danger that people who are more risk tolerant may both choose to work in a risky industry and choose not to save much, biasing downwards the estimate of the effect of an exogenous change in risk.

One recent paper attempts to get around this problem by using a natural experiment: Fuchs-Schündeln and Schündeln (2005) show that, before the collapse of the Berlin Wall, East German civil servants had similar income uncertainty to that faced by other East Germans. However, after the collapse of Communism, income uncertainty went up dramatically for most East Germans – but not for civil servants, who were given essentially the same risk-free jobs in the new merged government that they had had before the collapse. Fuchs-Schündeln and Schündeln (2005) show that, in accord with a model that includes substantial precautionary effects, saving rates of most East Germans increased sharply after unification, but saving rates of civil servants did not. By contrast, the West Germans – who would have been subject to more selection into jobs based on risk preferences – exhibited little difference in saving rates between civil servants and others with riskier jobs, either before or after reunification.

Survey Evidence

Given the difficulties of obtaining reliable quantitative measures of precautionary motives using the revealed preference econometric techniques sketched above, some researchers have turned to approaches that involve asking survey participants more direct questions.

Kennickell and Lusardi (2005) find that, when respondents for the 1995 and 1998 US *Survey of Consumer Finances* are asked their target level of precautionary wealth, most have little difficulty in answering the question: desired precautionary wealth represents about eight per cent of total net worth and 20 per cent of total financial wealth. They find that respondents cite a broad array of risks in making their precautionary targets: in addition to labour income risk, they face health risk, business risk, and the risk of unavoidable expenditures (such as home repairs). (Consumers are clearly aware of the theoretical point that a given dollar of wealth can provide self-insurance against multiple different kinds of risks, since the risks are not likely to be perfectly correlated with each other.)

Carefully designed survey questions can in principle also be used to elicit information on the strength of underlying preferences (like risk aversion) that determine precautionary behaviour. The principle that whenever risk-bearing increases with assets, the precautionary saving motive (prudence) must be stronger than risk aversion provides an important theoretical lower bound on the degree of prudence. Using survey responses to hypothetical gambles over lifetime income in the *Health and Retirement Study*, Kimballet al. (2005) estimate that relative risk aversion has a median of 6.3 and a mean of 8.2. (Note that because of Jensen's inequality, the mean of relative risk aversion $E\rho$ is larger than the reciprocal of the mean of relative risk tolerance $\frac{1}{E(1/\rho)}$.) These estimates of relative risk aversion imply precautionary saving motives much stronger than those that have been used empirically to match observed wealth holdings. This discrepancy remains unresolved.

Conclusion

The qualitative and quantitative aspects of the theory of precautionary behaviour are now well established. Less agreement exists about the strength of the precautionary saving motive and the magnitude of precautionary wealth. Structural models that match broad features of consumption and saving behaviour tend to produce estimates of the degree of prudence that are less than those obtained from theoretical models in combination with risk aversion estimates from survey evidence. Direct estimates of precautionary wealth seem to be sensitive to the exact empirical procedures used, and are subject to problems of unobserved heterogeneity. Thus, establishing the intensity of the precautionary saving motive and the magnitude of precautionary wealth remain lively areas of debate.

Predator–Prey Models

R. M. Goodwin

Quite independently, two basic advances were made in the theory of animal populations by A.J. Lotka in 1925 and by Vito Volterra in 1926 and again in 1931. The resulting dynamical problem has implications for a wide range of cases, involving as it does, the possibilities of the extinction of one species, or the evolution to an equilibrated coexistence, or to a continuing oscillation. The problem was brought to Volterra by Ugo d'Ancona, who had found clear evidence for continued oscillation in the type of fish catches in the upper Adriatic. Volterra formulated and solved a system of two non-linear differential equations, in which the proportionate growth rate in each depended only on the level of the other. His solution is stable and positive, but is inappropriate for applied analysis, since it is structurally unstable. It is inappropriate in the sense that a mathematician may assume, as he does, a parameter to be exactly zero, but it is impermissible in an applied or empirical analysis like that of animal populations. In 1931 the Russian mathematician Kolmogoroff gave an elegant generalization which was both dynamically *and* structurally stable, yielding the three types of solution above, including a demonstration of a stable equilibrium motion, that is, a limit cycle. Various elaborations, along with qualitative analysis in phase space, are given in Hirsch and Smale (1974).

In spite of a potential relevance, these developments appear to have had no effect on economic theory until the appearance of a paper by Goodwin in 1965, and independently, two by Samuelson, in 1967 and again in 1971. In the latter the analysis is in terms of exploitation in conditions of diminishing returns, along with a limit cycle in connection with increasing returns. In the former, the symbiosis of workers and capitalists is presented in terms of conflict and yet mutual interdependence. Assuming steady growth of labour productivity and of labour force, a formulation in ratios results in a cycle of growth rates rather than levels. If wages are too high and profits too low, there is low growth and growing unemployment. Conversely, low wages and high profits bring high growth and falling unemployment. Too high and too low are defined in terms of producing that rate of accumulation necessary to keep the average growth rate of employment equal to that of the available labour force in such a way as to remain in the neighbourhood of full employment. Thus by dealing in distributive shares, the cycle includes growth and growth proceeds cyclically, a feature not present in the biological model. Consequently, though fluctuating, the economy produces a long-run, constant, average distribution of income, growth rate, and degree of unemployment. Even exogenous disturbances, leading to variations in initial conditions, do not alter the long-run averages, since they are independent of initial conditions and equal to equilibrium values. The model is susceptible to more realistic elaboration by the introduction of nominal and real wages, degree of capacity utilization, game theoretic formulation of wage bargaining, and more endogeneous treatment of productivity growth.

The model may be formulated in terms of the ratios, u, the share of wages in income, and *v*, the ratio of employment to available labour force. The result is the following matric equation:

$$\left\{\begin{matrix}\dot{u}/u\\ \dot{v}/v\end{matrix}\right\} = \begin{bmatrix}0 & +\alpha\\ -\rho & 0\end{bmatrix}\left\{\begin{matrix}u\\ v\end{matrix}\right\} + \left\{\begin{matrix}-\gamma\\ +\delta\end{matrix}\right\}$$
$$\times(\text{all parameters positive}).$$

Apart from the proportional growth rates, one sees the simplest, first order, linear differential equation, with the positive equilibria, $\bar{u} = \rho/\rho$ and $\bar{v} = \gamma/\alpha$. Because u depends positively on v and v negatively on u, it must oscillate, and because of the zeros on the diagonal it is stable dynamically and unstable structurally. Kolmogoroff wrote $\dot{u}/u = f(u,v)$ and $\dot{v}/v = g(u,v)$ giving an elegant, qualitative demonstration of all the possible types of motion, including an asymptotically stable limit cycle.

The system can be dazzlingly generalized from von Neumann's steady-state general equilibrium growth model. His turnpike, dynamic equilibrium path, being unstable, will alternately produce a high growth rate, rising real wage and decelerating growth, leading to low growth, low (relative to productivity) wage and rising growth rate. Hence the growth rate will vibrate about its equilibrium, never remain there, and will yield a constant, average, long-run growth rate.

Suitably modified this type of theory is of great importance for economists. It avoids the usual assumption that trend and cycle are independent, in the sense that each would exist in the absence of the other. It also is the natural way to treat technological progress, that is, an innovation in the form of either a new process of production or of a new good, is analogous to the introduction of a new species into a given ecological environment. The consequence is an explicable dynamical evolution to changing economic equilibria. This gives the essential view of capitalism as a permanent evolutionary process, or continuing morphogenesis.

Predatory Pricing

Janusz A. Ordover

Abstract

Predatory pricing is a response to a rival that sacrifices part of the profit that could be earned under competitive circumstances were the rival to remain viable, in order to lessen competition and gain consequent monopoly profit. The presence of intertemporal cost and/or demand linkages as well as network effects complicates the formulation of pricing rules that would distinguish legitimate from exclusionary pricing behaviour, and suggests that standard (non-strategic) ▶ models of markets do not necessarily offer much help in gauging the rationality of predation.

Although neither courts nor legal and economic scholars agree on a broad definition of predatory behaviour, the minimal consensus (if such exists) is that predatory pricing entails selling a product ‘below cost’ in order to induce a rival’s exit, or deter future entry or competition. More broadly, ‘predatory behaviour is a response to a rival that sacrifices part of the profit that could be earned under competitive circumstances, were the rival to remain viable, in order to [lessen competition] and gain consequent monopoly profit’ (Ordover and Willig 1981, pp. 9–10).

The broader definition is necessary, at least in part because in many market scenarios, comparisons of prices to marginal cost offer little guidance as to what constitutes competitive, as opposed to predatory, pricing. A multi-product firm might offer one of a pair of complementary products at a price above incremental cost, and yet still be engaged in predation if the price at which it offers the pair as a bundle is sufficiently higher than the incremental cost of the second component (see, for example, Baumol and Sidak 1994, ch. 7). Another scenario is markets with intertemporal scope economies, as in Cabral and Riordan (1994), in which two firms race to exploit learning economies or establish their respective products as industry standard. In such markets, it may be profitable for the ‘leading’ firm to price below cost in order to induce the rival’s exit. Discouraging such pricing would damage competition for the market for the sake of protecting competition in the market.

Similar issues arise in markets of network goods, where the product is more valuable to a user the more other people use it (for example, fax machines). These markets are characterized by increasing returns, and may be subject to a ‘tipping’ point at which one firm achieves natural monopoly, which is an efficient outcome since it increases consumer welfare by increasing network benefits through standardization. Farrell and Katz (2005) find that although rules to prevent predation, such as the Ordover–Willig rule, can improve welfare, they can also harm it in network markets ‘by preventing firms from internalizing the benefits of increasing returns to scale’.

In these cases, aggressive pricing is not designed to drive the rival into bankruptcy, but to make it realize that the ‘game’ is over from a strategic standpoint. When the market participants jockey for market leadership, pricing below short-run marginal cost (SRMC) could be a rational, non-predatory strategy. Evans and Schmalensee (2002) go so far as to advocate an approach under which, ‘if a defendant can establish that the relevant market is characterized by winner-take-all competition, then they have provided a complete defense against a charge of predatory behaviour’.

Another setting in which simple pricing rules can lead to wrong inferences involves pricing by so-called two-sided platforms, intermediaries that link two distinct groups of customers (for example, Rochet and Tirole 2003, 2006; Armstrong 2007). Such intermediaries frequently subsidize customers on one side in order to induce the other side to join the platform and enhance the value to all participants. Thus, below-cost pricing is compensated by above-cost pricing on the other side and by its impact on the overall level of activity on the platform. Such pricing may, of course, harm rivals who only operate on one side of the platform.

The presence of intertemporal cost and/or demand linkages as well as network effects of various kinds complicates the formulation of pricing rules that would sort out legitimate from exclusionary pricing behaviour. It also suggests that standard (non-strategic) models of markets do not necessarily offer much help in gauging the rationality of predation.

The Apparent Irrationality of Predatory Pricing

The Chicago School critique of traditional views of predatory pricing rested on the hypothesis that losses sustained during the predatory campaign will ordinarily exceed the more speculative gains from attempted supercompetitive pricing following the elimination of the prey. In his examination of *Standard Oil of New Jersey v. US* case, McGee (1958) pointed out that, in order for the predator to succeed in driving out an equally efficient rival, it must be prepared to serve the whole market by itself at an unremunerative price, while the prey can temporarily shut down its operations and restart them during the recoupment phase. Moreover, even if the prey exists permanently, productive assets may remain and could be purchased at scrap value by an opportunistic buyer. Easterbrook (1981) further observed that customers might protect themselves against post-predation exploitation by keeping the prey in business, even if the product is available from the predator at a lower price, thereby denying the predator an opportunity to drive the rival out. And the prey may also be financed by lenders who (correctly) anticipate that, once the predator gives up, additional profits will be generated with which to repay the loan. McGee also noted that it is generally cheaper to purchase the rival rather than to prey on it. Hence, according to McGee, even if feasible, predation is irrational.

There are several problems with McGee's merger argument: buying a single rival may induce others to enter solely to be bought out at a premium (Rasmusen 1985); the acquisition price itself may depend on the predator's established reputation for aggressive pricing (Burns 1986; Saloner 1987); there may be legal constraints on mergers so that when it is most advantageous, it is also likely to violate anti-merger legislation (Posner 1976).

McGee's critique significantly influenced antitrust policies regulating pricing conduct, but stopped well short of offering a rigorous model in which predation was irrational. Selten's (1978) *chain store paradox* does so. Intuition suggests that an incumbent operating in a sequence of markets, each with an entrant, may predate in the first few markets to establish a 'reputation' for toughness and thereby deter the remaining entrants. The intuition fails, however, by 'backward induction': the entrant in the last market will correctly disregard the incumbent's behaviour in the preceding markets and conclude that its entry will be accommodated because, with no reputation to be concerned about, the incumbent has no reason to predate. The penultimate entrant reasons additionally that its predation will not deter entry into the next, and so it too enters, expecting to be accommodated. Inexorable logic leads to the conclusion that the incumbent will not predate and entry will occur in all the markets (see Ordover and Saloner 1989; Phlips 1995).

Economic Models of Rational Predation

In settings that dispense with some of Selten's assumptions, predation can emerge as a rational strategy.

The Long Purse

One typical predatory pricing story involves an incumbent with a 'deep pocket', who by pricing aggressively can drive out a financially constrained rival (see Telser 1966). In order to induce exit, the incumbent drops the price to the *rival's (not necessarily its own) variable cost*. The rival, who also incurs fixed costs, soon exhausts its financial resources and leaves the market, enabling the incumbent to raise its price to monopoly level to recoup the costs of the predatory campaign.

Here, the mere threat of rational predation drives the opponent out. Clearly, a rational rival should leave at the first indication of predation, and not squander resources when exit is inevitable. In fact, rational firms with limited resources ought to stay out of a market occupied by an incumbent with a long purse. The 'long purse' story is not an entirely plausible basis for rational predation, but rather of entry deterrence, via a *credible threat* of post-entry predation – indeed, a costless one, as Benoit (1984) shows.

The long-purse model also ignores the possibility of profit-seeking investors financing the preyed-upon firm, in order to extend its purse. In Bolton and Scharfstein (1990) and Fudenberg and Tirole (1986), the predator imposes losses on its prey in order to signal to investors that the prey is financially troubled. Even when everyone knows it is profitable for the rival to remain in the industry, Bolton and Scharfstein argue that financial market predation induces exit because agency problems in financial contracting mean that reducing the sensitivity of the refinancing decision to the firm's performance exacerbates managerial incentive problems.

Predation for Reputation

Other models operate by making 'predation for reputation' a *rational strategy* (see Ordover and Saloner 1989; Milgrom and Roberts 1990; Phlips 1995, for more detailed analyses). For example, the game may have no 'end' from which to reason backwards (see Milgrom and Roberts 1982b). Or there may be incomplete information, with different incumbent 'types', as in the seminal papers by Kreps and Wilson (1982), Milgrom and Roberts (1982b), and Kreps et al. (1982). A 'weak' incumbent, who would otherwise prefer to share a market, can falsely establish a 'tough' reputation by fighting at the first opportunity, and so convince all possible future entrants of its toughness and deters future entry, since if every incumbent were to predate, the reputational value of fighting would be dissipated and entry would occur, the probability of equilibrium predation must be positive, but less than one. This predatory story can be enriched in several ways: see, for example, Milgrom and Roberts (1982b) and Easley et al. (1985), whose work is reviewed in Phlips (1995).

Signalling Predation

Under imperfect information, predation can also be used to induce the rival's exit. For example, the rival may not have perfect knowledge of the incumbent's costs or its new product's demand. In these plausible market settings, the better-informed incumbent may price low in order to *signal* to the rival that exiting the market is preferable to staying (see for example, Milgrom and Roberts 1982a). Even if low pricing does not deter entry, it may convince the rival to curtail its competitive ardour. Or, as Saloner (1987) shows, turning McGee's merger argument on its head, it may improve the terms of a buyout offer, by convincing the quarry that accepting a cheap offer is preferable to sharing a market with a low-cost competitor.

Signalling predation will be especially effective when the rival firm tries to gauge a new product's profitability from its reception in the 'test market'. Firms with competing products will wish to 'jam' the signal (see Salop and Shapiro 1980; Scharfstein 1984; Roberts 1986).

Empirical Evidence

Recent empirical work has supported the rational predation models. A broad survey found that predatory pricing was present in 27 of 40 litigated cases in which the legal record was sufficiently informative (Zerbe and Mumford 1996). In addition, several case studies, taken collectively, provide evidence that dominant firms have engaged in predatory behaviour, thereby undermining the Chicago School's claims about its irrationality.

Weiman and Levin (1994) provide evidence of predatory behaviour by Southern Bell Telephone Company from 1894 to 1912 when independent phone companies threatened entry. Genesove and Mullin (2006) provide evidence of predatory behaviour in the American sugar refining industry before the First World War. They show that the price wars following two episodes of entry were predatory by comparing price to marginal costs and by constructing predicted competitive cost margins that they show to exceed observed margins. Granitz and Klein (1996) re-examine McGee's Standard Oil case and find evidence that Standard had in fact acted as a predator, by threatening to withhold crude shipments from any railroad that did not participate in a railroad cartel, in return receiving discounted shipping rates that left Standard's competitors to sell out at depressed prices.

Von Hohenbalken and West (1984) and West and Von Hohenbalken (1984) provide evidence that a leading Canadian supermarket chain engaged in a predatory location strategy. In a subsequent study (1986), they show that the strategy also gave the chain a reputation for aggressive pricing that deterred future entrants, thereby supporting the reputation model of Kreps and Wilson (1982) and Milgrom and Roberts (1982b), among others.

Burns (1986) similarly finds systematic empirical evidence supporting the theory that firms can acquire a reputation for following through on predatory commitments from past predatory behaviour. He finds that the American Tobacco Company from 1891 to 1906 set up bogus independents that it secretly controlled to sell at low prices in the prey's territories, thereby allowing the predator to maintain its monopoly by acquiring the assets of the prey, as well as other competitors not yet preyed upon, at artificially low prices. This study lends considerable credence to the view that predation can improve the terms of a takeover.

In contrast, Lott (1999) argues on the basis of an empirical survey of firms accused of predation between 1963 and 1982, that such firms did not have the necessary contractual and non-contractual arrangements to provide managers with incentives to engage in costly predatory behaviour, which should be necessary to lend credibility to the strategies. This critique is quite powerful but it goes deeper than just an attack on the credibility of predation. It suggests that, unless the principals (owners) can induce agents (managers) to forgo current profits for the sake of any future monopoly profits, managers may simply decide not to implement such strategies. On the other hand, even the most casual empiricism also suggests that such obstacles need not be insurmountable.

Legal Tests for Price Predation

Price predation is easily confused with intense competition. Sharp demarcation lines are particularly difficult in strategic environments in which price predation could prove profitable. What should the public policy response be to the inherent difficulties in formulating antitrust rules governing dominant firm pricing? The legal–economic literature offers three distinct responses.

At one extreme, the Chicago School has urged removal of virtually all constraints on single firm pricing behaviour (as well as other forms of unilateral conduct). The rationale is simple: firms should not be discouraged from aggressively competing for and protecting their market positions. Further, since markets are quickly self-correcting (unless protected by governmental grants of monopoly), marketplace advantages unrelated to superior skill and efficiency are quickly driven away by competition. Consequently, anti-competitive conduct – including price predation – is, in general, irrational, and any attempts to forbid such conduct are likely to do more harm than good.

At the other extreme lies an open-ended, rule-of-reason analysis without any specific rules (see, for example, Scherer 1976; Comanor and Frech 1984). There are serious problems with this approach, however. First, it is not clear whether it can be implemented effectively in the adversarial setting of antitrust litigation. Second, because it offers no standards for what constitutes lawful conduct, this approach complicates business planning and may increase incentives for the abuse of antitrust laws.

The third public policy response is consistent with most legal–economic commentary and judicial practice. Although the US courts have rarely found price predation, they have been unwilling to rule it out completely. Instead, the courts have adopted a set of 'filters' designed to screen potentially meritorious claims of anticompetitive pricing conduct from those that are probably without merit (see, for example, Joskow and Klevorick 1979; Easterbrook 1984; Baker 1994; Elzinga and Mills 1994). The rest of this section discusses these filters, first reviewing proposed direct tests for predatory pricing and then addressing the question of 'recoupment' as a precondition for a finding of price predation.

Pricing Tests

The Areeda–Turner Test (Areeda and Turner 1975, 1978)

Areeda and Turner proposed that any price above 'reasonably anticipated' SRMC should be lawful, and any below, deemed predatory. US courts rapidly embraced this test, which is now a dominant test (see, for example, Areeda and Hovenkamp 1993; Denger and Herfort 1994; Green et al. 1996).

Because SRMC is difficult to estimate, Areeda and Turner recommend the average variable cost (AVC) as a workable surrogate. However, AVC is a good surrogate only when it does not diverge significantly from SRMC. Indeed, Areeda and Turner's analysis of the appropriate measures of AVC is inadequate because it does not derive correct cost concepts from the analysis of the predatory conduct itself and, consequently, fails to provide adequate guidance on how to treat such important components of costs as capital and advertising expenses (see Ordover and Willig 1981; Baumol 1996). The main problem with the Areeda–Turner test, however, is that it is based on an analysis of a firm's behaviour in a market situation – a temporary price cut by a single-product single-market firm – in which profitable predation is unlikely.

The Areeda-Turner Paper

The Areeda and Turner paper generated a flow of alternative tests. For example, the *Joskow–Klevorick test* (1979) offers a two-tier test for price predation. The first step examines whether the structural preconditions for successful and rational predation exist. Because the first step eliminates many baseless claims, Joskow and Klevorick tighten the price comparison in the second step, and propose that any price below average *total* cost be presumptively illegal. The rationale is that in a competitive market, the equilibrium, long-run price will equal AVC and that, furthermore, it is unlikely that a post-entry price in a market predisposed to predation would be so low as to impose losses on the incumbent dominant firm. Some courts have used the Joskow–Klevorick test as an alternative to the Areeda–Turner test, especially when entry barriers are high. Moreover, an analysis of structural and other requirements for rational predation is now central to the analysis of a predatory pricing case.

Williamson (1977) and Baumol (1979) propose tests that isolate the *strategic* aspects of the incumbent's responses to entry. Both would condemn 'window shade'- type behaviour by the incumbent, that is, low price (high output) when the rival is in, followed by high price (low output) when the rival is out, and require that the dominant incumbent stick with its aggressive strategy for a prescribed period of time. These tests have not, however, been adopted by the courts.

Both these proposals can be criticized on various grounds (see Ordover and Saloner 1989; Phlips 1995). Areeda and Hovenkamp (1993) offer a spirited defence of the original Areeda–Turner rule against its critics and review the alternatives, which they find less desirable than the Areeda–Turner rule.

Above-Cost Predation and the Edlin Test

In recent years a debate has ensued whether 'above-cost' pricing can also be predatory. In 1999, for example, the United States sued American Airlines on the theory that it was predatory to respond to entry with business practices that, even if above cost, 'clearly' sacrificed profits because it allegedly shifted airplanes from profitable routes to routes on which it was fighting the low-cost carriers. Edlin (2002) supports the move to prohibit above-cost predation because '[a]n incumbent monopoly with a significant cost or noncost advantage over entrants . . . can use these advantages to drive entrants from the market by pricing below their cost, but above its own' and proposes a rule that would prohibit an incumbent monopoly, when faced with an entrant charging at least 20 per cent below the prevailing price, from cutting its own prices for 12–18 months or until it loses its monopoly position.

According to Edlin, this rule means that matching competitors' prices after entry is no longer a cheap substitute for actually charging low prices in the first place, so consumers benefit. He explains that existing predation law means that the incumbent will not lower prices until there is an entrant and, since the potential entrant will not, in fact, enter, consumers always pay high prices to the incumbent. The predatory problem, he explains, occurs not after exit, but before entry. His rule, he argues, would address the problem by allowing firms that would otherwise fear being driven out of the market with above-cost predation to enter profitably, and it would benefit consumers because incumbents would charge lower prices to limit entry and because there would be more entry of competitors.

P

Elhauge (2003) responds that an above-cost pricing rule is ill-advised for three reasons: (*a*) it can often penalize efficient pricing behaviour when incumbents do not even have the market power to restrict output, for example when above-cost price cuts are an efficient response to deviations from the output-maximizing price-discrimination schedule in competitive markets; (*b*) it has mainly undesirable effects, such as raising post-entry prices and harming consumer welfare when the entrant is less efficient than the incumbent; and (*c*) it suffers from unavoidable implementation difficulties, such as ascertaining the moment of entry, dealing with quality changes designed to evade the restriction, and defining a post-entry price floor that will cause inefficiencies. He argues that part of the reason for the debate about whether to expand predation to above-cost pricing is ambiguity over the definition of 'costs' in the legal tests. He concludes that costs should be defined functionally as whichever cost measure assures that prices above costs cannot deter or drive out equally efficient rivals, a definition which he argues would resolve apparent anomalies in current predatory pricing law. Of course, from the standpoint of basic economics, it is always the 'opportunity cost' that provides the right measure of cost to be used. But this may be too much for the courts as calculations of opportunity costs are far from simple.

The Recoupment Test

The recoupment test is a potentially useful step in a summary judgement proceeding because it enables the fact-finder to dismiss allegations of predation without engaging in an extensive (and time-consuming) investigation of price-cost margins and other indicia of predatory *conduct*. On the other hand, the evidence that price is below the pertinent cost floor should perhaps obviate the need to enquire whether recoupment is feasible or not: the firm's conduct *reveals* its belief that recoupment is possible. In essence, the recoupment test substitutes the court's assessment of the likelihood of success for the independent business judgement of the alleged predator. Likewise, Hemphil (2001) argues that the recoupment analysis should not consider the firm's conduct at all, but rather should limit itself to an analysis of the structural features of the market, such as asymmetric information and linkages across markets, that might deter entry and allow the predator to profit from its ill-gotten monopoly once the competitor has been eliminated (see also Ordover and Willig 1981). The recoupment test has also been criticized by Edlin and Farrell (2004) on the grounds that quantifying how the predator might benefit from its behaviour is difficult; courts should thus pay more attention, they argue, to serious consumer harm or harm to economic efficiency – 'recoupment as harm' rather than 'recoupment as reality check'.

Critiques of the Current Legal Test of Predation

The Supreme Court's two-prong test in *Brooke Group* (1993) (price-cost and recoupment) created a high burden of proof for plaintiffs that solidified the Court's embrace of the Chicago School view that predatory pricing is 'rarely tried, and even more rarely successful'. In the ensuing six years after *Brooke Group*, plaintiffs had not won a single predatory pricing case in federal court and, more striking, all but three of 39 reported decisions were dismissed or failed to survive summary judgment (see Brodley et al. 2000).

Brodley et al. (2000) criticize the courts for adhering to this 'static, non-strategic view of predatory pricing' at the same time that modern economic theory and empirical evidence have demonstrated the prevalence of predatory pricing. Based on this modern strategic theory, they propose a legal rule that, they argue, would augment existing practice in two critical respects: (1) it would explicitly permit proof of predation based on modern economics, and (2) it would expand the standard efficiencies and business justification defences to encompass pro-competitive dynamic gains, such as the learning-by-doing and network markets discussed earlier.

In reply, Elzinga and Mills (2001) fault the proposal for ignoring that predatory pricing is in practice very uncommon. They also argue that such theory lacks factual support and is not yet well developed enough to incorporate into antitrust rules. As a result, to permit predation to be proven by reference to modern strategic theory risks over-enforcement. (Bolton et al. 2000, respond by noting that the heavy factual burdens on the defendant and fully developed efficiencies defence available to the defendant mitigate the risk of over-enforcement.)

Marx and Shaffer (1999) argue that, for intermediate goods markets, the Supreme Court's two-prong test in *Brooke Group* may be over-inclusive, as low-cost pricing and recoupment can both occur with the rival supplier, although harmed, remaining in the market, and welfare actually increasing (because the increase in consumer surplus outweighs the reduction in overall joint profit associated with the pricing distortion).

Conclusion

The three decades of research on predatory pricing since Areeda and Turner (1975) lead to the following policy lessons.

First, the strategic approach to modelling pricing debunked the comfortable position that predation is more costly to predator than prey, and hence irrational and unlikely to occur.

Second, given the non-competitive structure and asymmetries of information in the relevant markets, there is no bright line standard for predatory pricing that both proscribes pricing behaviour that reduces economic welfare and does not discourage pro-competitive behaviour.

Third, the focus on price predation to the exclusion of other types of business conduct seems misplaced, given the richness of strategies used by firms in their battles for market share (Ordover and Willig 1981). Many of these strategies are likely to be more successful than price predation in inducing the exit of efficient rivals, and do not require sustained periods of losses.

Fourth, the courts' shift from vague inquiries into the 'intent' of the alleged predator's actions to more rigorous price and cost comparisons and assessments of the likelihood of recoupment has not benefited plaintiffs in predatory pricing litigation.

Prediction

P. Whittle

Any rational theory of prediction must be based upon a model. Enoch Powell expresses this view when he says, ‘The prophets were not soothsayers; they were expounders.’

We shall formulate models in discrete time, so that the time variable *t* can be assumed to take integral values. The value of a variable *x* at time *t* will be denoted x_t. We shall frequently denote the observation taken at time *t* by y_t (usually vector-valued) and shall then denote the *observation history*

$$(y_t, y_{t-1}, \ldots)$$

available at time *t* by Y_t. The estimate of a quantity *u* based upon Y_t will be denoted $u^{(t)}$. Thus $x_{t+m}^{(t)}$ is, for positive *m*, the predictor of x_{t+m} formed at time *t*. The linear *linear least square* (LLS) criterion chooses $u^{(t)}$ as the linear function of Y_t that minimizes the mean square deviation $E[u\text{–}u^{(t)}]^2$ (or a matrix analogue if *u* is vector-valued). If all variables are jointly normally distributed (*Gaussian*, henceforth), then this $u^{(t)}$ can also be characterized as the conditional expectation $E[u|Y_t]$ or as the maximum likelihood (ML) estimate of *u* for given Y_t.

There are two techniques useful in the calculation of such estimates and predictors: *recursive methods* (associated with Markov models) and *generating function methods* (associated with cases in which structure is time-invariant and prediction errors are stationary).

If *x* and *y* are random vectors of zero mean then we shall use cov(*x, y*) to denote the crosscovariance matrix $E(xy')$ and shall write cov(*x, x*) simply as cov(*x*).

Recursive Methods: Markov Models and the Kalman Filter

Consider the dynamic equation, typical of many econometric models:

$$x_{t+1} = Ax_t + \in_{t+1} \qquad (1)$$

Here the process variable *x* is supposed to be a vector, and so *A* a corresponding square matrix, and ε_t is assumed to be vector white noise of zero mean and with covariance matrix *N*. One special feature of this model is that it is linear; another is that it is Markov (at least if ε is Gaussian). This is, that *x* is a state variable which constitutes a complete description, in that all aspects of the future which can be predicted from

$$X_t = (x_t, x_{t-1}, \ldots)$$

can also be predicted from x_t.

Suppose indeed that just $(x_t, x_{t-1}, \ldots)$ is observable at time *t*, so that $Y_t = X_t$. From (1) we deduce the solution

$$X_{t+m} = A^m x_t + \sum_{s=0}^{m-1} A^s \in_{t+m-s} \qquad (2)$$

for a future value $x_{1\ +\ m)}$ in terms of the current state x_t and future noise. Now, the white noise character of ε implies that $E[\varepsilon_{t+\tau}|X_t] = 0 \quad$ for $\tau > 0$. That is, a future noise value is unpredictable in that it has no better predictor than its unconditioned mean value: zero. We deduce then from (2) the simple expression for the predictor $x_{t+m}^{(t)} = E[x_{t+m}|X_t]$:

$$x_{t+m}^{(t)} = A^m x_t \quad (m \geqslant 0) \tag{3}$$

This obeys the recursion in *m:*

$$x_{t+m+1}^{(t)} = A x_{t+m}^{(t)} \quad (m \geqslant 0) \tag{4}$$

In other words, one predicts into the future just by solving the dynamic equation (1) with future noise set equal to its best prediction: zero. The predictor (3) would be *exact* for sequences $\{x_t\}$ generated from the noise-free version of (1):

$$x_{t+1} = A x_t \tag{5}$$

In the case (1) of noisy dynamics we see from (2) and (3) that the m-step prediction error will have covariance matrix

$$\mathrm{cov}\left[x_{t+m}^{(i)} - x_{t+m}\right] = \sum_{s=0}^{m-1} A^s N (A\prime)^s. \tag{6}$$

All these results remains true whatever the nature of A (and indeed have analogues if A is timevarying). If A has all its eigenvalues inside the unit circle, then system (1) is stable and will generate a stationary process. In other cases, $\{x_t\}$ will not be stationary, but conclusions (3), (4) and (6) still hold, and the prediction errors are stationary in time. For example, if A has a k-fold eigenvalue at unity, then the noise-free equation (5) will generate a polynomial trend in time of degree k – 1 (which (3) will predict exactly) and the actual dynamic equation (1) will generate a disturbed such trend. If A has other eigenvalues on the unit circle, then (1) will generate disturbed cyclicities (*undamped*, and possibly of polynomially increasing amplitude). Allowance of these possibilities provides the most ‘structural’ way of incorporating trends and seasonalities. If A has eigenvalues outside the unit circle, then (5) will have exponentially growing solutions (again predicted exactly by (3)) and (1) will have disturbed such solutions.

However, it will seldom be the case that the full state variable x will be observable. One must in general regard x as the state variable of an ideal Markov model, and indeed as a latent variable, which can be observed only partially. The usual and natural assumption is that, at time t, one can observe a vector y_t related to x by

$$y_{t+1} = C x_t + \eta_{t+1} \tag{7}$$

where $\{\varepsilon_1, \eta_t\}$ jointly constitute vector white noise with covariance matrix

$$\mathrm{cov}\begin{pmatrix} \in \\ \eta \end{pmatrix} = \begin{pmatrix} N & L \\ L' & M \end{pmatrix}. \tag{8}$$

Relations (1) and (7) together express process and observation structure.

Let us denote $x_t^{(t)}$ by $\widehat{x}_t$ the estimate of current state based on current observations. From (1), (7) and the properties of LLS estimates one can deduce that $\widehat{x}_t$ obeys the recursion

$$\widehat{x}_{t+1} = A\widehat{x}_t + H_t\left(y_{t+1} - C\widehat{x}_t\right) \tag{9}$$

where the matrix H_t is determined in terms of

$$V_t = \mathrm{cov}(\widehat{x}_t - x_t) \tag{10}$$

by the recursions

$$\begin{aligned} V_{t+1} = \quad & N + A V_t A' - (L + A V_t C') \\ & \times (M + C V_t C\prime)^{-1} (L' + C V_t A') \end{aligned} \tag{11}$$

$$H_t = (L + A V_t C')(M + C V_t C\prime)^{-1}. \tag{12}$$

Relation (9) constitutes the celebrated *Kalman filter* (a ‘filter’ being an operation for generating one sequence from another; in this case $\{\widehat{x}_t\}$ from $\{y_t\}$. The shortest of its many proofs is quite short (see, for example, Whittle 1983, p. 147).

There are many points to be made aboutthe Kalman filter. It is an updating relation, to be used in real time, to produce the new estimate of current state $\widehat{x}_{t+1}$ from the old one $\widehat{x}_t$ as a new observation $y_{t+ 1}$ becomes available. It takes the form of the dynamic equation (1) of the model itself, but driven, not by noise, but by the *innovation* $\left(y_{t+1} - C\widehat{x}_t\right)$. The innovation is to be interpreted as that part of the new observation $y_{t\,+\,1}$ which is not predictable from previous observations Y_t.

Once one has the state estimate, then prediction is simple. Because both process noise ε and observation noise η are supposed white one has

$$\begin{array}{rcll} x_{t+m}^{(t)} & = & A^m\widehat{x}_t, & (m \geqslant 0) \\ y_{t+m}^{(t)} & = & CA^{m-1}\widehat{x}_t, & (m > 0). \end{array} \tag{13}$$

Recursion (9) and relations (13) explain between them virtually all recursions (in t or m) between predictors to be found in the literature.

If appropriate conditions are satisfied (referred to as *observability* or *detectability* conditions), then, in the absence of plant and observation noise, the error in state estimate $\widehat{x}_t - x_t$ will tend to zero with increasing t. Under these same conditions the matrices V_t and H_t will tend to limit values V and H in the noisy case. Further, the matrix $\Omega = A - HC$ will be a stability matrix (so that Ω^s tends to zero exponentially fast with increasing s)

The Kalman filter (9) can then be written

$$\widehat{x}_{t+1} = \Omega\widehat{x}_{t+1} + Hy_{t+1} \tag{14}$$

with ‘solution’

$$\widehat{x}_t = \sum_{s=0}^{\infty} \Omega^S H y_{t-s}. \tag{15}$$

are of state and observation, and not of the parameters of the model itself, which are presumed known for present purposes.

$$g_{xy}(z) = \sum_{s=-\infty}^{\infty} z^s \mathrm{cov}(x_t, y_{t-s}),$$

a matrix function of the scalar marker variable z. Generating functions such as $g_{xy}(z)$ are closely related to Fourier ideas and the frequency concept; the power series becomes a Fourier series if we set $z = \exp(i\omega)$.

Suppose that $g_{xx}(z)$ has a *canonical factorization*

$$g_{xx}(z) = B(z)B\left(z^{-1}\right)' \tag{16}$$

where both $B(z) = \sum_{s=0}^{\infty} b_s z^s$ and $B(z)^{-1}$ are analytic in $|z| \leq 1$. Then the stationary process $\{x_t\}$ has both a *moving average representation*

$$x_t = \sum_{s=0}^{\infty} b_s \varepsilon_{t-s}, \tag{17}$$

where $\{\varepsilon_t\}$ is white noise with $\mathrm{cov}(\varepsilon) = I$ and an *autoregressive representation*

$$\sum_{s=0}^{\infty} a_s x_{t-s} = \in_t \tag{18}$$

where a_s is the coefficient of z^s in the expansion of $B(z)^{-1}$ in non-negative powers of z.

Suppose X_t is the observable at time t. Then, by the argument which led us from (2) to (3), the optimal predictor is:

$$x_{t+m}^{(t)} = \sum_{s=m}^{\infty} b_s \in_{t+m-s} \tag{19}$$

and this can be expressed explicitly in terms of X_t:

$$x_{t+m}^{(t)} = \sum_{s=m}^{\infty} \gamma_s x_{t-s} \tag{20}$$

by using (18) to express the ε variables of (19) in terms of the x variables. One can express this solution for the optimal prediction coefficients γ_s in generating function form

$$\sum_{s=m}^{\infty} \gamma_s z^s = \left[z^{-m}B(z)\right]_+ B(z)^{-1}, \tag{21}$$

where the operator $[]_+$ has the effect that all terms in negative powers of z in the series enclosed by the brackets are discarded.

Suppose, as is more usual, that x_t is not completely observable, but that at time t one has observed the values $y_t, y_{t-1} \ldots$ of some associated variable y. Then the predictor will now have the form $x_{t+m}^{(t)} = \sum_{s=0}^{\infty} \gamma_s y_{t-s}$, and the generalization of solution (21) is:

$$\sum_{s=m}^{\infty} \gamma_s z^s = \left[z^{-m} g_{xy}\left(g_{yy}^{-}\right)^{-1}\right]_{+}\left(g_{yy}^{+}\right)^{-1}. \qquad (22)$$

Here we have omitted the z-arguments for simplicity, and have assumed that the matrix generating function $g_{yy}(z)$ has canonical factorization

$$g_{yy} = g_{yy}^{+} g_{yy}^{-}. \qquad (23)$$

$$x_{t+m}^{(t+1)} = x_{t+m}^{(t)} + H\left(y_{t+1} - y_{t+1}^{(t)}\right) \qquad (24)$$

$$\begin{aligned} A(T)x_t &= \varepsilon_t \\ y_t + C(T)x_t &= \eta_t \end{aligned} \qquad (25)$$

where $A(T) = \sum_{s=0}^{\infty} A_s T^s, C(T) = \sum_{s=0}^{\infty} C_s T^s$, and T is the backwards translation operator, with effect $Tx_t = x_{t-1}$. We make the same assumptions about the noise variables as before: that they are white with covariance matrix (8).

Then appeal to the fact that $x^{(t)}$ can be regarded as an ML estimator (in the Gaussian case) as well as an LLS estimator leads to the conclusion that it satisfies a recursion

$$\begin{bmatrix} N & L & A(T) \\ L' & M & C(T) \\ A\left(T^{-1}\right)' & C\left(T^{-1}\right)' & 0 \end{bmatrix} \begin{bmatrix} \lambda \\ \mu \\ x \end{bmatrix}_{\tau}^{(t)} = \begin{bmatrix} 0 \\ y_\tau \\ 0 \end{bmatrix}, \quad (\tau \le t) \qquad (26)$$

(see Whittle 1983, p. 155). Here λ and μ specify Lagrangian multiplier sequences whose significance will emerge shortly, and the lag operator T operates on the running argument τ not on the fixed value t.

Note that relations (26) determine estimates of past and present stat $x_\tau^{(t)}(\tau \le t)$. However, once these have been derived, then predictors are easily calculated recursively from:

$$A(T)x_\tau^{(t)} = 0 \quad (\tau > t) \qquad (27)$$

Equivalently, (26) can be regarded as holding for all τ with λ, μ set equal to zero for $\tau > t$.

Relations (26) constitute an equation system to be solved, semi-infinite if observation indeed extends back into the indefinite past. Write the system as:

$$\Phi(T)\xi_\tau = \zeta_\tau \qquad (28)$$

Then a reduction that provides as explicit a solution for $x_t^{(t)}$ as is possible in the general case in the following. Suppose that the Hermitian matrix generating function $\Phi(z)$ has canonical factorization

$$\Phi(z) = \Phi^{+}(z)\Phi^{-}(z) \qquad (29)$$

Then under generalized observability conditions it is permisible to partially invert (26) to:

$$\Phi^{-}(T)\xi_\tau = \Phi^{+}(T)^{-1}\zeta_\tau \quad (\tau \le t) \qquad (30)$$

with the formal end condition $\xi_\tau = 0(\tau > t)$. Relation (30) for $\tau = t$ gives an explicit solution for $x_t^{(t)}$ in terms of Y_t; the relation for $\tau = t - 1$ then determines $x_{t-1}^{(t)}$ etc.

To see the wider significance of this approach one must consider the wider purpose of prediction. One will usually require predictions (or estimates of unobservables) to support actions. Suppose actions are chosen to minimize the expections $E(Q)$ of some quadratic function Q of process and action variables. If follows then from the certainty equivalence theorem that LLS (or ML) predictors are the optimal ones to use. However, suppose that one instead minimizes a criterion $-\theta^{-1}\log E\exp(-\frac{1}{2}\theta Q)$. Here θ is a measure of risk-sensitivity, implying risk-seeking behaviour (optimism) for $\theta > 0$ and risk-aversion (pessimism) for $\theta < 0$. This risk-sensitivity modifies the estimators, which we shall now term *minimal stress* estimates, for reasons explained in Whittle and Kuhn (1986). Remarkably, the above analysis still goes through, with the simple change that Φ has the modified definition

$$\Phi(T)=\begin{bmatrix} N & L & A(T)\\ L' & M & C(T)\\ A\left(T^{-1}\right)' & C\left(T^{-1}\right)' & -\theta R\end{bmatrix}.$$

Here R is a matrix corresponding to a component $\sum_t (x' Rx)_t$of Q which penalizes deviations of the process variable from a desired profile. Moreover, one can now establish the identity

$$\begin{bmatrix}N & L\\ L' & M\end{bmatrix}\begin{bmatrix}\lambda\\ \mu\end{bmatrix}_\tau^{(t)} = \begin{bmatrix}\varepsilon\\ \eta\end{bmatrix}_\tau^{(t)}$$

which relates λ and μ to the minimal stress estimates of noise.

Prediction Formulas

Charles H. Whiteman and Kurt F. Lewis

Abstract

Prediction formulas for multi-step forecasts and geometric distributed leads of stationary time series are derived using classical, frequency domain methods. Starting with the Wold representation, optimal squared-error loss predictions are derived using the analytic function theory approach of Whittle. This approach is easily adapted to the problem of making predictions that are robust under model misspecification. Forecasts and expected present value calculations are illustrated under both objectives for low-order autoregressive and moving average processes.

Introduction

This article reviews the derivation of formulas for linear least squares and robust prediction of stationary time series and geometrically discounted distributed leads of such series. The derivations employed are the classical, frequency-domain procedures employed by Whittle (1983) and Whiteman (1983), and result in nearly closed-form expressions. The formulas themselves are useful directly in forecasting, and have also found uses in economic modelling, primarily in macroeconomics. Indeed, Hansen and Sargent (1980) refer to the cross-equation restrictions connecting the time series representation of driving variables to the analogous representation for predicting the present value of such variables as the 'hallmark of rational expectations models'.

The Wold Representation

Suppose that $\{x_t\}$ is a covariance-stationary stochastic process and assume (without loss of generality) that $Ex_t = 0$. Covariance stationarity ensures that first and second unconditional moments of the process do not vary with time. Then, by the Wold decomposition theorem (see Sargent 1987, for an elementary exposition and proof), x_t can be represented by:

$$x_t = \sum_{j=0}^{\infty} a_j \varepsilon_{t-j} \tag{1}$$

with

$$a_0 = 1, \sum_{j=0}^{\infty} a_j^2 < \infty$$

and

$$\varepsilon_t = x_t - P(x_t | x_{t-1}, x_{t-2}, \ldots), E\varepsilon_t^2 = \sigma^2$$

where $P(x_t|x_{t-1}, x_{t-2}, \ldots)$ denotes the linear least squares projection (population regression) of x_t on x_{t-1}, x_{t-2} , . . . Here, 'represented by' need not mean 'generated by', but rather 'has the same variance and covariance stmcture as'. By construction, the 'fundamental' innovation ε_t is uncorrelated with information dated prior to t, including earlier values of the process itself: $E\varepsilon_t\varepsilon_{t-s} = 0 \; \forall \; s > 0$. This fact makes the Wold representation very convenient for computing predictions. The convolution in (1) is often written $x_t = A(L)\varepsilon_t$ using the polynomial $A(L) = \sum_{j=0}^{\infty} a_j L^j$ in the 'lag operator' L, where $L\varepsilon_t = \varepsilon_{t-1}$.

Squared-Error Loss Optimal Prediction

The optimal prediction problem under squared-error loss can be thought of as follows. Given $\{x_t\}$ with the Wold representation (1) we want to find the stochastic process y_t,

$$y_t = \sum_{j=0}^{\infty} c_j \varepsilon_{t-j} = C(L)\varepsilon_t$$

that will minimize the squared forecast error of the h-step ahead prediction

$$\min_{\{y_t\}} E(x_{t+h} - y_t)^2.$$

Equivalently, the problem can be written as

$$\min_{\{y_t\}} E\left(L^{-h} x_t - y_t\right)^2$$

or

$$\min_{\{c_j\}} E\left(L^{-h} \sum_{j=0}^{\infty} a_j \varepsilon_{t-j} - \sum_{j=0}^{\infty} c_j \varepsilon_{t-j}\right)^2. \tag{2}$$

The problem in (2) involves finding a *sequence* of coefficients in the Wold representation of the unknown prediction process y_t, and is referred to as the *time domain problem*. By virtue of the Riesz–Fisher theorem (see again Sargent 1987, for an exposition), the time-domain problem is equivalent to a *frequency domain problem* of finding an analytic function $C(z)$ on the unit disk $|z| \leq 1$ corresponding to the 'z-transform' of the $\{c_j\}$ sequence

$$C(z) = \sum_{j=0}^{\infty} c_j z^j$$

that solves

$$\min_{C(z) \in H^2} \frac{1}{2\pi i} \oint |z^{-h} A(z) - C(z)|^2 \frac{dz}{z} \tag{3}$$

where H^2 denotes the Hardy space of square-integrable analytic functions on the unit disk, and $\oint$ denotes (counterclockwise) integration about the unit circle. The requirement that $C(z) \in H^2$ ensures that the forecast is causal, and contains no future values of the ε's; this is equivalent to the requirement that $C(z)$ have a well-behaved power series expansion in non-negative powers of z.

Each formulation of the problem is useful, as often one or the other will be simpler to solve.

This stems from the fact that convolution in the time domain becomes multiplication in the frequency domain and vice versa. To see this, consider the two sequences $\{g_k\}_{k=-\infty}^{\infty}$ and $\{h_k\}_{k=-\infty}^{\infty}$. The convolution of $\{g_k\}$ and $\{h_k\}$ is the sequence $\{f_k\}$, in which a typical element would be:

$$f_k = \sum_{j=-\infty}^{\infty} g_j h_{k-j}.$$

The z-transform of the convolution is given by

$$\begin{aligned}
\sum_{k=-\infty}^{\infty} f_k z^k &= \sum_{k=-\infty}^{\infty}\left(\sum_{j=-\infty}^{\infty} g_j h_{k-j}\right) z^k \\
&= \sum_{k=-\infty}^{\infty}\sum_{j=-\infty}^{\infty} g_j z^j h_{k-j} z^{k-j} \\
&= \sum_{(k-j)=-\infty}^{\infty}\sum_{j=-\infty}^{\infty} g_j z^j h_{k-j} z^{k-j} \\
&= \sum_{s=-\infty}^{\infty}\sum_{j=-\infty}^{\infty} g_j z^j h_s z^s \,(\text{Substituting} \quad s = k-j) \\
&= \sum_{s=-\infty}^{\infty} h_s z^s \sum_{j=-\infty}^{\infty} g_j z^j = g(z)h(z).
\end{aligned}$$

Thus the 'z-transform' of the convolution of the sequences $\{g_k\}$ and $\{h_k\}$ is the product of the z-transforms of the two sequences.

Similarly, the z-transform of the product of two sequences is the convolution of the z-transforms:

$$\sum_{k=-\infty}^{\infty} g_k h_k z^k = \frac{1}{2\pi i}\oint g(p)h(z/p)\frac{dp}{p}.$$

To see why this is the case, note that

$$g(p)h(z/p)p^{-1} = \sum_{j=-\infty}^{\infty} g_j p^j \sum_{k=-\infty}^{\infty} h_k z^k p^{-k-1},$$

implying

$$\begin{aligned}
&\frac{1}{2\pi i}\oint g(p)h(z/p)p^{-1}dp \\
&= \frac{1}{2\pi i}\oint \sum_{j=-\infty}^{\infty}\sum_{k=-\infty}^{\infty} g_j h_k z^k p^{j-k-1} dp.
\end{aligned}$$

But all of the terms vanish except where $j = k$ because

$$\frac{1}{2\pi i}\oint z^k \frac{dz}{z} = 0$$

except when $k = 0$. To see why, let $z = e^{i\theta}$. As θ increases from 0 to 2π, z goes around the unit circle. So, since $dz = ie^{i\theta}d\theta$, we have that

$$\begin{aligned}
\frac{1}{2\pi i}\oint z^k \frac{dz}{z} &= \frac{i}{2\pi i}\oint e^{i\theta k} d\theta \\
&= \begin{cases} 1 & \text{if} \quad k = 0 \\ \dfrac{1}{2\pi}\dfrac{1}{ik} e^{i\theta k}|_0^{2\pi} = 0 & \text{otherwise.} \end{cases}
\end{aligned}$$

Thus,

$$\begin{aligned}
\frac{1}{2\pi i}\oint g(p)h(z/p)p^{-1}dp &= \sum_{j=-\infty}^{\infty} g_j h_j z^j \frac{1}{2\pi i}\oint \frac{dp}{p} \\
&= \sum_{j=-\infty}^{\infty} g_j h_j z^j
\end{aligned}$$

by Cauchy's Integral formula.

The frequency domain formulas can now be used to calculate moments quickly and conveniently. Consider Ex_t^2:

$$\begin{aligned}
Ex_t^2 = E(A(L)\varepsilon_t)^2 &= E\left(\sum_{j=0}^{\infty} A_j \varepsilon_{t-j}\right)^2 \\
&= \sigma_\varepsilon^2 \sum_{j=0}^{\infty} A_j^2. \qquad (4)
\end{aligned}$$

The result in Eq. (4) comes from the fact that $E\varepsilon_t\varepsilon_{t-s} = 0, \quad \forall s \neq 0.$ Using the product-convolution relation, we see that

$$\begin{aligned}
\sum^{j=0\infty} A_j^2 &= \sum_{j=0}^{\infty} A_j^2 z^j|_{z=1} \\
&= \frac{1}{2\pi i}\oint A(p)A(z/p)\frac{dp}{p}|_{z=1} \\
&= \frac{1}{2\pi i}\oint A(p)A\left(p^{-1}\right)\frac{dp}{p} \\
&= \frac{1}{2\pi i}\oint |A(z)|^2 \frac{dz}{z}. \qquad (5)
\end{aligned}$$

Returning to the prediction problem, the task is to choose c_0, c_1, c_2, . . . to

$$\min_{\{c_j\}} \frac{1}{2\pi i} \oint |z^{-h}A(z) - \sum_{j=0}^{\infty} c_j z^j|^2 \frac{dz}{z}. \qquad (6)$$

The first order conditions for the optimization in expression (7) are

$$\begin{aligned} 0 &= \frac{1}{2\pi i} \oint \{z^j[z^h A(z^{-1}) - C(z^{-1})] \\ &+ z^{-j}[z^{-h}A(z) - C(z)]\} \frac{dz}{z} \\ &= \frac{1}{2\pi i} \oint z^{-j}\left[z^{-h}A(z) - C(z)\right] \frac{dz}{z} \\ &- \frac{1}{2\pi i} \oint p^{-j}\left[p^{-h}A(p) - C(p)\right] \frac{dp}{p} \end{aligned} \qquad (7)$$

for $j = 0, 1, 2, \ldots$, where the second integral is the result of a change of variable $p = z^{-1}$ so that $dp = \; -z^{-1}dz$, resulting in

$$\frac{dp}{p} = z\left(-z^{-2}dz\right) = -\frac{dz}{z}.$$

The result is that in the second integral, the direction of the contour integration is clockwise. Multiplying by -1 and integrating counterclockwise, the second integral becomes identical to the first, and we can write the set of first-order conditions as

$$\begin{aligned} 0 &= \frac{1}{\pi i} \oint z^{-j}\left[z^{-h}A(z) - C(z)\right] \frac{dz}{z} j \\ &= 0, 1, 2, \ldots \end{aligned} \qquad (8)$$

Define $F(z)$ such that

$$F(z) = z^{-h}A(z) - C(z) = \sum_{j=-\infty}^{\infty} F_j z^j.$$

From Eq. (8), it must be the case that all coefficients on non-negative powers of z equal zero:

$$F_j = 0, \quad j = 0, 1, 2, \ldots .$$

Multiplying by z^j and summing over *all* $j = 0$, ± 1, ± 2, . . . , we obtain

$$F(z) = \sum_{-\infty}^{-1} \qquad (9)$$

where the term on the right-hand-side of (9) represents an unknown function in negative powers of z. Thus

$$z^{-h}A(z) - C(z) = \sum_{-\infty}^{-1} \, ,$$

which is an example of a ‘Wiener–Hopf’ equation. Now apply the (linear) ‘plussing’ operator, $[\cdot]_+$, which means ‘ignore negative powers of z’ The unknown function in negative powers of z is ‘annihilated’ by this operation, resulting in

$$\begin{aligned} C(z) &= \left[z^{-h}A(z)\right]_+ \\ &= \left[z^{-h}a_0 + z^{-h+1}a_1 + z^{-h+2}a_2 + \ldots\right]_+ \\ &= \left[z^0 a_h + z^1 a_{h+1} + z^2 a_{h+2} + \ldots\right] \\ &= \sum_{j=h}^{\infty} a_j z^{j-h} \\ &= z^{-h}A(z) - pr\left[z^{-h}A(z)\right] \end{aligned}$$

where $pr[z^{-h}A(z)]$ is the principal part of the Laurent expansion of $z^{-h}A(z)$ about $z = 0$. (The principal part of the Laurent expansion about $z = 0$ is the part involving negative powers of z.) This provides a very simple formula for computing forecasts.

AR(1) Example

Suppose that $x_t = ax_{t-1} + \varepsilon_t$. This means that $A(z) = 1/(1 - az)$. In this case:

$$\begin{aligned} C(z) &= \left[z^{-h}A(z)\right]_+ \\ &= \left[z^{-h}(1 + az + a^2z^2 + \ldots)\right]_+ \\ &= a^h(1 + az + a^2z^2 + \ldots) \\ &= \frac{a^h}{(1 - az)} \end{aligned}$$

and the least squares loss predictor of x_{t+h} using information dated t and earlier is

$$P_t^{LS} x_{t+h} = y_t = C(L)\varepsilon_t = C(L)A^{-1}(L)x_t = a^h x_t.$$

The forecast error is

$$x_{t+h} - a^h x_t = \varepsilon_{t+h} + a\varepsilon_{t+h-1} + \dots \quad + a^{h-1}\varepsilon_{t+1},$$

which is serially correlated (for $h \geq 2$), but not correlated with information dated t and earlier.

MA(1) Example

Supposed that $x_t = \varepsilon_t - \alpha\varepsilon_{t-1}$, meaning $A(z) = 1 - az$. Thus,

$$C(z) = \left[z^{-h}A(z)\right] = \left[z^{-h}(1 - \alpha z)\right] = \begin{cases} \alpha \text{ if } & h = 1, \\ 0 & \text{otherwise.} \end{cases}$$

So, the best one-step ahead predictor is

$$\alpha\varepsilon_t = \alpha\left(1 + \alpha L + \alpha^2 L^2 + \dots\right)x_t$$

and the best predictor for forecasts of horizon two or more is exactly zero. For two-step-ahead (and beyond) prediction, the forecast error is x_{t+h} itself, which is serially correlated but not correlated with information dated t and earlier.

Least Squares Prediction of Geometric Distributed Leads

A prediction problem that characterizes many models in economics involves the expectation of a discounted value. Perhaps the most common and widely studied example is the present value formula for stock prices. Abstracting from mean and trend, suppose the dividend process has a Wold representation given by

$$d_t = \sum_{j=0}^{\infty} q_j \varepsilon_{t-j} = q(L)\varepsilon_t \quad E(\varepsilon_t) = 0, \qquad E\left(\varepsilon_t^2\right) = 1. \tag{10}$$

Assuming that the constant discount factor is given by γ, we have the present value formula

$$p_t = E_t \sum_{j=0}^{\infty} \gamma^j d_{t+j} = E_t\left(\frac{q(L)}{1 - \gamma L^{-1}}\varepsilon_t\right) = E_t\left(p_t^*\right). \tag{11}$$

The least-squares minimization problem the predictor faces is to find a stochastic process p_t to minimize the expected squared prediction error $E\left(p_t - p_t^*\right)^2$. In terms of the information known at date t, the agent's task is to find a linear combination of current and past dividends, or, equivalently, of current and past dividend innovations ε_t, that is 'close' to p_t^*. Writing $p_t = f(L)\varepsilon_t$, the problem becomes one of finding the coefficients f_j in $f(L) = f_0 + f_1 L + f_2 L^2 + \dots$ to minimize $E\left(f(L)\varepsilon_t - p_t^*\right)^2$. Using the method described in the previous section, the problem has an equivalent, frequency-domain representation

$$\min_{f(z)\in H^2} \frac{1}{2\pi i}\oint \left| \frac{q(z)}{1 - \gamma z^{-1}} - f(z)\right|^2 \frac{dz}{z}. \tag{12}$$

The first-order conditions for choosing f_j are, after employing the same simplification used in (7),

$$-\frac{2}{2\pi i}\oint z^{-j}\left[\frac{q(z)}{1 - \gamma z^{-1}} - f(z)\right]\frac{dz}{z} = 0, \quad j = 0, 1, 2, \dots. \tag{13}$$

Now define

$$H(z) = \frac{q(z)}{1 - \gamma z^{-1}} - f(z)$$

so that (13) becomes

$$-\frac{2}{2\pi i}\oint z^{-j} H(z)\frac{dz}{z} = 0.$$

Then multiplying by z^j and summing over all $j = 0, \pm 1, \pm 2, \dots$ as above, we obtain

$$H(z) = \frac{q(z)}{1 - \gamma z^{-1}} - f(z) = \sum_{-\infty}^{-1},$$

the Wiener–Hopf equation for this problem. Applying the plussing operator to both sides yields

$$\left[\frac{q(z)}{1-\gamma z^{-1}}\right]_+ - [f(z)]_+ = 0$$

implying

$$f(z) = \left[\frac{q(z)}{1-\gamma z^{-1}}\right]_+ = \left[\frac{zq(z)}{z-\gamma}\right]_+$$

because *f*(*z*) is, by construction, one-sided in non-negative powers of *z*. As in the previous section,

$$[A(z)]_+ = A(z) - P(z)$$

where *P*(*z*) is the principal part of the Laurent series expansion of *A*(*z*). To determine the principal part of $[(z-\gamma)^{-1}zq(z)]$, note that *zq*(*z*) has a well-behaved power series expansion about $z=\gamma$, where 'well-behaved' means 'involving no negative powers of $(z-\gamma)$'. Thus $[(z-\gamma)^{-1}zq(z)]$ has a power series expansion about $z=\gamma$ involving a single term in $(z-\gamma)^{-1}$:

$$\left(\frac{zq(z)}{z-\gamma}\right) = \frac{b_{-1}}{z-\gamma} + b_0 + b_1(z-\gamma)^1 + b_2(z-\gamma)^2 + \ldots .$$

The principal part here is the part involving negative powers of $(z-\gamma)$: $\mathrm{b}_{-1}(z-\gamma)^{-1}$. To determine it, multiply both sides by $(z-\gamma)$ and evaluate what is left at $z=\gamma$ to find $b_{-1}=\gamma q(\gamma)$. Thus

$$f(z) = \left[\frac{q(z)}{1-\gamma z^{-1}}\right]_+ = \left[\frac{zq(z)}{z-\gamma}\right]_+ = \frac{zq(z)-\gamma q(\gamma)}{z-\gamma}. \qquad (14)$$

The 'cross-equation restrictions' of rational expectations refer to the connection between the serial correlation structure of the driving process (here dividends) and the serial correlation structure of the expected discounted value of the driving process (here prices). That is, when dividends are characterized by *q*(*z*), prices are characterized by *f*(*z*), and *f*(*z*) depends upon *q*(*z*) as depicted in (14).

To illustrate how the formula works, suppose detrended dividends are described by a first-order autoregression; that is, that $q(L)=(1-\rho L)^{-1}$. Then

$$p_t = f(L)\varepsilon_t = \frac{Lq(L)-\gamma q(\gamma)}{L-\gamma}\varepsilon_t = \left(\frac{1}{1-\rho\gamma}\right)d_t. \qquad (15)$$

It is instructive to note that, while the pricing formula (15) makes p_t the best least squares predictor of p_t^*, the prediction errors $p_t - p_t^*$ will not be serially uncorrelated. Indeed

$$\begin{aligned} p_t - p_t^* &= \gamma\left\{\frac{Lq(L)-\gamma q(\gamma)}{L-\gamma} - \frac{q(L)}{1-\gamma L^{-1}}\right\}\varepsilon_t \\ &= \frac{-\gamma^2 q(\gamma)}{L-\gamma}\varepsilon_t = -\gamma^2 q(\gamma)\frac{L^{-1}}{1-\gamma L^{-1}}\varepsilon_t \\ &= -\gamma^2 q(\gamma)\left\{\varepsilon_{t+1} + \gamma\varepsilon_{t+2} + \gamma^2\varepsilon_{t+3} + \ldots\right\}. \end{aligned}$$

Thus the prediction errors will be described by a highly persistent (γ is close to unity) first-order autoregression. But because this autoregression involves *future* ε_t's, the serial correlation structure of the errors cannot be exploited to improve the quality of the prediction of p_t^*. The reason is that the predictor 'knows' the *model* for price setting (the present value formula) and the dividend process; the best predictor $p_t = E_t p_t^*$ of p_t^* tolerates' the serial correlation because the (correct) model implies that it involves *future* ε_t's and therefore cannot be predicted. If one only had data on the errors (and did not know the model that generated them), they would appear (rightly) to be characterized by a first-order autoregression; fitting an AR(1) (that is, the best *linear* model) and using it to 'adjust' p_t by accounting for the serial correlation in the errors $p_t - p_t^*$ would decrease the quality of the estimate of p_t^*. The reason is the usual one that the Wold representation for $p_t - p_t^*$ is not the economic model of $p_t - p_t^*$, and (correct) models always beat Wold representations. This also serves as a reminder of circumstances under which one should be willing to tolerate serially correlated errors: when one knows the model that generated them, and the model implies that they are as small as they can be made.

Robust Optimal Prediction of Time Series

The squared-error loss function employed to this point is appropriate for situations in which the model (either the time series model or the economic model) is thought to be correct. But in many settings the forecaster or model builder may wish to guard against the possibility of misspecification. There are many ways to do this; an approach popular in the engineering literature and recently introduced into the economics literature by Hansen and Sargent (2007) involves behaving so as to minimize the maximum loss sustainable by using an approximating model when the truth may be something else. The ‘robust’ approach to this involves replacing the squared-error loss problem

$$\min_{\{C(z)\}} \frac{1}{2\pi i}\oint |z^{-h}A(z) - C(z)|^2 \frac{dz}{z}$$

with the ‘min-max’ problem

$$\min_{\{C(z)\}} \sup_{|z|=1} |z^{-h}A(z) - C(z)|^2,$$

so that minimizing the ‘average’ value on the unit circle has been replaced by minimizing the max. This problem can also be written

$$\min_{\{C(z)\}} \sup_{|z|=1} |A(z) - z^h C(z)|^2.$$

This is known as the ‘minimum norm interpolation problem’ and amounts to finding a function $\varphi(z)$ to

$$\min ||\varphi(z)||_\infty$$

subject to the restriction that the power series expansion of $\varphi(z)$ matches that of $A(z)$ for the first $h - 1$ powers of z. This means that the following must hold:

$$\sum_{j=0}^{h-1} \varphi_j z^j = \sum_{j=0}^{h-1} a_j z^j. \tag{16}$$

Theorem 1 *The minimizing $\varphi(z)$ function is such that $|\varphi(z)|^2$ is constant on $|z| = 1$. Moreover,*

$$\varphi(z) = M \prod_{j=1}^{h} \frac{z - \alpha_j}{1 - \overline{\alpha}_j z}$$

where M, α_1, α_2, ... ,α_n are chosen to ensure that (16) holds.

Proof: see Nehari (1957).

To see that $\varphi(z)$ must be of the indicated form, note that the ‘Blaschke factors’ in the product have unit modulus:

$$\frac{z-\alpha_j}{1-\alpha_j z}\left(\frac{z^{-1}-\overline{\alpha}_j}{1-\alpha_j z^{-1}}\right) = \left(\frac{z-\alpha_j}{1-\alpha_j z}\right)\left(z^{-1}z\right)$$
$$\left(\frac{z^{-1}-\overline{\alpha}_j}{1-\alpha_j z^{-1}}\right) = \left(\frac{1-\alpha_j z^{-1}}{1-\alpha_j z}\right)\left(\frac{1-\alpha_j z}{1-\alpha_j z^{-1}}\right) = 1,$$

so that $|\varphi(z)|^2 = M^2$.

In the general h-step-ahead prediction problem, we have that

$$\varphi(z) = M \prod_{j=1}^{h-1} \frac{z - \alpha_j}{1 - \overline{\alpha}_j z} = A(z) - z^h C(z),$$

meaning that

$$C(z) = \frac{1}{z^h}\left(A(z) - M \prod_{j=1}^{h-1} \frac{z - \alpha_j}{1 - \overline{\alpha}_j z}\right).$$

This is analogous to the solution in the least-squares case, but, instead of subtracting the principal part of $z^{-h}A(z)$, we subtract a different function from $z^{-h}A(z)$. Note also that because

$$M \prod_{j=1}^{h-1} \frac{z - \alpha_j}{1 - \overline{\alpha}_j z}$$

matches the power series expansion of $A(z)$ up to the power z^{h-1}, $C(z)$ is of the form

$$C(z) = c_0 + c_1 z + c_2 z^2 + \ldots$$

Finally, note that the forecast error is serially uncorrelated because $\varphi(z)$ is constant on $|z| = 1$.

Example. AR(1)

Let

$$A(z) = \frac{1}{1 - az}.$$

For $h = 1$, we see that $\varphi(z) = A(z) - zC(z)$ must be constant on $|z| = 1$, and that $\varphi(0) = A(0) = 1$. Thus, $\varphi(z) = M = 1$, so that

$$C(z) = \frac{A(z) - 1}{z} = \frac{az}{(1 - az)z} = \frac{a}{1 - az},$$

which implies that the robust one-step ahead forecast is

$$y_t^R = ax_t,$$

which coincides with the best least-squares forecast. This equivalence between the robust and least-squares one-step ahead forecasts is to be expected because the best one-step-ahead least-squares forecast also has serially uncorrelated errors. For $h = 2$, we have that

$$\varphi(z) = \frac{M(z - \alpha)}{1 - \overline{\alpha} z}$$

where (again) $\varphi(0) = 1$, but now we also see that $\varphi'(0) = a$. Thus,

$$\varphi(0) = 1 = -\alpha M \Rightarrow M = -\frac{1}{\alpha},$$

and furthermore

$$\begin{aligned}\varphi'(0) = a &= \frac{(1 - \overline{\alpha} z)M - M(z - \alpha)(-\overline{\alpha})}{(1 - \overline{\alpha} z)^2}|_{z=0} \\ &= M - M(\alpha\overline{\alpha}) = M(1 - \alpha\overline{\alpha}).\end{aligned}$$

Therefore, the solution will have the property that

$$\begin{aligned}a = -\frac{1}{\alpha}(1 - \alpha\overline{\alpha}) \quad - a\alpha = 1 - \alpha\overline{\alpha} \;\; 0 \\ = 1 + a\alpha - \alpha\overline{\alpha}.\end{aligned}$$

That is, the roots are reciprocal pairs. Notice that the discriminant is positive $(a^2\alpha^2 + 4\alpha\overline{\alpha} > 0)$, meaning that we will always have a real solution, and we choose $|\alpha| < 1$. Then, we have that

$$\begin{aligned}C(z) &= \frac{1}{z^2}\left[\frac{1}{1 - az} - \frac{M(z - \alpha)}{1 - \alpha z}\right] \\ &= \frac{1}{z^2}\frac{1 - \alpha z - (1 - az)\left(1 - \frac{1}{\alpha}z\right)}{(1 - az)(1 - \alpha z)} \\ &= \frac{1 - \alpha z - 1 + az + \frac{1}{\alpha}z - \frac{a}{\alpha}z^2}{z^2(1 - az)(1 - \alpha z)} \\ &= \frac{-\frac{a}{\alpha}}{(1 - az)(1 - \alpha z)}.\end{aligned}$$

So, the robust prediction is given by

$$P_t^R x_{t+2} = -\frac{a}{\alpha}\sum_{j=0}^{\infty} \alpha^j x_{t-j},$$

in contrast to the least-squares prediction

$$P_t^{LS} x_{t+2} = a^2 x_t.$$

Example. MA(1)

Suppose that the process follows an MA(1), $x_t = \varepsilon_t - \beta\varepsilon_{t-1}$, and therefore $A(z) = 1 - \beta z$. The analysis from the previous example still holds, and all of the following are true:

$$\varphi(z) = \frac{M(z - \alpha)}{1 - \overline{\alpha} z}$$

while

$$\varphi(0) = 1 = -\alpha M \;\Rightarrow\; M = -\alpha^{-1}$$

and

$$\varphi'(0) = -\beta = -\frac{1}{\alpha}(1 - \alpha\overline{\alpha}).$$

Therefore,

$$0 = 1 - \alpha\beta - \alpha\overline{\alpha},$$

meaning that, again, we have real roots which are reciprocal pairs and we can choose $|\alpha| < 1$. Of course, α will depend upon the value of β, and we write $\alpha(\beta)$. Thus

$$\begin{aligned} C(z) &= \frac{1}{z^2}\left[1 - \beta z - \frac{M(z - \alpha(\beta))}{(1 - \alpha(\beta)z)}\right] \\ &= \frac{1}{z^2}\left[\frac{(1 - \beta z)(1 - \alpha(\beta)z)) - M(z - \alpha(\beta))}{1 - \alpha(\beta)z}\right] \\ &= \frac{1}{z^2}\left[\frac{1 - \beta z - \alpha(\beta)z + \beta\alpha(\beta)z^2 - Mz + M\alpha(\beta)}{1 - \alpha(\beta)z}\right] \\ &= \frac{\beta\alpha(\beta)}{1 - \alpha(\beta)z}. \end{aligned}$$

Therefore, we have the robust prediction

$$\begin{aligned} P_t^R x_{t+2} &= \frac{\beta\alpha(\beta)}{1 - \alpha(\beta)L}\varepsilon_t \\ &= \frac{\beta\alpha(\beta)}{1 - \alpha(\beta)L}[x_t + \beta x_{t-1} + \beta x_{t-2} + \ldots], \end{aligned}$$

while the least-squares prediction is the standard

$$P_t^{LS} x_{t+2} = 0.$$

Robust Prediction of Geometric Distributed Leads

Following the excellent treatment in Kasa (2001), a robust present-value predictor fears that dividends may not be generated by the process in (10), and so, instead of choosing an $f(z)$ to minimize the average loss around the unit circle, chooses $f(z)$ to minimize the maximum loss:

$$\begin{aligned} &\min_{f(z)\in H^\infty} \sup_{|z|=1} \left|\frac{q(z)}{1 - \gamma z^{-1}} - f(z)\right|^2 \\ &\Leftrightarrow \min_{f(z)\in H^\infty} \sup_{|z|=1} \left|\frac{zq(z)}{z - \gamma} - f(z)\right|^2. \end{aligned}$$

Unlike in the least squares case (14), where $f(z)$ was restricted to the class H^2 of functions finitely square integrable on the unit circle, the restriction now is to the class of functions with finite maximum modulus on the unit circle, and the H^2 norm has been replaced by H^∞ norm.

To begin the solution process, note that there is considerable freedom in designing the minimizing function $f(z)$: it must be well-behaved (that is, must have a convergent power series in non-negative powers of z on the unit disk), but is otherwise unrestricted. Recalling the Laurent expansion

$$\frac{zq(z)}{z - \gamma} = \frac{b_{-1}}{z - \gamma} + b_0 + b_1(z - \gamma) + b_2(z - \gamma)^2 + \ldots,$$

while in the least squares case $f(z)$ was set to ‘cancel’ all the terms of this series except the first, here $f(z)$ will be set to do something else. Now define the Blaschke factor $B_\gamma(z) = (z - \gamma)/(1 - \gamma z)$ and note that, because of the unit modulus condition, the problem can be written

$$\min_{\{f(z)\}} \sup_{|z|=1} \left|\frac{zq(z)}{1 - \gamma z} - \frac{z - \gamma}{1 - \gamma z}f(z)\right|^2.$$

Defining

$$T(z) = \frac{zq(z)}{1 - \gamma z}$$

we have

$$\begin{aligned} &\min_{f\in H^\infty} \sup_{|z|=1} |T(z) - B_\gamma(z)f(z)| \\ &\Leftrightarrow \min_{f\in H^\infty} ||T(z) - B_\gamma(z)f(z)||_\infty. \end{aligned}$$

Define the function inside the $||$’s as

$$\varphi(z) = T(z) - B_\gamma(z)f(z)$$

and note that $\varphi(\gamma) = T(\gamma)$. Thus the problem of finding $f(z)$ reduces to the problem of finding the smallest $\varphi(z)$ satisfying $\varphi(\gamma) = T(\gamma)$:

$$\min_{\varphi \in H^\infty} ||\varphi(z)||_\infty \text{ s.t. } \varphi(\gamma) = T(\gamma)$$

Theorem 2 (Kasa 2001). *The solution to* (17) *is the constant function* $\varphi(z) = T(\gamma)$.

Proof. To see this, first note that the norm of a constant function is the modulus of the constant itself. This is written as

$$||\varphi(z)||_\infty = ||T(\gamma)||_\infty = |T(\gamma)|^2. \tag{17}$$

Next, suppose that there exists another function $\Psi(z) \in H^\infty$, with $\Psi(\gamma) = T(\gamma)$ and also

$$||\Psi(z)||_\infty < ||\varphi(z)||_\infty. \tag{18}$$

Recall the definition of the H^∞ norm, and using Eqs. (17) and (18):

$$||\Psi(z)||_\infty = \sup_{|z|=1} |\Psi(z)|^2 < |T(\gamma)|^2.$$

The maximum modulus theorem states that a function f which is analytic on the disk U achieves its maximum on the boundary of the disk. That is

$$\sup_{z \in U} |f(z)|^2 \leq \sup_{z \in \partial U} |f(z)|^2.$$

Therefore, we can see that

$$\sup_{|z|<1} |\Psi(z)|^2 \leq \sup_{|z|=1} |\Psi(z)|^2 < |T(\gamma)|^2.$$

However, one of the values on the interior of the unit disk is $z = \gamma$, which can be inserted into the far left-hand-side of Eq. (6) to get the result

$$|\Psi(\gamma)|^2 \leq \sup_{|z|} = 1|\Psi(z)|^2 < |T(\gamma)|^2 \Rightarrow |\Psi(\gamma)|^2 < |T(\gamma)|^2.$$

This contradicts the requirement that $\Psi(\gamma) = T(\gamma)$. Therefore, we have verified that there does not exist another function $\Psi(z) \in H^\infty$ such that $\Psi(\gamma) = T(\gamma)$ and $||\Psi(z)||_\infty < ||\varphi(z)||_\infty$. □

Given the form for $\varphi(z)$, the form for $f(z)$ follows. After some tedious algebra, we obtain

$$\begin{aligned} f(z) &= \frac{T(z) - \varphi(z)}{B_\gamma(z)} \\ &= \frac{zq(z) - \gamma q(\gamma)}{z - \gamma} + \frac{\gamma^2}{1 - \gamma^2} q(\gamma) \end{aligned}$$

which is the least squares solution plus a constant. Thus the robust cross-equation restrictions likewise differ from the least squares cross-equation restrictions. After the initial period, the impulse response function for the robust predictor is identical to that of the least squares predictor. In the initial period, the least squares impulse response is $q(\gamma)$, while the robust impulse response is larger: $q(\gamma)/(1 - \gamma^2)$.

Because γ is the discount factor, and therefore close to unity, the robust impulse response can be considerably larger than that of the least squares response. Relatedly, the volatility of prices in the robust case will be larger as well. For example, in the first-order autoregressive case studied above,

$$\begin{aligned} p_t &= f(L)\varepsilon_t \\ &= \frac{1}{1 - \rho\gamma} d_t + \frac{\gamma^2}{(1 - \gamma^2)(1 - \rho\gamma)} \varepsilon_t \end{aligned} \tag{19}$$

from which the variance can be calculated as

$$\begin{aligned} \sigma^2(p_t) = & \left(\frac{1}{1 - \rho\gamma}\right)^2 \sigma^2(d_t) \\ & + \frac{2\gamma^2 - \gamma^4}{(1 - \rho\gamma)^2 (1 - \gamma^2)^2}. \end{aligned}$$

When the discount factor is large and dividends are highly persistent, the variance of the robust present value prediction can be considerably larger than that of the least squares prediction (the first term on the right alone).

Finally, recall that the least-squares present-value predictor behaved in such a way as to minimize the *variance* of the error $p_t - p_t^*$. Here, robust prediction results in an error with Wold representation

$$p_t - p_t^* = \gamma\left\{\frac{Lq(L) - \gamma q(\gamma)}{L-\gamma} + \frac{\gamma^2}{1-\gamma^2}q(\gamma) - \frac{q(L)}{1-\gamma L^{-1}}\right\}\varepsilon_t$$

$$= -\frac{\gamma q(\gamma)}{1-\gamma^2}\left\{\frac{1-\gamma L}{L-\gamma}\right\}\varepsilon_t.$$

The term in braces has the form of a Blaschke factor. Applying such factors in the lag operator to a serially uncorrelated process like ε_t leaves a serially uncorrelated result; thus the robust present value predictor has behaved in such a way that the resulting errors are white noise. Of course this comes at a cost: to make the error serially uncorrelated, the robust predictor must tolerate an error variance that is larger than the least squares error variance by a factor of $a^2/(1-\gamma^2)$, which can be substantial when γ is close to unity.

Prediction Market Design

David C. Croson

Abstract

This article surveys (*a*) the challenges of transitioning the results from prediction-market experiments under laboratory conditions to outside-world conditions devoid of laboratory controls, (*b*) the abilities of current (as of this writing, in 2007) implementations of prediction markets to address these challenges, and (*c*) opportunities for research into future market designs which are robust to these challenges.

prediction markets have made the jump from the laboratory to the field. In these markets, participants bid on Arrow securities, which pay one dollar in one state of the world and zero dollars in others. Since the pioneering work of Plott and Sunder (1982), experiments have generated results that are consistent with the idea that prices in controlled laboratory settings track predicted probabilities formed from the aggregated information of all participants (Hayek 1945). Emboldened by this general correspondence of theory and the general ability of laboratory experiments to test and validate these theories (see Sunder 1995; Plott 2000), prediction markets have escaped the laboratory. Markets offering opportunities to make real-money investments in predicting financial indices, political election results, entertainment awards, world events, and even the minutiae of sporting contests (now viewed with some suspicion as a highbrow form of gambling) have appeared in strength.

The history and general theory of such prediction markets is covered in prediction markets. This article combines (*a*) the challenges of transitioning the results from prediction-market experiments under laboratory conditions to outside-world conditions devoid of laboratory controls, (*b*) the abilities of current (as of this writing, in 2007) implementations of prediction markets to address these challenges, and (*c*) opportunities for research into future market designs which are robust to these challenges.

While there will necessarily be differences between strictly controlled laboratory studies and the real-world phenomena that they model, four particular cautions should be noted when attempting to extend the predictive abilities of laboratory-generated results to real-world prediction markets. The incidence of any of these four conditions will frustrate our ability to 'read' participants' collective estimation of probabilities from the equilibrium market prices for their associated securities: (*a*) extended duration of capital commitments; (*b*) differing levels of capital commitment across participants; (*c*) strategic objectives other than trading profits; and (*d*) influence by market participants over events on which the contracts are conditioned.

First, laboratory markets generally clear in short periods of time, so that participants face little or no opportunity costs from not investing their capital elsewhere for the duration of the experiment. In an outside prediction market, the lack of this quick-clearing condition means that prices will not generally sum to unity even when the alternatives are a complete partitioning of the possibility space. Participants' capital is tied up in their investment until its resolution, and the opportunity cost of tying up capital while awaiting resolution may be substantial. The common practice is for the exchange provider to capture the float by collecting deposits in time t dollars and paying in time $t + 1$ dollars at a 1:1 ratio, rather than a 1:$1 + r_f$ ratio; this distorts prices away from their associated probabilities. The problem is particularly acute when the time to expiry is relatively long over a high proportion of the contract life. An attempted resolution would be for the market organizer to pay the risk-free rate of return on all such committed capital and to allocate a fixed proportion $(1 - v)$ of the total amount collected (and earned) pro rata to the winners, with the result that the sum of the prices should converge towards $(1 - v)$; probabilities can be renormalized accordingly. In a first step towards addressing this problem, InTrade, a trade exchange market for social, political, and financial events, offered credit interest (at three per cent per annum) on all committed balances beyond a certain threshold account size, thereby reducing the time-value handicap faced by early investors in long-dated contracts.

Second, experimental market participants are allocated fixed amounts of capital, with any variation deliberate on the experimenters' part. When the capital is not uniform across participants, the resulting market prices may diverge from an unbiased estimate of participants' subjective probabilities, a situation hotly debated in the prediction-markets literature (Wolfers and Zitzewitz 2004; Manski 2006). The objection to interpreting prices as probabilities arises because the market price is both an input to decisions outside the market and the result of equilibration among these traders. Risk-neutral investors with subjective probabilities above (below) the current market price would wish to buy (sell) the contract, and thus the equilibrium price must balance the total capital of the players on the two sides of the current price. The price will reflect the subjective probability of the investor of the marginal dollar rather than the average subjective probabilities of the potentially large number of participants. With equal capital endowments, the side that prefers the low-probability (inexpensive) side of the contract demands more contract quantity, driving the price down; with unequal capital endowments, this problem can be either masked or exacerbated. The fact that 'heavy hitters' with bigger budgets (or optimistic beliefs about long-shot events) get more 'votes' in this system obscures the information gathered from the other participants. At best, market prices in these situations can be interpreted as the dollar-weighted averages of participants' beliefs, rather than the simple median.

Consider, then, the task of extracting information from such a market. A prospective decision-maker does not observe the budget weights and will thus be unable to correct for them in the weighted average of collective opinion. A simple solution would make public the holdings of investors with concentrated positions of more than five per cent of outstanding contracts (similar to the 13-D filings required in US securities markets to indicate heavy individual or institutional ownership), or to report measures of concentration in contract ownership or short position. The Iowa Electronic Markets (IEM) has, from its inception, imposed strict capital-inflow restrictions through limiting account funding to 500 dollars (Berg et al. 2006) allowing the IEM to avoid this problem. Substantially larger sums (often in the thousands, if not tens of thousands, of dollars) can be instantly committed at other markets to back a financial investor's probability estimates (for example, those based on the Dow Jones Industrial Average at InTrade).

The third issue is the possibility of strategic manipulation of market prices to achieve an outside goal not shared by all market participants. In a laboratory, the incentives (monetary and otherwise) may be substantial or tiny, but they are by design completely separable from any participant-specific objectives in the outside world. In the absence of such separability, agents with objectives other than capital gain in the prediction market may participate strategically, conveying distorted information to those who rely on unbiased market prices. In a political campaign, for example, it may be worth substantially more to candidates to generate the impression of public support for their preferred campaign than to make a profit on their investments in the information market. Paradoxically, the more credence is given by the general public to the prices-as-probabilities predictions, the higher the incentives for strategic investors to distort price by devoting relatively modest amounts of their private capital to moving the market. (This is an application of Goodhart's Law, wherein indirect measures targeted as policy goals lose their predictive ability.) In extreme cases, this strategic investment may affect voters' decisions on participation and on candidate selection, thus becoming a self-fulfilling prophecy. This could not only achieve election goals, but also generate capital gains from the information-distorting investment. Therefore, the cost of such a manipulation campaign can be zero or even negative, increasing its attractiveness but sapping the market's predictive power. The design of a prediction market to aggregate opinions and subjective probabilities without encouraging such strategic behaviour remains an open problem.

The fourth issue is the possibility of hidden control of seemingly random events. Under experimental conditions, experimenters control many basic aspects of the study, including randomization of events that are supposed to be random. Since real-world prediction markets generally lack such controls, we must thus be especially cautious in interpreting prices-as-probabilities when certain individuals can profit by exploiting their disproportionate ability to influence the occurrence of the event that is being predicted. As Croson and Kunreuther (2000) note in the analogous situation in the insurance market for natural catastrophic disasters against those caused by terrorism or war, moral hazard can destroy the risk-hedging functions of these markets. The social desirability of such a prediction market subject to moral hazard depends crucially on whether the efficiency value of early warning (caused by the propagation, through price changes, of the inside information) outweighs the equity or efficiency costs resulting from perverse incentives.

Several Fortune 500 companies (for example, HP and Google) have recently implemented prediction markets within the firm. These markets are designed to aggregate information among many employees and thereby produce reasonably accurate estimates that would otherwise be difficult (or impossible) for any single decision-maker to form. Such attempts effectively illustrate Hayek's famous argument (1945) that central planning cannot replicate the effects of distributed information; one can hardly fault these firms' desire for an unbiased, distributed information-gathering mechanism that communicates a clear message to decision-makers. Corporate motivations for these markets seem primarily aimed at the noble goals of selecting among several alternative investments, informing investment decisions in complementary activities, or attempting to predict future competitive opportunities; they conspicuously and simultaneously risk deviating from controlled experiments, however, in *all four* of the dimensions offered warningly above. Until such markets can be designed to resolve quickly, enforce equal participation among organization members at different ranks or economic stations, disentangle 'in-market' gains from 'out-of-market' gains, and disallow participation by employees who can influence the outcome of the events on which contracts are conditioned, the equilibrium prices shown by these markets will be suspect as a measure of participants' subjective probabilities. Accordingly, unless we develop tools to separate participants' choices from their jobs (effectively creating a 'virtual laboratory' inside the firm) or to correct for the biases induced by these deviations (extracting accurate and useful decision-support information from an unavoidably distorted market), the aggregate value of corporate use of these admittedly promising tools in non-laboratory conditions will be limited, and corporate successes using this powerful technique will be determined as much by chance as by economic science.

In strictly controlled laboratory studies, these four divisive effects can be minimized: such studies are completed over short periods of time (making the discounting problem minuscule); participants can be allocated exogenously fixed amounts of capital; the payoffs from successful experimental investments can be separated from outside gains, and the incidence of random events can be kept unpredictable. As prediction markets gain wider acceptance, more active participants, and public credence in the world outside the laboratory, however, the ability to interpret prices as the participants' subjective probabilities of Arrow events becomes increasingly tenuous. To profit from prediction markets outside the laboratory, corporations and investors must combine their knowledge of the established economics of such markets with skills in evaluating investor psychology, probability models more accurate than those of rival participants, and methods of extracting information from noisy and potentially biased signals.

Prediction Markets

Justin Wolfers and Eric Zitzewitz

Abstract

Prediction markets, sometimes referred to as 'information markets', 'idea futures' or 'event futures', are markets where participants trade contracts whose payoffs are tied to a future event, thereby yielding prices that can be interpreted as market-aggregated forecasts. This article summarizes the recent literature on prediction markets, highlighting both theoretical contributions that emphasize the possibility that these markets efficiently aggregate dispersed information, and the lessons from empirical applications which show that market-generated forecasts typically outperform most moderately sophisticated benchmarks. Along the way, we highlight areas ripe for future research.

Prediction markets, sometimes referred to as 'information markets,' 'idea futures' or 'event futures', are markets where participants trade contracts whose payoffs are tied to a future event, thereby yielding prices that can be interpreted as market-aggregated forecasts. For instance, in the Iowa Electronic Market traders buy and sell contracts that pay one dollar if a given candidate wins the election. If a prediction market is efficient, then the prices of these contracts perfectly aggregate dispersed information about the probability of each candidate being elected. Markets designed specifically around this information aggregation and revelation motive are our focus in this article.

Types of Prediction Market

The most famous prediction markets are the election forecasting markets run by the University of Iowa (Berg et al. 2006). Election forecasting provides a useful way to introduce a variety of different contract types, and Table 1, adapted from Wolfers and Zitzewitz (2004a), shows how different contracts can be designed to reveal various types of forecasts.

The three main types of contract link payoffs to the occurrence of a specific event (the incumbent wins the election), to a continuous variable (the vote share of the incumbent), or to a combination of the two, such as in spread betting (the vote share of the incumbent exceeds x per cent). In each case, the relevant contract will reveal the market's expectation of a specific parameter: a probability, a mean or a median, respectively. More complex contract designs can also be used to elicit alternative parameters. For instance, a family of winner-take-all contracts – each linked to different states of nature – can reveal the full probability distribution.

Prediction markets have been used to forecast elections, movie revenues, corporate sales, project completion, economic indicators and Saddam Hussein's demise. New corporate applications have emerged as firms have looked to markets to predict research and development outcomes, the success of new products, and regulatory outcomes. In the US public sector, the Pentagon attempted to use markets designed to predict geopolitical risks, although negative publicity stopped the project (Hanson 2006). An intriguing attempt to apply prediction markets to forecasting influenza outbreaks is detailed in Nelson et al. (2006). Rhode and Strumpf (2004) have detailed the existence of large-scale election betting as far back as the election of President Grant in 1868.

Prediction market contracts have been traded in a variety of market designs, including

Prediction Markets, Table 1 Contract types: estimating uncertain quantities or probabilities

Contract	Details	Example	Reveals market expectation of. . .	More general application
Binary option	Contract costs $$p$ Pays $1 if and only if event x occurs.	Event x: George Bush wins the popular vote.	Probability that event y occurs, $p\ (x)$.	Defining many events, $x_1, x_2, \ldots, x_n$ reveals probability distribution $F(x)$.
Index futures	Contract pays $$x$.	Contract pays $1 for every percentage point of the popular vote won by George Bush.	Mean value of outcome x: E[x].	Contract pays some function of x: $$g(x)$. Reveals specific moments, E[$g(x)$].
Spread betting	Contract costs $1 Pays $2 if $x > x^*$ Pays $0 otherwise. Bid according to the value of x^*.	Contract pays even money if Bush wins more than x^* % of the popular vote.	Median value of outcome, x.	$1 contract pays $$(1/q)$ if $x > x^*$w. Reveals specific quantile, $F_{1-q}(x)$.

continuous double auctions (both with and without market-makers), pari-mutuel pools, and bookmaker-mediated betting markets, or implemented as market-scoring rules.

Prediction Markets in Theory: Information Aggregation

The claim that prediction markets can efficiently aggregate information is based on the efficient market hypothesis. In certain cases, existing theoretical results regarding efficient capital markets can be applied directly. Grossman (1976) documents a set of sufficient conditions for the equilibrium price of index futures to summarize private information perfectly: in a market where traders with constant absolute risk aversion (CARA) utility functions each receive independent draws from a normal distribution about the true value of the asset, the market price fully summarizes their information.

Manski (2004) notes that much of the analysis of the price of binary options simply assumes that these revealed a market-based probability estimate, but that appropriate theoretical results are lacking. He illustrates the importance of this issue by way of an example where prediction market prices fail to aggregate information appropriately. In his model all traders are willing to risk exactly $100. Thus, if a contract paying $1 if an event occurs is selling for $0.667, then buyers each purchase 150 contracts, while sellers can afford to sell 300 contracts (at a price of $0.333). This can be an equilibrium only if there are twice as many buyers as sellers, implying that the market price must fall at the 33rd percentile of the belief distribution, rather than the mean. The same logic suggests that a prediction market price of π implies that $1 - \pi$ per cent of the population believes that the event has less than a π per cent chance of occurring. Clearly, the driving force in this example is the assumption that all traders are willing to risk a fixed amount.

Wolfers and Zitzewitz (2005a) provide sufficient conditions under which prediction market prices coincide with average beliefs among traders (and hence aggregate all information in the Grossman set-up). They consider individuals with log utility and initial wealth, y, who must choose how many prediction market securities, x, to purchase at a price, π, given that they believe that the probability of winning their bet is q:

$$Max\ EU_{j_{\{x\}}} = q_j Log\left[y + x_j(1-\pi)\right] + (1-q_j)Log\left[y - x_j\pi\right]$$
$$yielding: \quad x_j^* = y\frac{q_j - \pi}{\pi(1-\pi)}$$

The prediction market is in equilibrium when supply equals demand:

$$\int_{-\infty}^{\pi} y\frac{q-\pi}{\pi(1-\pi)}f(q)dq = \int_{\pi}^{\infty} y\frac{\pi-q}{\pi(1-\pi)}f(q)dq$$

If beliefs (q) and wealth (y) are independent, then this implies:

$$\pi = \int_{-\infty}^{\infty} qf(q)dq = \overline{q}.$$

Thus, under log utility, the prediction market price equals the mean belief among traders. If wealth is correlated with beliefs, then the prediction market price is equal to a wealth-weighted average belief. This finding is general in the sense that no assumptions are required about the distribution of beliefs, but it is also quite specific in that it holds only under log utility. Experimenting with a range of alternative utility functions and distributions of beliefs typically yields prediction market prices that diverge from the mean of beliefs by only a small amount.

Both the Manski and the Wolfers–Zitzewitz models are silent as to the sources of the different beliefs across traders, which allows them to sidestep the theoretical difficulty posed by Milgrom and Stokey (1982), namely, that under common beliefs no trade will occur. The logic of the 'no trade theorem' is simply that traders should always be wary that anyone seeking to trade with them possesses an information advantage, and hence should moderate their beliefs accordingly. Why there should be any trade in prediction markets remains an important open theoretical question. Wolfers and Zitzewitz (2006) provide a simple adaptation of the Kyle (1985) model in which trade is driven by uninformed outsiders with either hedging- or entertainment-driven demand for the prediction security, or by manipulators attempting to influence market prices.

Another important role of prediction markets is that potential trading profits provide an incentive for *information discovery*. Grossman and Stiglitz (1976) consider the case where information is expensive to garner. They point to the impossibility of prices being fully efficient: if prices fully reflect information, then there is no incentive for any trader to gather that information. Instead, they construct a model in which prices never fully reflect all of the information possessed by informed traders; in equilibrium the inefficiency in pricing is just sufficient to induce a proportion of traders to become informed.

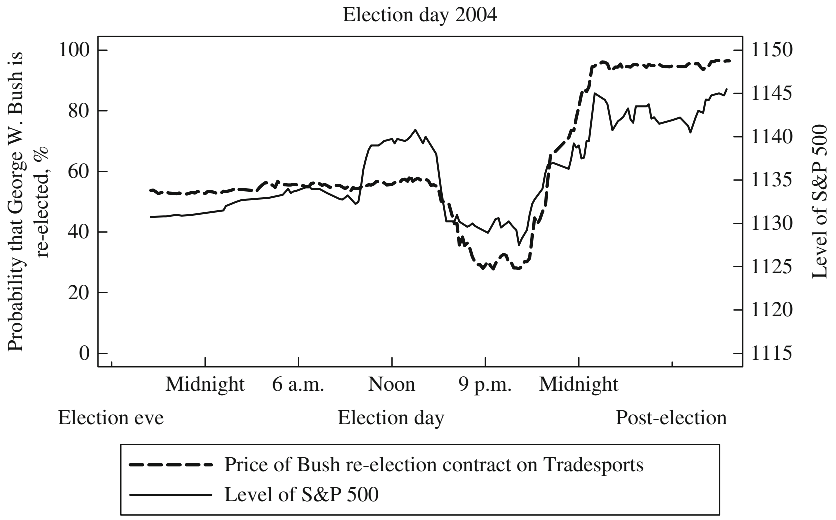
Another key advantage of prediction markets over alternative approaches to information aggregation is that they provide incentives for *truthful revelation* of beliefs. If prediction markets are to be used as inputs into future decisions, this may provide a countervailing incentive to trade dishonestly to manipulate prices. While such manipulation would typically lead the manipulator to lose money, Hanson and Oprea (2005) have shown that these losses increase the rewards for informed trading, which may ultimately increase the accuracy of prediction market prices.

Prediction Markets in Practice

While we are still accumulating evidence on the behaviour of prediction markets in different contexts, already a few generalizations can be drawn from existing, albeit piecemeal, evidence.

First, market prices tend to respond rapidly to new information. Figure 1 draws an interesting example from Snowberg et al. (2006): movements in the price of the Tradesports contract on the re-election of US President Bush, around election day, 2004. Early exit polls suggesting victory by John Kerry, the Democrat candidate, were leaked at around 3 p.m., and prices started to move immediately. Indeed, the figure shows that they moved in lockstep with prices on the much larger equity markets. As the count proceeded, it became clear that these early polling numbers were wrong, and the market reversed course sharply. This is only a single anecdote but is representative of the rapid incorporation of new information by prediction markets observed in many domains.

Second, in most cases, the time series of prices in these markets appears to follow a random walk, and simple betting strategies based on publicly available information appear to yield no profit opportunities. That is, these markets appear to meet the standard definition of weak-form efficiency.



Prediction Markets, Fig. 1 Bush's re-election prospects and the stockmarket (*Source*: Snowberg et al. (2006))

Third, the law of one price appears to (roughly) hold, and the few arbitrage opportunities that arise in these markets are fleeting and involve only small potential profits.

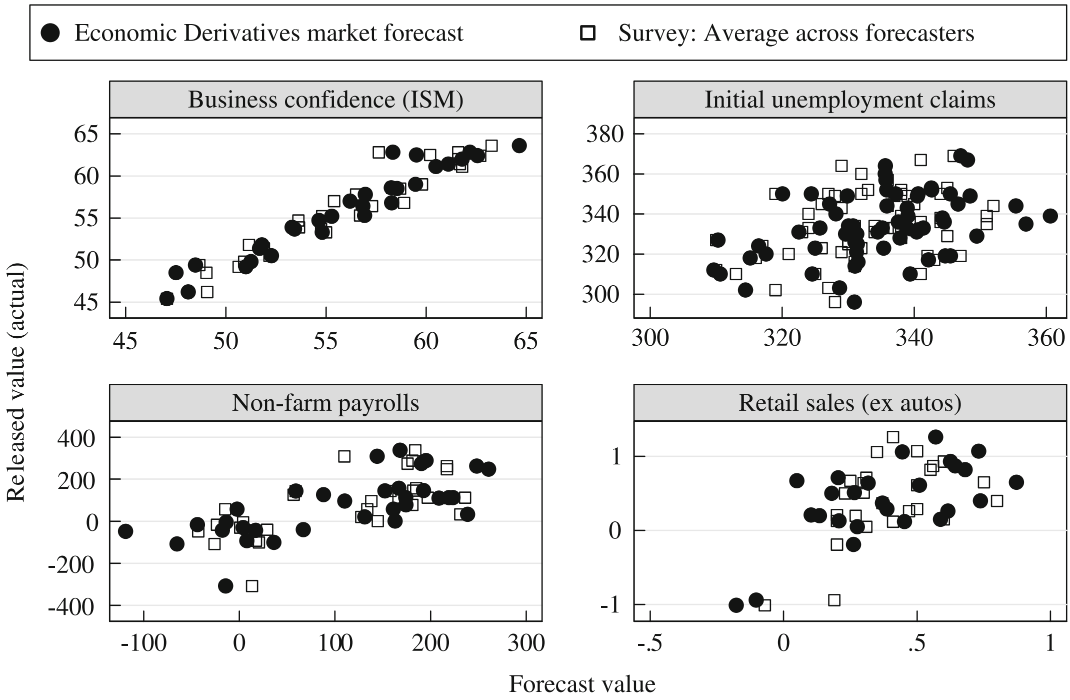
Fourth, attempts to manipulate these markets typically fail. Camerer (1998) attempted to manipulate pari-mutuel betting on horse races by canceling $500 or $1,000 bets at the last moment. Rhode and Strumpf (2006) report attempts by specific political campaigns to manipulate the election betting odds on their candidates in the large-scale betting markets operating in the early 20th century. They also analyse an attempt to manipulate the price of a Kerry victory on Tradesports in 2004, as well as their own attempts to manipulate prices on the Iowa Electronic Markets in 2000. Hanson et al. (2006) created experimental prediction markets in which several traders were given an incentive to raise the price. None of these attempts at manipulation had a discernible effect on prices, except during a short transition phase.

Finally, prediction markets usually provide quite accurate forecasts and have typically outperformed alternative prediction tools.

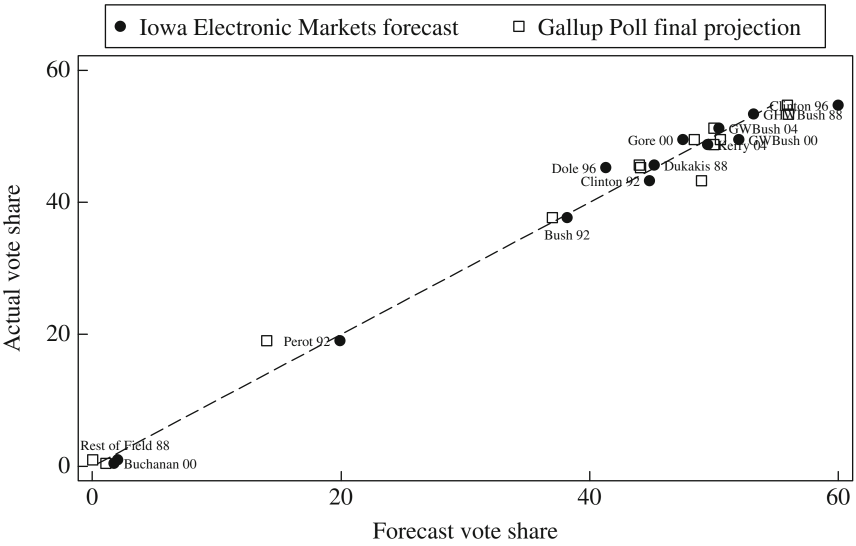
Figure 2 shows evidence collected by Gürkaynak and Wolfers (2005) on the relative performance of a prediction market (the 'Economic Derivatives' market established by Goldman Sachs and Deutsche Bank) and a survey of economists in predicting economic outcomes. They show that the market-based forecast encompasses the information in the survey-based forecasts. Moreover, the behavioural anomalies that have been noted in survey-based forecasts are not evident in the market-based forecasts.

Figure 3 compares the forecasting performance of the Iowa Electronic Markets and the Gallup Poll in predicting the outcomes of presidential elections in the United States. Over the 13 major candidacies from 1988 to 2004, the average absolute error of the market-based forecasts was 1.6 percentage points, while the corresponding number for the Gallup Poll was 1.9 percentage points. As Berg et al. (2003) discuss, the forecasting advantage of markets over the polls is probably even larger over long horizons, as polling numbers tend to be excessively volatile through the electoral cycle. The initial success of these forecasting methods in the United States has led to similar analysis of election forecasting markets in Austria, Australia, Canada, Germany, the Netherlands and Taiwan.

Tests of prediction markets and expert opinions have also been conducted in a range of other domains. The Hollywood Stock Exchange has generated forecasts of box-office success and of

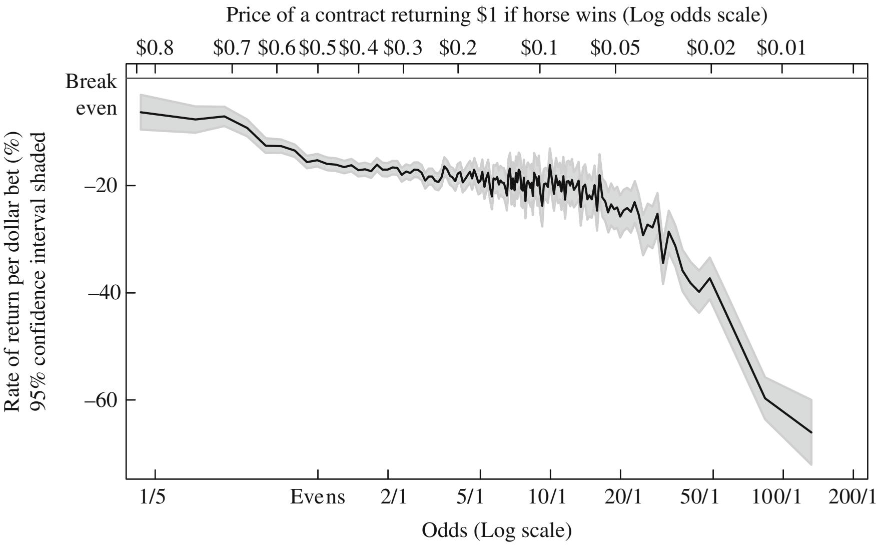


Prediction Markets, Fig. 2 Forecasting economic outcomes. Graphs by economic data series (*Source*: Gürkaynak and Wolfers (2005))



Prediction Markets, Fig. 3 Forecasting presidential elections. *Note*: Market forecast is closing price on election eve; Gallup forecast is final pre-election projection

Oscar winners that have been more accurate than expert opinions (Pennock et al. 2001). Both real and play-money markets have generated more accurate forecasts of the likely winners of NFL football games than all but a handful among 2,000 self-professed experts (Servan-Schreiber et al.



Prediction Markets, Fig. 4 Favourite-longshot bias: rate of return at different odds (*Source*: Trackmaster, Inc. Sample is all horse races in the United States, 1992–2002, n = 5,067,832 starts in 611,807 races)

2004). In the corporate context, the market established by Chen and Plott (2002) within Hewlett-Packard yielded more accurate sales forecasts than the firm's internal experts. Similarly, Ortner (1998) reports that an internal market correctly predicted that the firm would definitely fail to deliver on a software project on time, even when traditional planning tools suggested that the deadline could be met.

Despite this impressive evidence, there remain a number of documented pathologies in prediction markets. Figure 4 shows evidence from Snowberg and Wolfers (2005) of the 'favourite-longshot bias', which describes a tendency to overprice low-probability events. A similar tendency has been documented in a range of other market contexts, suggesting that some caution is in order in interpreting the prices of low probability events.

Laboratory experiments also find that, while prediction markets can be successful in some contexts (Plott and Sunder 1982), in others they may fail to aggregate information (Plott and Sunder 1988). Sunder (1995) and Plott (2000) provide excellent reviews of experimental prediction markets, including experiments showing market designs that lead to the appearance of bubbles, false equilibria or excess volatility.

Economic Analysis of Prediction Market Prices

Prediction markets are a useful way to elicit predictions, but how might they be used? The most direct form of inference involves simply using these predictions directly. For instance, forecasts of election outcomes may be of intrinsic interest.

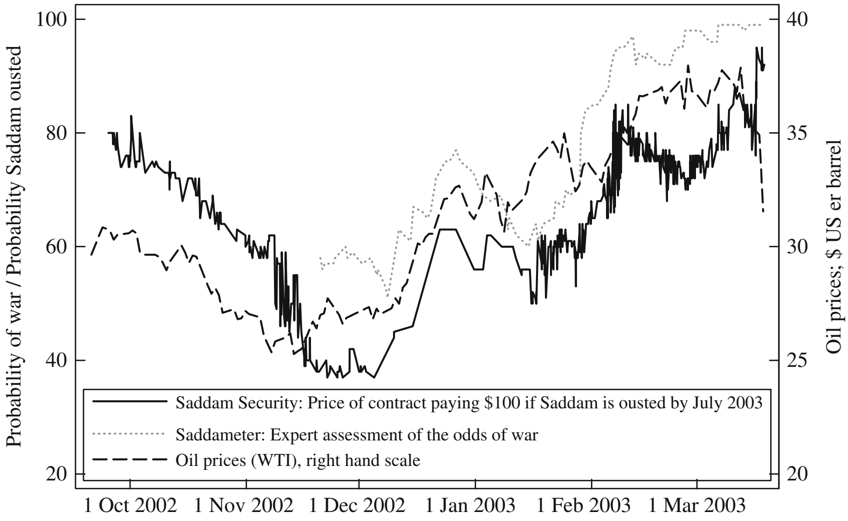
Some analyses have tried to link the time series of expectations elicited in prediction markets with time series of other variables, so as to isolate a causal influence. For instance, Roberts (1990) analyses changes in the betting odds posted by Ladbrokes on US President Ronald Reagan's re-election in 1984 and the returns to holding stocks in defence firms, inferring that Reagan led to more robust defence spending. Likewise, Herron et al. (1999) and Knight (2006) analyse the correlation of industry stock indices and individual stocks with movements in the 1992 and 2000 Iowa Electronic Markets US presidential election markets. Snowberg et al. (2006) conduct a similar analysis for the aggregate equity and bond markets at an intraday frequency, using the data shown in Fig. 1, to infer partisan impacts of the 2004 election. Slemrod and Greimel (1999) examine the effect on municipal bond prices of changes in the probability of a 1996 Republican nomination for Steve Forbes, whose 'flat tax' would have eliminated the tax exemption for municipal bond interest.

To move beyond *ex post* studies of elections, Wolfers and Zitzewitz (2005b) report on an *ex ante* analysis of the co-movement of oil and equity prices with a contract tracking the probability of a US attack on Iraq in 2002–3 (Fig. 5). The results suggest that a substantial war premium was built into oil prices (and a discount built into equities).

The contracts we have described thus far have depended on only one outcome. The same principles can be applied to contracts tied to the outcomes of more than one event. These contingent contracts potentially provide insight into the correlation between events. For instance, Wolfers and Zitzewitz (2004b) ran experimental markets on the online betting exchange Tradesports.com in the run-up to the 2004 US presidential election. In one example, they ran markets linked to whether George W. Bush would be re-elected, whether Al-Qaeda leader Osama bin Laden would be captured prior to the election, and whether *both* events would occur. These markets suggested a 91 per cent chance of Bush being re-elected *if* Osama had been found, but a 67 per cent unconditional probability. Berg and Reitz (2003) report on contracts whose payoff was linked to 1996 Democratic vote shares conditional on different potential Republican nominees; on the basis of these prices they argue that alternative nominees, such as Colin Powell, would have outperformed Bob Dole, the actual nominee.

The potential to apply these markets to determine the consequences of a range of contingencies has led Hanson (1999) to term these 'decision markets'. Indeed, Hanson (2003a) has suggested that such markets could be used to remove technocratic policy implementation issues from the bureaucracy, a suggestion endorsed in Hahn and Tetlock (2006). Moreover, while the previous example involves only one contingency, Hanson (2003b) suggests that market scoring rules can allow traders to simultaneously predict many combinations of outcomes. The basic intuition of his proposal is that, rather than betting on each contingency, traders bet that the sum of their errors over all predictions will be lower.

However while contingent markets can be used to estimate the joint probability of choice A and outcome B, care must be taken before inferring that choice A should be made because it will maximize the probability of outcome B. That is, while these markets can highlight the correlation between events, the difficulty of inferring causation remains.



Prediction Markets, Fig. 5 Risk of war in Iraq. Prediction markets, export opinion and oil markets (*Source*: Trade-by-trade Saddam Security data provided by Tradesports.com; Saddameter from Will Saletan's daily column in Slate.com)

Conclusion

The healthy bibliography below attests to the fact that interest in prediction markets has boomed in recent years. Many questions remain. Theoretical research holds the promise of better understanding the institutional design features that yield optimal information aggregation and efficient pricing. The practical agenda includes developing new ideas about how and when prediction markets can aid decisionmaking by business and government.

Preference Reversals

Chris Starmer

Abstract

Preference reversal is a widely observed behavioural tendency for the preference ordering of a pair of alternatives to depend on the process used to elicit it. The phenomenon appears to be both a robust and a systematic departure from conventional preference theory. Competing theoretical explanations variously interpret it as a violation of procedure invariance (the presumption that preferences should be independent of the method of eliciting them); a failure of transitivity; or a consequence of loss-averse (and reference-dependent) preferences. This article discusses these interpretations, the related evidence, and reflects on some of the broader implications of the phenomenon.

Preference reversal (PR) is a widely observed behavioural tendency for the preference ordering of a pair of alternatives to depend, in a predictable way, on the process used to elicit it.

The existence of preference reversal sets an empirical challenge to fundamental assumptions of conventional economic theory: PR is an apparent failure of procedure invariance (that is, the traditional presumption that preferences should be independent of the method of eliciting them).

Some see it as a challenge to the very idea that human decisions are governed by preferences.

Much of the empirical PR literature has examined decisions relating to pairs of simple gambles. One of the gambles (typically called the ‘P-bet’) will offer a relatively good chance of winning a modest prize, otherwise nothing (or sometimes a small loss); the other bet (the ‘$-bet’), offers a relatively small chance of winning a larger prize. In classic PR experiments, subjects are required to make straight choices between such pairs of bets and to provide separate (usually monetary) valuations for each bet. For any individual and gamble pair, conventional economic theory implies that the chosen gamble would also be the more highly valued of the pair. But while many individuals are so consistent, a significant proportion, typically, are not. The existence of some such inconsistency, by itself, is not especially surprising. People might, for instance, make a mistake in one or more task, leading to some level of inconsistency in comparisons of rankings. Interest in PR, however, stems largely from the fact that observed inconsistencies tend to be patterned in a highly predictable way: the typical finding is that considerable numbers of subjects choose the P-bet and value the $-bet more highly (let us call this the standard reversal), while very few commit the opposite reversal ($-bet chosen and P-bet valued more highly). It is this *asymmetric* pattern of inconsistencies between rankings based on choice and valuation that constitutes the intriguing PR phenomenon.

Evidence

PR was first predicted and then observed by psychologists (Lichtenstein and Slovic 1971; Lindman 1971). It was later brought to the attention of economists by Grether and Plott (1979) who described its potential significance for economics in the following passage:

> Taken at face value the data are simply inconsistent with preference theory and have broad implications for research priorities within economics. The inconsistency is deeper than mere lack of transitivity or even stochastic transitivity. It suggests that no optimisation principles of any sort lie behind even the simplest of human choices. (Grether and Plott 1979, p. 623)

Like many economists who have followed in their footsteps, Grether and Plott did not immediately accept this face-value interpretation and, instead, looked for ways of explaining PR while retaining the assumption that individuals do have a unique preference ordering over gambles. A substantial body of research in this spirit has examined whether PR might be an experimental artefact arising from imperfectly designed experiments. Early research of this genre – including Grether and Plott (1979), Reilly (1982) and Pommerehne et al. (1982) – investigated issues such as whether PR might be a consequence of subjects failing to understand the tasks confronting them, or of having insufficient motivation to take those tasks seriously. But a large body of evidence now shows that PR is a highly replicable phenomenon, robust to many variations in experimental procedures. Seidl (2002) provides a review.

A more subtle critique of PR experiments and evidence emerged in the late 1980s with the publication of a series of theoretical papers (Holt 1986; Karni and Safra 1987; Segal 1988) arguing that PR might be a spurious artefact of experimental design after all. These papers shared a common strategy, pointing to a potential weakness of two experimental procedures which had been commonly used to incentivize decision tasks in PR experiments: the (Becker et al. 1964) mechanism and the random lottery incentive system. The thrust of these papers is to show that, if individuals have non-expected utility preferences (violating either the independence axiom of expected utility theory, or the reduction of compound lotteries principle, or both), these standard incentive mechanisms could be biased and might generate the spurious appearance of PR. On this interpretation, PR would not be evidence against procedure invariance: instead it would be evidence of consistent, but non-expected utility, preferences interacting with specific features of experimental design. This interpretation has, however, been largely discounted in the light of subsequent research (including Tversky et al. 1990 and Cubitt et al. 2004) which reproduces the PR phenomenon in experiments using incentive mechanisms immune to this critique of earlier studies.

Theory

There remains considerable interest in trying to find a satisfactory explanation of PR. In what follows, we discuss three types of theory that may contribute to that objective: *regret theory, reference-dependent theory,* and *constructed preference theory.*

Regret theory (Loomes and Sugden 1982, 1983) explains PR as a form of intransitivity. In this theory preferences are defined over pairs of acts which map from states of the world to consequences (as in Savage 1954). Suppose A_i and A_j are two potential acts that result in, respectively, outcomes x_{is} and x_{js}, in state of the world s. If A_i is chosen, the resulting utility in each state is given by a 'modified utility function' $M(x_{is}, x_{js})$. Notice that this function allows the consequences of the chosen act to depend upon those that *might have been* experienced under the forgone act A_j. In particular, the utility from having x_{is} may be suppressed by 'regret' when x_{is} is worse than x_{js}. Regret theory assumes that individuals attempt to maximize the expectation of modified utility $\Sigma_s\ p_s.\ \mathrm{M}\ (x_{is}, x_{js})$ where p_s is the probability of state s. Regret theory reduces to expected utility theory in the special case where $(M\{x_{is}, x_{js}) = u(x_{is})$ and $u(.)$ is a von Neumann–Morgenstern utility function.

Loomes and Sugden (1982) show that, if preferences in this theory satisfy particular restrictions, then regret theory provides a possible explanation of several well-known violations of expected utility theory including some cases of the famous Allais paradox. The most important of these restrictions is a property (subsequently) called regret aversion and, in a follow-up paper, Loomes and Sugden (1983) show that regret aversion may also explain PR. The argument works roughly as follows. Consider the following three acts labelled $, P and M with monetary consequences x > y > m > 0 defined over three states.

	State1	State 2	State 3
$	x	0	0
P	y	y	0
M	m	m	m

The acts labelled $ and P have the structure of typical $- and P-bets: they are binary gambles where $ has the higher prize, and P the higher probability of 'winning'; the third act gives payoff m for sure. Regret theory allows choices over acts with this structure to be non-transitive and, if preferences are regret averse, if a cycle occurs it will be in a specific direction: P chosen over $; M over P; and $ over M. Now recall that, in a typical PR experiment, the standard reversal occurred when a subject chose P over $ but valued $ more highly than P. So, if we interpret choices from {$, M} and {P, M} as analogues of valuation tasks asking 'is $ (or P) worth more or less than M?', then the cycle predicted by regret theory can be interpreted as a form of PR.

This explanation for PR has been tested via experiments designed to look for the pure choice analogue of PR by confronting subjects with pairwise choices among triples of bets with the structure of $, P and M above. The outcome of this strand of research has produced good and bad news for regret theory. The good news is that the non-transitive choice cycles predicted by it have been observed and replicated (Loomes et al. 1991). Since these choice cycles occur in studies that involve no valuation tasks at all, this is evidence for the intransitivity interpretation of PR. The bad news is that subsequent research (Starmer and Sugden 1998) has cast considerable doubt on regret theory's account of these choice cycles. The current state of play appears to be that regret theory has led to the discovery of a surprising new choice phenomenon, but it turns out not to be the right explanation for it! It remains possible that these intransitive choice cycles are manifestations of regret-type influences at work but that formal models of regret must be refined to properly account for them. Another possibility is that they have nothing to do with 'regret' and that their discovery, as a consequence of testing regret theory, was just accidental.

A new account of PR has emerged in the form of reference-dependent subjective expected utility theory (Sugden 2003). In this model, preferences are again defined over acts. The key structural departure from Savage's (1954) subjective expected utility theory is that consequences in each state are modelled as gains and losses relative to a *reference act* (the status quo). The resulting theory is a formulation of expected utility (that is, a model that is linear in probabilities) that can accommodate loss aversion (that is, losses of a given size being weighted more highly than corresponding magnitude gains). Sugden demonstrates that, when preferences are loss averse, this model predicts standard PR in experiments where values are elicited as selling prices (which they usually are). This prediction depends on the assumption that, in selling tasks, an agent's reference act is the lottery being sold: given this, seemingly reasonable, assumption, $ valuations become particularly 'inflated' by consideration of the large $ prize which becomes a (probabilistic) loss if the $-bet is given up for a certain amount of cash. Hence, on this account, PR is the consequence of loss aversion operating through selling tasks. As yet, there have been no direct tests of this explanation, though the evidence of loss aversion operating in other contexts (see Starmer 2000, for some discussion) perhaps gives it some initial credibility.

Thus far we have discussed various preference-theoretic accounts of PR. The final type of explanation we discuss is the oldest and belongs to a class of theory that has evolved in the psychology literature. From the outset, most psychologists accepted PR as evidence against the very thing that economists have invested their efforts in defending: the presumption that behaviour can be adequately explained in terms of unique underlying preferences. Psychologists have, instead, focused on accounts of PR which attribute it to aspects of human *decision processes.* Viewed from this perspective, there is nothing fundamentally surprising about the fact that rankings delivered via choice and valuation tasks differ; those working within this paradigm will, typically, attempt to read such inconsistencies as clues to the, potentially distinct, mental heuristics invoked in those different tasks.

Numerous theories in this spirit have been proposed as putative accounts of PR, and one of the best known examples is the scale-compatibility hypothesis due to Tversky et al. (1988). The general hypothesis assumes that the way in which an individual is required to respond to a task ('the response mode') can affect the weights that he or she places on particular dimensions of alternatives being evaluated. In application to PR, the hypothesis implies that, because valuation tasks require a money amount as output, individuals place particularly high (low) weight on the money (probability) dimension, leading to relatively 'inflated' values for $ bets. Some recent support for this particular hypothesis is reported in Cubitt et al. (2004). There is, however, a vast theoretical and empirical literature connecting PR with the constructed preference approach and, for those interested in pursuing it, an excellent source is Lichtenstein and Slovic (2006).

Developing Themes

One developing theme in empirical PR research examines the persistence of PR in environments where individuals receive feedback on the consequences of their decisions. A famous experiment by Chu and Chu (1990) exposed preference reversers to 'money pumps': subjects who committed PR had their stated preferences implemented across a series of trades which ultimately resulted in monetary losses. Individuals quickly learned to avoid PR in this environment. While this is an interesting finding, since Chu and Chu use such an explicit method for disciplining inconsistent preferences, it would be a mistake to view this as persuasive evidence that PR would be eroded in any naturally occurring market. There is some limited evidence to suggest that PR may decay in some specific experimental markets (Cox and Grether 1996) but the findings here are both tentative and mixed, and further investigation is warranted before any firm conclusions can be drawn.

Another theme of current research explores the implications of preference anomalies (including PR) for the formulation of economic policy. A discussion of this topic is contained in Braga and Starmer (2005).

Preferences

Georg Henrik von Wright

The concept of preference holds a pivotal position in value theory. It may even be considered a 'value radical' or common conceptual root of the three main types of evaluative discourse, namely, aesthetic, economic and moral.

In economics and the behavioural sciences generally, the role of this concept has recently been enhanced by the creation of 'exact' theories of 'strategic thinking' such as game theory, Bayesian decision theory, and a general theory of utility.

The concept of (individual) preference is not, on the whole, considered controversial by economists. Philosophical logicians, however, tend to regard the concept as problematic, and there is little agreement among them about the basic principles of a 'logic of preference'. The situation is a little like the one in probability theory. Probability is extensively used and successfully applied in both the physical and the social sciences – and yet philosophers notoriously disagree about its 'true meaning'.

The first systematic inquiry into the foundational problems of preferences seems to have been von Wright in 1963. It has at least one noteworthy precursor, Halldén (1957), which explores the related notion of 'betterness'. Significant contributions have been made later by R. Chisholm (1966, 1975), E. Sosa (1966) and N. Rescher (1967, 1969), and by the Swedes S. Danielsson (1968), P. Gärdenfors and B. Hansson (1968).

A statement of preference of the type which I shall call 'pure' or 'intrinsic' is a *value judgement.* It is *subjective* in the sense that it expresses somebody's preference of something over something else. It is *relative* in the sense that a subject's pure preferences may change in the course of time. Such changes can be spoken of as 'changes of taste'. (Another instance of relativity will be mentioned below.)

Sometimes we ask *why* a person prefers, say, *x* to *y.* And sometimes, not always, there is an answer at hand. The person can give a *reason* for his preference. For example: he prefers *x* to *y* as a means to the end *E* because *x* is, say, cheaper or quicker or safer than *y.* That *x* is cheaper (quicker, safer) is a factual statement, true or false as the case may be. That a person, other things being equal, prefers the cheaper means to the more expensive one is a valuation.

A preference for a reason I shall call 'extrinsic'. As seen from the example, an extrinsic preference is *linked* to an intrinsic one by means of an objective judgement (the reason). When the intrinsic preference is one which most people share, one often calls the preferred thing *preferable.* For example, the use of a safer means to a given end may be deemed preferable to the use of a less safe one. A judgement of preferability has an 'objective appearance'. It is an open problem in the philosophy of value whether *all* such judgements ultimately depend on subjective valuations expressed in pure preferences.

Sometimes the answer to the above Why? question is that the subject *likes x better* than *y.*

This is not to give a reason for the preference. It is a new verbalization of a pure preference. 'Liking better' is just another term for '(simply) preferring'.

The symbol '*xPy*' shall mean that *x* is preferred to *y,* subject and time left unspecified. For a 'logic' of the preference relation one could lay down the following axiomatic principles:

$$\begin{aligned}&\text{A1.}\quad xPy \rightarrow \sim(yPx)\\&\text{A2.}\quad xPy \rightarrow xPz \vee zPy.\end{aligned}$$

The first says that the *P*-relation is asymmetrical. The second says that if x is preferred to *y* then any third thing *z* is such that either *x* is preferred to it or it is preferred to *y.* This amounts, in effect, to saying that the *P*-relation is *connected,* that is, if two things are comparable for preference then any other thing may be compared to them.

From A1 and A2 one easily derives the following two theorems:

$$\begin{aligned}&\text{T1.}\quad xPy\,\&yPz \rightarrow xPz\\&\text{T2.}\quad \sim(xPx).\end{aligned}$$

They state that the *P*-relation is transitive and irreflexive.

We can define a relation of indifference as follows:

$$xIy =_{\mathrm{df}} \sim(xPy)\& \sim(yPx).$$

If the *P*-relation is assumed to obey A1 and A2, it may be proved that the *I*-relation is reflexive, symmetrical, and transitive. One can then say that

xIy means that x and y are of *equal* (intrinsic) *value* to the subject under consideration.

We can now also prove the theorems

$$\text{T3.}\quad xPy\,\&yIz \rightarrow xPz$$
$$\text{T4.}\quad xPy\,\&yIz \rightarrow zPy$$

They state that things of equal value are interchangeable in the preference relation.

The assumption that the *P*-relation is connected is a very strong assumption, the realism of which may be questioned. One might, for example, replace it by the weaker assumption of transitivity.

A *P*-relation which is (only) asymmetrical and transitive determines a *partial* ordering or ranking of alternatives. A *P*-relation which is in addition connected determines a *complete* ranking order. In a partial ordering, the *I*-relation is not provably transitive. Therefore it does not amount to value-equality. In a logic of partial orderings value-equality ('strong indifference') is a primitive concept. This concept cannot be defined in terms of preference (and negation), nor preference in terms of it.

The terms *x, y,*· · · of a *P*-relation can represent many different types of entity. They can be *goods,* for example when a person prefers apples to pears. Or they can be *means* to an end, for example travelling to a destination by bus rather than by train. Or *states of affairs* when, for example, revolt or war is preferred to continued oppression and slavery.

A person who professes a preference of some good *x* over another *y* presumably likes a state of affairs better in which he enjoys or possesses or uses or lives with *x* than one in which he has *y.* It may be held true that a relation of (pure) preference is basically a preference between two different states in which a person imagines himself to be.

Economists, it seems, usually treat the terms of the *P*- and *I*-relation as goods or other 'thing-like' entities, whereas logicians and philosophers tend to study them as states or otherwise 'proposition-like' entities. Technically, the second approach looks more interesting because it allows us to apply Boolean operations to the terms. As indicated, this may also be the more 'basic' approach.

For *P*-relations, the terms of which are 'thing-like', the assumption of connectedness seems, in general, too strong. A person prefers, say, (the taste of) apples to (the taste of) pears. He also prefers the music of Bach to that of Beethoven. But if asked whether he prefers apples to Bach or vice versa, his best answer is probably that he finds the alternatives 'incomparable'. By suitably limiting the *range* of things compared, one may, however, be able to secure that the preference order is complete and not only partial. Tastes of fruits, for example, may be throughout comparable for preference.

A theory of *P*-relations, the terms of which are states of affairs, needs some axiomatic principles in addition to those mentioned above. The new principles concern the 'behaviour' of the Boolean connectives in *P*-relations. On the details of the matter, however, there is widespread disagreement between researchers.

One could raise the question: What does it *mean* to prefer a state *x* to another one *y?* and answer: It means to think it better if the first state obtains but the second does not than the other way round, the second but not the first. One then accepts an equivalence $xPy \leftrightarrow x \;\&\; \sim y\; P \sim x \;\&\; y.$ From it one can easily derive a 'law of contraposition' for preferences, $xPy \leftrightarrow\; \sim y\; P \sim x$. Objections raised against it on intuitive grounds seem to me to confuse pure preferences between states with some other types of preference.

Another controversial question concerns the case when one or both terms of the relation are *disjunctive* states. An employee says he prefers an increase in salary *or* a shortening of his working day (salary remaining the same) to the status quo of his employment. Does this mean that he both thinks increased salary *and* also thinks reduced working hours preferable to his present position? To interpret the preference thus is to subscribe to an idea that a 'disjunctive preference' is resolvable into a *conjunction* of *P*-relations, the terms of which are not disjunctive.

The reader can easily satisfy himself that, taking 'contraposition' into account, a preference $x \vee yPz \vee u$ then is equivalent with a conjunction of

16 P-relations between 4-termed conjunctions of states and/or their negations.

A P-relation with the above properties is *holistic* in the following sense: A subject's preference of state x over state y obtains in a frame of 'accompanying circumstances'. Of great interest is the case when it obtains *ceteris paribus* or 'other things being equal'. Let these 'other things' be some conjunction of n states and/or their negations. There are in all 2^n such conjunctions or 'possible worlds', $C_1, \cdots, C_{2n}$. That x is preferred to y *ceteris paribus* means that every conjunction $x \,\&\, \sim y \,\&\, C_i$ is preferred to $\sim x \,\&\, y \,\&\, C_i$. xPy is then equivalent with the conjunction (totality) of the 2^n relations $x \,\&\, \sim y \,\&\, C_iP \sim x \,\&\, y \,\&\, C_i$.

The states x and y and the n states in C_i constitute the *preference horizon* of the person who has the preference. 'Ideally' this horizon should comprise every possible state in the world. In practice, however, it is limited to those states the possible relevance of which to his preference the subject happens to take into account.

Consider three P-relations xPy, yPz, and xPz. If we are to be able to infer the third from the first two, the preference must be taken relative to a preference-horizon which includes *at least* the states x, y, and z. xPy then means that x is preferred to y regardless of whether z or $\sim z$ obtains; yPz that y is preferred to z regardless of x; xPz that x is preferred to z regardless of y.

Thus xPy is explicated as $(x \,\&\, zPy \,\&\, z) \,\&\, (x \,\&\, \sim zPy \,\&\, \sim z)$. And similarly for yPz and xPz. It is easily seen that transitivity is then secured. If the three preferences had not fallen within one and the same 'horizon', transitivity need not have followed. It has sometimes been questioned whether the P-relation *is* (always) transitive. The answer is that transitivity is there only if due attention is paid to the preference-horizon.

The 'possible worlds' within a given preference-horizon may be ranked in a complete order of preference. But the ranking order of *all* the possible alternatives within such a horizon cannot be complete, but will have to be partial. This is a consequence of the fact that a conception of the P-relation as resolvable into a *conjunction* entails a conception of the I-relation as a *disjunction.* And this I-relation is not an equivalence (a value-equality). Thus a holistic conception of preferences between states entails that one must differentiate between 'mere' indifference and value-equality.

Must preference between states be conceived holistically? The opposite of a holistic conception is to consider the terms of the P-relation 'alone and taken by themselves'. This makes good sense when the terms are 'thing-like'. The taste of apples 'by itself' may be compared with the taste of pears 'by itself'. But whether a similar comparison makes good sense when the terms are 'proposition-like' (states) seems to me debatable. A non-holistic logic of intrinsic preferences between states has been proposed by Chisholm and Sosa (1966).

A question of interest to value theory is whether the *absolute* notions of goodness and badness can be defined in terms of the *relative* notion of betterness (preference).

Long ago, A.P. Brogan (1919) suggested that a state of affairs is good if it is better than its contradictory. In terms of preference:

$$\mathrm{Good}\, x =_{\mathrm{df}} xP \sim x.$$

Conversely, a state is bad if its contradictory is preferred to it.

If $xI \sim x$ holds good, x will be called indifferent *in itself.* If xIy holds, x and y will be called indifferent *between themselves.*

A weakness, among others, of the suggested definition of good is that one cannot prove that states which are indifferent in themselves are also indifferent between themselves. Thus it may happen that two states are indifferent in themselves, neither good nor bad, and one of them preferred to (thought better than) the other. This is counter-intuitive. Things which are neither good nor bad have no value and therefore should not be possible to rank as better or worse.

A similar objection can be made against the definition of goodness suggested by R. Chisholm (1975). It says that a state is good if it is preferred to some state which is indifferent in itself. But unless states indifferent in themselves are all equal in value it may happen that one and the same state is both good and bad. This also is counter-intuitive.

The upshot seems to be that the value-absolutes cannot be defined in terms of preference alone. They require in addition an independent concept of *zero*-value or (complete) valueneutrality.

One must distinguish between *preference* and (preferential) *choice.* A preference is an attitude, a choice an action.

If a subject has a pure preference for *x* over *y* it may be taken as analytic that, if he is offered a choice (option) between the two states, he will choose the former. It is then presupposed that the two states are being presented to him, so to say, 'on a tray' – that he can 'pick out' the one or the other without having to consider further prerequisites for or consequences of his choice.

From choices and options of this kind one must distinguish another type. I shall call these other options *conditional.*

A farmer is offered a choice between, on the one hand, getting a horse if it is raining tomorrow and a cow if it is not raining and, on the other hand, a cow if it is raining and a horse if it is not. He prefers getting a horse to getting a cow; this is a 'pure preference'. But which of the offered alternatives does he prefer? Assume that he professes to be indifferent as between them. How shall we then understand his attitude?

To this question there is an answer, first proposed by F.P. Ramsey, which has later come to play a great role in so-called Bayesian decision theory (Ramsey 1931; Savage 1954; Davidson 1955). Ramsey thought that an attitude of indifference here *means* that the person rates the two events, 'rain' and 'not rain', as *equally probable.* Accepting this, one can then proceed as follows:

Assume that our farmer is next presented with this option: On the one hand a horse if it is raining and a sheep if it is not raining and, on the other hand, a cow if it is raining and a hog if it is not raining. Again he says he is indifferent. This, on Ramsey's view, means that the value to him of a cow is *as much less* the value of the horse as the value of a sheep is less that of a hog. With this the way is open to a *metrization* of value and the introduction of *utility functions.* This done, one can use attitudes of indifference in other, more complex, conditional options for defining arbitrary degrees of (subjective) probability . The product of the value of a good and the probability of its materialization is called *expected utility.* Attitudes of preference in options aim at maximizing this quantity.

Ramsey's method is elegant and ingenious. Nevertheless, it seems to rest on a mistake. It ignores the distinction between the two senses of 'indifference'.

The farmer who, when presented with the first of the above two options, professes an attitude of indifference can do so for one of two reasons. Either he 'simply has no idea' about the chances of rainfall for tomorrow and therefore cannot make up his mind about which alternative is more to his advantage. This does not *mean* that he thinks rain and not-rain equally likely; he simply suspends judgement. *Or,* he considers them equally likely and *therefore* judges the two alternatives to be equally advantageous. He could, for example, support his attitude with the argument that if he repeatedly opted for one of the alternatives, no matter which one, on average half the number of times he would 'probably' get a horse, which is to his advantage, and half the number of times a cow, which is to his disadvantage. So therefore he is indifferent as between the alternatives. It is, in other words, not his judgement of indifference which gives meaning to the probabilities for him; but it is his prior estimate of the probabilities which determines his attitude of indifference. This estimate, moreover, seems normally to go with a corresponding expectation of frequencies.

P

The above criticism of Ramsey's procedure is not committed to a frequency theory of the 'meaning' of probability. But it assigns to expected frequencies a much more basic position for understanding probabilities than modern 'Bayesians' have tended to do (cf. von Wright 1962).

By a group-preference one can understand a ranking of alternatives in an order of ('objective') preferability based on the (subjective) rankings for preference of those alternatives by the members of the group. The derivation of the collective preference has to conform to some principles which seem intuitively plausible or 'rational'.

The problem of determining a group-preference is connected with notorious difficulties. Any proposed solution will depend partly upon which rational standards it is thought that the derivation should satisfy, and partly upon which demands are imposed upon the *P*- and *I*-relations involved.

In his influential book *Social Choice and Individual Values* (1951), K.J. Arrow showed that a derivation cannot collectively satisfy certain principles which individually seem plausible.

The result is known as Arrow's 'Impossibility Theorem'. It has been the topic of much subsequent discussion both by economists and logicians.

Group-preferences will not be further treated in this article. Let it be mentioned, however, that in the writer's opinion discussion has tended to neglect the complications connected with the concept of *indifference*. It is usually assumed that the *P*-relation is, at least, transitive and that the *I*-relation is an equivalence relation. In a preference ranking which is a partial ordering, this requirement on the *I*-relation is not automatically fulfilled. And even if the *I*-relation for individual preferences were an equivalence, it may not be 'reasonable' to demand or expect the *I*-relation for a group-preference to be this. Observing the distinction between 'mere' indifference and value-equality may therefore be helpful in efforts to cope with the conceptual difficulties in this area.

Preindustrial Inequality

Branko Milanovic

Abstract

This article considers inequality in pre-industrial societies, defined as those prior to the industrial revolution and subsequent non-industrial societies that are not systematically integrated into the advanced world's economy. Although data on individual incomes and wealth in these societies are limited, increasingly they are becoming available. On the basis of these data, inequality as measured by the Gini coefficient is often on a par with modern industrialized societies, but the income gradient tends to be different, with a mass of people at subsistence level or marginally above, few at the mean, and a small affluent class. More work remains to be done, particularly on the relationship between income inequality and economic progress.

Defining Preindustrial

We need to circumscribe the scope of preindustrial. At one level, it is easy: preindustrial economies are characterized by low urbanization rates, high share of agriculture in GDP, low literacy rates, and of course low overall GDP per capita. However, many of today's poor countries share precisely these features. They are however 'non-industrial' or 'non-industrialized' rather than 'preindustrial' economies: this is because they are part of the modern world, systematically included in trade and voluntary movements of factors of production ('globalization') and have social structures which are very different from those of preindustrial societies. The life expectancy of their populations as well as the immunization and school enrolment rates exceed many times those of 'true' preindustrial societies. Not the least important is the fact that political compulsion of slave or serf labour, so ubiquitous in all preindustrial societies, is – except in a few pockets – largely absent.

Our definition of preindustrial includes all societies prior to the industrial revolution, and those that have not engaged with the industrial revolution, only up to a point when they began to be integrated systematically, rather than episodically, into the world economy. For many of them, integration coincides with colonization. Thus, broadly speaking – since we are painting with a very broad brush here – we can set limits around the end of the Napoleonic wars for Western Europe and the United States and Canada, and the end of the 19th century for everybody else. Twentieth-century societies, even when poor and hardly industrialized, belong to a different category.

A cut-off date around 1815–20 is convenient for at least three reasons. Politically, it coincides with a 'rearrangement' of Europe and, as later emerged, the world. It marks the beginning of the 'long 19th century'. Economically, it marks, according to the new English wage data series produced by Clark (2005), the beginning of a long-run rise in real wages which is continuing to this day. In terms of history of economic thought, Ricardo's *Principles* were published in 1817.

An obvious, but nevertheless important, clarification is that we are concerned here with income inequality: that is, inequality that includes all sources of income and reflects differences in households' and individuals' living standards. This, for example, rules out wage or rural–urban inequalities as such. (Wage inequality has meaning only if calculated across all wage-earners; income inequality includes the entire population.)

Implicit Theory

We do have an implicit theory about income inequality in preindustrial economies. The Kuznets hypothesis (formulated in 1955), the bread and butter of inequality economics, posits that inequality charts an inverted U shape as economy transforms from predominantly agricultural to predominantly industrialized or modern. In Kuznets' own words:

> One might thus assume a long swing in the inequality characterizing the secular income structure: widening in the early phases of economic growth when the transition from the preindustrial civilization was

> most rapid, becoming stabilized for a while; and then narrowing in the later phases. (Kuznets 1955, p. 276)

The same hypothesis, albeit without the mechanism that generates the inverted Ushaped curve, was formulated 120 years before Kuznets by Tocqueville:

> If one looks closely at what has happened to the world since the beginning of society, it is easy to see that equality is prevalent only at the historical poles of civilization. Savages are equal because they are equally weak and ignorant. Very civilized men can all become equal because they all have at their disposal similar means of attaining comfort and happiness. Between these two extremes is found inequality of condition, wealth, knowledge-the power of the few, the poverty, ignorance, and weakness of all the rest. (de Tocqueville 1835, pp. 42–3)

From both we should retain the sense that inequality is supposed to emerge only when societies are richer, and thus inequality in preindustrial societies may be expected to be low. But differently, we also have an image of preindustrial societies as combining abject poverty in the bottom with extravagant wealth on the top. For example, in ancient Rome, Goldsmith (1984, p. 287) notes the extraordinarily high income of the rulers relative to Great Britain in the early 19th century. Could both these images be right? As we shall argue below, yes – and this is one of the key features that distinguishes inequality in premodern times from inequality in modern times.

But in order to speak about inequality in preindustrial societies, we must also assume that preindustrial societies were 'modern' in the sense that they were (predominantly) market-oriented economies with non-negligible monetized sectors – and when they were non-monetized, goods and services given or received for political or power reasons could be valued at some meaningful 'market' prices. This is a position not universally accepted. In a famous debate about the later Roman Empire (and, by extension about all ancient economies) and 'modernity', there were two camps: that of 'primitivists' led by Polanyi (1944), Finley (1985) and Schiavone (1995), and that of 'modernists' (Rostovtzeff 1926; Walbank 1946). The first believed that Rome lacked most of the modern concepts that we associate with a market economy. Market relations, even when present, were of peripheral importance, and a market economy, itself a recent phenomenon, is perhaps, in a historical sense, only a brief episode (Polanyi 1944). For the 'modernists', the links between a preindustrial society like Rome and modern capitalism were obvious. Both Rostovtzeff and Walbank write of Roman 'bourgeoisie'. Whatever our opinion about the respective merits of 'primitivists' and 'modernists', it is important to realize that once we attempt to make some tentative estimates of economic inequality in preindustrial societies, we *ipso facto* accept that, while preindustrial societies might have been poorer and with a different social structure from modern societies, the differences are of magnitude, not of kind. For if such key concepts of market economy as prices, wage-labour and private property are vague, insufficiently understood by the population, not sanctioned by custom or law, then applying modern economic categories may be meaningless. Every attempt to study preindustrial societies empirically using today's economists' tools must assume that 'ancient' and 'modern' are fundamentally the same – so that that the 'ancient' can be described and understood using economic concepts developed from Adam Smith onwards.

Private property must enter the list above with a caveat. No one would deny that socialist societies, where private property was limited, were not modern. Moreover, they regarded themselves as the epitome of modernity. Similarly, societies with largely communal ownership of land (as in Africa) are modern too. Thus, private property of the means of production seems to be less of a requirement for a modern society than for example monetization. Rawls (1971), who can hardly be seen as a non-modernist, allows in his *Theory of Justice* for both private and nonprivate ownership of the means of production (see pp. 54, 240–1).

Data for Preindustrial Inequality

Where do data for preindustrial inequality come from? Since the Second World War, empirical studies of income distribution have been based on household surveys (nationally representative samples of households who are anonymously interviewed about their household characteristics, spending patterns and income). The earliest household surveys are from late 18th-century England. There were a few sporadic surveys in the 19th century (continental Europe, rural Russia) but they spread broadly only after the end of the Second World War, and as far as Africa and China are concerned, surveys became available only more recently, from the early 1980s. Obviously, such surveys were not conducted in any preindustrial society – even if censuses (driven by government tax needs) were. However, there are relatively abundant sources that economists can use to gauge income distribution in preindustrial societies, although the sources are often buried in hard-to-access archives and books, written in languages and alphabets that are not widely known, and requiring large amounts of both money and effort to be brought to light in a usable form. (For example, Ottoman censuses are written in Turkish but using Arabic script, rather than Latin as is used in today's Turkish. To process them requires knowledge of an often archaic Turkish and an alphabet into which this language is no longer written. See Cosgel 2002, 2004.) And then lots of heroic assumptions are needed in order for them to be 'translated' into modern economic categories. This has severely limited the use of ancient sources, and this is probably why only a fraction of such sources has been used so far.

The most comprehensive contemporary sources are tax data and government censuses undertaken in order to supply governments with information about taxation and the war-waging capacity of the populace (number of men, houses, horses, grain). Early documentary evidence includes government edicts (such as Diocletian's edict on maximum prices and wages from 301, recently studied by Allen 2007), as well as numerous Roman papyri preserved in the dry climate of Egypt. The English Domesday survey of 1086 is perhaps the best known of such sources.

From the Byzantine Empire, we have a few preserved *praktika* that provide descriptions of household characteristics, inventories of possessions and taxes paid, although they cover only limited areas (towns or ecclesiastical communities). (See the multi-volume *Economic History of Byzantium: From the Seventh through the Fifteenth Century* edited by Angeliki Laiou 2002.) Ottoman censuses (*defterlar*) from approximately the 14th century onward, conducted to assess the wealth and military capacity of newly conquered territories, provide detailed information on settlements (hamlets, villages, small and larger towns) but then present it in average amounts for each settlement (not by individual household). If inequality within settlements is not huge, and the number of settlements included is large, censuses can be used to assess overall income distribution within a country or a region.

A much-used source is the Florentine *Catasto* from 1427. (The data were originally collated by Herlihy and Klapisch-Zuber 1985. Currently, they are available on the Internet.) The Spanish *Ensenada Cadastre*, similar to modern-day household surveys, was carried out in the 1750s for the purposes of a neverimplemented fiscal reform. It has recently been used by researchers, and will be no doubt analysed more once it is digitized. Inequalities for the cities of Paris, Amsterdam and London were studied from tax data for respectively 1292–1313 (Sussman 2005), 1732–42 (McCants 2007; Soltow 1989) and 1797–1801 (Schwarz 1979). However, they refer to wealth inequality (there is no attempted 'conversion' to income), cover very truncated data sets, focus either on the rich – those subject to taxation – or the poor (McCants 2007), and of course include single cities only. Incidentally, all examples but one used by Pareto in the formulation of his famous 'iron law' of income distribution come from various European tax data from the end of the 19th century (see Pareto 1896). The data on Latin America, produced by various Spanish *Visitas*, which collected detailed information on population, age, land ownership and agricultural output, have been published in numerous volumes but not used for estimates of income distribution. (For Peru, books with detailed notes from *Visitas* for the years 1562, 1567 and 1604–05 have been published.)

What is common to these sources is that they are in principle surveys of stocks (people and wealth) and require a huge effort of price imputation; first, to 'transform' a stock into a meaningful annual yield (income), then to convert produced quantities, expressed in local 'natural' units (such as Egyptian *modii* of wheat), into kilograms, and finally to convert all of these into monetary units. Then the researcher needs to resort to even more heroic assumptions to calculate other sources of income, from husbandry, vineyards, honeybee cultivation, fruits and plants, services provided by farmers, and not least, from manufacturing activities like pottery, glass or clothmaking, or provision of urban services from the shoe-maker to the teacher (for which, at least some wage data are generally available). Particularly vexing is the issue of measurement units, volumes or weights with often confusingly similar or identical names, which nevertheless imply different physical amounts from one region to another; or when money units are provided, the issue of silver or gold conversion between them. But such sources, however frustrating. can and do provide very useful evidence about ancient living standards and distribution of income.

The second contemporary evidence is provided by social tables. This is what William Petty termed 'political arithmetick'. They aim to describe the structure of a society by listing all salient social classes (or professions) and estimating their average incomes (per household, or less often per person). For modern economists, these sources are much easier to use because the classification into presumably socially important groupings and estimates of their money-equivalent incomes provide us with most of what we need to know for the derivation of income distribution. England was the pioneer in the production of social tables, beginning with the famous one of Gregory King for 1688 (which contains 33 social groups with their population sizes and average incomes), and continuing with Massie (1759) and Colquhoun (1801–3). (None of the social tables, or the results obtained from them, is without its critics: for a critique of King's social table, see Arkell 2006; for Colquhoun, see Schwarz 1979; for a critique of Lindert–Williamson's use of English social tables, see Feinstein 1988.) Much more recent authors have produced similar social tables for a number of countries (see, for example, Morrisson and Snyder 2000, for France in 1788, Bértola et al. 2006, for Brazil in 1872, van Zanden 2003, for Java in 1880, Berry 1990, for Peru in 1876). These new social tables are of course not contemporary sources but they were produced, using bits of dispersed primary or most often secondary sources, by economic historians who specialize in various eras and countries, and they represent our best guess at social structure at remote points in time. The work of Milanovic et al. (2009; hereafter MLW), who made the first systematic attempt to measure and analyse preindustrial inequality, is largely based on such (contemporary and recent) social tables.

Empirical Evidence

To translate preindustrial inequality into modern economics, we must not only hold that preindustrial societies were largely monetized (and whatever was not monetized could be ultimately expressed in money), but also hold that their inequality can be meaningfully handled by Gini, Theil or any other currently used inequality measure. Otherwise we lack a common yardstick with which to compare past and present.

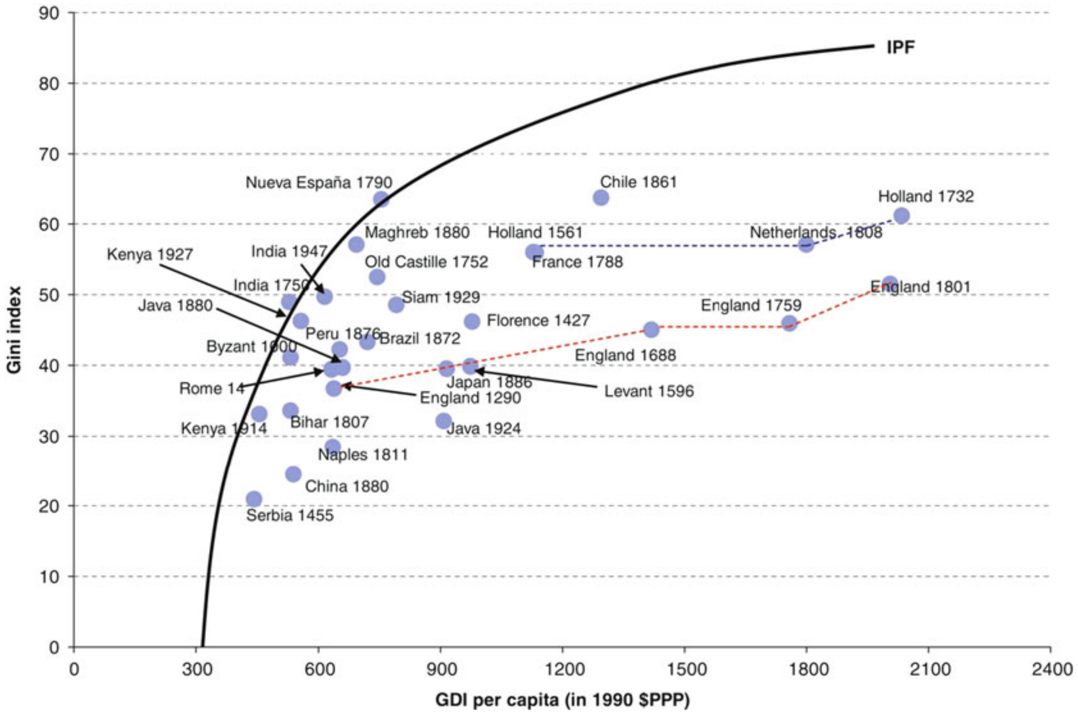
Using mostly social tables from 30 preindustrial societies, MLW calculated Gini coefficients. They found that the preindustrial Ginis range from the mid-20 s to around 65, with a mean of 45 and standard deviation of 11. (Gini is the most commonly used measure of inequality, and ranges from a theoretical zero (everybody has the same income) to a theoretical maximum of 100 (everybody but one person has a zero income, and the richest person takes the entire income of the community).) This is almost the same as the range of Ginis in modern societies. In fact, the modern equivalents of the preindustrial societies included in MLW sample (such as Turkey for Byzantium, Syria for the Levant, today's United Kingdom for the 1688 England and Wales) have an average inequality of 40 Gini points with a standard deviation of 10. However to make such a simple comparison and leave it at that would be erroneous. Preindustrial and modern societies were very different, even when compared in the language of modern economics.

First, it is very likely that the income gradient (how income increases as we move from poorer to richer income classes) was much flatter in preindustrial that in modern economies (see MLW 2009). Using Jan Pen's (1971) metaphor of dwarfs and giants, where people are visualized as marching in a 60-minute parade, from the poorest to the richest, with everyone's height reflecting their income, preindustrial societies can be seen as societies of dwarfs who would take some 40 to 45 minutes to file past. They contained large groups of people (most of the time, the vast majority of the population) living at, or just above, the subsistence minimum. Percentage differences in income among this vast mass of people were small. The income gradient was flat up to a very high point in income distribution. But then, and quickly, as we approach the very end of the parade, the gradient would suddenly increase, much more so than in modern societies. Thus, unlike a modern parade which would be characterized by a steady increase of the gradient, in preindustrial societies the middle was not much different from the bottom. There was a dearth of people whom we would (using modern terminology) identify with the middle class. (It is worth pointing out that this 'middle class' is not defined in terms of absolute income, or what we would consider today to be middle-class requirements, but entirely in terms of the period average income.) We can thus see why both of our preconceived notions – of generalized equality and drastic income disparity among the ancient – are true: they just refer to different parts of income distribution.

This difference in structure implies that the same calculated measures of inequality have different meanings. Ginis, as we have already indicated, were broadly in the same range then and now. But a Gini of 40, estimated independently for the Roman Empire by MLW (2009) and Scheidel and Friesen (2009), had an altogether different meaning from the same Gini in the contemporary United States. (The MLW estimate refers to the year 14 (at the death of Octavian), Scheidel's estimate to the mid-second century.) The Roman Empire's mean income was about twice the physiological subsistence level (*s*). If we require that all members of a society have at least the subsistence minimum – for otherwise the society will tend to shrink and disappear – then a very low level of mean income, regardless of how tiny the upper class is, limits the extent of measured inequality. Simply put, the extent of inequality is limited by the size of average income. That ceiling is more binding when a society is poor. To realize this, assume that society's mean income is just a fraction above *s*. If all but a tiny elite live merely on *s*, the elite cannot be extravagantly rich because total income is low, and Gini or Theil indexes, which take into account incomes differences between all individuals, cannot be very high either. This is the idea underlying the Inequality Possibility Frontier (IPF: see Fig. 1), defined by MLW (2009) and Milanovic (2006).

The frontier gives a maximum Gini (or Theil) coefficient which is compatible with a given level of mean income and maintenance of society as a going concern. The maximum Gini is equal to $(a-1)/a$ where $a =$ mean income divided by *s*, or the number of subsistence minima contained in the mean. As can be seen from the formula, the maximum feasible Gini rises with mean income (a), but at a decreasing rate. If average income is twice the subsistence ($a = 2$), the maximum Gini will be 50. Thus, we see that the Roman inequality of 40 exhausted some 80 per cent of maximum feasible inequality. But for the modern-day United States, where the mean income stands at more than 100 *s*, the maximum Gini is 99. The actual inequality will have exhausted only 40 per cent of its maximum value. Hence, the social meaning of the same Gini is entirely different. To sustain high inequality, societies must be relatively rich.

We have left the issue of defining the subsistence minimum deliberately vague. Depending on whether we pitch this physiological (note: not social, not relative) minimum higher or lower, the IPF will move down or up, but the same logic will hold.



Preindustrial Inequality, Fig. 1 The Inequality Possibility Frontier (*Source*: MLW (2009))

The difference in the income structure (income gradient) also shows why some other measures, like top-to-bottom ratio or top 1 per cent share, may not be very useful in the preindustrial context. They show the extent of the gap between the richest and the poorest, but they disregard the entire distribution in-between, which in the past has been much more equal than in today's societies.

IPF imposes a consistency check on our inequality calculations, a fact which is particularly useful for preindustrial societies where the evidence is scant. As illustrated in the figure, once we know the mean income of a society, and estimate its Gini, we know that this estimate must be within, or at the maximum on, the frontier. If it is not, there is something wrong with either the income or the inequality estimate, or the society is doomed to experience a dwindling population and ultimately extinction. It is not surprising that MLW found that all six cases of ancient societies with inequalities close to the frontier were colonies: India in 1750 and 1947, Kenya in 1914 and 1927, Nueva España (Mexico) in 1790, and Maghreb in 1880. Colonizers were clearly much less concerned about the welfare of the populations they ruled than, or did not have to fear them as much as, native rulers.

Preindustrial Inequality and Modern Debates

Empirical evidence on preindustrial inequality has a direct bearing on several contemporary debates. Evidence from the two most advanced economies at the time (England and Holland) paints a picture of increasing inequality from 16th century to the beginning of the Napoleonic wars. (The exception is Soltow 1968, who found English inequality to have been flat throughout the 18th century.) Premodern growth seem to have exacerbated inequality even in the areas that were characterized by an already high inequality of wealth and income (such as the South Midlands in England, considered by Allen 1992). Using social tables, Lindert (2000) and Lindert and Williamson (1982, 1983) document the increase of inequality in England between 1750 and 1801. All four observations available for England and Wales in the MLW database (1290 – from Campbell 2007–1688, 1759 and 1801–3) show both mean income and inequality rising with time. Similarly, van Zanden (1995), and Soltow and van Zanden (1998) find that income inequality increased in Holland during its 'Golden age': between 1561 and 1732: the urban area Gini rose from 53 to 59, and the rural area Gini from 35 to 38. According to a pioneering study by Hoffman and colleagues (2002), 'real' European inequality between 1500 and the early 19th century increased even more because the prices of wage-goods, consumed by the poor, rose relative to the prices of 'luxuries'.

The upswing of the Kuznets curve seems to be strongly in evidence in all these cases. But what drove it? Was it a 'classical explanation' (as van Zanden 1995, terms it), namely a shift in the functional distribution of income toward property owners (and their rising concentration) and away from labour – a mechanism that Marx would easily have recognized? (For Spain, Prados de la Escosura 2008, uses functional distribution of income, and also finds a clear Kuznets upswing from 1850 to around 1914.) Or was it, as argued by Lindert and Williamson (1985) and Williamson (1982, 1985), caused by the 'wage-stretching' which continued well into the 19th century and involved labour-saving technological progress and increased pay-ratios for skilled labour in the presence of demographic pressure from mostly unskilled population? Education responded only very slowly, and the process continued for a couple of centuries until massive European emigration reversed it. The latter is a very neoclassical mechanism familiar to every economist working on poor or rich countries today. The focus is on the functioning of factor markets, not on the division of society into capitalists and workers.

If countries where the industrial revolution originated went through a period of sustained increase in inequality prior to the industrial revolution, does it shed some light on the relationship between higher inequality and the industrial take-off? A number of recent writings (most famously, Pomerantz 2000; Frank 1998; and more recently Wen 2009; Shiue and Keller 2007) have contrasted China and Western Europe in the 17th and 18th centuries, trying to understand why these two large areas that seemed in many respects similar (for instance in market integration, level of income, technological innovations) charted such different paths in the following three centuries. Does income distribution have to do something with it? Unfortunately, we do not yet have even the intimation of an answer because the historical data for China are not available. However a recent upsurge in archival research on Chinese sources might help throw some new light on this issue.

The work of Engerman and Sokoloff (1997) has profoundly affected our conception of the role of inequality in explaining the economic success of North America and relative decline of Latin America. But while there is little doubt that Latin America was more unequal (particularly in land ownership) that the North, recent historical evidence contrasting Western Europe and Latin America finds no perceptible difference in inequality between the two. Williamson (2009) thus wonders why Western Europe and Latin America have followed different growth trajectories. If the inequality explanation works for one set of regions (the two 'New Worlds'), why does it seem not to work for another (Europe and Latin America)? Moreover, it is not evident that Latin America was 'always' unequal. Prados de la Escosura (2007) and Bértola et al. (2009) argue that strong expansion of inequality occurred during the previous round of globalization (1870–1920). Prados de la Escosura (2007, p. 298) sees the explanation as consistent with the factor-price equalization theorem: opening up Latin America to trade raised land rents, and since land was unequally distributed, increased the concentration of incomes. The data prior to around 1870 are not available (although some estimates for 1870 show inequality in the Southern Cone countries to be at the same level as in Spain: Prados de la Escosura 2008, Fig. 8, p. 307), but we could wonder whether our 'acquired idea' of an always high inequality in Latin America is not mistaken – or perhaps it was not inequality,

P

but the inequality extraction ratio that was high. Recasting the issue in this way suggests that the Latin American problem was a low level of income rather than a high Gini.

Conclusion

Studying inequality in its historical context, an area which will doubtlessly loom larger in economics as the search to uncover our economic past progresses, is important not only because it helps us learn about history but because it helps us understand today's economic problems. Actually, as every historian and politician knows, studying the past is about the future.

Preobrazhensky, Evgenii Alexeyevich (1886–1937)

Michael Ellman

Abstract

Preobrazhensky was an Old Bolshevik and an original and perceptive Marxist theorist. His main contribution to Marxist political economy concerned the building of socialism in a predominantly agrarian country at a low level of economic development. He argued that socialist accumulation in such a country would require an initial period of original socialist accumulation. That is, economic growth on the basis of investment generated within industry would have to be preceded, in backward Russia with its limited industry, by a period of economic growth on the basis of investment resources obtained from outside the state sector.

An Old Bolshevik and a distinguished Marxist theoretician, Evgenii Alexeyevich Preobrazhensky joined the Russian Social Democratic Workers' Party (which split into Bolshevik and Menshevik factions) in 1903 and became a professional revolutionary, being repeatedly arrested and twice subject to internal exile. He led the local party organization in the Urals during the October Revolution. In 1918 he was a member of the Left Communist group within the party which opposed the treaty of Brest-Litovsk (which ended the Russian–German war by an agreement with 'imperialist' Germany rather than by a revolution within Germany). He played an active role in the Civil War (1918–20). He was a full member of the Central Committee of the Russian Communist Party (Bolsheviks) and also Central Committee Secretary in 1920–1. In 1921–2 he was critical of the New Economic Policy (NEP – a mixed-economy policy which permitted peasant households to utilize freely the land they cultivated and also permitted small-scale private enterprise in both villages and towns, while at the same time reserving the railways, large-scale industry, banking and international trade for the state). He was worried about concessions to the peasantry and their implications for rural stratification and Soviet power. A signatory to the Platform of the 46 (October 1923), he was an active oppositionist in 1924–7; he was expelled from the party in December 1927 and exiled to Siberia. Under the influence of Stalin's move to the Left, he broke with the Opposition and in July 1929 accepted Stalin's leadership. He attended the Seventeenth Party Congress (1934) where he praised Stalin and collectivization, denounced both himself and Trotsky (Stalin's chief political opponent), and advocated unity and unconditional acceptance of the party line and Stalin's leadership. Arrested in 1935, he served as a prosecution witness at the trial of Zinoviev (the former Politburo member and former chair of the executive committee of the Communist International) in 1936. Arrested again in 1936, he was not brought to a public trial, probably because of his refusal to confess to non-existent crimes. He was shot in 1937. In 1988 he was rehabilitated.

Preobrazhensky was the author of a large number of books and articles. They covered the exposition of Marxist-Leninist theory, financial and monetary questions, economic policy in France and economic policy in the USSR. Preobrazhensky's most original and important work concerned the problem of building socialism in a backward, overwhelmingly agrarian country.

Marx and Engels did not analyse how a future socialist economy would be organized and strongly opposed utopian socialism with its speculations divorced from current reality. Nevertheless, from their criticism of the anarchy of production under capitalism and their analysis of the views of rivals in the socialist movement, it is possible to draw inferences about how they expected a socialist economy to function. At the end of the 19th century Marxists had worked out some preliminary ideas for the transition to socialism and the organization of a socialist economy, as can be seen, for example, from the 1891 Erfurt Programme of the German Social Democratic Party and Kautsky's *Das Erfurter Programm* (1892), which is a commentary on it. They assumed, however, that the country concerned would be predominantly working-class and have a highly developed industry. In the 1920s, however, the Bolsheviks found themselves in power in a predominantly agrarian country at a low level of economic development. How should they build socialism in these circumstances? It is in answering this question that Preobrazhensky made his main contribution.

In *Novaia ekonomika* (1926a) he argued that, just as capitalist accumulation had required an earlier period of original accumulation as analysed in Marx (1867, vol. 1, part 8), so socialist accumulation would require an initial phase of original *socialist* accumulation. That is, economic growth on the basis of investment generated within industry would have to be preceded, in backward Russia with its limited industrial apparatus, by a period of economic growth on the basis of investment resources obtained from outside the state sector. He generalized his argument into a fundamental law of socialist accumulation which runs as follows:

> The more backward economically, petty-bourgeois, peasant, a particular country is which has gone over to the socialist organization of production, and the smaller the inheritance received by the socialist accumulation fund of the proletariat of this country when the social revolution takes place, by so much the more, in proportion, will socialist accumulation be obliged to rely on alienating part of the surplus product of pre-socialist forms of economy and the smaller will be the relative weight of accumulation on its own production basis, that is the less will it be nourished by the surplus product of the workers of socialist industry. Conversely, the more developed economically and industrially a country is, in which the social revolution triumphs, and the greater the material inheritance, in the form of highly developed industry and capitalistically organized agriculture, which the proletariat of this country receives from the bourgeoisie on nationalization, by so much the smaller will be the relative weight of pre-capitalist forms in the particular country; and the greater the need for the proletariat of this country to reduce non-equivalent exchange of its products for the products of the former colonies, by so much the more will the centre of gravity of socialist accumulation shift to the production basis of the socialist forms, that is, the more will it rely on the surplus product of its own industry and its own agriculture. (1926a, 1965 translation, p. 124)

As methods to obtain investment resources from the non-state sector (predominantly peasant agriculture), Preobrazhensky recommended the state monopoly of foreign trade, price policy, railway tariffs, taxation and state control of the banking system. He paid particular attention to the advantages of price policy as opposed to the use of coercion.

Preobrazhensky's analysis was very controversial when it was first published and led to a very heated debate. The reason for this is that the political basis of the Soviet regime in the 1920s was the precarious compromise between the Bolsheviks and the peasantry represented by the NEP. In addition, economic policy was based on the encouragement by the Bolsheviks for the peasants to 'enrich yourselves'. It was hoped that the development of peasant agriculture, in a mixed economy in which the commanding heights were in the hands of the state, would provide the food, raw materials, exports, internal market and labour force necessary for Soviet economic development. Hence Preobrazhensky's argument, with its presentation of the case for accumulation at the expense of peasant agriculture, was both politically and economically very disturbing. In particular, the analogy with original capitalist accumulation was distinctly ominous. According to Marx, original capitalist accumulation was based mainly on force, in particular on the use of force to expropriate the land from the peasantry. In the minds of the supporters of NEP, Preobrazhensky's analysis raised the spectre of a revival of the methods of War Communism (that is, requisitioning based on direct coercion, rationing, and attempted state control of the whole economy, rather than market economy methods).

Preobrazhensky's ideas evolved over time. In a paper of 1921 (1980, pp. 3–19), the very year the NEP was introduced, he anticipated an armed conflict between the Soviet state and the kulaks. He regarded this as inevitable and argued in good Stalinist style that 'the outcome of the struggle will depend largely on the degree of organization of the two extreme poles, but especially on the strength of the state apparatus of the proletarian dictatorship'. He concluded his argument, which was published at a time of serious famine and disease, partly caused by the class-war policies of the Bolsheviks, by warning his readers 'to prepare for everything that will ensure victory in the inevitable class battles that are to come'. In a paper of 1924, the thesis about the inevitable conflict between the state and the peasantry still plays a central role, but economic levers (for example, price policy) rather than coercion play the key role in resolving the conflict in the interests of socialist accumulation.

In a paper of 1927, attention has shifted to the conditions for growth equilibrium. The Harrodian conclusion about the essential precariousness of dynamic equilibrium is reached. The lesson is drawn that 'The sum of these contradictions shows how closely our development towards socialism is connected with the necessity – for not only political but also for economic reasons – to make a break in our socialist isolation and to rely in the future on the material resources of other socialist countries.'

In an unpublished paper of 1931 he criticized over-investment and pointed out the danger of an 'overaccumulation crisis'. His argument that 'socialism is production for consumption's sake' was unacceptable during the frenzy of the Soviet Great Leap Forward and was condemned as heretical. His position in 1931 seems to have been similar to that of Rakovsky, another Left Communist intellectual, who in an article of 1930 (published in 1931 and translated into English in 1981) warned against the coming Soviet economic crisis (which shook the whole economy in 1931–3) and stressed the wasteful and inefficient methods of Stalinist industrialization.

The accumulation that Preobrazhensky theorized about was *socialist* accumulation, that is, accumulation leading to the development of socialist relations of production. It is entirely natural, for example, that the imaginary author of Preobrazhensky's book *From NEP to Socialism* (1922), which takes the form of lectures supposedly given in 1970, is simultaneously a university professor and a fitter in a railway workshop. This reflected Preobrazhensky's expectation that the division of labour would be sharply reduced under socialism.

Preobrazhensky's work has had an enormous influence throughout the world. In the USSR in the 1920s he played a major role in the debate about the main directions of economic policy. In the West he was rediscovered in Erlich's famous paper in the *Quarterly Journal of Economics* (1950) and has been much discussed ever since. In the Third World his ideas play an important role in theoretical discussions and policy debates. He is rightly considered one of the outstanding Marxist economists of the 20th century.

A preordering (also called a weak ordering or a quasi-ordering) is a reflexive and transitive binary relation which is not necessarily complete.

A binary relation R defined on a set S is a set of ordered pairs of elements of S, that is, a subset of the Cartesian product of S with itself, $S \times S$. One writes xRy (or $(x,y) \in R$) to mean that $x \in S$ stands in realtion R to $y \in S$. A preordering is a binary relation, R, which satisfies two properties: (i) reflexivity: for all $x \in SxRx$, and (ii) transitivity: for $x, y, z \in S$, if xRy and yRz, then xRz.

A simple example is given by the binary relation weak vector dominance which we denote V. Suppose S is Euclidean N-space, then xVy if and only if $x_n \geq y_n$, $n = 1,..., N$. V is clearly reflexive and transitive; it is just as clearly not complete, that is, not all elements of S are ranked. For example if $N = 2$, $x = (1, 2)$, and $y = (2, 1)$ then it is not the case that xVy or that yVx.

Quasi-orderings have played their largest role in welfare economics where consistency in decision making is a desirable requirement but where one may be dubious about being able to rank all possible outcomes. Two examples follow for which the notion of a subrelation is useful. Suppose R and S are binary relations: S is a subrelation of R if xSy implies xRy. For example, strong vector dominance, $\overline{V}$ is the binary relation which results when the above weak inequality is replaced with a strict inequality. Clearly, $\overline{V}$ is a subrelation of V.

Interpreting the elements of N-space as vectors of utilities, it is possible to define a quasi-ordering which is a subrelation of both the utilitarian and the Rawls criteria: Define the binary relation M by xMy

if and only if $\sum_{i=1}^{N} x_i \geq \sum_{i=1}^{N} y_i$ and $\min\{x_1, \ldots, x_N\} \geq \min\{y_1, \ldots, y_N\}$. M is clearly reflexive, transitive and not complete. The distributional insensitivity of the utilitarian principle is tempered by the Rawls's difference principle.

As an alternative, consider evaluating social states by weighted utility sums where the weights represent utility comparisons but these comparisons are not precisely fixed. Instead, the weights are drawn from a subset of N-dimensional Euclidean space, say B. More formally define the quasi-ordering F by xFy if and only if $\sum_{i=1}^{N} b_i x_i \geq \sum_{i=1}^{N} b_i y_i$ for all $(b_1, \ldots, b_N) \in B$. Suppose that we try to evaluate the desirability of burning down Rome while Nero fiddles. The quasi-ordering F may show a gain for burning Rome only if the set of interpersonal weights is such that Nero is given extreme consideration. (These examples are taken from the articles listed below.)

Prescott, Edward Christian (Born 1940)

Stephen L. Parente

Abstract

\Edward Prescott was awarded the Nobel Prize in Economics in 2004 with Finn Kydland for their contributions to dynamic macroeconomics. Prescott is a member of a small group of economists who, starting in the 1970s, revolutionized macroeconomics by challenging the Keynesian consensus. While he is best known for his research on business cycles and the optimal design of economic policy, he has made important contributions to other applied fields, such as finance and development, as well as to economic theory. He has also made important contributions to methodology, having pioneered many of the standard contemporary techniques and tools in macroeconomics.

Edward Christian Prescott is one of the leading macroeconomists of our time. He received the Noble Prize in Economics in 2004, an award he shared with Finn Kydland. Prescott's influence on the evolution of macroeconomics has been profound and far-reaching.

Prescott is a member of a small group of economists who, starting in the 1970s, revolutionized macroeconomics by challenging the Keynesian consensus that had held sway for half a century. This revolution, known as the ‘Rational Expectations Revolution’, occurred primarily at Carnegie Mellon University, the University of Chicago, the University of Minnesota, the University of Pennsylvania and Rochester University. Initially, this revolution was seen as the start of a new school of economic thought – New Classical Economics – that was based on the assumptions of market clearing and rational expectations. Today this revolution is seen simply as the start of an alternative approach to macroeconomics, one that advocates dynamic general equilibrium models with strong microeconomic foundations. This approach now dominates macroeconomics.

Prescott is best known for his applied research on business cycles, economic development and growth, and financial markets. In addition to his applied work, Prescott has produced a number of theoretical papers. A major line of this research demonstrates how to apply classical competitive analysis to economies with frictions, economies that previously had been regarded as outside the realm of such analysis. Within the profession, however, some of Prescott’s most lasting impacts have come in the methodology used for macroeconomic research. Many of the standard contemporary tools and techniques in macroeconomics were pioneered by Prescott. Finn Kydland and Edward Prescott together introduced calibrated models to macroeconomics; in doing so, they fundamentally changed the way applied macroeconomics is carried out. Prescott’s work has also been important for the development and diffusion of dynamic general equilibrium techniques and recursive methods. His work has also altered the ways in which economists handle data; for example, the so-called Hodrick–Prescott filter has become a standard tool of those working with time series data displaying trends. Thus, through applied work, theory, and methodology, Prescott has made lasting contributions to economics.

History

Edward C. Prescott was born in Glenn Falls, New York on 26 December 1940. He graduated from Glenn Falls High School in 1958 and Swarthmore College in 1962, with a BA in mathematics. In 1963 he received a Masters degree in Operational Research from Case University, which later became Case Western University. Thereafter, he enrolled in the Ph.D. programme at the Graduate School of Industrial Administration at Carnegie Mellon University (CMU), completing his doctorate in 1967.

Prescott started his academic career in 1967 as an assistant professor in the economics department at the University of Pennsylvania. In 1971 he left and accepted a position at CMU at the rank of assistant professor. He was promoted to the level of associate professor in 1972 and full professor in 1975. In 1974 he visited the Norwegian School of Business and Economics for a year at the invitation of Finn Kydland, who had written his dissertation under Prescott’s supervision at CMU. The visit is significant, as it was the occasion for much of the work for which the pair were later awarded the Nobel Prize. Prescott officially left CMU in 1980. Between 1978 and 1982, Prescott was a visiting professor at both the University of Chicago and Northwestern University. In 1981 he accepted a position at the University of Minnesota, where (with the exception of 1998, when he was a professor at the University of Chicago) he remained until 2003. At Minnesota Prescott was appointed a Regent’s Professor in 1996 and the McKnight Presidential Chair in Economics in 2003. In 2003 he left Minnesota to become the W.P. Carey Professor at the W.P. Carey Business School at Arizona State University. In addition to these academic positions, Prescott has served as an advisor to the Federal Reserve Bank of Minneapolis since 1981.

Prescott has received numerous honours in his distinguished career, with the Nobel Prize in 2004 being the most prestigious. He was elected to the Econometric Society in 1980 and the American Academy of Arts and Sciences in 1992. He is the recipient of the 2002 Erwin Plein Nemmers Prize in Economics, awarded by Northwestern

University biannually to an outstanding economist. He was chosen to give the First Lionel McKenzie Lecture at the University of Rochester in 1990, the Third Walras–Pareto Lecture at the Univeristé de Lausanne in 1994, and the First Lawrence Klein Lecture at the University of Pennsylvania in 1997. In addition, he was chosen to give the Richard T. Ely Lecture to the American Economic Association in 2002.

Research

Prescott's graduate training was largely in statistics. His thesis advisor was Mike Lovell. In addition, Maurice de Groot, one of the greatest Bayesian statisticians, was involved in the supervision of Prescott's work. Prescott's dissertation, titled 'Adaptive decision rules for macroeconomic planning', was an exercise in Bayesian statistical decision theory.

By his own admission Prescott was more of a statistician than an economist in the first years of his career. This changed in 1969, the year, he wrote 'Investment under uncertainty' with Robert E. Lucas (1971), whom Prescott had met while he was a graduate student at CMU. The paper studied the optimal investment decision of firms in an industry faced with stochastic demand. The paper was still in the tradition of the Keynesian 'system of equations' approach pioneered by Lawrence Klein that dominated macroeconomics at that time; its purpose was to derive a better investment equation to be used in large macro models. As such, it followed the trend established by Milton Friedman, Franco Modigliani, James Tobin and Trygve Haavelmo, who sought to base the individual equations in these systems on microeconomic theory.

The paper marks a watershed in the development of macroeconomics, however. It is one of the first to incorporate John Muth's hypothesis of rational expectations. The assumption of rational expectations forced Lucas and Prescott to develop and apply a new set of tools and concepts that have since become standard in macroeconomic research. For example, the paper introduced the concept of an equilibrium as a stochastic process. The paper is also important in the development of dynamic general equilibrium analysis; although the paper studied a partial equilibrium problem, the rational expectations assumption required that Lucas and Prescott simultaneously study the optimization problems of agents as well as the industry equilibrium. The paper also demonstrated how the competitive equilibrium could be solved from the social planner's problem of maximizing consumer surplus.

The 'Investment under uncertainty' paper is also important in that it showed how dynamic programming techniques developed in statistics and operations research could be successfully applied by economists to solve complicated optimization problems. In this respect, Prescott's previous training at Case University proved extremely valuable. The paper was to some extent a precursor to the concept of a 'recursive competitive equilibrium', that is, a set of time-invariant decision rules and prices that are functions of limited number of state variables.

In the 1970s Prescott continued to develop the recursive methods that now are commonplace in macroeconomics. In 1980, he published a paper with Rajish Mehra that extended and generalized recursive equilibrium theory. He also collaborated with Nancy Stokey and Robert Lucas in writing a comprehensive and complete book on the subject, *Recursive Methods in Economic Dynamics.*

Classical Competitive Analysis

The problems that Lucas and Prescott encountered in the 'Investment under uncertainty' paper necessitated that they read a number of papers in mathematical economics. One of these papers was Debreu's classic (1954) paper on competitive equilibrium analysis, 'Valuation equilibrium and Pareto Optimum'. This paper had a great impact on Prescott's thinking. First, the paper taught Prescott that many apparent market failures disappeared if mutually beneficial trades were permitted. Additionally, the paper showed to Prescott the power and importance of framing economic problems using the correct mathematical and verbal language.

Since the 1980s Prescott has written several papers that show how classical competitive analysis can be applied to a number of economies with frictions once the commodity space (that is, the set of tradable objects) is appropriately reframed. For many economies, the appropriate commodity space is defined over lotteries, namely, contracts with random components over goods and actions. Prescott and Townsend (1984) apply this approach to economies with moral hazard. Prescott and Rios-Rull (1992) do this in economies where people move between locations or occupations, and where at any one location there is imperfect information on the state of the other occupations. Hornstein and Prescott (1993) demonstrate how a number of potentially important production structures can also be mapped into this structure. Finally, Cole and Prescott (1997) show how this can be done in a class of economies where agents voluntarily form associations or clubs that carry out joint activities. These theoretical contributions were all intended to allow macroeconomists to address applied issues of policy relevance.

Industrial Organization

Prescott stopped teaching macroeconomics for a period in the 1970s, saying that it made little sense to teach a subject that one did not understand. During this period he primarily taught graduate courses in industrial organization (IO). A number of IO papers grew out of this teaching, such as Prescott (1973) and Prescott and Visscher (1977, 1980). Prescott and Visscher (1980) is an extremely important work. The paper shows that the acquisition of information, or organizational capital, by firms acts as an important cost of adjustment that limits firm growth. The paper makes an important contribution to the IO literature because it explains a number of empirical regularities, including Gibrat's law that firm size and growth are independent. It also makes an important contribution to the macroeconomic literature because the concept of organizational capital, which the paper introduced, has been used by a large number of researchers to understand a variety of phenomena.

Rules and Real Business Cycle Theory

During this period Prescott did not abandon research in the field of macroeconomics; in fact, he wrote with Finn Kydland two of the most important papers in macroeconomics: 'Rules rather than discretion: the time inconsistency of optimal plans', published in 1977, and 'Time to build and aggregate fluctuations,' published in 1982. The Nobel Prize Committee pointed to these two papers as the basis for awarding Kydland and Prescott the Noble Prize in 2004.

The substance of those papers is well known. Almost every undergraduate macroeconomic textbook written since the mid-1980s provides extensive coverage of both topics. The 'Time inconsistency' paper showed that people were made better off if the policymaker were to use a good rule instead of his discretion. Discretion – the ability of the policymaker to change his mind – leads to a worse outcome because the announced policy is typically not the optimal one to follow at the date of implementation. The 'Time to build' paper showed that productivity shocks account for roughly two-thirds of the volatility of US output over the business cycle in the post-war period. This productivity-driven view of the business cycle has come to be known as 'real business cycle theory'.

The idea that productivity shocks, which correspond to changes in the economy's stock of knowledge as well as changes in regulation or institutional factors, account for most of the US business cycle initially met fierce resistance. This was not surprising as it challenged the Keynesian view that the business cycle was a demand-driven phenomenon that called for government intervention on account of frictions. Many people objected to the theory on the grounds that the model contained no monetary side. These critics not only missed the point but they missed the fact that the precursor of the 'Time to build' paper (Kydland and Prescott 1980) did contain a monetary side based on Lucas's (1972) misperceptions theory. As that paper found that monetary shocks were quantitatively unimportant for understanding the US business cycle, Kydland and Prescott abstracted from money in their 1982 paper.

Over the years, resistance to Kydland and Prescott's theory of the business cycle has waned. The theory has been examined intensively, in fact probably more so than any other theory in economics to date. Attempts to discredit it have proven unsuccessful. Today, the idea that most of the US business cycle is a supply side phenomenon driven by productivity shocks is almost universally accepted.

The contribution of the 'Time to build' paper to the field of macroeconomics goes well beyond this substantive point. It also makes an important methodological point. Specifically, it lays the foundation for the use of deductive inference or model calibration to the application of macroeconomic issues. In this approach, the model is viewed as a measuring device, a so-called thermometer, to deduce or derive the quantitative implications of theory. This is in contrast to the inductive inference approach, or statistical estimation, that dominated the Keynesian 'system of equations' approach. There, the researcher attempts to discover the model out of a class of models that is the one to have most likely generated the data.

In effect, the 'Time to build' paper was an attempt to derive the quantitative implications of neoclassical growth theory for business cycles. Kydland and Prescott posed the question of whether the widely studied neoclassical growth model could be used not only to analyse long-run growth in the US economy but also to study business cycles. Starting with a standard neoclassical model, Kydland and Prescott restricted the values of the model parameters so that it quantitatively matched the trend growth of the US economy. They then modified the model so that productivity did not grow mechanically from year to year but instead followed a stochastic process that was based on the properties of 'Solow residuals' calculated from the data. Kydland and Prescott then reinserted these stochastic productivity shocks into the model and computed the equilibrium properties of the model. A striking result was that the model economy displayed business cycles that mirrored those found in the macro data, provided the labour supply was reasonably elastic.

Model calibration has become the dominant methodology in macroeconomics. It is widely used to test and develop theory as well as to evaluate policy. It is particularly useful in evaluating policy scenarios that are far 'out of sample' compared with historical experience. By using calibrated models, economists can conduct experiments on entire economies in a way that is not generally possible (or desirable!) with real economies.

Since 1982 Prescott and Kydland have continued to develop this line of research. They have subsequently written a number of articles to educate the profession in the use of model calibration (Kydland and Prescott 1991a, 1996; Prescott 2001). They have also written a number of articles that modify the model in their 1982 paper in order to explore further the implications of growth theory for understanding business cycles (Kydland and Prescott 1988, 1991b; Cooley et al. 1995).

The Equity Premium and International Income Differences

The application of the calibration methodology to a large number of macroeconomic questions has yielded important insights. As its founder, no person has used this methodology more effectively than Prescott. In addition to business cycles, Prescott's work has produced important insights in finance and economic development and growth.

Prescott's paper, 'The equity premium: a puzzle', co-authored with Rajnish Mehra and published in 1985, is a seminal work in financial economics. The paper sought to determine how much of the 6.2 percentage point difference between the average historical after-tax real rate of return on equity and the average historical after-tax return on bonds in the United States could be attributed to a premium for bearing non-diversifiable aggregate risk. The paper shows convincingly that households' aversion to risk cannot account for most of the difference in real rates of returns between bonds and equity. Prescott and Mehra's work has spawned an entire literature in financial economics, the goal of which is to solve the puzzle they uncovered.

Prescott's research has also fundamentally changed the way we think about the wealth and poverty of nations, and has set the direction of subsequent research in the area of economic development and growth. Prescott is among the very first researchers to argue that a theory of relative income levels, rather than relative growth rates, is the goal of development economics. Prescott did not start out with this view. Prescott's first paper on economic growth co-authored with John Boyd (Boyd and Prescott 1987) is an endogenous growth model whereby differences in policies or preferences across countries generate permanent differences in growth rates. After examining the development and growth facts over the period 1950–85 (Parente and Prescott 1993), however, Prescott concluded that the data did not support such a theory. The switch to a theory of relative income levels is evident in Parente and Prescott (1994). Today, the vast majority of papers that attempt to explain the huge disparity in international incomes take this relative income approach. Prescott is also one of the first researchers to have argued rigorously that differences in total factor productivity (TFP; that is, the efficiency with which a country uses its resources) account for most of the differences in international incomes. This is the main message of his 1997 Lawrence R. Klein Lecture, 'Needed: a theory of total factor productivity', published in 1998. Today, this view is almost universally accepted.

It should be no surprise that Prescott himself went on to provide a theory of TFP. In *Barriers to Riches*, Parente and Prescott (2000) demonstrate how a country's TFP is determined by policies that effectively constrain firms in their choice and use of technologies. Parente and Prescott (1999) completed the theory by arguing that these constraints typically exist to protect groups who stand to lose through the introduction of better technology.

No Decrease in TFP

Prescott has continued to remain highly productive; if anything, his productivity has increased in recent years. This recent research is mostly applied in nature. Like much of Prescott's previous work, it derives the implications of neoclassical growth theory for a variety of macroeconomic phenomena. One branch of this recent research uses the growth model to examine several longstanding hypothesis and puzzles in financial economics, including the equity premium (McGrattan and Prescott 2000, 2003, 2004). A different branch of this recent work uses the growth model to understand the reasons for the different experiences of OECD countries in the postwar period (Prescott 2003, 2004; Hayashi and Prescott 2002).

Teaching and Mentoring

It would be a serious omission not to mention Prescott's long-lasting commitment to teaching and advising. Prescott has supervised over 55 dissertations in his career, and many of his students are well-known economists such as Tom Cooley, Costas Aziaridis, Finn Kydland, Charlie Holt, Ed Green, Rajnish Mehra, Barbara Spencer, V.V. Chari, Hugo Hopenhayn, Richard Rogerson, Gary Hansen, Rody Manuelli, Gerhard Glomm, Jim Schmitz, Ayse Imrohoglu, Andreas Hornstein, Victor Rios- Rull, Fernando Alvarez, Dirk Krueger and Betsy Caucutt. Prescott's popularity as mentor reflects his philosophy that students should be treated as colleagues and that a good teacher has as much to learn from his students as they have to learn from him. The success of his students clearly speaks for the rigour that Prescott demands as well as the independence and confidence he instils in them. Prescott's students feel extremely fortunate to have had such a generous, engaging and inspiring advisor.

Conclusion

Edward C. Prescott is one of the most influential economists in the history of macroeconomics. His work has fundamentally changed the way economists conduct macroeconomic research and altered the way economists think about a large number of macroeconomic issues. Perhaps Robert E. Lucas in his introduction to Prescott's 2002 Richard T. Ely lecture best summarized Prescott's effect on economics, when he wrote

> We can remember the way we thought about the issues before Prescott's analysis, and the comparison with the way we think about them now gives a measure of the enormous effect each paper has had on our thinking... [Prescott's] papers met with resistance, but in the end [he has] caused us to rearrange important parts of our vision of how the economy works, to start over in many respects.

Present Value

Stephen F. LeRoy

Abstract

The present value relation says that, under certainty, the value of a capital good or financial asset equals the summed discounted value of the stream of revenues which that asset generates. Otherwise arbitrage would be possible. Under uncertainty, and if risk neutrality is assumed, the future payoffs are replaced by their conditional expectations. Under risk aversion either the natural probability measure under which expectations are taken must be replaced by a 'risk-neutral measure', or the discount factor must be modified by a factor that reflects risk. The present value relation leads to bubbles if a convergence condition is not satisfied.

The present value relation says that, under certainty, the value of a capital good or financial asset equals the summed discounted value of the stream of revenues which that asset generates. The discount factor is that determined by the interest rate over the relevant period. The justification for the present value relation lies in the fact that (in perfect capital markets) an asset must earn a rate of return exactly equal to the interest rate.

Otherwise arbitrage opportunities emerge, which is inconsistent with equilibrium.

Derivation of the Present Value Relation

If r_t is the one-period interest rate at t, p_t is the (ex-dividend) price of an asset and d_t is its dividend, it must be true that

$$r_t = \left(d_{t+1} + p_{t+1}\right)/p_t - 1, \tag{1}$$

since the right-hand side equals the rate of return on the asset. Solving for p_t,

$$p_t = \frac{d_{t+1} + p_{t+1}}{1 + r_t}. \tag{2}$$

Replacing t by $t + 1$, (2) becomes an equation expressing p_{t+1} as a function of r_{t+1}, d_{t+1} and p_{t+2}. If the resulting expression is substituted to eliminate p_{t+1} in (2), and if this operation is repeated n times, it follows that

$$p_t = \sum_{i=1}^{n} \frac{d_{t+i}}{\prod_{j=0}^{i-1}\left(1 + r_{t+j}\right)} + \frac{p_{t+n}}{\prod_{j=0}^{i-1}\left(1 + r_{t+j}\right)}. \tag{3}$$

If speculative price bubbles are assumed not to occur (see below), the rightmost term in (3) converges to zero as n goes to infinity, so there results the present value equation

$$p_t = \sum_{i=1}^{\infty} \frac{d_{t+i}}{\prod_{j=0}^{i-1}\left(1 + r_{t+j}\right)}. \tag{4}$$

If in addition the interest rate is constant at $r_t = \rho$, (3) may be written as

$$p_t = \sum_{i=1}^{n} (1 + \rho)^{-i} d_{t+i} + (1 + \rho)^{-n} p_{t+n}. \tag{5}$$

or, if the convergence condition is satisfied, as

$$p_t = \sum_{i=1}^{\infty} (1 + \rho)^{-i} d_{t+i}. \tag{6}$$

In the special cases in which d_{t+i} is constant at d, or grows from d_t at rate g, (6) simplifies to

$$p_t = \frac{d}{\rho} \tag{7}$$

or

$$p_t = \frac{d_t(1 + g)}{\rho - g}, \tag{8}$$

respectively.

Present Value in Capital Budgeting

In introductory finance courses, the present value relation makes an early appearance in the chapter on capital budgeting, where it is taught that corporations should accept any investment project that promises a positive present value (net of costs), and only these. This wealth-maximization decision rule is the correct one independent of agents' preferences because, regardless of preferences, the consumption set that it generates dominates that generated by any other capital budgeting criterion. This is Irving Fisher's separation principle. Other criteria, such as accepting that project with the shortest payback period, or that with the highest internal rate of return, are either equivalent to present value maximization, ambiguous (sometimes, for example, a single project may have no real internal rate of return, or more than one) or wrong, depending on the characteristics of the project's returns.

Present Value Under Uncertainty

Under uncertainty, but on the assumption of risk neutrality, the present value relation may be written as

$$p_t = \sum_{i=1}^{\infty} (1 + \rho)^{-i} E_t(d_{t+i}), \tag{9}$$

which differs from (6) only in that future dividends is replaced by its conditional expectation.

This version of the present value relation has received extensive study, especially in the early finance literature. It is easily shown to imply

$$E_t(r_t) = \rho, \tag{10}$$

saying that the conditional expectation of the rate of return on the asset equals a constant independent of the conditioning set (Samuelson 1965, 1970). Here r_t is defined in (1); use of the same notation for the interest rate above and the rate of return on any asset here reflects the fact that under certainty the return on any asset equals the interest rate. This strong restriction provides the basis for most empirical tests of what has been called 'capital market efficiency' (Fama 1970; LeRoy 1989): if (10) is true, no information publicly available at t should be correlated with the rate of return on the asset from t to t + 1. In this sense prices 'fully reflect' all publicly available information.

The present value relation may also be interpreted from the vantage point of its martingale implication: if the asset is priced according to (9), the value x_t of a mutual fund which holds the asset and reinvests all of its dividend income will follow a martingale with drift, defined by

$$E_t(x_{t+1}) = (1+\rho)x_t. \tag{11}$$

To see this, assume that the mutual fund holds h_t shares of the asset so that

$$x_t = h_t p_t \text{ and } x_{t+1} = h_{t+1} p_{t+1}. \tag{12}$$

When dividend income is reinvested, h_{t+1} is given by the value that solves

$$h_{t+1} p_{t+1} = h_t \left(p_{t+1} + d_{t+1}\right). \tag{13}$$

Then

$$\begin{aligned} E_t(x_{t+1}) &= E_t\left(h_{t+1} p_{t+1}\right) \\ &= h_t E_t\left(d_{t+1} + p_{t+1}\right) = x_t(1+\rho). \end{aligned} \tag{14}$$

Here we used (1) and (10). To see that the correction for dividends payout is needed, observe that (10) implies that

$$\rho = \frac{E_t(d_{t+1})}{p_t} + \frac{E_t\left(p_{t+1}\right)}{p_t} - 1, \tag{15}$$

so that changes in the expected dividend yield are always offset one-for-one by changes in the expected rate of capital gain. If p_t by itself were a martingale the expected rate of capital gain would be a constant, implying that p_t is a constant multiple of expected dividends. But this is not an implication of the present value relation (take dividends as given by a first-order autoregressive process, for example). Hence p_t by itself does not follow a martingale.

The present value–martingale model appears in many contexts in finance. If a futures price is assumed equal to the conditional expectation of the relevant spot price, then the futures price will follow a martingale (Samuelson 1965). If owners of an exhaustible resource like petroleum extract it at optimal rates, then in some settings the price of reserves will appreciate according to a martingale with drift equal to the interest rate. Finally, the expected present value relation has implications for the volatility of asset prices. Informally, the expected present value relation implies that stock prices are like a moving average of the dividend stream to which they give title. Since a moving average is smoother than its components, it follows that stock prices should show less volatility than dividends. Volatility tests along these lines were originally reported by Shiller (1981) and LeRoy and Porter (1981). A number of subsequent papers extended and criticized the finding of excess volatility.

Equation (10), which requires that the conditional expectation of the rate of return does not depend on the value taken on by the conditioning variables, is very restrictive. Unlike its certainty analogue (1), which reflects only the assumption of zero transactions costs, (10) constitutes a strong restriction on the equilibrium probability distribution of the endogenously determined stock prices – much stronger than anything implied by the idea of capital market efficiency alone. The question becomes: what restrictions on preferences and the production technology are needed to derive (10)? LeRoy (1973) showed that, if agents are risk neutral, then in an exchange economy (10) will be satisfied (see also LeRoy 1982, for discussion in a more general setting). The result is a consequence of the obvious fact that if agents are risk neutral they will ignore moments in the distribution of rates of return higher than the first. Under nonzero risk aversion, however, the conditional expected rate of return will contain a risk premium which generally depends on the realizations of the conditioning variables. Hence (10) will generally not be true. LeRoy (1973) and Lucas (1978) discussed a class of models in which the expected present value property fails except as a special case.

If the assumption of risk neutrality is relaxed, the valuation equations must be changed. This can be achieved either by modifying the characterization of expected cash flows or by respecifying the discount factor. Modifying the characterization of expected cash flows involves distorting (relative to natural probabilities) the probability measure used to take expectations so as to put greater (lesser) weight on states in which agents have high (low) marginal utility. Such distorted probabilities always exist in the finite case, and exist under weak assumptions generally. When these ‘risk-neutral probabilities’ are used to compute expectations, security prices equal expected payoffs discounted at the interest rate, just as under risk neutrality (hence the name).

Alternatively, one can retain the natural probabilities but adjust the discount factor to allow for risk aversion. Under the capital asset pricing model, the risk premium on any security or portfolio is proportional to a beta coefficient, which equals the regression coefficient of the security’s return on that of the market portfolio. The constant of proportionality is the risk premium on the market portfolio. The idea is that risk-averse agents require high expected returns on high-beta securities since such securities increase portfolio risk on the margin.

Rational Bubbles

To return to the certainty case, if the rate of return on an asset is constant at ρ but the convergence condition

$$\lim_{n\to\infty}(1+\rho)^{-n}p_{t+n}=0 \tag{16}$$

is not satisfied, then asset prices are characterized by a rational speculative bubble. For a nontechnical introduction to rational bubbles, see LeRoy (2004). The asset’s price is higher than the present value of the stream of dividends the asset is title to, but nonetheless investors are willing to hold the asset because its price is expected to rise in the future. The definition of speculative bubbles under uncertainty is analogous (whether speculative bubbles exist or not has nothing directly to do with uncertainty). If speculative bubbles can occur, the present value Eq. (6) must be generalized to

$$p_t=\sum_{i=1}^{\infty}(1+\rho)^{-i}d_{t+i}+\gamma(1+\rho)^t, \tag{17}$$

where γ is an arbitrary non-negative constant capturing the magnitude of the speculative bubble. Equation (17) is the class of solutions to the difference equation

$$\rho=\frac{(d_{t+1}+p_{t+1})}{p_t}-1, \tag{18}$$

where γ is the constant of integration ($\gamma \geq 0$ results from the requirement that asset prices be always non-negative, a consequence of free disposal). In the special case $\gamma = 0$ speculative bubbles are absent and the present value relation results.

Bubbles cannot occur on a security that has a payoff only at one date, such as a zero-coupon bond. By induction, the same is true of securities that have payoffs at a finite number of dates. Existence of a bubble on such assets would imply an arbitrage opportunity: investors could sell the security short and purchase claims for its payoff at a cost equal to the present value of those payoffs. In the case of securities with payoffs at an infinite number of dates, it may or may not be possible to rule out bubbles on theoretical grounds. A few of the many papers dealing with this question are Tirole (1985), Gilles and LeRoy (1992a, b), Santos and Woodford (1997) and Huang and Werner (2000).

Present Value of the Past

Charles Wolf Jr.

One of the seminal ideas in economics is that future events have a present value, which is calculable through a private or social rate of discount. Nevertheless, present valuation is not of much help for solving some problems, and can lead to erroneous results in others. For these problems, it is as important to have a method for evaluating the past as the future.

The Heuristics of Past Valuation

Economists usually view the past as concluded, and inert. It is not. At issue is both the unreliability of memory, and the influence of present actions on what is remembered. To explain important classes of events, and predict others, requires a change in the usual perspective.

Three premises underlie the present valuation of the past (Wolf 1970). The first is that prior events enter as arguments in the utility of various individual and institutional actors. Individuals and organizations are not only forward-looking maximizers, but backward-looking maximizers (or minimizers, where regret is concerned).

The second premise is that the aggregation of prior events may be likened to a process that employs a backward-looking discount rate, or ‘decay rate’. Various empirical proxies exist for measuring decay rates.

Thus, the stream of prior events that affects utility is subject to attrition in recall, and this attrition is reflected in the decay rate. The decay rate may also be negative: events from the past may wax, rather than wane, in recollection.

The third premise is that the decay rate may be affected by present actions. For example, a current event may increase or decrease the vividness with which a prior event is recalled (corresponding, respectively, to a decrease or an increase in the decay rate). Revisiting a place or a person, or confronting a new situation containing familiar characteristics, can have this effect. Hence, actions taken in the present, which may increase utility with respect to arguments having a present or future subscript, may diminish utility with respect to arguments that have a past subscript, and vice versa.

Modeling the Present Value of the Past (PVP)

The process of present valuation of the past may be clarified by a simple structural model (Wolf 1970). (1) A utility function expressing current welfare, U_t, as a function of current income, Y_t, and the present value of a set of prior events, $\tilde{V}_t$. Y_t can also be viewed as the present value of future income discounted to the present in the usual manner, $\tilde{V}_t$ is often associated with status, reputation, and self-esteem. (The utility function is thus similar to games that combine status and welfare (Shubik 1975).) (2) A function that specifies the present value of prior events, $\tilde{V}_t$ in terms of their values at the time of their original occurrence, *V,* mediated to the present by the decay rate, r^*. (3) A decay rate function, expressing r^* as a function of a particular choice, *i,* among a set of *n* feasible policies, P_{ti}, for *changing* income in period *t*. (4) An income growth equation (associated with (3) above), which specifies $\dot{Y}_t$ as depending on the policy choice P_{it}. (5) An income identity defining current income as prior income Y_{t-1}, plus the income change, $\dot{Y}_t$.

Some Examples of PVP: Sunk Costs and Social Inequities.

Sunk Costs

According to a familiar economic theorem, sunk costs should not influence decision, only marginal costs. To the ordinary person's complaint ('prior costs really do matter'), the usual response is either an evasion ('people are just irrational'), or a tautology (marginal costs can be redefined to include pain associated with an otherwise preferred choice because of its connection with prior events). Present valuation of the past provides a more satisfactory explanation.

The sunk costs example applies to many situations in which present action is influenced by a desire to preserve a present benefit whose magnitude is indicated by the scale of prior (sunk) *costs*.

A classic example is provided by Agamemnon's stratagem for persuading the Greeks to preserve in the Trojan wars by pointing out that withdrawal would cause dishonour to those whose lives had already been lost (Homer, *Iliad*).

If two alternative actions have the same expected yield but the decision maker has previously expended resources on one, which will (should) he choose? The descriptive answer is easy; the normative answer involves more elusive considerations of prestige, credibility, and the desire for personal vindication, which can be readily related to PVP. When the yields are not equal, the proper analytic precept is not to choose the higher, but rather to show exactly how much higher it is, so that this margin, ΔY_t, can be compared with the possible loss of other (prior) values, $\Delta \tilde{V}_t$, in arriving at a utility-maximizing choice.

PVP also applies to a familiar phenomenon sometimes associated with ageing. People often find it tolerable, or even gratifying, to acknowledge their currently inadequate performance if they can thereby claim that it contrasts with their superior performance in prior years ('You should have seen me ten years ago!').

People seem to normalize for time in relation to their past, which they have accumulated in different amounts. One implication for the PVP model is that an increase in current income, *Yt,* may seem smaller in relation to changes in the decay rate, r^*, and to the present value of the past, $\tilde{V}_t$ the older a person is. People who have lived longer simply have more sunk costs tied up in PVP, and changes in the decay rate are therefore relatively more important to them than changes in current income.

The Negative Present Utility of Past Injustice

Over a century ago, de Tocqueville posed a well-known paradox based on his studies of the French Revolution (de Tocqueville 1856). De Tocqueville's paradox can be formulated in more general terms: Why is it that improvements in welfare and in social justice often intensify resentment and unrest?

In this case, PVP is the discounted aggregate of prior costs or injuries. It is likely to be a heavily weighted argument in the utility functions of these who believe they have been previously exploited.

As with sunk costs, the choice of a policy, P_{ti}, for influencing present income affects the present value of the past by changing the decay rate, r^*. If a rise in current income lowers the decay rate, the sense of past injustice becomes more vivid and painful, and the negative present utility of prior inequalities is thereby magnified.

Thus, it is not necessarily the largest positive change in current income, $\dot{Y}_t$ that will make the biggest positive contribution to utility. A lower $\dot{Y}_t$ may be preferable because it does not lower the decay rate (and hence, the present value of the past), as much. Moreover, there may be no current incomes policy which in fact raises utility. The choice may be between allowing current income to stagnate, or raising current income, but actually lowering utility (hence, resentment and violence) if utility is to be raised at some future time.

Pretesting

Jan R. Magnus

Abstract

This article briefly discusses the meaning and dangers of pretesting in estimation procedures. It outlines the proof of the equivalence theorem, and compares the pretest estimator with three other estimators: the 'usual' estimator, the 'silly' estimator and the 'Laplace' estimator.

Model Selection Versus Estimation

Suppose data are generated by a linear relationship

$$y = X\beta + \gamma z + u, \quad u \sim N\left(0, \sigma^2 I_n\right), \qquad (1)$$

where X is an $n \times k$ matrix of explanatory variables and z is an additional $n \times 1$ vector of explanatory variables. In our role as investigator we do not know this relationship. Our interest is in the effect of X on y, that is, we want to estimate β. Since we don't know that y is generated by (1), we formulate a model that will serve as a vehicle to estimate β. Let us assume that we know that the relationship is linear, that X is certainly in the model, and that z is perhaps in the model. For simplicity we assume also that σ^2 is known. Thus our 'model space' consists of only two models: the unrestricted model (where $\gamma \neq 0$) and the restricted model (where $\gamma = 0$).

Our interest could be in finding the 'true' model, in which case we are concerned with *model selection*. In that case we should select the unrestricted model, however small γ turns out to be. Our interest, however, is in the *estimation* of β and the model is not of interest *per se* – it is only a means towards our goal. Even if we knew that γ is nonzero, this would not necessarily mean that we should include z in our regression. This is because, if γ is close to zero, a small bias in the estimates of β will result if we use the restricted model, but their variances may increase substantially, and hence the mean squared error will also increase substantially. (Recall that the bias depends on the value of γ but the variance does not.) So even if we know the truth, it is typically wise to simplify for the purposes of estimation.

What Is Pretesting?

The ordinary least squares (OLS) estimator for β in the restricted model is of course

$$b_r = (X'X)^{-1}X'y. \tag{2}$$

If we define

$$M = I_n - X(X'X)^{-1}X', q = \frac{\sigma}{\sqrt{z'Mz}}(X'X)^{-1}X'z,$$
$$\theta = \frac{\gamma}{\sigma/\sqrt{z'Mz}},$$

then we can write the OLS estimators for β and γ in the unrestricted model as

$$b_u = b_r - \hat{\theta}q, \quad \hat{\gamma} = \frac{z'My}{z'Mz}, \tag{3}$$

where

$$\hat{\theta} = \frac{\hat{\gamma}}{\sigma/\sqrt{z'Mz}} = \frac{z'My}{\sigma\sqrt{z'Mz}} \sim N(\theta, 1) \tag{4}$$

denotes the t-ratio, which is normally distributed in this case because σ^2 is assumed known. We call θ the *theoretical* t-ratio.

Since we don't know which of the two models we should use in order to estimate β, the typical econometric practice is to perform a preliminary test (pretest) on γ, and to include z in our regression if the t-ratio $\hat{\theta}$ is 'large' and exclude it if $\hat{\theta}$ is 'small'. This leads to the so-called *pretest estimator*

$$b = \begin{cases} b_r & \text{if} \quad \left|\hat{\theta}\right| \leq c, \\ b_u & \text{if} \quad \left|\hat{\theta}\right| > c, \end{cases} \tag{5}$$

where c is some positive number such as 1.96. We can also write (5) as

$$b = \lambda b_u + (1-\lambda)b_r, \quad \lambda = \begin{cases} 0 & \text{if} \quad \left|\hat{\theta}\right| \leq c, \\ 1 & \text{if} \quad \left|\hat{\theta}\right| > c, \end{cases} \tag{6}$$

which emphasizes that the pretest estimator is a weighted average of the estimators in the available models. The weights, however, are random variables because they depend on $\hat{\theta}$ The pretest estimator is therefore a complicated nonlinear estimator.

The problem with pretesting is not so much that people do it, but that they ignore the consequences. In typical econometric practice, model selection takes place using t-ratios and other diagnostics, after which a single model is selected (stage 1). Then estimates and standard errors are obtained in the selected model (stage 2), and these are reported. It is then tacitly assumed that the reported estimates are unbiased and that their standard errors are given by the usual OLS formulae. This assumption, however, is incorrect. The estimates are biased and their standard errors are not given by the usual OLS formulae. This is the pretest problem.

The Equivalence Theorem

Things are made simpler by the equivalence theorem, originally proved by Magnus and Durbin (1999), and improved and extended by Danilov and Magnus (2004a).

Theorem 1 (Equivalence Theorem) Let $b = \lambda b_u + (1 - \lambda)b_r$, where $0 \leq \lambda \leq 1$ and $\lambda = \lambda(My)$.

Then, letting $\widetilde{\theta} = \lambda\hat{\theta}$, we have

$$E(b) = \beta - E\left(\widetilde{\theta} - \theta\right)q, \mathrm{var}(b) = \sigma^2(X'X)^{-1} + \mathrm{var}\left(\widetilde{\theta}\right)qq'$$

and hence

$$MSE(b) = \sigma^2(X'X)^{-1} + MSE\left(\widetilde{\theta}\right)qq'.$$

Proof

We know from (3) that $b_u = b_r - \hat{\theta}q$, so that

$$b = \lambda b_u + (1 - \lambda)b_r = b_r - \lambda\hat{\theta}q = b_r - \hat{\theta}q.$$

The crucial ingredient is that b_r and My are independent, so that

$$E(b_r|My) = E(b_r), \quad \mathrm{var}(b_r|My) = \mathrm{var}(b_r).$$

Also, since both λ (by assumption) and $\hat{\theta}$ as given in Eq. (4) depend only on My, we see that $\hat{\theta} = \lambda\hat{\theta}$ depends only on My. Hence,

$$E(b|My) = E(b_r) - E\left(\hat{\theta}|My\right)q = \beta + \theta q - \widetilde{\theta}q$$
$$= \beta - \left(\widetilde{\theta} - \theta\right)q$$

and

$$\mathrm{var}(b|My) = \mathrm{var}(b_r|My) = \mathrm{var}(b_r)$$
$$= \sigma^2(X'X)^{-1}.$$

Now using the well-known relationships between conditional and unconditional moments, we obtain

$$E(b) = E(E(b|My)) = \beta - E\left(\widetilde{\theta} - \theta\right)q,$$

and

$$\mathrm{var}(b) = E(\mathrm{var}(b|My)) + \mathrm{var}(E(b|My))$$
$$= \sigma^2(X'X)^{-1} + \mathrm{var}\left(\widetilde{\theta}\right)qq',$$

and hence

$$\begin{aligned} MSE(b) &= \mathrm{var}(b) + E(b - \beta)(b - \beta)' \\ &= \sigma^2(X'X)^{-1} + \mathrm{var}\left(\widetilde{\theta}\right)qq' \\ &\quad + \left(E\left(\widetilde{\theta} - \theta\right)\right)^2 qq' \\ &= \sigma^2(X'X)^{-1} + MSE\left(\widetilde{\theta}\right)qq'. \end{aligned}$$

This completes the proof. ||

The equivalence theorem is important because it tells us that if we have a 'good' estimator for θ, say $\widetilde{\theta}$, then this defines $\lambda = \widetilde{\theta}/\hat{\theta}$ and *the same* λ will provide a good estimator for β, namely $b = \lambda b_u + (1 - \lambda)b_r$. The pretest estimator chooses

$$\widetilde{\theta} = \begin{cases} 0 & \text{if} \quad \left|\hat{\theta}\right| \leq c, \\ \hat{\theta} & \text{if} \quad \left|\hat{\theta}\right| > c, \end{cases}$$

which is not a good choice as we shall see.

Moments of the Pretest Estimator

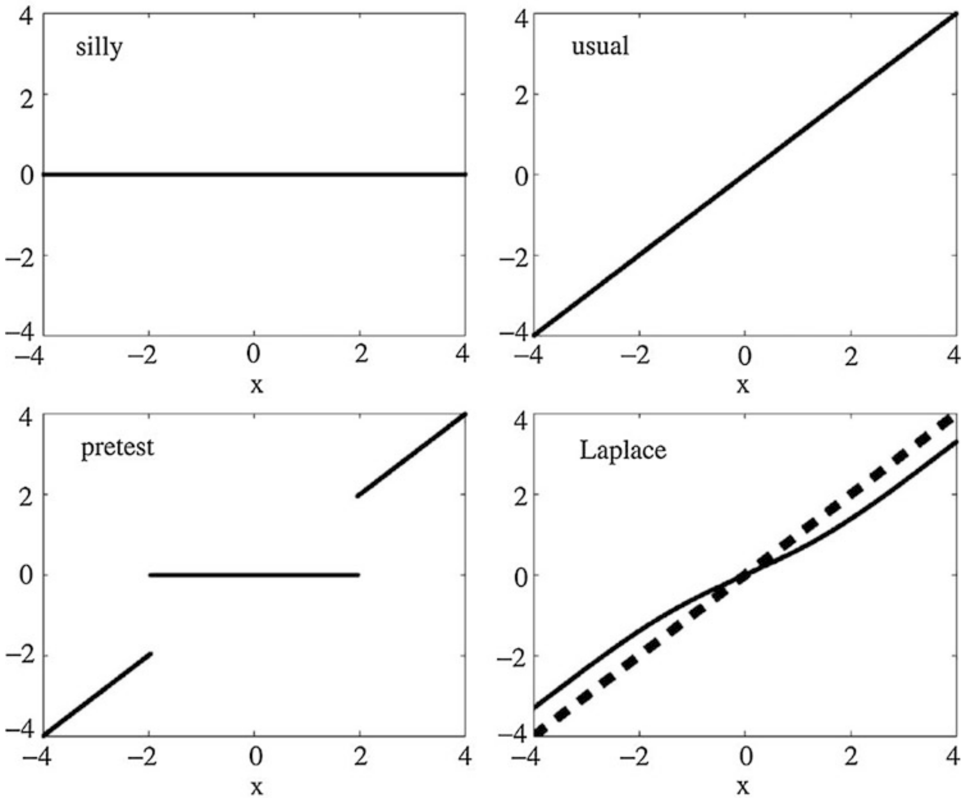
In the previous section we have seen that the pretest estimator is, in essence, of the form

$$t(x) = \begin{cases} 0 & \text{if} \quad |x| \leq c, \\ x & \text{if} \quad |x| > c, \end{cases} \tag{7}$$

where $x \sim \mathrm{N}(\theta, 1)$. When studying this estimator, we confront it with three other estimators: the 'usual' estimator $t(x) = x$, the 'silly' estimator $t(x) = 0$, and the 'Laplace' estimator introduced in Magnus (2002). The four estimators are graphed in Fig. 1 for $|x| < 4$.

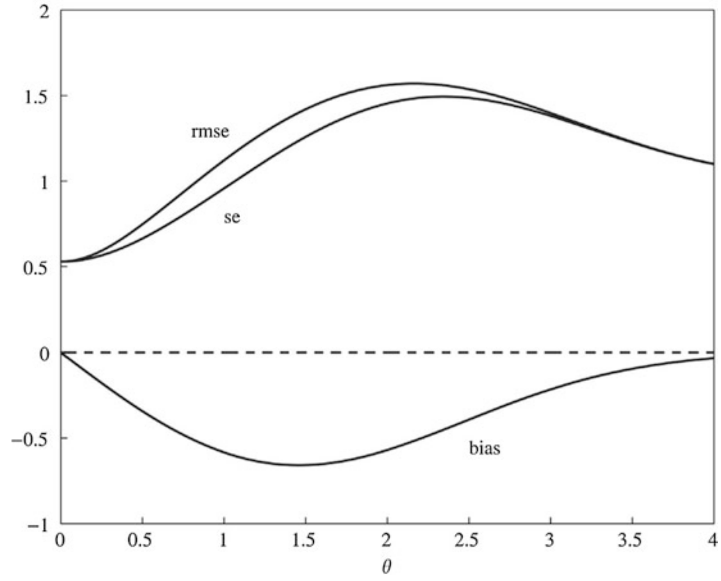
It is clear that the pretest estimator is discontinuous, hence inadmissible. But this is only one of its uncomfortable properties.

Theorem 2 (Moments of Pretest Estimator) Let $x \sim \mathrm{N}(\theta, 1)$ and let $t(x)$ be the pretest estimator defined in (7). Then,



Pretesting, Fig. 1 Four estimators $t(x)$ of θ

Pretesting, Fig. 2 Moments of the pretest estimator



$$E(t-\theta) = \phi(c-\theta) - \phi(c+\theta) - \theta P$$

and

$$E(t-\theta)^2 = 1 + (c+\theta)\phi(c+\theta) + (c-\theta)\phi(c-\theta) + \left(\theta^2 - 1\right)P,$$

where ϕ denotes the standard-normal density and $P = \int_{-\theta-c}^{-\theta+c} \phi(u)du.$

Proof
Letting $S = \{u : -\theta - c < u < -\theta + c\}$, we have

$$\begin{aligned} &E\,(t(x)) \\ &= \int_{-\infty}^{\infty} t(x)\phi(x-\theta)dx = \int_{|x|>c} x\phi(x-\theta)dx \\ &= \theta - \int_{|x|<c} x\phi(x-\theta)dx \\ &= \theta - \int_S (u+\theta)\phi(u)du \\ &= \theta - \int_S u\phi(u)du - \theta\int_S \phi(u)du \\ &= \theta + [\phi(u)]_S - \theta P = \theta + \phi(-\theta + c) \\ &-\phi(-\theta - c) - \theta P, \end{aligned}$$

using the fact that $\phi'(u) = -u\phi(u)$. Similarly, using the fact that $\phi''(u) = (u^2 - 1)\phi(u)$, we obtain the second result. ||

The bias, standard error and root mean squared error of the pretest estimator are graphed in Fig. 2.

We see that the bias is relatively small compared with the standard error. Since $bias(-\theta) = -\,bias(\theta)$ (so that θ and $bias(\theta)$ have opposite signs), and since we know from Theorem 1 that $bias(b_i) = -bias\left(\widetilde{\theta}\right)q_i$, we can determine the direction of the pretest bias.

Theorem 3 (Sign of Pretest Bias) Let $w := (X'X)^{-1}X'z$ with components w_i $(i = 1, \ldots, k)$. Then the pretest bias of b_i is positive (that is, $E(b_i) > \beta_i$) if and only if $\gamma_i w_i > 0$. As a consequence we can estimate the sign of the pretest bias of b_i by $sign(w_i\hat{\gamma}_i)$.

For purposes of exposition we have concentrated on the simplest case, but considerable generalization is possible to more than one additional z-variable, to unknown σ^2, and to general variance matrix.

Alternatives

We now compare the pretest estimator with the four estimators in Fig. 1. We graph the root mean squared error (RMSE) of each of the four estimators in Fig. 3.

The ‘usual’ estimator is unbiased and has variance one, independent of the value of θ. The ‘silly’ estimator is obviously better when θ is close to zero, the two estimators have the same RMSE when $\theta = 1$, corresponding to the fact that

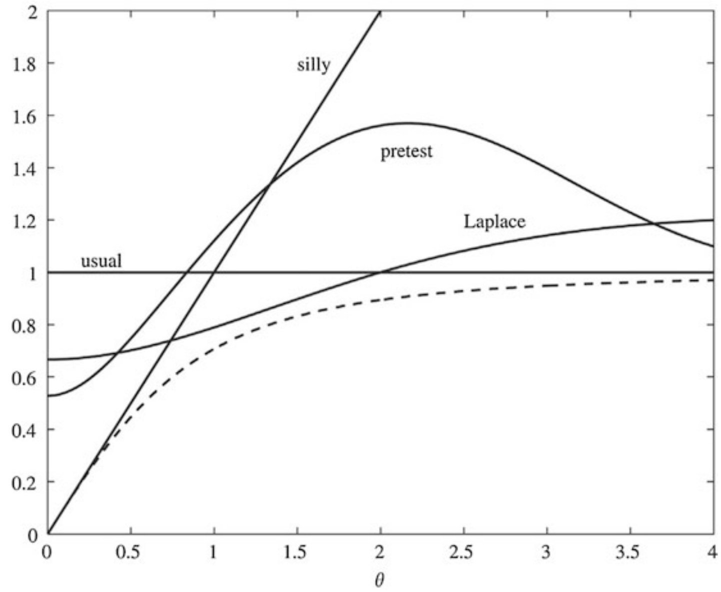
$$MSE(b_r) - MSE(b_u) = \left(\theta^2 - 1\right)qq',$$

but the RMSE of the ‘silly’ estimator is unbounded. The pretest estimator lies in-between the silly and the usual estimator, except in the important interval around $\theta = 1$ where the pretest estimator is *worse* rather than better than either of the two naive alternatives. This is a most unwelcome property of the pretest estimator, and it has given rise to thought about alternatives. An attractive alternative is the so-called Laplace estimator, which has a Bayesian and a non-Bayesian interpretation, is admissible, is based on a ‘neutral’ prior, and has good properties around $\theta = 1$. The dotted line $|\theta|/\sqrt{1+\theta^2}$ denotes the theoretical lower bound of the root mean squared error.

History

The implications of model selection on the estimators of the parameters of interest were already being discussed following Tinbergen’s (1939) study for the League of Nations. Both Keynes

Pretesting, Fig. 3 Root mean squared error of the four estimators



(1939) and Friedman (1940), in their respective critiques on Tinbergen, focused on the method of model selection when the estimation procedure repeatedly uses the same data to discriminate between plausible competing theories. The same point was made in Haavelmo (1944, Section 17). Koopmans (1949) suggested that a completely new theory of inference was required to solve the dilemmas implied by the model selection problem.

Early work on the pretest estimator includes Bancroft (1944, 1964), Huntsberger (1955), Larson and Bancroft (1963), Cohen (1965), Wallace and Ashtar (1972), Sclove, Morris and Radhakrishnan (1972), Bock, Yancey and Judge (1973b), and Bock, Judge and Yancey (1973a). The harm of ignoring the effects of pretesting was analysed by Danilov and Magnus (2004a, b). Important surveys are provided by Judge and Bock (1978, 1983), Judge and Yancey (1986), Giles and Giles (1993), and Magnus (1999).

Price Control

John Kenneth Galbraith

Abstract

In modern times price control has been used to keep down food prices, as part of prices and incomes policies, in wartime economic management, to help governments win elections, and to tackle inflation. Along with macroeconomic restraint and specific commodity restraint by rationing, price controls used by the Allies in the Second World War succeeded in countering inflation. The ineffectiveness of price control in Latin America has helped give it a bad name. There are radically different forms of controls in greatly differing contexts; price control should be seen as a diversely applicable policy, sometimes advisable, sometimes not.

The fixing of prices by public action is of exceedingly ancient origin; popular economic cliché associates it with the Edict of Diocletian, and economic history dwells at length on the controls exercised and imposed by the medieval guilds. Only in modern times, roughly the last 200 years, has it fallen under the general disapproval and interdict of orthodox economic attitudes and has it been seen therein as a temporary or aberrant departure from free-market principles.

In a more adequate view, controls have not one but several forms, some of which are, in their context, a reflection of necessary and appropriate policy, as other designs in other contexts are not.

Specifically, some five employments of price controls can be identified, apart from public-utility and like regulation which reflects the different and largely accepted need to maintain a public surveillance and restraint on natural or legislated monopoly power. There is:

(1) The use of controls to address particular wartime pressures of demand on supply, as in the

United States and other countries in World War II, and to keep down the price of food for urban dwellers, as now in African countries and elsewhere. These can perhaps be called episodic or casual controls.

(2) The use of controls as part of what has come to be called a prices and incomes policy. They here act on the specific problem of wage/price inflation.

(3) The use of controls as part of a comprehensive exercise in wartime economic management, backed by rationing of consumers' goods, allocation of materials and labour and a general restraint on aggregate demand.

(4) The use of controls as a highly temporary expedient to get by an election.

(5) The use of controls in the face of an enduring inflationary movement propelled by a persisting excess of aggregate demand, as recently in Latin America and of late in Israel.

Two of the above employments of controls – to limit the wage/price dynamic and as an adjunct to a comprehensive mobilization of economic resources, as in World War II – have modern policy relevance. In the highly organized modern economy of strong corporations and viable and effective trade unions, price inflation can come from the microeconomic effect of prices and living costs on wages and of wage demands on prices. Much recent experience shows that this wage/price dynamic can be arrested by conventional monetary or fiscal action only by the restraining force of substantial unemployment on wage demands and much idled plant capacity on prices. In other words, conventional monetary and fiscal policy arrest wage/price inflation only as they cause a recession or depression.

Accordingly, attention has focused on direct restraint by the state. Avoiding the unduly blunt reference to wage and price controls, this has come to be called 'an incomes and prices policy'. Austria, Germany, Japan and other industrial countries have, formally or informally, resorted extensively to such restraints. The English-speaking countries and their economists, businessmen and unions have been more reluctant.

Market forces must not be impaired. Still, by a growing minority such restraints are viewed as a necessary alternative to economically and politically more painful designs for restraining wage/ price inflation. There continue to be repetitive suggestions that such intervention distorts the market allocation of resources. Mention is not made of the way that strong unions and strong corporations in the modern economy have already invaded resource-allocation procedure and accommodated it to their purposes.

A more serious problem lies outside the field of economics. Where fiscal and monetary restraints need only a negligible administrative apparatus, any effective form of price and wage control requires a substantial administrative one. And, of course, the public intervention to limit price or wage increases is highly visible. Thus it invokes the ever-present suspicion or dislike of government intervention and bureaucracy. Fiscal and monetary action, even when more painful in overall effect, encounters far less resistance.

The second acceptable form of controls was the comprehensive design used in all of the industrial countries in World War II. In combination with macroeconomic restraint on demand by fiscal policy and specific commodity restraint by rationing, such controls successfully countered the threat of price inflation in Britain, the United States, Canada and other participants in those years. In the case of non- rationed non-essentials, the controls substituted shortage or non-availability for rationing by price. Some evasion of controls by black market operations was present, but this, though greatly publicized and deplored, was, in general, relatively limited.

Once controls were fully in place in the United States, price increases were nominal, and, overall, there is no memory of inflation from the war years. Increases then or following the removal of controls were insignificant as compared with the double-digit inflation, as it was called, of the 1970s.

The circumstances, especially in the United States during World War II, were, however, exceptionally and perhaps uniquely favourable for successful use of price controls. After ten years, depression had come to be considered by the early 1940s a normal and inevitable peacetime phenomenon. Accordingly, after the war, unemployment and associated hardships would recur. From this came a powerful incentive to save – to save, among other reasons, for the cars and others durables that would only later be available. Labour, in effect, was employed against the promise of future consumption. At the same time there was in the United States the large increase in the supply of non-durables as previously unemployed plant and labour were drawn into production. Overall civilian consumption increased, and this further reduced the pressure of demand on the controls. A similar *general* use of controls following a period of high employment and serious or even incipient inflation with associated expectations would be a far more difficult matter.

Of the other uses of controls there is less to be said. Isolated or piecemeal controls (in contrast with a broad-based incomes and prices policy) can, indeed, have the effect of diverting resources from the area of control and into uncontrolled and thus more remunerative employments. This has been a consequence of one of the more persistent manifestations of isolated or piecemeal controls, that of rents. Its yet more serious manifestation has been in the poor countries, notably of Africa. There the use of price controls to keep down food costs has been an important contributing cause of the food distress and famine.

Controls in the face of a massive excess of demand have been a frequent resort in Latin America. A case can be made for such action to alter expectations, themselves a cause of inflationary pressures of demand, before instituting strong macroeconomic restraints. More frequently, such controls have been a separate and often desperate response to demand-induced inflation. The resulting evasion, ineffectiveness and eventual collapse have contributed notably to the poor reputation of controls in general.

In 1971–3, President Richard Nixon used general controls with great effect to suppress wage–price inflation and allow of companion fiscal and monetary support to employment. Largely, if not principally, in consequence, he carried every state but Massachusetts and the District of Columbia in the election of 1972. Such success for controls must, however, be accounted for and judged in the field of politics, not economics. The removal of the controls after the election restored with some precision the circumstances that had led to their being involved with a strong recurrence of inflation.

A common tendency of orthodox economics has been to deal with all forms of price control as a homogeneous exercise. This, it will be evident, is a grave oversimplification. In fact, there are radically different forms of controls in greatly differing contexts. Reasonable and, indeed, necessary sophistication requires that these differences be recognized, that price control be seen as a diversely applicable policy, sometimes greatly advised, sometimes wholly the reverse.

Price Discrimination

Louis Phlips

Price discrimination is as common in the market place as it is rare in economics textbooks. It appears under many disguises and explains a large number of business practices which are difficult to rationalize otherwise. Its ubiquity results from the fact that there is price discrimination whenever two varieties of a commodity are sold (by the same seller) to two buyers at different *net* prices, the net price being the price (charged to the buyer) corrected for the cost associated with what differentiates one variety from another. Transportation and storage costs are examples that readily come to mind. Costs of product design and of services offered by distributors are less obvious examples (as is the cost associated with demand uncertainty). Given such costs, there is no price discrimination when these costs are fully reflected in the prices. Price discrimination typically implies that part of these costs is 'absorbed': delivered or future prices increase by less than the cost of carrying the good over space or time; models of better quality are sold at a better price–quality ratio; better service is not fully charged. Alternatively, a product or service produced at the same cost is offered at a price that decreases as the quantity bought increases.

This type of pricing is profit maximizing when the seller has some monopoly power, the opportunity to sell in several sub-markets and therefore the possibility of maximizing overall profits (rather than maximizing profits separately in each region, in each time period, or for each particular product specification). It works only to the extent that (a) arbitrage (i.e. transfers of commodities between sub–markets) is impossible or costly; (b) customers can be sorted according to the intensity of their demand; and (c) their demands are in fact different. When these conditions are met, a discriminating price policy is more profitable than a nondiscriminating one: if you can price discriminate, it is always profitable to do so. The reason is simple. Compared with a uniform price, discriminating prices are not only closer to the highest price a particular customer is ready to pay (his 'reservation price'): they also make it possible to serve customers who would not be able to buy at the uniform price or to induce them to consume more than they would otherwise.

Pigou (1920, pt. 2, ch. 17) makes a useful distinction between three types of price discrimination. *First-degree* discrimination 'would involve the charge of a different price against all the different units of commodity, in such wise that the price exacted for each was equal to the demand price for it, and no consumers' surplus was left to the buyers' (p. 279). *Second-degree* discrimination is an approximation to perfect discrimination. It obtains when a firm is able to make n separate prices such that all units with a reservation price greater than p_1 are sold at the price p_1, all with a reservation price less than p_1 and greater than p_2 at a price p_2, and so on.

Buyers are separated into n groups and there is one (identical) price per group, so that some buyers have a consumers' surplus. All buyers with a reservation price greater than p_n are served. *Third-degree* discrimination would obtain if the monopolist were able to distinguish among his customers n different groups, separated from one another more or less by some practicable mark, and could charge a separate monopoly price to the members of each group . . ..This degree, it will be noticed, differs fundamentally from either of the preceding degrees, in that it may involve the refusal to satisfy, in one market, demands represented by demand prices in excess of some of those which, in another market, are satisfied (p. 279).

While second-degree discrimination refers to individual reservation prices for one unit of a commodity, third-degree discrimination refers to sub-market demand curves. Let there be three adjacent spatial sub-markets with different demand curves and let \$90, \$95, and \$100 be the three profit maximizing delivered prices. Suppose the transportation cost per unit from one sub-market to the next (and back) is \$10 (so that there is freight absorption). This is third-degree price discrimination, since buyers located in the market with demand prices smaller than $100 but higher than $95 are unable to buy anywhere, the cost of transportation being prohibitive. The same is true for buyers located in the second market with demand prices lower than $95.

First- and Second-degree Price Discrimination

First-degree price discrimination is often, understandably, called ‘perfect’. On the one hand, it is the most profitable form of discrimination, since it extracts the entire consumer surplus. On the other hand, each buyer is able to buy the product he or she wants to buy and reveals the value of the product by paying the highest price he or she is ready to pay.

In real life, frequently used techniques are to bargain reductions in prices or in carrying costs. (One possible result is that higher rates may be charged for carrying passengers or freight over a short distance than over a long distance – see Friedman 1979.) Another commonly used practice is to offer a two-part tariff. Such tariffs are feasible when the product cannot be resold at a reasonable cost among consumers – a requirement met by most service industries. They are easy to implement when a connection or entrance fee (the first part) can be charged in addition to price per unit consumed (the second part).

The economics of two-part tariffs can best be understood with reference to the pricing policy of an amusement park such as Disneyland. In his seminal paper, Oi (1971) showed that the best way to extract the entire consumers’ surplus is to charge the highest possible entrance fee to each visitor and thus to discriminate at the entrance gate, with the implication that the price of a ride inside the amusement park should be set equal to its marginal cost – since the surplus cannot be extracted twice from the same visitor. Such a two-part tariff is Pareto optimal. In practice, it is approximated by charging *n* different entrance fees to *n* different groups of visitors: discounts are granted to senior citizens, groups, military, children, etc.

Block tariffs such as those charged by public utilities for the supply of electricity, gas, water, etc. often take the form of a series of two-part tariffs, the total expenditure on a first block being the entrance fee to the next (cheaper) block. Consumers are free to decide which block they want to be in (by adjusting their consumption) and thus reveal how much they are ready to pay.

In fact, each consumer ends up paying a different average price depending on the quantity consumed. Prices are quantity dependent or ‘non-linear’ and decrease with the quantity consumed. Defining ‘reservation outlays’ (the maximum amount a consumer in a given income class is ready to pay for a given number of units of the good) as increasing functions of income, Spence (1977, 1980) is able to show that a profit-maximizing seller will extract the entire surplus from the lowest income class and proportionally less as income increases (in order to persuade the richest customers to buy the largest quantities) but will provide the optimal quantity to the richest customers. When quantities are replaced by qualities, similar conclusions arise (Phlips 1983, ch. 14). On using reservation prices (per income class) for purchase in a particular time period, the same analysis leads to the conclusion that the richest customer, though first to buy a new product at the highest price, will keep the highest surplus while the poorest will be the last to be served with no surplus left. This is the so-called ‘skimming pricing’ (Dean 1949, pp. 419–21; Stokey 1979).

A move from a uniform price to a non-linear price can be welfare improving. Leland and Meyer (1976) and Littlechild (1975) have shown that such a move benefits consumers in the aggregate, with the gainers able to compensate those who lose. Willing (1978) and Spence (1980) show that for any price different from marginal cost, there is a change to a non-linear outlay schedule that directly benefits all consumers, without the need for transfers effected outside the market.

First and second-degree discrimination can also result from tying the sale of one good to that of another, where the first is typically a durable (a copying machine) and the second a nondurable (paper). Here it is profit-maximizing to lease the durable at a very low rental price (a very low entrance fee, in fact) to attract as many users as possible and to extract the individual surplus through a high price per copy made. When tying is impossible (e.g. because ordinary paper can be used on the copying machine), the intensity of use of the machine is measured with the help of a meter. By his or her decision on the number of copies made, each individual user reveals his or her reservation price *for the machine*! And this value is extracted via the price per copy. If the machine were sold at a uniform price, fewer consumers would be served and profits would be lower (Telser 1965, 1979). An even more subtle form of surplus extraction is to offer simultaneously two or more goods separately and in a bundle, at a special (lower) price for the bundle (Adams and Yellen 1976).

Third-degree Price Discrimination

A profit-maximizing monopolist facing *n* markets with different demand curves will set the *n* prices in such a way that marginal revenues are equal from market to market. Indeed, the *n* first order conditions form a system of equations, each of which equates the marginal revenue in a particular market to the marginal cost of production. And since this marginal cost takes a unique value (the value associated with total production), all marginal revenues must be equal to it and therefore to each other. This is the fundamental (third-degree) price discrimination rule.

In an abstract world, in which the causes of market separation are not specified, it is not possible to give a general answer to the question of whether third-degree price discrimination increases output or welfare. The discussion therefore concentrates on particular specifications of the demand curves and of the marginal cost curve. For example, Robinson (1933, bk 5) has shown geometrically – and Schmalensee (1981) has generalized this result – that if a single-price monopoly selling in two markets under constant costs is allowed to discriminate between them, total output is unchanged if both markets have linear demand curves. This result depends critically on the unrealistic assumption that markets are served under *both* regimes. When some form of product differentiation (spatial, temporal, etc.) is introduced, price discrimination typically serves to open *new* markets and thus to increase sales and welfare.

Consider a spatial monopolist serving several adjacent market areas. Marginal revenue equalization implies that only delivered prices are quoted and that part of the freight is absorbed. (If market area demands are linear, exactly one half of the cost of transportation between two points in space is absorbed (Beckmann 1976).) As a result, distant markets that would not be served under a uniform f. o.b. pricing policy can be reached.

Next consider intertemporal profit maximization by a monopolist that can produce for inventory. Commenting on Smithies' pioneering 1939 paper, Shaw (1940, p. 469) remarks:

> There is an evident parallelism between the theory of inventory accumulation and discriminating monopoly. The former defines optimum distribution of a total supply between markets that are separated in time. The latter defines optimum distribution of a total supply between markets that are separated in space. Assuming appropriate discounting of future quantities, the definitions of optima are identical . . ..

The equalization of discounted marginal revenues over time leads to price stickiness over time and normal cost pricing (Phlips 1983, ch. 6). In the special case where inventories are produced by nature in the form of a stock of exhaustible resources, intertemporal price discrimination gives Hotelling's 1931 rule: the monopoly price of an exhaustible resource increases at a rate that is smaller than the real rate of interest.

The study of Nash equilibria for markets in which oligopolists discriminate is a new area of intensive research. The emergence of more or less uniform delivered prices as the result of oligopolistic competition in space is one of the new insights provided by Greenhut and Greenhut (1975), Norman (1981) and Neven and Phlips (1985). (See also the symposium edited by Phlips and Thisse 1982.) Intertemporal price discrimination in a dynamic game is shown by Phlips and

Richard (1985) to imply stagflation when the real rate of interest is positive. These preliminary results suggest that the study of games in which oligopolists are allowed to price discriminate will lead to a better understanding of pricing as it occurs in the real world.

Price Discrimination (Empirical Studies)

Frank Verboven

Abstract

Price discrimination occurs when the prices of similar products sold by the same firm show variation that cannot be attributed to cost variation. Recent empirical work has identified the presence of both direct and indirect price discrimination, after cost-based explanations have been accounted for. Furthermore, there is increasing evidence on the sources of price discrimination. The extent of price discrimination has often been found to increase as competition intensifies, in contrast to conventional wisdom but consistent with new theoretical insights. Finally, various empirical studies have considered the effects of price discrimination on profits, consumer welfare and efficiency.

Price discrimination occurs when the prices of similar products sold by the same firm show variation that cannot be attributed to variation in marginal costs. Direct (or third-degree) price discrimination serves to exploit observed differences in consumer characteristics; indirect (or second-degree) price discrimination exploits unobservable consumer heterogeneity. While price discrimination has been studied extensively by economic theorists, and illustrated with numerous textbook examples (for example, Scherer and Ross 1990), it has only recently become an area of rigorous empirical research. Empirical studies have focused on several questions: (*a*) the measurement or identification of price discrimination; (*b*) the sources of price discrimination, notably the role of competition; and (*c*) the effects of price discrimination on profits, consumer welfare and efficiency.

Measurement of Price Discrimination

The identification of price discrimination can be introduced in a simple framework in which a firm sells two products. The price difference Δp between the two products (assumed positive) can be decomposed in a cost difference Δc and a margin difference Δm, so $\Delta p = \Delta c + \Delta m$. Price discrimination exists to the extent that the observed price difference Δp is due to the margin difference Δm rather than a possible cost difference Δc. (An alternative definition is based on percentage rather than absolute margin differences. To consider this, reinterpret the variables in logs, Clerides 2004, compares the two approaches in empirical studies.) Identifying margin differences from cost differences is not an obvious task. Lott and Roberts (1991) provide plausible cost-based explanations for commonly viewed price discrimination cases. Several recent empirical studies have attempted to properly account for cost differences before drawing conclusions about the presence of price discrimination.

There have been two methodological approaches. The first approach uses direct cost information. Sometimes the cost difference can be derived from industry information about the production technology. An early example is Benston (1964), who finds that 76 per cent of the higher interest rates charged to small businesses can be attributed to additional costs. In contrast, Clerides (2002) attributes only five per cent of the average price difference between hardback and softback books to higher production costs. In other cases, the production technology is not known, but the cost difference Δc is reasonably assumed to be zero or negative, so that the observed positive price difference Δp provides a lower bound for the extent of price discrimination. Graddy (1995) finds that Asians pay seven per cent less at a fish market, while there are no reasons to believe that these customers have lower servicing costs. Degryse and Ongena (2005) find that bank customers pay lower interest rates as their distance from the bank increases, whereas costs, if anything, are expected to be increasing in distance. Shepard (1991) provides a neat variation on this theme. As in the above framework, she observes the price difference Δp between a high-quality and a low-quality product sold by multi-product firms (full service and self-service at gas stations). In addition, she essentially also observes the analogue price difference Δp^S for single-product firms (selling either full-service or self-service). She defines the extent of price discrimination as the difference between the markup difference for multi-product firms Δm and that of single-product firms Δm^S. Because her qualitative evidence indicates that the cost difference Δc between the high-quality and low-quality product for multi-product firms is no larger than the corresponding cost difference Δc^S for single-product firms, the difference between Δp and Δp^S provides a lower bound for the extent of price discrimination. She finds that the extent of price discrimination for full-service versus self-service gasoline amounts to at least nine cents a gallon.

The second approach to identifying price discrimination does not use cost information, but instead infers the price–cost margin difference Δm from a model of pricing behaviour. This approach essentially replaces cost-side information by demand-side information. For example, Verboven (2002) finds evidence of indirect price discrimination between high-mileage and low-mileage drivers. He uses information on the relative popularity of high-quality and low-quality products (diesel and gasoline cars) and the distribution in consumers' willingness to pay for quality (mileage). He infers that 75–90 per cent of the price premium for the high-quality products can be attributed to a higher margin, a finding that is confirmed by direct cost information.

Sources of Price Discrimination

Several empirical studies have gone beyond the basic question of identifying price discrimination to uncover its sources, in particular the role of competition. Theoretical work has revealed that competition does not necessarily reduce the incentives to price discriminate. The extent of direct price discrimination depends on both the price elasticity of market demand and the cross-price elasticities with respect to competing products; it is therefore not necessarily smaller under competition. For example, Borenstein (1991) looks at price discrimination in the competitive retail gasoline market. Margins on unleaded gas were initially higher than margins on leaded gas. The decline in the number of competing stations offering leaded gas caused an increase in the margins on leaded gas relative to the margins on unleaded gas, hence a reduction in price discrimination. This illustrates that competition can be a source of price discrimination: stations take into account the buyers' possibilities to substitute to competing stations when setting their prices. Borenstein and Rose (1994) take up a similar question for the US airline industry. Since they observe more than two prices on a given airline/route, they use the Gini coefficient as a summary measure of price dispersion (rather than the price difference Δp for every product pair). They find that the expected price difference for two randomly selected passengers on a given airline/route is 36 per cent of the average ticket price. An increase in the number of competitors raises the extent of price dispersion by a large amount. Goldberg and Verboven (2001) measure margins based on the estimated own- and cross-price elasticities. They find that car manufacturers earn higher margins in their domestic markets than in their foreign markets, because markets are segmented according to country of origin and there is more competition in the foreign segments. Asplund et al. (2002) find that newspaper subscriptions in Sweden are more often sold at (often introductory) discounts in duopoly regions than in monopoly regions. They interpret this as evidence of poaching, that is, discrimination to attract new customers from rival firms.

The existence of indirect price discrimination is not obvious under competition, as shown in theoretical work. Nevertheless, empirical work has documented that competition may strengthen indirect price discrimination. Verboven (1999) finds a significant percentage price premium for optional engine power in the more competitive car segments, and percentage discounts in the less competitive segments (the latter being consistent with a monopoly discrimination). Busse and Rysman (2005) compare the prices of large and small ads in Yellow Pages directories. Their identification strategy relies on the assumption that cost differences between the two types of ads do not depend on the degree of competition. As such, they do not measure the extent of price discrimination per se, but instead ask how it varies with competition. They find that competition raises the discounts to large buyers: adding one competitor lowers the price of small ads by only six per cent, whereas it lowers the price of large ads by 12 per cent.

Economic Effects of Price Discrimination

Several empirical studies have also assessed the economic implications of price discrimination for profits, consumer welfare, tax revenues and economic efficiency. Leslie (2004) considers monopoly price discrimination. He finds that direct price discrimination for a Broadway theatre play, in the form of a currently observed 50 per cent discount at the discount booth known as the TKTS, raises profits five per cent above the profits under a uniform price strategy. However, he also finds that the current 50 per cent discount is too large to maximize profits, thereby generating too much substitution out of the full-price tickets. Lowering the discount to 30 per cent would raise profits seven per cent above the profits under a uniform price strategy. Leslie also estimates the aggregate consumer welfare effects from price discrimination, and finds them to be relatively small.

Under competition, the effects of direct price discrimination on profits are ambiguous even if the discriminatory prices are chosen optimally. The possibility to discriminate may lead to a situation of all-out competition, in which all discriminatory prices are lower than the uniform prices, thereby reducing profits. This occurs when the weak (elastic) market of one firm is the strong (inelastic) market of the other firm. Nevo and Wolfram (2002) find suggestive evidence of all-out competition, documenting that price discrimination (in the form of coupons) may lower the prices of all products, and may hence lower profits. Besanko et al. (2003) consider a situation of uniform pricing (for ketchup), and compute the new equilibrium under the assumption that firms would be able to discriminate between three (latent) customer segments. They find that all firms perceive the same customers as weak or strong. Price discrimination thus does not lead to all-out competition; quite the contrary, it increases profits. Brenkers and Verboven (2006) consider the reverse case in which car manufacturers currently discriminate between consumers from different countries, and would no longer be able to do this in the future (because of improved market integration). In their application, all-out competition appears more likely a priori, since domestic and foreign firms have the reverse strong and weak markets. Nevertheless, they find no evidence of all-out competition: an elimination of price discrimination would lower the prices of domestic firms, but raise the prices of foreign firms. Price discrimination correspondingly has relatively modest effects on industry profits and welfare (unless the high prices in the United Kingdom would be due to collusion).

The effects of indirect price discrimination under competition have also received attention recently. Miravete and Roller (2003) find that a single two-part tariff achieves 94 per cent of the potential profits and 63 per cent of potential welfare under a fully nonlinear tariff. McManus (2004) assesses the extent to which coffee shops distort their qualities (cup sizes) from the efficient levels, as a way to segment customers based on willingness to pay for quality. Consistent with economic theory, he finds that there are quality distortions, tending towards zero for the top qualities. Crawford and Shum (2007), using a somewhat different approach, also find evidence of quality degradation in the cable television industry.

Price Discrimination (Theory)

Eugenio J. Miravete

Abstract

Price discrimination comprises a wide variety of practices aimed at extracting rents from a base of heterogeneous consumers. When consumer types are private information and only their distribution is known to the monopolist, finding the optimal nonlinear tariff involves solving a constrained variational problem that characterizes the optimal markup for each purchase level so that consumers of different types have no incentive to imitate the behaviour of others. Fully separating equilibrium is ensured when the distribution of types fulfills the increasing hazard rate property and individual demands can be unambiguously ranked. Outside this framework, optimal tariffs are difficult to characterize.

A monopolist price discriminates when he sells two identical units of a good at different prices, either to two different buyers or to the same customer. Two basic elements serve to classify the numerous methods whereby firms price identical units of the product differently: the amount of information available to the seller regarding how different the valuations of consumers are, and the seller's ability to avoid arbitrage. Avoiding arbitrage when firms sell personal services is easy and inexpensive, and thus price discrimination becomes a common practice in such industries. Conversely, in the absence of restrictions on the transferability of commodities, low-valuation customers could certainly benefit from reselling to higher-valuation customers, thus effectively impeding the seller from actually charging two different prices for the product.

Classification of Price Discrimination Practices

Pigou (1922) distinguished between first-, second-, and third-degree price discrimination depending on the amount of information regarding consumers' preferences that is available to the seller. In the case of first-degree price discrimination, the seller observes the actual valuation of each consumer and, provided that individual pricing is feasible, he could ask each consumer for her individual reservation price. Individual pricing is, however, rarely observed in reality, but such a pricing strategy has the theoretical appeal of leading to the efficient competitive outcome, although obviously with a quite different distribution of rents. This efficiency result vanishes when the seller knows only the distribution of consumers' valuations, as in second-degree price discrimination, or when he knows even less – just a signal about consumers' valuations – as in the third-degree price discrimination case.

Market segmentation, either geographical or personal, may serve as a way to avoid arbitrage. Price differentials across countries are likely to be larger than across neighbourhoods of a city as consumers move more freely in the latter case. Thus, the ability to price-discriminate will be partially determined by the importance of consumers' transaction costs in purchasing from different markets. Similarly, the cost of enforcing market segmentation may lead to different pricing schemes. Charging different individuals a different price for a service depending on their location, age, gender or race is far less expensive in terms of monitoring costs than tying prices to the income of each individual. In some circumstances, when third-degree price discrimination is used, location, age, gender, race or any other observable characteristics can be used in an economically efficient (although sometimes morally rotten) way to infer average individual valuations of products and increase profits by extracting a larger share of the consumer surplus of those individuals with higher valuations. Thus, in the third-degree price discrimination case, solving the price discrimination problem comes down to finding the optimal monopoly price in several independent markets. If there were numerous firms instead of a single seller, the well-known inverse elasticity rule should be modified to account for the existence of substitute goods.

More interesting is the case of second-degree price discrimination, when the seller needs to avoid the possibility of transferability of demand among consumers of different valuations. Since only the distribution of valuations is known, and not the valuation of individual consumers, finding the optimal pricing scheme requires one to solve a complex problem where the monopolist attempts to extract as much rent as possible from each consumer while at the same time ensuring that they do not imitate the behaviour of other consumers with lower valuations. In other words, price discrimination becomes a mechanism-design problem where a nonlinear tariff charging a different unit price for each unit sold maximizes the expected profits of the monopolist, while ensuring incentive compatibility.

Technical Issues of Single-Dimensional Price Discrimination

To solve this problem, consumers' preferences are assumed to be fully described by $U(q, \theta)$ where q represents the amount of good purchased by a consumer of type θ. This single-dimensional index captures the relevant difference in demand of diverse consumers, and leads to non-price-related shifts of individual demands. Type θ

remains private information for each consumer while the monopolist knows only its distribution $F(\theta)$ on $\Theta = \left[\underline{\theta}, \overline{\theta}\right]$. The variational problem that the monopolist faces consists of finding the optimal nonlinear tariff function $T(q)$ that maximizes his expected profits with respect to the distribution $F(\theta)$ provided that in their choices consumers are guided to maximize the net utility $U(q, \theta) - T(q)$. A fully separating equilibrium exists whenever individual demands can be ranked unambiguously, $Uq\theta(q, \theta) > 0$, and when the distribution of consumer types $F(\theta)$ fulfills the common increasing hazard rate property (these are sufficient, not necessary, conditions). In such a case, the optimal nonlinear tariff $T(q)$ is a concave function leading to quantity discounts that assigns different quantities and payments to consumers of different types. Maskin and Riley (1984) and Mussa and Rosen (1978) (in a framework of quality discrimination) first fully characterize the solution to this canonical version of the price discrimination problem. Contrary to the first-degree price discrimination case, now only the highest consumer type, θ, is efficiently priced – the efficiency at the top result – while all other consumers are charged a positive markup that induces them to self-select the optimal level of consumption according to the intensity of their preferences, θ. The magnitude of this markup depends on how difficult is to enforce the incentive compatibility condition, which is summarized by the hazard rate of the distribution $F(\theta)$. And the difficulty of separating different consumers depends on how these consumer types are distributed. Thus, the more numerous the consumers with a high valuation are, the larger is the average markup that low-valuation consumers should face in order to minimize the incentive of high-valuation types to purchase a small amount of the good. Intuitively, the more numerous high-valuation consumers are, the more likely some of them will be to attempt to behave as low-valuation consumers. To prevent it, a higher markup charged to low-valuation consumers is needed in order to reduce sufficiently the outside option of those more numerous high-valuation consumers. Consequently, if all consumers are alike, the distribution of consumer types, $F(\theta)$, becomes degenerate, and the optimal nonlinear tariff is a two-part tariff with a slope equal to the marginal cost of production and a fixed fee equal to the individual consumer surplus of a buyer.

Engineers (Dupuit 1849; Hadley 1885) rather than economists discovered long ago the advantages of charging different prices to different customers in order to cover the fixed costs of operating transportation services. The solution to the second-degree price discrimination problem described above attracted the attention of economists only after the contribution of Mirrlees (1971) in the area of nonlinear taxation. His approach to finding the optimal tax that maximized a social welfare function could easily be adapted to analyse the Ramsey pricing problem of regulated industries contemplated by Ramsey (1927) and Boiteux (1956). With the development of incomplete information games, the nonlinear pricing problem was rapidly reformulated as a direct revelation mechanism (Goldman et al. 1984; Guesnerie and Laffont 1984), thus helping to uncover the technical assumptions that ensured well-behaved solutions of the canonical single-product, single-parameters case.

Extensions of Monopoly Pricing

The solution to this canonical price-discrimination problem serves as a point of departure for many extensions that have attempted to incorporate either a more general theoretical approach or particular features of specific industries where nonlinear pricing is used to cover fixed costs or to fulfill distributional objectives set by regulators.

A first extension included the possibility that income effects were non-negligible and that consumers could be risk averse. Effectively, this means that the net utility of consumers is not additively separable in payments. Extensions in this direction includes the work of Mirrlees (1976), Roberts (1979), and Wilson (1993, ch. 7).

Another early extension addressed the rationing of stochastic individual demands in the presence of capacity constraints. The nonlinear tariff now attempts to distribute the cost of installed capacity among consumers according to their usage, as consumers with different loads contribute differently towards the cost of providing the service. But this peak-load pricing solution also provides the firm with incentives to reduce the size of consumers' loads in order to minimize the cost of distributing efficiently the existing capacity among all consumers. Oren, Smith and Wilson (1985) and Panzar and Sibley (1978) are the two basic references on capacity pricing.

More recently, the basic canonical model of price discrimination has been modified to contemplate the possibility of sequential screening, a process common in many industries where consumers first subscribe to one of the many optional tariffs available and later decide on their optimal level of consumption. The canonical model is modified to allow consumers to learn about their valuation of the product, thus distinguishing between *ex ante* and *ex post* types – the valuation of customers before and after contracting with the seller – as well as *ex ante* and *ex post* incentive compatibility constraints. Courty and Li (2000) consider the case where the *ex ante* type determines the distribution from where the *ex post* type will be drawn, while Miravete (1996) considers a framework in which the *ex post* type is the sum of the *ex ante* type and an independently distributed shock. Both approaches lead to ambiguous results that can be somewhat qualified depending on the stochastic dominance of the composition or convolution distribution, respectively, of the *ex post* relative to the *ex ante* valuation. Miravete (2005) further evaluates the welfare performance of nonlinear tariff options using data directly linked to *ex ante* and *ex post* types of consumers.

The most challenging extension of the canonical problem is multidimensional types. Wilson (1996) presents a concise description of the difficulties that arise when types are multidimensional or the monopolist sells several products. Type dimensions capture different features of consumer demands (intercept, curvature, or others) that are independent of prices but are relevant to capturing consumer heterogeneity. Multiple products introduce the possibility of accounting for complementarity and substitution effects and thus designing optimal discounts for bundles that include a variable proportion of each good. The difficulty arises because the multidimensional screening problem imposes a continuum of boundary conditions that translate into a large number (the number of type dimensions minus one) of additional partial differential equations that constrain the multidimensional variational problem. Explicit solutions do not exist beyond particular cases such as those studied by Armstrong (1996), Laffont, Maskin and Rochet (1987), or Wilson (1993, chs. 13, 14). A common result reported by Armstrong (1996) and Rochet and Choné (1998) is that low-valuation customers are always excluded, thus leading to bunching at the bottom.

Competitive Nonlinear Pricings

Besides the technical difficulties in solving multidimensional price-discrimination problems, numerical solutions show that tariffs may become non-monotone and that even the efficiency at the top result may not hold depending on the support of the distribution of types and the interaction among type dimensions given by the specification of the utility function. Perhaps because of these unsurmountable difficulties, the generalized one-dimensional nonlinear pricing framework of Rochet and Stole (2002) offers the most promising alternative for advancing in this area of research. Their approach consists of adding a second independent type dimension that enters additively into consumers' utility function. This little modification of the canonical problem disassociates the participation and consumption decisions. While in the canonical problem higher-valuation consumer types always participate and purchase more than low-valuation customers if lower types participate, now participation is driven by consumer-specific outside options. Now, relative to the canonical price-discrimination case, the monopolist loses some ability to extract consumer surplus as profit maximization requires him to balance informational rent extraction from high-valuation customers with the participation of low-valuation customers.

Characterizing the optimal tariff solution in this model with endogenous participation becomes more involved (although much more feasible) than the general multidimensional case, and it requires solving a two-point boundary problem instead of a simpler recursive first-order differential equation with a boundary condition given by the marginal consumer type that decides to participate in the market. Bunching may also occur at the bottom, but only at the bottom, and the tariff is well behaved, continuously approaching the fully efficient solution on the one hand and the solution to the canonical pricing problem on the other. Furthermore, the efficiency at the top result survives, and the efficiency at the bottom arises in cases where all consumer types are served.

The model of Rochet and Stole (2002) is also appealing because it offers the possibility of addressing competitive environments where firms' tariff are the best response to each other's offering and where the tariff offered by the competitor defines the outside option of consumers. This is a model of exclusive agency where consumers subscribe to only one of the firms competing in the industry. The most important result of this literature, also documented by Armstrong and Vickers (2001), is that, in industries with full market coverage and where all firms face the same marginal cost, the equilibrium tariff solution is a simple cost-plus tariff (Coasian two-part) leading to an efficient allocation of consumption among buyers.

Price Dispersion

Ed Hopkins

Abstract

Price dispersion occurs when different sellers offer different prices for the same good. Empirical studies have identified price dispersion as widespread and persistent. The most frequent explanation for this is that consumers do not have perfect information about prices. Only recently have economists succeeded in modelling price dispersion as an equilibrium phenomenon: that is, where consumers' decisions to acquire price information are a best response to the distribution of prices, and sellers' pricing decisions are a best response to consumers' search behaviour.

Keywords

Price dispersion occurs when different sellers offer different prices for the same good in a given market. Thus, it differs from price discrimination under which a single seller offers different prices to different groups of buyers or in different geographical locations. A simple explanation for price dispersion is that it arises from imperfect information on the part of consumers, who do not all buy from the lowest price seller because some at least do not know who the lowest priced seller is. It is an important topic in the field of the economics of information in that there is considerable empirical evidence that price dispersion is widespread and significant. Yet it has proven surprisingly difficult for economists to derive satisfactory models that support price dispersion as an equilibrium phenomenon.

The rise of electronic commerce at the end of the 20th century gave new impetus to empirical studies of pricing behaviour. Baye et al. (2004) analyse detailed information on prices of 1000 items collected from a price comparison site. Price dispersion is found to be significant and persistent. Baye, Morgan and Scholten find an average coefficient of variation of about nine per cent for goods sold online. This is comparable with the results of Lach (2002) for conventional retailers who finds a lower coefficient for the price of refrigerators, but higher variation for grocery items such as coffee or flour.

Such empirical work on price dispersion is often disputed on the basis of two arguments, both of which claim that any apparent price dispersion is largely illusory. First, variance in prices might be explained by hidden heterogeneity in the good being offered for sale. For example, a retailer that charges high prices might survive not because of consumer ignorance of cheaper sellers, but because it offers superior service, something not captured by evidence on prices alone. A second line of scepticism is that dispersion in posted prices may not be inconsistent with uniformity in prices actually paid. Those who post high prices may not in fact sell anything. Certainly, one would expect low-priced sellers to sell more than those charging high prices, so that prices weighted by market share will be less dispersed than if all sellers are given equal weight.

The first criticism is addressed by Baylis and Perloff (2002) who find that, in fact, some online sellers persistently offer both high prices and poor service. The second is answered at least in part by Baye et al. (2004) who in their empirical study concentrate on the difference between the lowest and second lowest price, rather than the difference from lowest to highest or standard deviation, as their measure of dispersion. Furthermore, their data comes from a price comparison site where listings are costly for sellers. Why pay to list a price at which you think there will be no sales?

In any case, it is certainly possible to construct theoretical models in which prices are dispersed and yet high prices yield positive sales. Such theory is recent, however. In an influential survey, Rothschild (1973) identified serious difficulties with the then existing models of price dispersion. At that time, no one had produced a model where price dispersion was shown to be the result of equilibrium behaviour. The challenge was to show that charging a range of prices could be a rational response by sellers to the search behaviour of consumers, and vice versa.

It took some years for this challenge to be met. The difficulty in doing so is illustrated by the earlier work of Diamond (1971), who found that once one introduces imperfect information for consumers, a natural outcome is not price dispersion, but monopoly pricing by sellers. The essence of Diamond's result is the following. Suppose there are a large number of identical buyers who each want to buy one unit of a good from one of a large number of identical sellers, provided it costs no more than a maximum price p^*. The buyers know the distribution of prices but each only knows the price currently being charged by one seller. Each must then must decide whether to learn the price of one more seller at a fixed cost (imagine searching on foot, or by telephoning a succession of sellers). The optimal search policy in this situation of sequential search is to buy the first time one sees a price that is equal or below a reservation level r, which varies with the unit search cost s and distribution of prices $F(p)$. Now, if all consumers have the same unit search cost, then for a given distribution of prices, they will have the same reservation price r. The optimal price for all sellers must then be r. But if there is no dispersion in prices, it cannot be optimal to learn more than one price. Thus, the only equilibrium is where all sellers charge p^* and all buyers do not search, even when the unit cost of search is arbitrarily small. Ironically, this equilibrium satisfies Rothschild's criteria. Consumer behaviour is optimal since, when prices are identical, paying to learn additional prices is a waste of effort; pricing at the monopoly level is optimal since, when there is no search, there is no incentive for sellers to cut prices to increase sales.

Not surprisingly, therefore, many of the earliest successful equilibrium price dispersion models (Salop and Stiglitz 1977; Varian 1980) take a different route from Diamond and do not assume sequential search. Instead, they are what have been called by Baye et al. (2004) 'clearinghouse' models. By buying a newspaper or by visiting a price comparison website, a consumer can obtain information about the prices of a number of sellers all at once. The simplest clearinghouse assumption is that it is possible for consumers to become informed of all current prices. Suppose a proportion q of consumers remain uninformed and hence pick a seller at random. The other $1 - q$ consumers are informed and only purchase from the lowest priced seller. All consumers wish to buy one unit of the good if the price does not exceed a common maximum price p^*. Then, given n sellers and L consumers, if one seller charges a price strictly lower than all others, she sells to both informed and uninformed, a total of $qL/n + (1 - q)L$. The other sellers sell only to the uninformed and expect sales of qL/n. That is, demand is decreasing but discontinuous in price.

For simplicity, let us follow Varian (1980) and assume that sellers have constant marginal cost c. There is then no pure strategy equilibrium for sellers as long as there are both informed and uninformed consumers, that is if $q\ A\ (0,1)$. To see this, note that if all sellers charged the same price, it would generally be profitable for an individual to undercut this price in order to attract the informed buyers. However, because of the presence of uninformed consumers who are not price sensitive, charging the monopoly price p^* gives a guaranteed minimum profit of $(p^* - c)qL/n$, and so when the prices of other sellers are close to c, the most profitable price may be p^*. There is a symmetric mixed equilibrium in which all sellers randomize according to the same continuous distribution. This mixed equilibrium is a dispersed price equilibrium, because since sellers randomize over the prices they charge, realized prices will vary over sellers.

However, to have an equilibrium that fully satisfies Rothschild's challenge, it is necessary to make the consumer's decision to become informed endogenous. Varian (1980) assumed differing information costs, with high-cost consumers remaining uninformed, and low-cost consumers paying for information. However, Burdett and Judd (1983) showed that it is possible to close a clearinghouse model even with identical buyers. For example, given the symmetric mixed equilibrium described above, consumers who pay to become informed will buy from the lowest-priced seller whose expected price is equal to the expected value of the lowest of *n* independent draws from the equilibrium price distribution. In contrast, those who remain uninformed expect to pay the simple expectation of the distribution. If *q* is zero or 1, the equilibrium price distribution will collapse on *c* or *p** respectively. However, for interior values of *q*, the difference between the price paid by the informed and uninformed will be positive. Thus, it can be shown that for a value of *s* sufficiently low, there is at least one interior value of *q* such that the resulting equilibrium distribution of prices is sufficiently dispersed such that consumers are indifferent as to whether they pay or remain uninformed.

That is, there is at least one internally consistent dispersed price equilibrium. The proportion of informed consumers generates exactly the right amount of expected price dispersion such that consumers are indifferent between being informed and uninformed. This is an elegant but delicate construction. In contrast, the Diamond outcome (no consumers pay to be informed, all firms charge *p*)* is a simple pure equilibrium of this game that coexists with any dispersed price equilibria. Thus the Varian model and the similar models of Salop and Stiglitz (1977) and of Burdett and Judd (1983) have multiple equilibria (though the Bertrand outcome where all consumers pay to be informed and all firms charge marginal cost is not an equilibrium here, since consumers have no incentive to pay to be informed if all prices are the same).

A reasonable question is whether introducing heterogeneity, either under sequential search or in clearinghouse models, makes dispersed price equilibria more robust. However, consumer heterogeneity does not remove the Diamond paradox as an alternative equilibrium. Even if consumers have a range of search costs, if there is no price variation at all, then there is no incentive to search (unless one makes the implausible assumption that a mass of consumers have zero search costs). That is, if all sellers share the same monopoly price, then all charging that price can be an equilibrium if consumer search is costly. But if instead there is sufficient seller heterogeneity, an outcome where all sellers charge their monopoly price may not be an equilibrium. Suppose no consumer searches, each seller would then charge his or her monopoly price. However, suppose all consumers have the same continuous increasing demand function (in contrast to the unit demand assumed up to now), then a dispersion of costs amongst sellers would lead to heterogeneity in monopoly prices. This could be sufficiently diverse so that consumers would have an incentive to search. Thus, in the equilibrium of Reinganum (1979), low-cost sellers charge their monopoly price, but high-cost sellers must charge less than their monopoly price to make sales.

Finally, when one has heterogeneity of both buyers and sellers, there are two advantages. First, by the above argument, a Diamond-type outcome cannot be an equilibrium and so uniqueness of the dispersed price equilibrium is possible (Benabou 1993). Second, the dispersed price equilibrium can be pure and strictly monotonic: higher-cost firms charge higher prices. This follows because sufficient buyer heterogeneity can make demand to be continuous in prices, unlike the discontinuous demand in Varian's clearinghouse model. For example, if there is a continuum of buyers who search sequentially and have a continuous density of unit search costs, then there is the possibility of a continuous density of reservation prices. So, demand will increase smoothly as a seller lowers the price.

What are the major conclusions that can be drawn from these equilibrium models of price dispersion? The first is that both social and consumer welfare are typically decreasing with search costs. A reduction in search costs for some consumers can have a positive externality on other consumers, as increased search brings down prices for all. Other predictions can sometimes be counterintuitive. For example, an increase in the number of sellers actually raises the average price charged in the Varian model. However, this result does not hold for all price dispersion models. Further, Baye et al. (2004) find empirically that both average prices and the degree of price dispersion fall with an increase in seller numbers. Finally, we have seen that models with homogenous sellers give rise to mixed equilibria, while models with bilateral heterogeneity can generate pure equilibria. Randomization over prices would imply regular change in price order amongst sellers. That is, sometimes a given seller would have the highest price, sometime the lowest, and sometimes in the middle. A monotone pure equilibrium would give rise to a stable price ranking. Baylis and Perloff (2002) find that price ranking on online sales of electronic goods are very stable. In contrast, Lach (2002) finds that price ranking in data on prices charged by different Israeli supermarkets is highly variable.

One possibility is that the difference arises because Lach's data are for groceries that are purchased with greater frequency than the electronic goods in Baylis and Perloff's data set. But this highlights that the current theoretical literature on price dispersion has rarely addressed the related issues of repeat purchases, frequency of purchase and search patterns that depend on past experience, for example returning to sellers that have had low prices before. This would seem the area that is in most the need of further research.

Price Level

P. Bridel

Until the end of the 19th century, it may be said that the quantity theory was everybody's theory of money and the price level. This does not mean that it was universally accepted: many writers submitted Hume's formulation to some very sharp criticisms. However, short of any viable alternative, all the leading economists adhered to one or another of the marginally different versions of the quantity theory.

The common feature of early-19th-century classical and late-19th-century neo-classical quantity theory is the well-known notion that an expansion or a contraction of the money supply – other things equal – would lead to an equiproportional change in the price level (or alternatively to an equiproportional change in the value of money). That) 'other things equal' is reflected in the assumption of a stable demand for money function, or, more specifically, a fixed level of output. The similarities between the Classical and Neo-classical approaches come however to an end here. Whereas in the latter approach the fixed (full employment) output assumption, and hence the causal relationship between money and prices, is the result of a theoretical analysis of the determination of output along marginalist lines, in the former it results from the adoption of Say's

Law. In other words, Classical quantity theory is based not on a theory of output but on the lack of such a theory comparable with its theory of value of distribution.

Accordingly, and despite attempts made by some of its leading proponents (like Thornton) to work their way toward a monetary analysis of the economic process as a whole in which price-level issues fall into secondary place, the Classical monetary theory, up until and including J.S. Mill, gave the pride of place to the so-called 'direct mechanism'. This) 'transmission mechanism' is older than economic theory itself. Much earlier than Hume's classical version, and well before economics was born as an independent subject, the idea that a change in the money supply would eventually cause prices to rise in the same proportion was part and parcel of most writings on money.

Even if Hume and Cantillon paid great attention to the manner in which a cash injection is disbursed and to the various lags involved in the process, and although they were well aware that an increase of money raises prices equiproportionately only if everyone's initial money holdings are increased equiproportionately, their attempts to prove it were thwarted by the very logic of the Classical framework. It is only with the Neoclassical effort to integrate money and value theories that the first serious attempts were made (mainly by Marshall and Wicksell) to escape from this Classical dichotomy and to prove the proportionality theorem by providing a proper stability analysis. However, and at least up until the early 1940s, most economists kept arguing that people spend more money because they receive more cash, not because the value of their real balances has increased beyond the amount determined by the Marshallian *k*. With his path-breaking analysis of the real-balance effect, Patinkin finally connected people's increased *flow* of expenditures with their feeling that their *stock* of money is too large for their needs. The sweeping endorsement of this theoretical argument by the economics profession allowed an apparently successful counter-attack against Keynes's claim that a fully competitive economy could well get trapped in (unemployment) disequilibria. Despite serious divergences among macroeconomists about the actual workings of the real-balance effect, it was widely held that, if prices and wages are flexible, a Walrasian equilibrium (with a positive value for money) would exist both in the short run and the long run. These investigations also confirmed that money is neutral; that is, excluding all distributional effects, in a neoclassical model coupled with unitelastic expectations, a once-and-for-all scalar change of all agents' initial cash holdings would change in the same proportion the equilibrium of money prices and nominal money balances at the end of the period, leaving unaltered relative prices and real variables. Price and wage rigidities are thus the only reasons that, in the short run, the excess demands for goods and money might not be homogeneous of degree zero and one respectively, with respect to nominal prices and initial balances.

The 'indirect mechanism' has a history that until the interwar period played second fiddle to that of the 'direct mechanism'. It is only with Marshall's, Wicksell's and, later on, Fisher's attempts to give an explicit rôle to the rate of interest in the transmission mechanism connecting money and prices that it rapidly took pride of place in the economist's monetary toolbox. In fact, the argument that monetary equilibrium (and hence the stability of the price-level in an economy) exists only when the money rate in the loan market equals the rate of return on capital (the traditional 'natural' rate) in the capital market is the basic framework within which some of the most famous discussions in the realm of monetary theory took and are still taking place. In all these analyses in terms of saving and investment, cumulative process, Gibson's paradox, forced saving, trade and credit cycles, etc, the price-level plays a crucial rôle as an indicator of the degree of tension within the system. Hence the wealth of introductory chapters on index numbers found in most textbooks and treatises of that period (the most famous being Book II in Keynes's *Treatise on Money* [1930], 1971).

With his cumulative process, Wicksell was indeed the driving force behind the impetus given toward the very end of the 19th century to this 'trailing rate' doctrine. Building on Tooke's 1844 insights, and in contradiction to Ricardo's pronouncements, Wicksell argued that, following a credit expansion, the market rate of interest and the price-level are positively correlated. As a matter of fact, the discrepancy (created by such a credit expansion between the market rate and the expected yield on investment) is a disequilibrium situation in which, period after period, net investment is positive and constantly increasing. Such a cumulative process need neither create inflation if voluntary savings is simultaneously generated via higher market rates (unless a 'pure credit' hypothesis is made) nor be explosive (thanks to the internal drain on banks' reserves). However, in order to preserve price stability, if the economy is operating at full employment and/or if there are signs of inflation, the bank rate would have to be raised in order to ensure that net investment does not exceed voluntary savings. Hence, a stable price level would not only be synonymous with equality between the real (or) 'normal') rate of return on investment and the market rate, but also with equality between the market and the bank rates. As Robertson put it later very succinctly:

It is on the difference between [Saving and Investment] and consequently between 'natural' and market rates that the movement of the price-level . . . depends' (1933, p. 411).

Within such a framework there began nearly half a century of intensive theorizing in terms of Wicksell's three criteria. The market rate is in equilibrium if it is equal to the rate of return of capital (or 'natural' rate), at which: (i) the demand for loans is equal to the supply of savings; and (ii) the price level is stable ([1896] 1936, pp. 192–9).

If the market rate trails behind the 'natural' rate, prices will begin to move up; if, furthermore, the bank rate diverges from the market rate, this creates an additional discrepancy between the market rate and the real rate of return on investment: the rate of inflation would of course gather up speed. In macroeconomic terms, the whole of this argument was ultimately incorporated in the loanable-funds theory of interest: the market rate of interest is determined by the demand for (investment demand and demand for cash balances) and the supply of loanable funds (voluntary savings and bank credit). If planned savings are equal to planned investment, net credit creation is equal to the demand for cash, the market rate, the bank rate and the 'natural' rate of interest are one and the same thing and, last but not least, the price level is stable.

Marshall in his stability analysis of the value of money (1923), Fisher in his famous equation (1911), Hawtrey with his purely monetary theory of the cycle (1913), Robertson with his) 'four crucial functions' (1928, pp. 105–7 and 182), most members of the Stockholm School (notably Myrdal 1929), Keynes in his famous 'fundamental equations' (1930) and Hayek (1932) with his forced saving analysis (to name only but a few of the most celebrated contributors to this debate) all tried, by putting a different emphasis on the various components of this indirect mechanism to offer a dynamic analysis of the price level. Having thus added money to a relativeprice system in which it has, by definition no part to play, these theorists tried in a certain sense to 'eliminate' it again by defining the monetary policy best suited to make money 'neutral' as concerns the operation of the economic system. By defining the prerequisites for money to be 'neutral', these authors were clearly implicitly (and sometimes explicitly) taking for granted the stability of the system. Rigidities, lags and inelasticities of all types, external shocks and technical progress, and of course monetary impulses could temporarily disrupt the dominant forces at work in an economy; but, ultimately, in the long run, the system would tend towards a full employment equilibrium along Walrasian lines. As Keynes wrote in his *Treatise:* 'Monetary theory, when all is said and done, is little more than a vast elaboration of the truth that "it all comes out in the wash"' (1930, II, p. 366).

Thus by the early Thirties and despite a great deal of activity in the field of monetary theory, the simple and straightforward) 'direct' and 'indirect' transmission mechanisms traditionally used to determine the price level were superseded because they proved, as Hayek argued, 'a positive hindrance to further progress' (1931, pp. 3–4). However, the rich harvest of new formulations and the stepping stones laid down by Hayek, a handful of Swedish economists and Hicks in the field of temporary equilibrium sustained no further work after the publication of Keynes's *General Theory of Employment Interest and Money.* With his *magnum opus,* Keynes simply changed the agenda of questions economists were to think about in the next thirty years. In particular, the central part played by the price level as the indicator *par excellence* in the course of the cycle was relegated together with the quantity theory to caricatural classroom teaching.

When Friedman resurrected the quantity theory as a theory of demand for money rather than as a theory of the price level (1950, p. 52), his intentions were originally to develop an alternative to the Keynesian liquidity preference argument. However, by asserting that the demand for money function was *empirically* stable and that it is *autonomously* determined, monetarist economists were able to relate again directly nominal income and price changes to changes in the stock of money. Friedman was thus explicitly in a position to consider his contribution as a theory of the aggregate price level the purpose of which is to provide the missing equation in a Walrasian system (1970, p. 223). The neo-classical synthesis having reached not too dissimilar conclusions, the Monetarist *vs* Keynesian controversy was ultimately seen by both sides as a debate on IS–LM elasticities, speed of adjustment and rigidities. In other words, and to quote Friedman, 'the fundamental differences between [these two streams] are empirical not theoretical' (1976, p. 315). All this suggests of course not only that there is an accepted theory of the economy but also that this theory is capable of yielding both monetarist and other conclusions. In other words, disagreements seem only to arise as far as the speed at which the economy converges to long-run equilibrium is concerned. Besides the fact that it is by no means the case that the IS–LM cross is a generally accepted theory of the economy (the Walrasian story monetarists see behind these two curves would certainly bar them from having income as one of their arguments), the assumptions one finds in the monetarist and New Classical Macroeconomic literature about the neutrality of money are not particularly plausible, let alone theoretically verifiable. In particular, they do not imply the uniqueness of such an equilibrium. Theorists like Hahn (1982) and Grandmont (1983) have shown that there are many, mostly a continuum of rational expectation equilibria over a finite horizon and there may also be many for an infinite horizon. Thus the belief that the long-run equilibrium of a competitive monetary economy is unique and stable and that a scalar change in the quantity of money holdings will generate the same scalar change in all nominal values remains today more than ever at the centre of a formidable theoretical debate. If the neo-classical monetary paradigm has survived, it is more because many economists *think* it yields important insights into the working of decentralized economies than for its theoretical solidity. Hence, and despite the empirical stability of the money demand function reported by many applied economists, and according to the maxim that what is witnessed if not explained is not understood, a proper *theory* of the price level remains yet to be written.

Price Revolution

J. E. C. Munro

Abstract

The Price Revolution was a unique period of inflation in European economic history, enduring for 130 years, from the early 16th to the mid-17 century. It was fundamentally monetary in origins and character, having commenced with a fivefold increase in silver supplies from the central European mining boom and then sustained and expanded both by a financial revolution in negotiable credit instruments and then by the great influx of silver from the Spanish Americas. The extent of the inflation was, however, influenced by various real factors, especially demographic, which had their greatest impact on the income velocity of money.

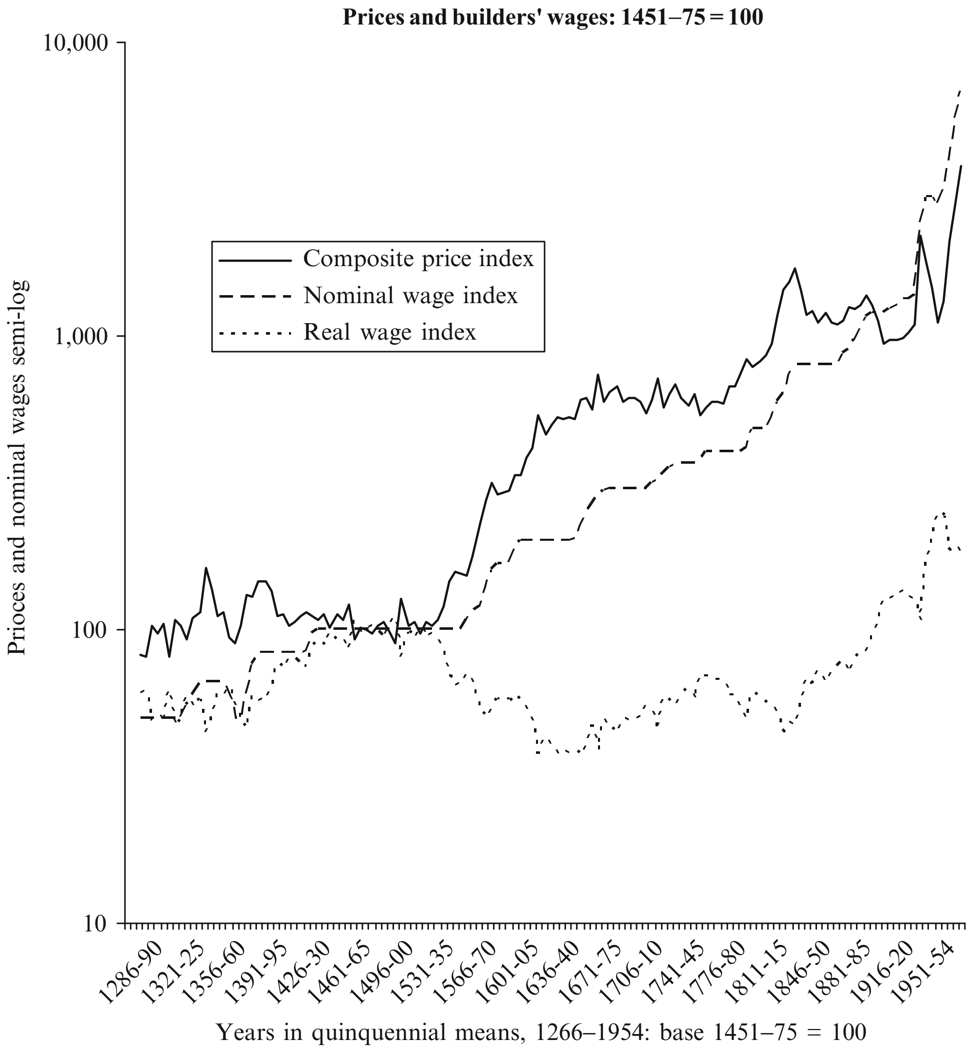
The Price Revolution, dating from about 1515 to the 1650s, was a long period of persistent inflation in Europe that was unique for the pre-20th-century economy. The sustained rise in prices, or rather in the Consumer Price Index (CPI) is clearly visible in Fig. 1 for English prices from 1266 to 1954 (base 1451–75 = 100), and in Fig. 2 for prices in southern England, the southern Low Countries (Brabant), and Spain, from 1501 to 1650. With a common base of 1501–10 = 100 (CPI) for all three regions, we find that, over the next century and a half to 1646–50, the index number for Spanish prices rose to 343; for Brabantine prices, to 845; and for English prices, to 698.

Average annual rates of price increases of less than two per cent in the Price Revolution era may have been mild in comparison with 20th-century inflations: but all pre-20th century inflations were based on commodity moneys, not government issues of fiat money, as in the modern world. Before 1914, western Europe experienced, to be sure, other periods of long-term inflation, particularly, if only periodically, during the ‘long’ 13th century (1180–1315) and in the early Industrial Revolution era (1760–1815). But these produced price-level changes that were far smaller than those of the Price Revolution.

All long-term inflations are fundamentally monetary in nature, even though secondarily influenced by real factors. That may be best understood through the Cambridge cash balances equation, $M = k.P.y$, in which k indicates the quantity of cash balances (high-powered money M) held as a proportion of net national income (y). It is also the inverse of V, the income velocity of money, in the more familiar quantity-theory equation: $M. V = P.y$. Since the opportunity cost of holding cash is forgone interest income, changes in k should therefore depend partly on interest rates. Though an increase in M (money stocks) may prove inflationary, the equation indicates why the extent of such inflation is unpredictable. For such an increase in P can be offset by a rise in k (especially if an increased M reduces interest



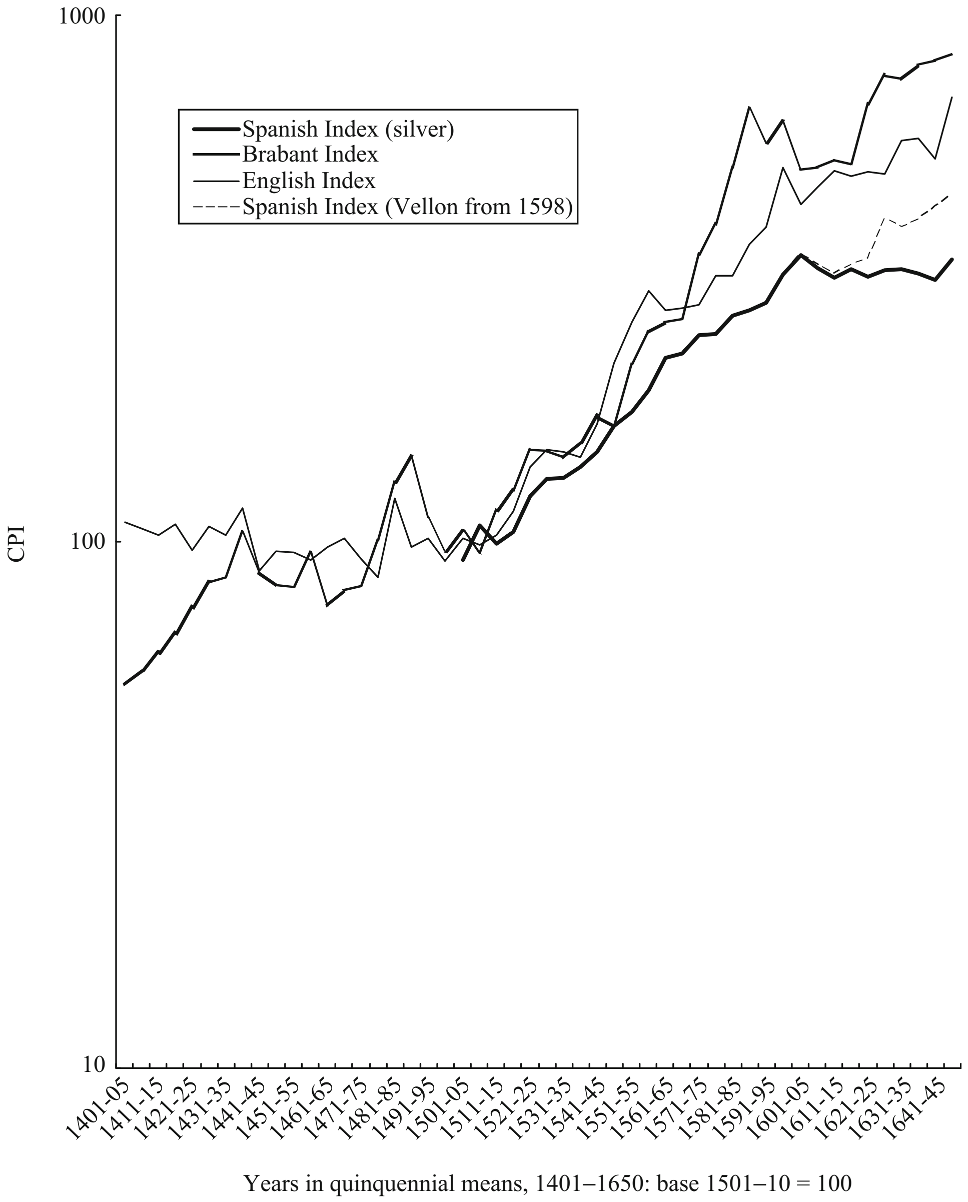
Price Revolution, Fig. 1 Consumer prices and wages for master building craftsmen in southern England, in quinquennial means: 1266–1954 (Phelps Brown and Hopkins indices). *Source:* Phelps Brown and Hopkins (1981, pp. 13–59)

rates), that is, a fall in *V,* or by an increase in y, stimulated by increased spending and falling interest rates.

Demographic Versus Monetary Explanations

Regrettably, amongst historians population growth has provided the most popular explanation for the Price Revolution. Contemporary explanations for the Price Revolution, especially in the debate between the French philosophers Jean Bodin and Jean Malestroit (1568), were instead purely monetary: that is, concerning the influx of Spanish-American silver during the 16th and 17th centuries. Modern opponents of this thesis have, however, rightly pointed out that virtually no American silver was imported before the 1530s, and only insignificant volumes were received before the 1560s, while inflation was clearly under way by 1515–20.

Yet to assume that consequently demographic factors provide the only possible alternative



Price Revolution, Fig. 2 Price indexes: England, Brabant, and Spain, 1401–1650. *Source:* England, as Fig. 1. Brabant, Van der Wee (1975, pp. 413–35). Spain, Hamilton (1934; pp. 262–403)

explanation is an absurd non-sequitur. There are two major problems with the demographic thesis. First, its most common form confuses microeconomic with macroeconomic changes. Although population growth, with fixed amounts of land and a static technology, should lead to a rise in the *relative* price of grains compared with those for manufactures, it can not explain a rise in the general price level. Second, the populations of both England and the Low Countries in the 1520s were at their late-medieval nadir, about half of what they had been around 1300 (when the English CPI was only 102); and thus any demographic recovery from such a low level could not possibly have provided the initial cause of an inflation that was under way in that very same decade.

The actual origins of the European Price Revolution lie instead in alternative monetary explanations, commencing with the central European silver-copper mining boom in the 1460s. This was an era of severe deflation (in silver-based prices) that had thereby augmented the purchasing power of silver and provided the key profit incentives for two crucial technological innovations: (*a*) in mechanical engineering: water-powered piston drainage pumps that permitted deeper mining, reaching richer ores; and (b) in chemical engineering, the *Saigerhütten* process using lead to smelt silver–copper ores, thus for the first time separating the two metals, which were present in vastly larger ore bodies than those of silver alone. The resulting silver–copper mining boom increased aggregate output of European mined silver about fivefold by the 1540s, producing far more silver than was imported from the Americas until the 1580s. By my own conservative estimates, central European silver production itself rose from an average annual of 12,873 kg in 1471–5 to 55,704 kg in 1536–40.

As late as 1556–60, only 27,145 kg of American silver were imported yearly into Seville; but in 1566–70 annual mean imports jumped to 83,274 kg, thanks to another technological innovation: the mercury amalgamation method, employed first at Potosi (Peru) and Zacatecas (Mexico). Thereafter, rising imports, reaching a maximum of 273,821 kg per year in 1591–5, but still amounting to an impressive 223,023 kg per year in 1621–5, continued to fuel the inflation. When the Price Revolution ended in 1656–60, silver imports had diminished to an annual mean of just 27,965 kg. Spanish-American mines were then experiencing severely diminishing returns, while far more metal was being retained for use in the Americas, and more and more silver was being exported across the Pacific, in trade with the Philippines and China.

There was one additional monetary factor to explain the European Price Revolution, namely, a veritable financial revolution in the Habsburg Netherlands, whose towns (from 1507) and then the Estates General (1539–43) established all the legal requirements for negotiability, including legalization of interest and discounting, to protect the rights of third parties in transferable bills, so that bills obligatory and bills of exchange could circulate from hand to hand in commercial and financial transactions as though they were paper money. This financial revolution also established full-fledged negotiability and thus far wider use of government debt instruments, internationally traded on the Antwerp *beurse* from 1531, as perpetual annuities known as *rentes* or *juros.* One measure of their vastly growing importance is the increased issue of Spanish *juros,* from 3.6 million ducats in 1516 to 80.4 million ducats in 1598, most of them held abroad. This financial revolution also increased the income velocity of high-powered money.

Demography and the Income Velocity of Money

Just the same, demographic factors are not irrelevant to our understanding of the dynamics of the Price Revolution, not when population growth became so much more dramatic from the 1540s to the 1640s. First, in various ways that have been elaborated by Harry Miskimin (1975), Jack Goldstone (1984) and Peter Lindert (1985), that population growth, combined with more urbanization, the development of more complex commercial and financial networks, and changes in the age pyramid (with more dependants), may have increased the income velocity of money. Furthermore, as Nicholas Mayhew (1995) has shown, the Keynesian predictions of a fall in income velocity with continued expansions in monetary stocks (and falls in interest rates) seems to hold true from the 13th to the 20th century, with one singular exception: the Price Revolution era.

The Role of Coinage Debasements

Finally, what explains the differences in the inflation rates revealed across the three countries in Fig. 2: why did Spanish prices rise less than

English, and English prices rise less than Brabantine? Coinage debasement (depreciation) seems to have played a role in these differences. Spain experienced no silver coinage debasement. England experienced one mild coinage debasement, in 1526, and one set of very severe debasements between 1542 and 1552 (though the silver coinage was only partially restored, in 1560–61); but none thereafter. Brabant, on the other hand, suffered a long series of coinage debasements, during the 16th and 17th centuries. Thus, the explanations for the European Price Revolution involve a complex set of monetary and real factors, though monetary factors predominated.

Price, Langford Lovell Frederick Rice (1862–1950)

A. Petridis

Langford Price was born in London on 20 July 1862 and died in Brighton on 26 February 1950. He had a distinguished career as a student at Oxford, where he was elected to the first scholarship at Trinity College, graduating with firsts in Honours Moderations in 1882 and Literae Humaniores in 1885. Alfred Marshall lectured to Price at Oxford in 1885 and played an important part in his selection as first lecturer under the Toynbee Trust in 1885. Price held appointments as an extension lecturer at Oxford University until in 1888 he became a fellow and treasurer of Oriel

College, holding the fellowship until 1923. In 1907 he was appointed to the inaugural lectureship in economic history at Oxford, and in 1909 to the inaugural readership. He resigned from the readership on his retirement in 1921.

At the outset of his career Price had a conventional approach to economics, an approach greatly influenced by Marshall, who was both his teacher and mentor. However, after his appointment to the Toynbee Trust lectureship Price began to research into industrial relations problems in the shipbuilding industry on Tyneside, and his experience led him to gradually adopt a less orthodox approach to economics.

Price closely observed the operation of various wage systems (reinforced by interviews and correspondence with union officials and working men) and was persuaded that the competitive model of the labour market was unsatisfactory. Stimulated by the academic discussion and criticism of the published version of his Toynbee Trust lectures (*Industrial Peace,* 1887), Price published (1888) a unique analysis of short run bilateral monopoly which was one of the earliest attempts to grapple with aspects of the problem of bargaining. The 'model' postulated that in a bargaining situation there existed an upper and lower limit for the wage, these limits being established by competitive forces. Between these limits the actual wage is determined by bargaining power. The originality of Price's analysis at that time lay in his attempt to incorporate into the analysis of bargaining not only the direct costs but also the indirect costs of strikes which were to be set off against the costs of a particular wage settlement. Price's analysis was a precursor of modern bargaining theories and the theories of industrial disputes such as that developed by Sir John Hicks in the 1930s.

Price's questioning of the relevance of orthodox economic theory was reinforced by his teaching and research in economic history, and his growing identification with William Cunningham and William James Ashley in the dispute with Marshall over theory and facts in economic analysis. In 1903 Price made a final break from the Marshall-dominated laissez-faire school of economic theorizing. On 15 August 1903 *The Times* published a letter (the 'manifesto' as it came to be known) from a group of 14 leading economists who were opposed to the British government's protectionist proposals for tariff reform. Price was one of the few economists of non-professorial status asked to lend his prestige by signing the letter, but he undermined the 'manifesto' by declining to be a signatory and taking the unusual step of sending a copy of his letter of refusal to *The Times*. This letter was published immediately below the 'manifesto'. Price thus ensured maximum publicity for his dissenting views and his call for a Royal Commission.

After 1903 until his retirement in 1921 Price published only a few articles and participated only peripherally in professional societies, concentrating instead on his teaching in economics and economic history at Oxford. In those years Price filled the vacuum left by Edgeworth's lack of interest in the teaching of economics. Not only did Price teach economic history and history of economic theory courses each year, but he was active in the guidance and counselling of all students enrolled in the new diploma course in economics, which had been established in response to Price's representations to the Vice-Chancellor and the university community. In 1915 both Price and Edgeworth served on a committee which recommended the establishment of a new degree in economics, but the war prevented further action so that it was not until 1920 that a new honours school in Philosophy, Politics and Economics was established. Price publicly denounced the new honours school for not according a sufficient place to economics; despite his objections, the new degree structure for students who chose economics as their major subject was modelled on the diploma in economics Price had helped initiate and nurture through its early years.

Langford Price was never accorded full recognition for his original contributions to the analysis of bargaining under bilateral monopoly, for his strong and effective opposition to the use of the authority of economists to support the free trade position on tariff reform, and for his seminal role in the establishment of the teaching of economics at Oxford University. A complex of social, political and psychological factors would help to explain why he never received the accolades he richly deserved.

Prices and Quantities

A. Brody

These are the most directly and readily observable attributes of commodities (goods and services produced for and exchanged on the market). Both price and quantity relate to a unit (piece, bushel, barrel, pound etc.), established usually by commercial practice as the customary unit of reckoning.

The intrinsically numerical character of prices and quantities renders accounts and statistics, the incessant measurement of the stream of commodities, feasible. This preoccupation is motivated by and yields motivation to business and economic interests. It also seems to be responsible for the profound drive to develop economic theories with the aid of mathematical tools, applied already successfully to the exigencies of natural sciences.

The units of measurement are manifold on the various markets and are also arbitrary to a certain extent. If the units undergo any changes, say, when measuring in grammes instead of ounces, then the numerical magnitude of both prices and quantities changes accordingly. Nevertheless this change in their numerical expression must not alter the total value (volume) of a given amount of commodities so measured: if the unit is doubled then the price of the new unit doubles likewise but the numerical expression of the quantity is halved.

This interdependence of prices and quantities prompted an historically early perception of their parallel, dual character. To this was soon added the appreciation of the mutual effect they exert on each other on the market. As Smith (1776) explained: if the quantity brought to market surpasses the effective demand, that is if an oversupply exists, this will depress prices. On the other hand, a high or excessively profitable price will induce a stepped up production of the commodity in question, possibly also a reduction in its effective demand. This skew-symmetric relationship, with quantities acting negatively on prices while prices influence quantities positively, has remained the popular wisdom of everyday economics up to the present day.

Later investigations and descriptions pointed to the existence of different mechanisms; be it the 'target farmer' in Third World countries who reacts to a rise in prices by reducing the quantity brought to market, or instances of administratively guided economic situations where the economic agents try to minimize their productive effort once prices are fixed. Still the basic form of interdependence on the market, as elucidated by Smith, remained valid in the majority of economic transactions and gained popular and scientific sanction and consensus.

Smith argued that there was a more or less perfect functioning of the 'invisible hand' of the market forces that promote equilibrium (equality of production and consumption, prices and costs) on almost all markets almost all of the time. Equilibrium therefore came to be seen as the normal state of affairs: the productive effort geared to match effective and solvent needs of the society. Random shocks, whether caused by changes in taste, technology or circumstances, were believed soon to be adjusted to. Hence the general prescription to economists (and politicians): not to interfere with this near perfect mechanism and not to tolerate obstacles, constraints, monopolies hampering the smooth operation of markets.

Here the economic profession split for the next two centuries. Economists less convinced about the fairness and impartiality, optimality and efficiency of markets and worried also about the historically emerging adverse tendencies, started critical investigations. They still accepted equilibrium as a theoretical tool of reasoning yet became increasingly aware of certain inadequacies observed on the market. With Ricardo (1817) and Marx (1867) the school of the labour theory of value came into being. This school maintained that prices and quantities are regulated in last instance by the respective amounts of live and congealed labour bestowed on the production of the commodities in question. They were interested mainly in long run tendencies in the economic circumstances of whole societies and used equilibrium reasoning to spell out these tendencies and also as a critical tool against existing imperfections. They were also responsible for developing more clearly the dual categories of value-in-use and value-inexchange: the extensive and intensive attributes of commodities. Marx particularly excelled in developing economic terminology in decidedly dual categories with analogous and parallel reasoning for price-type and quantity-type theorems as, for instance, the process of production and the process of realization, surplus product and surplus value, technical and organic composition of capital etc. This he considered as the main achievement of his approach.

> The best thing in my book is: 1. the emphasis on the dual character of labour, right in the first chapter, according to whether the labour is expressed in use value or exchange value (this is the basis of the whole understanding of facts).

The other school, less critical about the market and seeking rather the perfection of market mechanisms, has been interested more in short run responses of the economic system, looking for local and particular explanation of the actual behaviour found on the diverse markets. They maintained that prices and quantities are determined by the marginal adjustments needed to adapt to equilibrium; thus prices, in particular, depend on marginal costs and quantities will be determined by maximizing profits. Among others it has been mainly Pareto (1896) and Marshall (1920) who honed the economic arguments to the textbook precision of present day economics.

With Böhm-Bawerk (1896) the battle between the two schools became exacerbated and they spared no argument in refuting 'inimical' standpoints. This confrontation remained heated and mostly unjust on both sides, harbouring a sometimes implicit, sometimes explicit, political content roughly dividing the two camps into evolutionary and revolutionary protagonists.

Considering its strictly theoretical merits the feud, nevertheless, resembles the altercation in mechanics: Newton's followers starting from equilibrium considerations and in search of the *causa efficiens,* while d'Alembert's disciples fight for an optimizing approach and are looking for the *causa finalis,* the aim and purpose of motion. It took much time and pain to acknowledge finally the basic equivalence of the two seemingly inimical and antagonistic approaches.

A similar insight has been injected into economics by von Neumann (1937). The theoretical roots of his approach to and model of General Economic Equilibrium can be found partly in earlier unifying efforts in mathematical economics and partly in thermodynamic reasoning.

As a pioneer in mathematical economics Walras (1874–7) had already developed a model to determine the prices and quantities of a given economic system simultaneously. By establishing $2n$ equations in the $2n$ unknowns, n prices and

n quantities, he claimed the problem to be theoretically solved.

The idea was brilliant, the set-up ingenious, the proof incomplete. By counting equations it is not possible to prove existence and uniqueness of a mathematical solution. Even in the relatively simple case of linear equations where all the unknowns appear in their simplest form, multiplied only by some coefficients and then added up, the equations may be inconclusive. They may be contradictory, not permitting any solution at all. They may also be redundant and allow multiple solutions. And even if a solution exists and is unique we cannot exclude on *a priori* grounds some negative elements. Yet negative prices or negative quantities are usually meaningless in an economic context and cannot be accepted as genuine solutions.

These perplexing problems were eliminated finally by von Neumann in the following way.

Let $A = \{a_{ik}\}$ be the matrix of commodity inputs, $i = 1, 2, \ldots, m$ required to sustain one unit of the process $k = 1, 2, \ldots, n$ and similarly $B = \{b_{ik}\}$ the matrix of outputs yielded by the respective processes. Then, given p prices and x quantities (or 'intensities of production') pAx and pBx will express the total value of inputs (respectively, outputs). Thus $\lambda = \lambda\ (p, x) = pBx/pAx$ represents the rate of interest (as a relation of proceeds to advances in the process of realization, or the rate of possible growth as a relation of commodities produced to commodities consumed in the production process).

Analysing the gradients of this function leads to the following dual conclusion: If $\partial\lambda/\partial x = (pB - \lambda pA)/pAx$ is non-positive, that is if

$$pB \leq \lambda pA \tag{1}$$

then λ cannot be further increased by any variation of x and hence will be maximal. If inequality obtains in (1) for any k, then $x_k = 0$ because the process operates at a loss and should be discontinued.

If on the other hand, $\partial\lambda/\partial p = (Bx - \lambda Ax)/pAx$ is non-negative, that is if

$$Bx \geq \lambda Ax \tag{2}$$

then λ cannot be further diminished by any variation of p and hence will be minimal. If inequality obtains in (2) for any i, then $p_i = 0$ because the commodity is produced in a superfluous quantity and thus turns into a 'free' good.

Von Neumann now proved that the function λ (p, x) has a 'saddle point' for positive prices and quantities, where the maximal rate of growth equals the minimal rate of interest. Thus he succeeded in solving the economic problem of equilibrium by defining a so-called potential function and replacing equations by inequalities. Existence and positivity of prices and quantities in equilibrium still permit multiple equilibria, in a double sense.

Firstly, as can be seen, every multiple of the equilibrium price system yields the same equilibrium value and likewise every multiple of the equilibrium quantities is again a system in equilibrium. Thus only proportions and not absolute magnitudes are determined. Yet by choosing, as Walras did, one of the prices as 'numeraire' and expressing all the others as multiples of this 'numeraire' – and fixing one of the quantities as the reference unit – the system can be made wholly determinate.

Secondly, there are certain cases – they could be called) 'degenerate' – where true multiplicity of entirely different solutions may emerge. This problem can sometimes be remedied by a small perturbation of the initial data. Yet, it now appears that the possibility of multiple equilibria cannot be ruled out *ab ovo,* because they may appear in real economic systems just as well.

The theoretically decisive root of von Neumann's approach can be found in phenomenological thermodynamics, especially with Gibbs (1875), whose treatise 'On the Equilibrium of Heterogeneous Substances' synthesized classical thermodynamics and opened the way for physical chemistry. He applied first a 'max-min' criterion for equilibrium: maximizing entropy and minimizing energy, just as von Neumann maximized the growth rate and minimized the rate of interest, and he seems to have been the first to apply inequalities as well as equations in the description and analysis of equilibrium.

Von Neumann was fully aware of the analogy and stressed it when setting up his potential function Φ (X, Y) to be maximized by quantities X and minimized by prices Y:

> A direct interpretation of the function Φ (X, Y) would be highly desirable. Its rôle appears to be similar to that of thermodynamic potentials in phenomenological thermodynamics; it can be surmised that the similarity will persist in its full phenomenological generality (independently of our restrictive idealization).

Von Neumann's original notation followed the then accepted usage in physics: X for 'extensive magnitudes', that is quantities, and Y for 'intensive magnitudes', that is prices. The gradients of a potential function (the partial derivatives according to the variables) spell out the 'force field' in physics, and the vanishing of those gradients is the necessary requirement of equilibrium. In the von Neumann model, as in thermodynamics, theoretical considerations induce a complex) 'saddle point' problem: instead of simply maximizing the potential function the saddle point can be found only through minimizing by some and maximizing by other variables.

It is not pure coincidence that this thermodynamic approach proved to be so fertile in handling economic problems. New investigations in the axiomatic foundation of thermodynamics indicate (Giles 1964, p. 26) that 'any experimentally verifiable assertion of thermodynamics can be expressed in terms of states with the aid of the operation + and the relation → alone'.

Though the axioms related to the permitted → transformations may turn out slightly differently in economics – there is important work undertaken concerning variously formulated basic axioms, Debreu (1959) being a powerful and articulate example – it is evident that the mathematical structure underlying the two scientific disciplines is closely similar in each case.

The new approach, because of the unification of criteria of optimality with criteria of equilibrium, did much to bridge the gap between the two opposing schools of economic thought. Both found their basic ideas tolerably well reflected in the set-up of the von Neumann model and hence a new round of revision and even partial reconciliation could be started.

One should stress: it has been surely the 'restrictive idealization' that facilitated the general acceptance of the new approach. The model only encompasses linear processes with a linear combination of inputs, resulting in a likewise linear combination of commodities. It represents, furthermore, only the production of freely reproducible commodities, that is: it does not contain any external constraints on the scale of production. Such a model keeps data and computational requirements relatively modest and is also easy to grasp.

With matrix notation now universally accepted this convenient shorthand made the model mathematically transparent. The very simple statement of dual equilibrium: $\lambda pA = pB$ and $\lambda Ax = Bx$ could not possibly be simplified further.

We now have an almost complete mathematical theory of so-called 'matrix pencils', that is matrices of the form $A + \lambda B$. It is interesting to note that Weierstrass (1867) reported on his investigations concerning this form in the same decade in which most of the ingredients, indispensable for our topic to take its present shape, were published. Marx, Walras, Gibbs and Weierstrass made known their results in the same decade not only independently but without having the slightest notion about each other.

With the advent of computers, also pioneered by von Neumann, matrices with several thousands of rows and columns became manageable and this permitted and motivated an everbroadening use and proliferation of a family of models having their theoretical and mathematical source in the von Neumann model.

Some very important and justly famous models were developed in the next decades. Being all equivalent in a mathematical sense to the Neumann model, as it has been demonstrated in most instances by the respective authors themselves, they can and should be considered as mathematical variants of the latter: input-output analysis, as proposed by Leontief (1941), linear programming, as investigated by Dantzig (1947) and Kantorovich (1940), the neo-Ricardian model set up by Sraffa (1960) and finally two-person game theory, an earlier product of von Neumann (1928), reaching broader scholarly circles only with the von Neumann and Morgenstern (1944) volume. (The last contains a further generalization to *n*-person games.)

In spite of the mathematical equivalence those models have been developed mostly independently and have roots in widely different economic considerations. Sraffa's approach, a careful and consistent restatement of Ricardo's value theory, proved to be particularly important. The underlying idea, if possible, is even more simple here. In a self-replacing system where, in the absence of growth, $\lambda = 1$ with no joint products, hence $B = 1$, the prices can be determined unequivocally by the postulate: the inputs required to reproduce the respective commodities have to be defrayed from the proceeds of selling the same commodities. Hence the proportions of prices and quantities are determined by the dual system of equations

$$pA = p \text{ and } Ax = x \tag{3}$$

Still in the more realistic cases, when extended reproduction and joint products have to be admitted, the description and solution is more rigorously and easily furnished by embedding the Sraffa system in a general von Neumann model.

Considering also the neo-Marxian restatement of labour theory as furnished by Brody (1970) and Morishima (1973), exploiting the Leontief model, where

$$p(A + \lambda B) = p \text{ and} (A + \lambda B)x = x \tag{4}$$

and B interpreted as a stock-input matrix, a certain consensus seems to be reached:

According to the neoclassical exposition of Hahn (1982), all the schools would compute the same numerical magnitudes for prices and quantities for an economic system in equilibrium. They would accept the same system of equations, though they would interpret those equations differently. Deeper and yet unreconciled differences emerge only when abandoning the critical point of equilibrium.

With painfully won reconciliation in sight a new theoretical attack on equilibrium reasoning takes shape. Kornai (1971), collecting all the critical observations and deeply influenced by the inadequacies of economic systems which endeavour to replace the market by equilibrium computations declared: the equilibrium school 'has become a brake on the development of economic thought'.

Paradigms – and equilibrium thinking is one such, with a domain much broader than economics alone – are seldom damaged by criticism. They may be done away with only by new and more powerful paradigms. Hence they rather thrive on objections – and all the internal problems already emerged with Smith who implicitly or explicitly maintained that equilibrium (i) exists, is (ii) optimal, is (iii) pursued and is also (iv) achieved.

Existence has been proved yet under 'restrictive idealization' in linear models but by a shrewd mind, knowing that it is permitted to approximate most functions, however complicated, linearly by taking their derivatives in the neighbourhood of the point analysed. (This may be achieved by taking a series expansion and neglecting terms of higher order.) The isomorphism of matrices and operators has been also well known to the pioneer of operator theory. So it is no wonder that all the models introduced are wide open to further generalization. Here non-linear programming, with Kuhn and Tucker (1956) and Martos (1975) and non-linear input–output models with Morishima (1964) have to be mentioned, also the success in generalizing the Neumann model by Medvegyev (1984) and applying operator calculus with Thijs ten Raa (1983). An increasing unification with linear and non-linear systems theory and with modern non-equilibrium thermodynamics can be safely predicted.

Optimality has also ethical, social, psychological and political connotations because one has to propose an entity (growth rate, utility, satisfaction, equity etc.) to be optimized. In this respect our subject belongs to the domain of welfare economics. Mathematically, the question is fairly simple: equilibrium and optimality can be made to correspond because solving equations is equivalent with minimizing the errors of the solution. That is: the solutions of $Ax = b$ and $Ax = r$ with $\Sigma\,(r - b)^2 \rightarrow$ minimal are the same if they both exist.

Ethical, political, and other convictions will of course always influence scholars in choosing and developing their topics but, luckily, they do not play any role in proving or refuting theorems and corollaries.

Stability, the question whether equilibrium can or cannot be achieved, if pursued, and maintained, once achieved, is the most interesting question in the forefront of present research. The stability analysis of economic systems, performed by methods borrowed again from physics and also thermodynamics: analysis of the eigenvalues of the response matrix, negative definiteness, discussion of the second partial derivatives, the le Chatelier–Braun principle etc. indicate that both market and planning systems are usually stable, yet seldom asymptotically stable, and if asymptotically stable the speed of convergence is usually very slow.

Stability means that a given deviation from equilibrium will not grow without bound: if the deviation is initially small it will not become infinite. This secures the feasibility of the system, its ability to function; yet a system may be stable and perform very poorly. Even asymptotic stability, that is achieving the decline and vanishing of discrepancies, is an unsatisfactory criterion in economic matters because by the time the equilibrium point is reached or approximated it may be already displaced by changes of the system itself.

In reality economic systems move not in slowly changing equilibrium states but along socalled transients, a succession of non-equilibrium positions. Thus we are still far from an acceptable theory of economic motion. The models introduced spell out requirements of equilibrium but not the actual forces bringing, or not bringing the system to equilibrium. Still, certain inroads have been made by models of cycles, for example, Kalecki (1935), Goodwin (1967) and Brody (1985).

But perhaps more important than analysis seems to be the task of synthesis. Acknowledging that neither plan nor market can avoid economic fluctuations, the quest for controlling prices and quantities in a smoother and more efficient way is understandable. Questions of optimal control in linear and nonlinear systems emerge and once approximately solved the search will go unavoidably deeper: how to control the position of equilibrium itself, how to become master of structure and technology. To shape interdependence itself in a conscientious manner, to influence the outcome of technological and structural change is the next item on the agenda of mathematical economics.

Prices of Production

G. de Vivo

This expression is used by Marx, mainly in Volume III of *Capital,* to indicate the exchange values of commodities, when he fully takes into account the inconsistency between the uniformity of the rate of profits and an exchange in proportion to labour embodied. He accordingly tables the famous 'problem' of the 'transformation of the Values of Commodities into Prices of Production' – i.e., into prices which would include profits at a uniform rate on *the whole* capital advanced ($c + v$), and which would therefore differ from relative embodied labours, when commodities differ in the 'organic composition of capital' (c/v). The expression 'prices of production' (which Marx regards as synonymous with 'cost-prices', and with Smith's 'natural prices') starts to be commonly used by Marx only some time after he had actually formulated the 'transformation problem', and provided his solution. In *Theories of Surplus Value* (1862–3), for instance, he would normally still employ its synonym 'cost-prices'. But 'prices of production' is used in the 1893 draft plans for Volume III of *Capital* (printed in Marx 1862–3, I, pp. 414–16).

Although the classical economists generally used the expression 'natural prices', 'prices of production' had some currency in the mid-1810s, when it was used by Torrens, in the first edition of his *Essay on the External Corn Trade* (1815, p. 229; at this time, it was also used by Malthus and Ricardo in their correspondence, but not in their published writings).

It is noticeable that Torrens not only preceded Marx in employing the expression 'prices of production', but also formulated something very similar to his 'transformation'. Torrens criticized Ricardo's labour theory of value on the ground that 'the rate of profit in the several occupations of industry always tends to an equality', and therefore 'as equal capitals generally put unequal quantities of labour in motion, . . . the products of equal quantities of labour will be of unequal value' (Torrens 1818, pp. 57–8). He accordingly states that the price of each commodity would be determined by adding profits at a uniform rate to the value (labour embodied) of the total capital employed in its production. This is basically what Marx does in his 'transformation'. The main difference is that Torrens does not determine the rate of profits as a ratio between the labour values of the profits and of the capital [$s/(c + v)$], and he is in general unable to determine it (for more details on Torrens's theory, see de Vivo 1986; see also Robbins 1958, p. 60 ff.).

Marx knew Torrens's 1815 *External Corn Trade*, which is quoted in Volume I of *Capital*. In Volume III of *Theories of Surplus Value* he discusses at length Torrens's conceptions on value, to some extent acknowledging Torrens's anticipation of his points (1862–63, III, p. 72).

Pricing on the Internet

Michael R. Baye and John Morgan

Abstract

While many conjectured that the information-rich and frictionless nature of online markets would result in marginal cost pricing, this has proved not to be the case. Price dispersion online is ubiquitous. The main reason is that price discovery occurs through platforms that have an incentive to ensure that prices are dispersed so that information is valuable. We survey models of platform pricing and trace the impact of their decisions downstream to e-retailers. Finally, we highlight the connection between empirical findings and theory predictions for e-retail pricing.

Overview

Initial studies of pricing on the internet focused on e-retail pricing, where many conjectured that the frictionless nature of online markets would result in marginal cost pricing and the 'law of one price'. More recent attention has centred on the pricing decisions of platforms – websites such as Google, Amazon, eBay and Facebook – that are basins of attraction for consumers as well as firms. The prices charged by platforms and e-retailers are intertwined: a platform's choices feed into downstream advertising and pricing decisions, and vice versa. Of course, both sets of prices affect consumer browsing and buying decisions.

This article recognises these interconnections and begins upstream, at the platform level. We discuss the evolution of the literature on platform pricing, including access fees, transaction fees, menu prices and auctions. We then examine how market structure influences platform pricing. Next, we move downstream to discuss the pricing and advertising decisions of e-retailers, and conclude by examining how market structure shapes these decisions.

Platform Pricing

Baye and Morgan (2001) provide the first model of optimal pricing by a platform that serves consumers and firms in a two-sided market for information. In their model, $n > 1$ geographically separated towns are each serviced by a local firm. While transaction costs preclude consumers domiciled in one town from physically visiting stores in other towns, a third player – an independent platform – operates a virtual marketplace that can tear down the geographic barriers separating consumers and firms. Firms advertise at the platform to gain access to consumers in distant towns; consumers visit the virtual marketplace, gain access to the list of advertised prices, and benefit if they find a price better than that charged by their local firm. The platform recognises that information is a valuable resource, and charges access fees to consumers and firms using its site. The access fee on the buyer side of the market represents a consumer's cost of subscribing to (or accessing) the platform's website, while on the seller side it is an advertising or listing fee.

The two main findings are: (1) the platform's optimal access fees result in e-retail prices that are dispersed even though firms are identical, and (2) the platform finds it optimal to charge consumers low (or even free) access fees, instead profiting from advertisers. Finding (1) stems from the value proposition of the virtual market: absent price dispersion, consumers find the platform's information to be worthless and, absent consumers, firms find the platform itself to be worthless. The platform therefore endogenously injects frictions into the market (by charging positive access fees on the seller side of the market) to maximise its profits. Finding (2) stems from an externality between the two sides of the market: by charging consumers low access fees, the platform attracts consumers, creating a virtuous circle inducing firms to advertise. Baye and Morgan show that the platform captures more value by maximising consumer participation than from extracting rents from both sides of the market.

The term 'two-sided market', which never appears in Baye and Morgan, became prominent due to Rochet and Tirole (2003). In contrast to Baye and Morgan, who emphasise within-side competition among sellers using the platform, Rochet and Tirole study situations where such competition is effectively absent. Additionally, while Baye and Morgan focus on the access fees charged to participants on different sides of the market, Rochet and Tirole study transactions fees.

In the Rochet and Tirole model, a buyer and seller meet to determine whether to conduct their transaction through the platform or not. While they couch the model in terms of credit card use, it also applies to online dating and other match-based services. A consumer will use the platform if her value (v^b) exceeds the price (p^b) charged by the platform for the transaction. Let $D_b(p^b)$ denote this probability (referred to as quasi-demand). Analogous conditions hold for sellers with a transactions value of v^s and a transactions price p^s. Assuming v^i are statistically independent, and there is a constant marginal cost of processing each transaction, the platform's per-transaction profit is

$$\pi = \left(p^b + P^s - c\right) D_b\left(p^b\right) D_s\left(p^s\right)$$

Assuming that quasi-demands are log-concave, optimal pricing depends, in a simple way, on relative elasticities. The transactions price in each side of the market satisfies a variant of the standard monopoly markup formula, but accounts for the connection between the two sides. Specifically, the optimal transaction fee satisfies

$$p^i = \frac{1}{1 - \eta^i}\left(c - p^j\right)$$

where η^i denotes the quasi-demand elasticity for a particular side i of the market.

This implies that, other things equal, an increase in the elasticity of quasi-demand on either side of the market reduces the total transactions price.

The transactions prices paid by parties on different sides of the market are determined by the ratio of their elasticities:

$$\frac{p^b}{p^s} = \frac{\eta^b}{\eta^s}$$

Thus, the predicted pricing behavior has the feature that the side with the *more* elastic demand pays the *higher* transactions fee. This prediction is the opposite of that for conventional markets, and illustrates how optimal pricing rules in two-sided markets differ from standard results.

This pricing structure depends critically on the log-concavity assumption, which rules out commonly used empirical demand specifications such as the constant elasticity formulation arising when values are Pareto-distributed. For this case, Bolt and Tiemann (2008) show that the platform charges *lower* prices to the more price-sensitive side of the market. More precisely, a profit-maximising platform sets a sufficiently low transaction fee to induce full participation on the more elastic side of the market, and captures surplus by charging higher fees on the less elastic side. This structure is identical to Baye and Morgan's finding in information markets, where the platform is restricted to *access* fees.

The broad lesson is that optimal platform pricing is sensitive to the structure of demand on each side of the market, the set of pricing instruments available to the platform, and the nature of externalities within and between sides of the two-sided market. There is no simple or universal solution to the problem of optimal platform pricing – details matter.

Recognising this, subsequent research generalised these early models along two key dimensions: expanding the set of price instruments available to the platform and the nature of network externalities between the two sides of the market. Armstrong (2006) is notable in both respects. His linear utility structure allows for variability in the value of each additional platform user to the other side of the market. He also allows the platform to offer a combination of access and transaction fees. As with Rochet and Tirole, within-side competitive effects are absent, primarily for tractability. Armstrong studies competition between horizontally differentiated platforms.

Two key insights emerge from Armstrong's analysis. First, despite the presence of network effects, platforms can coexist in equilibrium provided they are sufficiently differentiated. Second, these externalities actually sharpen price competition. Compared to the situation where such network effects are absent, platforms offer lower prices both as a defensive response to aggressive pricing by rivals as well as offensively to attract market share that makes their network more valuable. In equilibrium, platform pricing depends on the degree of market power and externalities on both sides of the market.

Baye et al. (2011) also enrich the set of pricing instruments available to platforms. In contrast to Armstrong, their setting features within-side competition among sellers. Their main finding is that, despite having the possibility of using two-part tariffs (a combination of fixed access fees and variable transactions fees), a monopoly platform optimally prices solely through transaction fees. This result rationalises an important trend in platform pricing during the decade of the 2000s. At the start of the decade, platforms such as price comparison sites typically based their fees on impressions (eyeballs) rather than actions of users (clicks). By the end of the decade, the so-called CPC (cost per click) model of advertising was dominant. Under CPC, advertisers only pay when a transaction (a click) occurs. While this shift was widely seen as a concession to advertisers in the face of uncertain returns to online advertising, their result implies that platforms, in fact, benefit from this pricing practice.

Weyl (2010) further expands the set of pricing instruments available to a monopoly platform to include price menus that depend on the level of participation on each side of the market. While he allows for general demand and externalities in the market, he excludes within-side competitive effects. In this setting, Weyl demonstrates the optimality of *insulating tariffs* – contingent pricing where prices on one side of the market depend on the level of adoption on the other side. Such pricing structures are common in advertising at traditional media outlets. For instance, standard television advertising contracts contain provisions that adjust the rates paid by advertisers based on the number of viewers of the show on which the advertisement appears.

A separate strand of the literature abstracts from network externalities entirely and focuses instead on mechanisms to deal with the apparently insoluble pricing problems confronting platforms. For instance, to optimally price an advertisement triggered by a search query, the platform must account for the query itself, information about the user, the time and location in which the query takes place and so on. Rather than using a top-down method for pricing, Google and other search platforms have turned to auctions, essentially letting participants on the advertiser side of the market solve the pricing problem for them. These so-called 'slot auctions' have their own unique structure: advertisers place a single bid, indicating their maximum willingness to pay per click. Bids are then sorted from the highest to lowest with the highest bid getting the top slot (i.e. the highest position on the page of search results), and succeeding bids are allocated the next lowest slot until all slots are taken up. In practice, a combination of factors determines an advertiser's position. Roughly speaking, the platform estimates the clicks generated by a given ad, and multiplies this by the bid to determine expected revenues, which are ordered by bidder. (The exact process by which this determination takes place is a trade secret of each platform.)

Most slot auctions use the generalised second price (GSP) rule to determine payments. A simple form of this rule has the highest bidder pay the second-highest bid, the second-highest bidder pay the third-highest bid, and so on. This pricing rule seems similar to the familiar second-price auction mechanism, and thus would appear to induce advertisers to bid their true (private) values, as in Vickrey (1961). This is not the case, however; Edelman et al. (2007) and Varian (2007) show that, generically, truthful bidding is not an equilibrium outcome. Nonetheless, there exists an equilibrium to a GSP auction that produces the same expected revenues as a Vickrey auction.

Another important difference between slot auctions and standard auctions concerns revenue equivalence. The predecessor to the GSP auction, a form introduced by the firm Overture, had each bidder simply pay its own bid. Based on the revenue equivalence theorem, one might be tempted to conclude that this auction form produces the same expected revenues as the GSP auction. Edelman et al. show that this is not the case either; in general, the GSP auction outperforms the Overture auction.

Market Structure and Platform Pricing

We now turn to the impact of market structure on platform pricing. The network effects typically present on both sides of the market can easily lead to a situation of natural monopoly and, indeed, in many real-world platform markets, there is a single dominant player. Facebook is the dominant social networking site, Google dominates search, eBay dominates online auctions, and so on. Other markets, however, are more fragmented; for instance, no single dominant platform has emerged in online dating. This section explores how industry fundamentals influence market power, and hence pricing.

A key dimension along which the examples above differ concerns the degree of horizontal differentiation. For dating platforms, horizontal differentiation is paramount. Indeed, one of the more popular platforms, Jdate, expects its users to be Jewish, which obviously limits the size of its potential market. By contrast, horizontal differentiation seems less important for the choice of operating systems. Competition in Rochet and Tirole (2003, 2006), Armstrong (2006), Armstrong and Wright (2007), and others is generated through sufficient horizontal differentiation among platforms. But what if such differentiation is absent?

Caillaud and Jullien (2003) provide an answer to this question in an important early paper studying competition between vertically differentiated platforms. In their model, platforms compete in access and transactions fees and differ in the efficiency with which they match the two sides of the market. Competitive effects on a given side of the market are absent in their setting. Their main finding is that monopoly structures emerge although the threat of entry limits the market power of the monopolist. This is consistent with the widely held view that platform coexistence is unstable when platforms are undifferentiated or vertically differentiated.

Ellison and Fudenberg (2003) and Ellison et al. (2004) challenge this view.

They point out that, while a platform with the larger market share generates scale effects (users of an online auction site benefit from greater breadth of offerings, for instance), within-side competition on a platform creates a countervailing *market impact effect* (additional sellers on an online auction platform lead to lower seller payoffs). They show that the market impact effect can be large enough to offset the scale effect and allow platforms of very different size to coexist.

A simple example captures their intuition. Suppose that an online auction market consists of three sellers and six buyers choosing between two identical platforms. Platform A attracts one-third of the buyers and sellers in this market while platform B attracts the remaining two-thirds. By virtue of its size, buyers and sellers on platform B enjoy higher surplus than those on platform A. This begs the question: Why don't the individuals on platform A simply switch to platform B? The key is the market impact effect. A buyer switching from A to B increases the competition on platform B and, consequently, raises the price for the item since there are now 5 buyers rather than 4 competing for the same 2 items. With a large enough price increase, this can more than offset the scale advantage and cause buyers to remain at the smaller platform. A similar effect is present for sellers at the smaller platform.

The lesson from this literature is that the presence of within-side competitive effects fundamentally changes conclusions about market structure, even when platforms are undifferentiated.

Brown and Morgan (2009) empirically examine the implications of the Ellison et al. models. They conduct field experiments by selling rare coins on two competing online auction sites in the US: eBay and Yahoo. They find no evidence of compensating market impact effects, instead concluding that this market was in the slow-motion process of tipping to eBay. (Subsequent to their experiments, Yahoo closed its US online auction site, leaving eBay as the single dominant player.) Using laboratory experiments Hossain et al. (2011) also investigate the dynamics of platform competition, varying the degree of horizontal and vertical differentiation, as well as market impact effects. Regardless of the magnitude of the market impact effect, they find that platforms coexist only when there is sufficient horizontal differentiation; otherwise, the market tends to tip to the more efficient platform. The phenomenon of tipping to quality appears in many empirical studies as well. For instance, Tellis et al. (2009) investigate market shares across competing technology platforms. They find that the higher-quality platform (as reflected by review sites) tends to dominate its market.

E-Retail Pricing

We now examine the implications of platform pricing on downstream retailers' pricing and advertising decisions. We highlight two key features of the landscape: price dispersion and the trend toward posted prices rather than auctions.

The primary focus of the early e-retail literature concerned price dispersion. While price dispersion was widely observed in offline markets, the main explanation for it, dating back to the seminal paper of Stigler (1961), was search friction, including 'shoe-leather' costs. The internet dramatically reduced search friction – physical visits to stores were no longer necessary and extensive product information was readily available online. It stood to reason that price dispersion should vanish in an internet world, a view capably summarised by *The Economist* (20 November 1999, p. 112), which argued:

> The explosive growth of the Internet promises a new age of perfectly competitive markets. With perfect information about prices and products at

> their fingertips, consumers can quickly and easily find the best deals. In this brave new world, retailers' profit margins will be competed away, as they are all forced to price at cost.

This 'brave new world' turned out to be a fiction. Brynjolfsson and Smith (2000), in the earliest comprehensive study of online pricing, document considerable price dispersion – the range in online prices for an identical product often exceeded 100% for the books and CDs they surveyed. They conclude that '…while there is lower friction in many dimensions of Internet competition, branding, awareness, and trust remain important sources of heterogeneity among Internet retailers' (p. 563).

The price dispersion documented above was for listed prices, but consumers care about *landed* prices, including shipping, handling and taxes. Since these additional costs constituted a large portion of the landed price of books and CDs (still mainly sold in physical rather than in digital form at the time of their study), consumers would economise by bundling their purchases. This led some to argue that the law of one price, while violated on a product-by-product basis, might still hold once one properly accounted for bundles of goods.

Baye et al. (2004) address this concern by focusing on higher priced consumer electronics products such as computer monitors, cameras, printers and PDAs (personal digital assistants). Shipping costs for these items represent a small fraction of the price (which averaged about $500 in their sample). Consequently, bundling is less important to purchase decisions. They too found evidence of considerable and ubiquitous price dispersion. Using even the most conservative measure, the gap between the lowest and second-lowest prices on offer, they found average dispersion levels of 5%, a far cry from the world envisaged by *The Economist.* Moreover, they found systematic differences in price dispersion depending on the number of firms listing prices at the comparison site (platform) they studied. The gap between the two lowest prices systematically shrinks with the number of competitors, but the range in prices increases in the number of competitors. A key point raised in the study is that the effect of competition depends crucially on the measure of price dispersion being used.

The first theoretical model that formally rationalised online price dispersion is that of Baye and Morgan (2001). As discussed above, firms in this model can advertise their prices on the platform to attract geographically distant shoppers. Firms must pay the platform a fee to advertise, but will only succeed in attracting these shoppers when they offer the lowest advertised price. Firms face a tradeoff between charging low prices and paying fees to attract distant shoppers, or charging the monopoly price, eschewing the platform, and catering to local customers. Resolving this tradeoff entails mixed, or randomised, pricing and advertising strategies. These strategies make both price and geographic reach unpredictable, thereby preventing rivals from systematically offering better deals on the platform.

The essence of the model is captured in a simple environment where S shoppers use the platform to buy at the lowest price and L loyal consumers per firm do not.

All consumers have unit demand up to a reservation price r for an identical product sold by n firms with constant marginal cost m. When the platform charges firms an access fee of ϕ, each advertises on the platform with probability

$$\alpha = 1 - \left(\frac{n\phi}{(n-1)(r-m)S}\right)^{\frac{1}{n-1}}$$

A firm that does not advertise on the platform charges a price of r, while a firm that does advertise sets its price $p \in [p_0, r]$ based on the distribution function

$$F(p) = \frac{1}{\alpha}\left(1 - \left(\frac{\frac{n}{n-1}\phi + (r-p)L}{(p-m)S}\right)^{\frac{1}{n-1}}\right)$$

The lower bound of the distribution of prices is

$$p_0 = m + \frac{\frac{n}{n-1}\phi L(r-m)}{L+S}$$

Notice that, despite the fact that firms compete purely on price and are identical in every way, prices are always above marginal cost. More importantly, this pricing formula highlights the link between upstream platform pricing (ϕ) and downstream e-retail pricing: the higher is the listing fee charged by the platform, the higher are the resulting e-retail prices (in the sense of first-order stochastic dominance). Thus, the strategic injection of "frictions" by the platform itself in the form of a positive listing fee, $\phi > 0$, impacts pricing, with higher fees softening of price competition and raising firm profits.

Several other models explaining price dispersion are nested in this specification, including Shilony (1977), Varian (1980), Rosenthal (1980), Narasimhan (1988) and Iyer et al. (2005); see Baye et al. (2004) for details. The key forces highlighted in these models are differences in consumer information and loyalty.

Specifically, Varian (1980) argues that informational differences among consumers are critical drivers of price dispersion. In his model, some consumers are perfectly informed about available prices while others are uninformed and face high search costs. One can think of these uninformed consumers as those on the wrong side of the 'digital divide', i.e. those lacking access to the internet or unaware of the search tools available online.

Rosenthal (1980) argues that brand loyalty drives price dispersion. In his model, some consumers are loyal to a particular firm and view its services as superior to those offered by all other firms. The remaining consumers are shoppers, who view all sellers as identical and purchase from the firm offering the lowest price.

Iyer et al. (2005) extend the above models to include targeted advertising *à la* Butters (1977). In their model, firms advertise not simply to inform consumers about prices, but also to alert consumers to their very existence, and this again produces price dispersion via mixed strategies.

A parallel literature explored the unique features of auctions as a selling mechanism. This literature is less relevant to the current e-retail landscape as fewer goods are sold online via auction. Online auctions fundamentally transformed a number of markets, particularly for collectibles, once dominated by small stores. Even for these items, auctions are now less used – over 70% of eBay's revenues now come from sales via posted prices. Largely this is because the types of items sold online now more closely resemble the mix sold offline. In addition to digital media, such as books, music and games, traditional offline goods such as apparel and white goods are now offered and sold online. The need for price finding via an auction is largely absent in markets for goods where a 'street price' may be readily ascertained. Of course, auction models are still useful for modeling some posted-price markets; see Spulber (1995).

We conclude by noting that, while many e-retailers responded to the plethora of information available online by cutting prices, today there is a renewed emphasis on non-price competition. This includes providing customers with high levels of service, fast shipping, one-stop shopping, seamless returns and so on. In terms of value creation, the greatest impact of the internet has arguably been the ease with which consumers can locate products. Brynjolfsson et al. (2003) proved prescient in this regard; they document that even in the very early days of the online book market, most of the value creation stemmed from consumers' abilities to find books in the 'long tail'.

Market Structure and e-Retail Pricing

Most people view e-retail as being extremely competitive, so presumably individual sellers face highly elastic demands. But just how elastic are the demands faced by e-retailers? Chevalier and Goolsbee (2003) use a clever identification strategy to provide an answer for online booksellers. By directly intervening in the book market and observing how their purchases affect a book's sales ranking, they deduce the demand elasticities faced by the two largest booksellers. They estimate Amazon's elasticity to be about 0.6 while Barnes & Noble's is about 4. In contrast, Ellison and Ellison (2009) report an elasticity in excess of 20 for a firm selling aftermarket RAM (computer memory) – much closer to perfect competition.

Baye et al. (2009) suggest that differing market structures for books and aftermarket RAM memory can account for these differing elasticity estimates. A few large players dominate the market for books, while the memory market is highly fragmented, with hundreds of small firms competing. Standard pricing models indicate that a firm's elasticity of demand varies with the number of its competitors; thus, one might expect more elastic firm demand for RAM than for books. They examine this hypothesis using clicks data on PDAs sold through Kelkoo, a price comparison site in the UK. When only a single seller lists a price, the estimated elasticity is around 2, but it rises to 6 when 15 sellers list prices. Thus, market structure appears to be an important determinant of an e-retail firm's demand.

One of the key implications of the models described earlier, which feature shopper/loyal or informed/uninformed consumer segments, is that a firm experiences a discontinuous jump in its demand when offering the lowest price on the platform. A firm that cuts its price from slightly above to slightly below the low-price competitor captures the price sensitive consumer segment. Baye et al. (2009) estimate that a firm experiences a 60% jump in demand in these situations, which is consistent with a situation where about 13% of Kelkoo's users are price sensitive 'shoppers'.

Another important feature of these models is that some consumer segments may not benefit from competition. For instance, in the Varian model, informed consumers expect to pay the *minimum* listed price, which falls with the number of competing firms owing to an order-statistic effect. In contrast, uninformed consumers pay the average listed price, which *rises* as more firms compete. The intuition for this perverse result is that, by reducing the chance that a firm will attract informed consumers, competition discourages firms from cutting prices. Thus, increased competition disparately affects the prices paid by consumers in different segments: there are both winners and losers.

The ease of price comparison and ready access to product information has turned some e-retail markets, such as aftermarket RAM, into landscapes resembling perfect competition. Firms have countered by developing a number of strategies to inject informational frictions back into the search process, thereby softening price competition. One such strategy is obfuscation (or, more bluntly, bait and switch). Here, an e-retailer offers a low-price/low-quality item at the platform and then attempts to upsell the consumer who clicks through to the e-retailer's own site. Ellison and Ellison (2009) note the effectiveness of such strategies in the computer memory market.

Another strategy is to break a price into various parts, such as a base price and a shipping charge, and make one of these parts (shipping, usually) difficult to ascertain. This strategy, termed price 'shrouding' by Gabaix and Laibson (2006), is increasingly prevalent among e-retailers. Gabaix and Laibson provided a theoretical rationale for such strategies, which Hossain and Morgan (2006), as well as Brown et al. (2010), explore empirically. They conducted field experiments in online auction markets for music CDs, video games and iPods, varying both the opening bid and the shipping charge. They find that consumers do not fully account for the shrouded aspects of prices, and that merchants can (and do) profit from these cognitive errors. In a large-scale follow-up study using eBay data, Levin (2011) confirms these results.

We conclude by noting that the rise of vertical integration makes it increasingly difficult to distinguish e-retailers from platforms. Leading this trend is Amazon, which began life as an upstart online bookseller, but has evolved into a retail platform featuring its own offerings, offerings of affiliated merchants, and even outside offerings determined through bidding, much like a search engine. Apple, which initially focused on hardware, is now the largest digital music platform. Its App Store represents an enormous software platform, and its aggressive move into e-books triggered a fierce fight with Amazon (and competition authorities) over its pricing practices. Google, meanwhile, has evolved from being purely a search engine to providing mobile operating systems, browsers and mobile hardware (through its acquisition of Motorola). How these changes affect online pricing represents an important open question. Chen (2008) provides an interesting initial look at how vertical integration by an 'information gatekeeper' into the product market it serves affects upstream and downstream pricing decisions.

Pricing Services Online, Economics of

Anja Lambrecht

Firms deliver a variety of services online, ranging from content, software and banking to entertainment and networking. This article examines a firm's pricing decision for online services. It first discusses how a firm's decision of pricing services online differs from offline pricing decisions. It then discusses how firms can price services online. It examines the firm's choice between 'fee' or 'free' revenue models. It then turns to a firm's decision on its pricing structure. This includes the decision whether to sell or to rent, and the choice between pricing plans (e.g. pay-per-use, flat-rate tariffs or more complicated multi-part tariffs) or bundling. Lastly, it turns to the role of pricing in new product adoption.

Introduction

There is a large and growing literature in economics and marketing that relates to how firms price services that can be delivered online and how consumers respond to firms' pricing strategies. Broadly, this falls into two areas. First, researchers study a firm's choice between 'fee' or 'free' revenue models. This means that firms may offer the service for free and instead focus on other sources of revenue, such as advertising. Second, researchers examine the firm's choice of pricing structure. This includes the choice between selling or renting, or between different pricing plans or tariffs such as pay-per-use, flat-rate tariffs or more complicated multi-part tariffs. Lastly, the choice of pricing plan may play an important role in new product adoption, which is particularly important in markets with network effects where fast take-off is important for later success.

In this article, we refer to online services as services that are sold and delivered online, such as online content, networking or games. We discuss the firm's choice between different pricing strategies for such services. The Internet is also used to reach consumers to sell a large range of products or services that are delivered offline (e.g. amazon.com). For such goods, the Internet has enabled experimentation with a wide variety of pricing mechanisms that may be more difficult to implement offline. These mechanisms include online auctions (e.g. eBay), reverse selling (e.g. Priceline), advance purchasing (e.g. Groupon), and the use of investors as a revenue source (e.g. Kickstarter). Since these are not online services per se, but use the Internet merely as a channel for reaching customers, we do not consider such settings.

Services Online

Firms deliver a variety of services online, including content (e.g. huffingtonpost. com, nytimes. com), software (mcafeestore.com), banking (ingdirect. com), Internet connection (comcast. com), networking (linkedin.com, facebook. com) and entertainment (netflix.com, zynga.com, itunes.com).

A firm's choice of pricing services online differs from offline pricing decisions along three dimensions. First, while fixed costs of production or of providing the service infrastructure may be substantial, the marginal cost of serving an additional customer online is most often zero or close to zero. This gives the firm great flexibility in pricing. Second, many firms may offer the service free of charge and instead sell advertising. The ability to select among different streams of revenue has both broadened and complicated a firm's choice of revenue models, which is no longer restricted to setting a price level. As a result, a firm may face a competitor that offers their service for free. Third, in digital environments it is relatively easy to meter a consumer's usage accurately and to implement usage-based price discrimination.

Fee or Free Pricing

Many firms that sell services online can choose either to charge users for access to all or part of their service, or to provide the service for free. When services are provided for free, firms sell advertising or other complementary services. Online content providers, for example, have chosen a variety of fee or free pricing strategies. For example, the *Los Angeles Times* offers all content for free, the *Times* requires a subscription to view any articles, and the *New York Times* offers 10 articles a month for free, but only subscribers can view additional articles. Broadly, the economics and marketing literature has taken two perspectives on a firm's choice between free and fee strategies.

Sampling when firms use sampling, they offer a free sample of the product and require consumers to pay for full usage (e.g. nytimes.com). The idea is that after sampling a service, consumers become more likely to sign up for its full version, which increases long-term sales (Bawa and Shoemaker 2004). Additionally, for digital goods, free samples alongside high prices can signal superior quality (Boom 2010). Halbheer et al. (2013) show that the choice of a sampling strategy is determined by the relationship between advertising effectiveness and content quality. Offering only paid content is optimal under low advertising effectiveness. For intermediate levels of advertising effectiveness, the publisher should switch to a sampling strategy. Only under high levels of advertising effectiveness is it optimal to offer all content for free.

Trading Off Advertising and Subscription Revenues the basic trade-off for firms that provide services for free is that charging for access to content reduces the number of page views by users and hence the potential for advertising revenues. The challenge is to identify when a 'free' or a 'fee' strategy may be optimal.

In early research, Shapiro and Varian (1998) and Bhargava and Choudhary (2001) show that offering both a paid and a free component can allow firms to implement quality differentiation, versioning or seconddegree price discrimination. Godes et al. (2009) more explicitly examine the trade-off between subscription and advertising revenues. They find that since greater competitive intensity may reduce advertising revenues, a firm in a duopoly is less willing to under-price content to increase demand than a monopolist. As a result, greater competitive intensity may increase profits from charging for content and decrease profits from advertising. However, offering paid content can lead to both a loss in visitors and to a positional disadvantage in advertising markets, since advertisers are willing to pay a premium to firms with a high expected share of loyal consumers (Athey et al. 2013). Prasad et al. (2003) do not consider the competitive setting, and instead focus on the effect of consumer heterogeneity in their willingness to pay to avoid ads. They find that in most cases the firm should combine payper- view and advertising revenues, rather than relying exclusively on either pay-per-view or advertising revenues. As Halbheer et al. (2013) illustrate, advertising effectiveness and content quality will further determine whether the firm should charge for access to content. These results illustrate the complexity of a firm's decision that needs to account for the competitive setting in the market for consumers and the market for advertisers, the attractiveness of its content, and the heterogeneity in consumers' tastes.

Empirically, Pauwels and Weiss (2007) find for an online content provider targeted towards marketing professionals that moving from free to fee can be profitable, despite the loss of advertising revenue. However, it is not clear whether such insights readily apply to consumer markets. Indeed, recent pricing research finds that among consumers the demand effect of changing from a zero to a small non-zero price may be significantly more pronounced than what price elasticities evaluated at other points of the demand curve would suggest (Odlyzko 2001; Shampanier et al. 2007; Ascarza et al. 2012). This likewise suggests that in consumer markets relatively low fees for online services may strongly discourage consumers from visiting the site.

In line with this insight, Chiou and Tucker (2011) find a strong negative effect of the introduction of a paywall by an online news site, particularly among younger consumers. Using micro-level data from the sports site ESPN, Lambrecht and Misra (2012) quantify the tradeoff between greater subscription and lower advertising revenues from offering paid content and find that whether the firm benefits from adding an additional paid article varies by whether a sport is offseason, in regular season or in post-season. They attribute these differences to a variation in the value of sport news across seasons and suggest that firms should pay attention to how consumer valuation of online content varies across time and dynamically adjust the amount of paid content. (Note that a firm's decision to sell advertising and offer the service for free may also affect the type of content a firm provides. Sun and Zhu (2012) show that when incentivised by ad revenues, blogs are more likely to show more popular content.)

In sum, these insights document that whether a firm can successfully charge for access to its service is related to consumers' valuation of the service, which may vary across customers and across time. They also show that in evaluating whether a fee or a free strategy is optimal, the firm needs to quantify both additional revenues from subscriptions and the loss in advertising revenues due to the increase in page views.

Note that how valuable a site is for advertisers also depends on how well such a site can target consumers. Search engines, for example, have proven highly valuable for advertising. By typing search terms, consumers directly reveal their intentions and preferences, including in many instances their intentions to purchase (Edelman 2009). As a result, Google is able to generate almost all its profits from advertising revenues and can provide the service for free to searchers. Other sites that offer neither a high-quality online environment that may allow brand advertising nor are able to target consumers may only be able to generate low advertising revenues. (Recently developed tracking techniques also allow firms that sell display advertising to target consumers with ads suited to their specific interests and purchase intentions (Lambrecht and Tucker 2013)).

Setting the Price Structure

A firm that charges for access to services needs to determine how to price its offering optimally. The ability to meter consumers' usage behaviour in real time on the level of each individual consumer means that firms may implement a wide range of pricing formats, including selling vs. renting, charging flat fees versus charging for usage, and different forms of usage-based price discrimination.

Selling vs. Renting Internet technology allows many firms to choose between renting or selling digital content to consumers. Renting usually limits a consumer's right to use a service (e.g. watch a movie) to a fixed period of time, whereas purchase grants unlimited rights of usage. Rao (2011) analyses whether an online movie provider should focus on a sell or rent strategy. She finds that consumer heterogeneity in one-time versus repeat consumption preferences drives purchase and rental offerings. As a result, a firm can use purchase and rental markets to differentiate between consumers.

Even when consumers typically require repeated usage, attempts have been made to rent products as a service instead of selling physical products. The firm is able to 'servify' the product, since digital technology allows close monitoring and charging for an individual's usage of a product. Such attempts to turn physical products into services go back to the early days of the Internet. For example, Electrolux Sweden piloted installing washing machines for free in consumers' homes and asked consumers to payper- wash, providing the service 'clean clothes' instead of a physical product (http://group.electrolux.com/en/electrolux-offers-7000-householdsfree- washing-machines-1885/). However, despite initial enthusiasm about the ability to price discriminate between consumers who require little usage (and hence would be better off renting the service) and intense users (who benefit from purchasing), such pricing techniques have never been fully embraced. Research suggests that this can be linked to consumers' preferences for paying flat fees rather than per use.

Flat Fees or Pay-Per-Use when a firm is able to meter consumers' usage it can charge for actual usage instead of a flat fee, so a consumer's bill more accurately reflects their consumption (Levinson and Odlyzko 2008). Yet research finds that consumers often prefer a flat-rate tariff to a tariff that charges for actual usage, even if the consumer's bill ex post would be lower on a tariff that charges per usage (Train et al. 1987; Kridel et al. 1993; Lambrecht and Skiera 2006; DellaVigna and Malmendier 2006). Lambrecht and Skiera (2006) document three reasons for the so-called flat-rate bias. First, consumers' dislike of metered usage may lead them to enjoy their usage less than they otherwise would (see also Prelec and Loewenstein 1998), also referred to as the 'taxi meter effect'. Second, consumers prefer a steady bill to variation in their bill over time, which can be linked to risk aversion and loss aversion. Third, consumers may over-estimate their usage and mistakenly believe they have chosen the optimal tariff. Findings by Iyengar et al. (2011) further confirm consumers preferences for flat-rate tariffs. Their research shows that customers derive a lower utility of usage under a tariff that charges per usage than under a flat-rate tariff.

Consumers' preferences for flat-rate versus pay-per-use pricing represent both advantages and challenges. It means that consumers often pay more than they would on a pay-per-use tariff, increasing firm revenues and consumer lifetime value (Lambrecht and Skiera 2006). But under flat-rate tariffs, a small proportion of very high-usage consumers may make a service offering unprofitable. Even under zero marginal costs, a firm may face capacity constraints (e.g. of the Internet access network or the amount of traffic a website can handle). To deal with particularly high users, some Internet service providers have started to impose usage caps, effectively cutting off consumers once they exceed a set limit (Edelman 2009). Alternatively, firms in various sectors have turned to usage-based price discrimination.

Usage-Based Price Discrimination two-part tariffs are the classic way to price-discriminate based on consumers' usage. A two-part tariff charges an access price and a usage-price for each consumed unit. When a firm offers a menu of optimal two-part tariffs, consumers self-select into a tariff, allowing the firm to price-discriminate between consumers (Oi 1971; Schmalensee 1981; Tirole 1988; Wilson 1993; for a summary see also Lambrecht et al. 2012). However, since consumers tend to dislike the pay-per-use structure of two-part tariffs, managerial practice has since moved to more complex pricing structures.

Specifically, three-part tariffs and bucket pricing have become increasingly prominent (Jensen 2006; Bagh and Bhargava 2013; Iyengar et al. 2007; Lambrecht et al. 2007; Grubb and Osborne 2012; Schlereth and Skiera 2012). Both three-part tariffs and bucket pricing charge an access price and offer an allowance of free units of consumption (e.g. free articles of an online content provider or free minutes by a mobile telephony service provider). Within this allowance, consumers are not charged a usage price and the consumer's cost function thus has the structure of a flat-rate tariff.

For any usage in excess of the usage allowance, a three-part tariff charges per unit of consumption, similar to a two-part tariff. Research has shown that, similar to the flat-rate bias, consumers choosing among multiple threepart tariffs that differ in the size of their usage allowance and access fees tend to choose a tariff with a higher allowance than optimal based on their ex post usage (Lambrecht and Skiera 2006).

Such behaviour is a result of their tariff-specific preferences, but also a rational outcome of their two-step decision process. A consumer initially chooses a tariff based on their expected usage, but is uncertain about the exact value of their ex-post consumption. Later, the consumer decides on their usage conditional on their previous tariff choice. Lambrecht et al. (2007) show that as usage uncertainty increases, tariffs with increasingly higher allowances and access fees become the optimal choice. As a result, usage uncertainty increases a provider's profits under three-part tariffs, but hurts consumer surplus. Evidence from Ascarza et al. (2012) illustrates that three-part tariffs may affect not only tariff choice but also usage. They find that consumers who switch from a two-part tariff to a three-part tariff that provides a 'free' component have a higher valuation of usage. As a result, they use more on the three-part tariff than would be expected based on their previous two-part tariff usage. This pattern reflects usage behaviour when AOL replaced their two-part tariffs with flat-rate tariffs in 1996 – over the next year usage tripled (Odlyzko 2001).

Bucket pricing limits consumption to the allowance or 'bucket' of free units. It does not allow incremental usage above the allowance, though some bucket pricing plans instead offer the possibility to purchase additional allowances of units (Schlereth and Skiera 2012). Web hosting firms, for example, may offer bucket pricing where a bucket includes an allowance of web space and, potentially, domains and applications (for example 1and1.co. uk/hosting). Similarly, mobile phone providers may offer a bucket that includes an allowance of minutes call volume and an allowance of data transfer volume (vodafone. co.uk).

Firms often choose bucket pricing, instead of three-part tariffs, when a bucket is defined by multiple attributes. It would then be more difficult to set up a three-part tariff where the bill would increase with usage along one dimension only and to communicate such a structure to consumers. Alternatively, some service attributes may be discrete rather than continuous choices (such as adding different applications), which may justify in the consumer's mind a step change in price.

Bundling online, it is very easy for firms to bundle since the marginal cost of 'repackaging' individual goods as bundles is low. Examples for bundling online includes songs bundled as a virtual CD or subscriptions for software packages such as Microsoft Office.

Bundling in a monopoly is generally profitable under two conditions: marginal costs are low and demand is heterogeneous (Crawford 2008; Bakos and Brynjolfsson 1999; Fang and Norman 2006; Olderog and Skiera 2000). For many services that can be provided online both are indeed the case. For example, the marginal cost of selling an additional song is very low. Likewise, consumers typically have heterogeneous tastes for music. Bakos and Brynjolfsson (2000) show how, even under competition, bundling can be optimal. This includes both upstream and downstream competition, competition between a bundler and a single good and between two bundlers.

Yet bundling of services online is not as widespread as one might expect. As discussed earlier, news stories are still largely offered for free instead of being sold in a subscription package. Online, songs are purchased more often separately than bundled as a virtual CD. The reason is the high degree of competition online alongside the possibility for firms to provide content for free (and instead sell advertising). Even competitive provision of only some of the components of the bundle, such as individual songs or news stories, significantly lowers consumers' willingness to pay for the bundle. This further illustrates the difficulty of a 'fee' strategy for online content and explains why only clearly differentiated online news sites such as the *Wall Street Journal, Financial Times* and *New York Times* have moved to a 'fee' model. It suggests that only firms that are able to clearly differentiate their service and brand will be able to bundle their services online.

Price as Barrier to Adoption

Consumers who consider adopting new online services often face a considerable cost of doing so. First, consumers often have high uncertainty about how much they value a new product.

Second, adopting a new service often requires multiple types of switching costs (Klemperer 1987). This may include monetary costs. It may also include non-monetary costs, such as the cost of time and effort to set up or learn how to operate a new service. Since consumers are sensitive to even small monetary prices (Shampanier et al. 2007), any positive price may inhibit product adoption by consumers who initially have high uncertainty about how much they value a new service. This is particularly challenging for firms in markets with network effects. When quickly reaching a large customer base determines long-term success, firms may opt to offer a service free of charge and instead charge advertising revenues (e.g. facebook.com), use sampling or charge a premium for advanced features, functionalities or virtual goods. The latter are sometimes referred to as 'freemium' models. For example, online gamers can often use the basic version of the game for free, but higher levels may require payment. Alternatively, users can buy add-ons or tokens for use in the game, e.g. to progress quicker to higher levels or for additional functionalities (zynga.com).

The benefit of 'freemium' is that a zero price eliminates one barrier to adoption and the firm can more easily acquire customers with initially high uncertainty about how much they value the good. With increasing product experience, a consumer's uncertainty decreases and, on average, their valuation increases. When firms require only more advanced consumers to pay, they can price-discriminate between new consumers with, on average, low valuation and high uncertainty and experienced consumers with, on average, high valuation and low uncertainty. Additionally, they can exploit consumer lock-in that may arise from learning how to use the product and increased product familiarity.

Non-monetary cost of time and effort, such as the hassle of installing a new service, can also impose significant costs on a consumer, and inhibit new services adoption. For example, when choosing a web hosting provider consumers may expect high hassle costs, in particular how easy it will be to set up a website with a specific hosting provider. Such hassle costs may deter consumers. Lambrecht and Tucker (2012) show how firms that sell service contracts can set their prices to attenuate the negative effect of hassle costs on adoption. Specifically, they should discount the period for which consumers expect hassle costs, even if this means slightly increasing prices in other periods.

Summary and Conclusion

This article examines how firms price services online, covering the decision whether to charge (fee or free), and then how to charge (rent or sell, pay-peruse, flat-rate, multi-part tariffs, bundling). Lastly, it considers how to price new services, in the context of overcoming price barriers to adoption. Reviewing the recent academic literature, the article examines the role played by usage caps and complex pricing structures in creating sustained profits, and emphasises the importance of close attention to consumer data and the consumer experience in setting up pricing structures.

Primary and Secondary Labour Markets

The primary/secondary distinction involves an application of the concept of economic dualism to the labour markets of advanced capitalist economies.

In the initial formulation, the primary and secondary segments of a dual labour market were distinguished principally by job characteristics. The rewards of primary jobs, in terms of earnings, working conditions, job security, training opportunities and career prospects, are high; those of secondary jobs, low. Increases in a worker's schooling and work experience lead to higher job rewards in the primary segment but not in the secondary one. Inter-segment mobility is limited, the working poor being confined to secondary jobs. A separate dichotomy in worker traits parallels that in jobs. Secondary workers are those with weak attachment to employment, a consequence of social roles in either the household (youths and married females) or the locality (inner-city minorities; Piore 1970).

Two important differences soon emerged in dualist interpretation. The central difference between the segments for some authors involves stability of employment; for others, pay levels (Piore 1970; Bluestone 1970). Some see the dualist classification as partial; others seek to classify all jobs and workers within an exhaustive schema. Exhaustiveness has become predominant, with the ensuing heterogeneity of an enlarged primary segment leading to further dualisms (upper/lower tier and core/periphery, by occupation and industry respectively) within primary employment (Bluestone 1970; Edwards et al. 1975; Piore 1975).

Dualist interpretations originate from two sources. The first is the failure in the 1960s of a manpower policy oriented to the enhancement of individuals' job skills to move large numbers of US inner-city residents into stable and well-paid work. The explanation was sought in the characteristics not of workers but of jobs, with the primary/secondary duality building upon the antecedent structured/unstructured one (Kerr 1954). The second source is the concern of radical economists to understand the political disunity of the US labour force, a painful anomaly for Marxist analysis. The key to political fragmentation has been sought in the differentiation of work experiences in a dual labour market (Edwards 1979; Gordon et al. 1982).

Dualism is a variant of segmentationism, sharing with it three attributes which distinguish both from orthodox labour theory. The first is the widening of the analytical scope beyond comparative statics with given preferences and indeterminate public policy. Thus the instability of inner-city employment is attributed to an interaction between worker attitudes and job attributes, with attitudes thereby made endogenous. The secondary status of female and youth labour is understood in terms not of autonomous preferences but rather of power relations within family and state (Humphries and Rubery 1984).

Secondly, the labour market is seen as systematically differentiating the job rewards achieved by comparable individuals. The market then becomes a source of inequality in its own right. Thus dualism in employment stability is understood to result not so much from the aversion of secondary workers to steady work as from their discriminatory exclusion from stable jobs. Similarly, the low pay of secondary workers is explained not so much in terms of low labour quality as of denial of access to the primary jobs which convert high potential into high actual productivity (Ryan 1981).

Finally, labour market outcomes such as pay and turnover are seen as determined principally by such product market attributes as demand variability, employer power and production technology. The part played by labour market influences, including trade unions, is a subsidiary one. An important role is given to competitive forces in determining labour outcomes, but such forces derive more from the product than from the labour market (Wilkinson 1981).

These three attributes rebut the criticism that the dualist and segmentationist approach is largely descriptive, taxonomic and compatible with competitive theory (Wachter 1974; Cain 1976).

Considering dualism as a subset of segmentationism, two interpretations may be placed upon their relationship. The first is descriptive. *Heuristic duality* describes vividly the idea of differential treatment in labour markets without implying discontinuity or universality. Thus to distinguish good and bad jobs for comparable workers need not rule out large numbers of medium jobs and unclassified jobs. Heuristic dualism is also seen in the distinction between sheltered and exposed sectors, familiar in 1920s Britain, when currency overvaluation depressed relative wages according to exposure to foreign competition (Dobb 1928). To postulate a sheltered/exposed dualism is to dramatize the issue without requiring that exposure itself be dichotomous or that a comprehensive theory of labour outcomes be built on such a limited basis.

The second interpretation of dualism is more demanding. *Strict duality* requires not just a substantial dispersion of job rewards for comparable individuals but also the polarization of their distribution into two clearly separate segments, each with low internal heterogeneity; a substantial distance between average job rewards in the two segments; and few cases falling in the intermediate range. Such bimodality must maintain and reproduce itself over time, while individuals and jobs should show low rates of mobility across a clear intervening boundary. Such conditions may fail to be realized literally in practice but strong tendencies towards them are required for strict dualism to be sustained.

Although the heuristic and the strict formulations of duality are frequently confused, leading dualist writers have explicitly espoused strict duality. The causes of a postulated strict dualism in job rewards have been sought in underlying dichotomies in three dimensions of industrial structure. The first explanation sees labour dualism in terms of employment stability. Selective worker organization in pursuit of job security leads to primary jobs in firms producing for the stable portion of product demand, with unstable secondary jobs where employers sell to the variable or unpredictable part (Berger and Piore 1980). The second approach sees dualism in terms of earnings, relating it to an underlying dichotomy amongst firms and industries in market and political power (Averitt 1968). The third explanation distinguishes firms whose organizational structures motivate and control their employees by providing stable jobs, career prospects and high pay from those which rely upon the traditional methods of low pay, insecurity and discipline. This dichotomy in control techniques overlaps with the preceding one by producer power, it being the large and powerful corporations which adopt sophisticated control strategies (Gordon et al. 1982).

These three theories of strict dualism all capture important sources of segmentation in labour markets. An empirical role is most evident for producer power, in the shape of significant associations between employee rewards and such power correlates as seller concentration, firm size and ties to the state. However, strict dualism oversimplifies the links between industrial structure and labour outcomes. These theories offer no reason for the distributions of demand variability, producer power or control strategies to become polarized in the first place. In practice, the nexus between product and labour markets proves empirically multidimensional and complex (Wallace and Kalleberg 1981; Hodson and Kaufman 1982). Moreover, while bimodality has been found in some attributes of industrial structure, this typically appears in only one of a set of several attributes; is found in data-sets which exclude more than half of national employment; and even then does not lead to any strict dualism in labour outcomes (Oster 1979; Buchele 1983).

The empirical status of segmentation (and heuristic duality) remains controversial, reflecting the difficulty of measuring labour quality and market structure. The evidence concerning strict duality, is, however, distinctly unfavourable. No clear boundary emerges between segments. Definitions of the secondary segment vary widely in size and composition from one study to another, with intermediate groups proving numerous and difficult to classify. The difference in average job rewards between segments in most dualist definitions proves only moderate in earnings and erratic in employment stability. Mobility between segments appears too high to support an inference of wholesale confinement to secondary employment.

The empirical failure of strict dualism in the domestic economy may be understood by considering a more promising candidate: the world labour market, treated as a potential whole (Singer 1970). The gap between the earnings of comparable workers in the two poles of advanced and developing countries is great; intermediate cases (the newly industrializing countries) are certainly numerous, but bimodality is still expected; while the distance in earnings between the two poles has proved not only durable but at times even increasing, with the attainment of higher rates of growth in productivity and earnings in advanced than in developing countries (Brandt Commission 1980).

Similar forces for dualist divergence function within the labour markets of both the advanced economies and the world economy. The international phenomena of uneven development and cumulative divergence, resting upon the attainment of higher rates of investment and productivity growth in advanced then in developing countries, have as their national counterpart the large and persistent differences in productivity growth across sectors (Salter 1960). Unequal exchange, or the systematic overvaluation of the output of advantaged countries at the expense of that of weaker ones, also finds its domestic analogue in the output prices of primary and secondary segment employers.

One reason why strict dualism applies more to the international than to the national labour market involves the greater obstacles to factor mobility across than within national boundaries. Two other influences are potentially more important. First, the dispersion of rates of growth of value productivity within advanced economies is limited relative to its international counterpart. In the domestic economy, sectors with low rates of growth of physical productivity experience either the transfer of production to developing countries (in the case of tradables) or the revaluation of their output by increases in relative price (in the case of non-tradables). The former mechanism has no counterpart in the international context. Second, the world economy lacks the institutions which prevent differences in rates of growth of value productivity from producing increasing dispersion (let alone polarization) within the distributions of job rewards of the advanced economy. Relativity bargaining (for the organized), statutory wage minima and indexed social security provision (for the unorganized) prevent substantial widening of the gap between earnings in high and low productivity growth employment. The only counterpart to these forces in the world economy is development aid, a pale reflection of social security in the domestic economy. The polarization of labour outcomes is therefore possible in the world labour market to an extent inconceivable in the domestic one.

The factors which curb the dispersion of labour outcomes within advanced economies have been weakened lately by the growth of unemployment and anti-regulatory sentiment. They remain nevertheless sufficiently powerful to restrain domestic tendencies toward dualist divergent development. The dual labour market provides a tenable account of labour market segmentation within advanced economies only in its weaker, heuristic formulation.

Primitive Capitalist Accumulation

Ross Thomson

The primitive (or original) accumulation of capital is a concept developed in Karl Marx's *Capital* and *Grundrisse* to designate that process which generates the preconditions of the ongoing accumulation of capital. The character of these preconditions is derived from the concept of capital, understood to be the process whereby money is invested in the purchase of means of production and labour-power (the worker's capacity to labour) which in turn produce commodities embodying surplus-value. Capital therefore presupposes money amassed to be accumulated, labour-power as the property of labourers separated from ownership of the means of production, and markets in which commodities can be sold. Primitive accumulation therefore must involve more than Adam Smith's notion that 'The accumulation of stock must, in the nature of things, be previous to the division of labour' (1776, p. 260), whether the stock consists of money, means of production or means of subsistence. For this notion ignores the need for a proletariat, the importance of which is shown by settler colonies which have wealth but, insofar as the availability of land precludes the emergence of a market for labour-power, no capital.

To grasp the process generating the preconditions of capital entails historical investigation, which for Marx focused principally on the first industrial capitalist power, England, during the historical period, extending from the mid-sixteenth century through 1770, called the stage of manufacturing. Primitive accumulation consisted of several distinct processes which transformed each of the elements of the inherited division of labour between the towns and the countryside: landed property which combined common with private rights of landlords and free peasant proprietors, merchant capital in wholesale trade, and craft production centred in the urban trades. We will identify and evaluate Marx's account of these processes and will then consider whether this account helps understand the rise of English industrial capitalism and the processes of primitive accumulation elsewhere. Partly to remedy misunderstandings brought about by Marx's intentionally one-sided emphasis on the role of force, we will emphasize the economic mechanisms at work.

The Agricultural Revolution

For Marx (1890, chs 27, 29), the first and foremost effect of the 'agricultural revolution' of the sixteenth through eighteenth centuries was to expropriate the peasant from the soil and establish capitalist agriculture. Marx argues that a new, money-oriented nobility and gentry forcibly enclosed desmesne, common and waste land, consolidated small farms into larger ones and at times converted to pasturage. Capitalist farmers grew from a differentiation of the peasantry. By 1800, both yeoman and communal rights had been eliminated.

While Marx did overemphasize both the coerciveness and the significance of enclosures, his basic point that a landless proletariat and capitalist agriculture had become widespread in the manufacturing period remains valid. Enclosures converted property characterized by shared rights into private property. Although enclosures usually accorded with the custom of the manor and were undertaken by agreement of those with property rights, they did rely on the local power of landlords and, especially in the second half of the eighteenth century, the centralized power of the state. As Tawney emphasized (1912), they were an important means of expropriation of those without legally enforceable rights to their land, notably leaseholders, squatters and cottagers.

But other factors may have been more important in separating peasants from the land. Engrossment combined many small farms into few larger farms and therefore replaced small leaseholders by larger capitalist tenants. The differentiation of the peasantry led to land sales by some (Lenin 1908; Dobb 1947). This process was facilitated by the presence of a land market and the growth of population from 1500 to 1640 and again after 1750. Demographic expansion among the landless further increased the numbers of proletarians (Tilly 1984).

Marx (1890, ch. 30) maintained that the transformation of agriculture had the significance of creating a proletariat for industry as well as agriculture. The supply of both agricultural goods and labour-power for other sectors of the economy increased as a result of growing labour productivity, a second facet of the agricultural revolution, combined with more intense work and lower consumption by workers compared to smallholders. This argument has received support from recent agrarian history, which points to productivity growth coming from convertible husbandry, new rotations including grasses and the turnip, and greatly improved animal husbandry (Chambers and Mingay 1966; Kerridge 1967; Jones 1974). Such innovation may have been aided by the accumulation of capitalist farmers and by the control and scale afforded by enclosure and engrossment. Moreover, enclosures were often depopulating, especially when they led to convertible husbandry or pasturage. Such changes allowed the share of nonagricultural population to rise from 40 per cent in 1688 to 64 per cent in 1801 in a period when England was largely self-sufficient in foodstuffs.

Finally, Marx correctly contended that with the decline of subsistence production, wage-labourers contributed to the expansion of the home market. But especially in periods of rising prices like the sixteenth century, the growing rural middle class may have added even more to market expansion, particularly for industrial products. Growing productivity may also have supported the home market by causing relative agricultural prices to fall, so that incomes in the industrial sector could rise while the income of farmers need not decline (John 1965; Jones 1974).

Commercial Accumulation and Market Expansion

The genesis of capitalist agriculture contrasts sharply with the birth of capitalist industry. While agriculture generated both its own capitalists and workers, the urban crafts played a distinctly secondary role in forming either pole of industry. Rather, the agricultural revolution inadvertently supplied the labourers, and merchants advanced much of the money to employ them and shaped markets in which their products were sold. To grasp the birth of industrial capital, we must first look at merchants.

The question is how merchant activity fostered primitive accumulation. In the genesis of capitalism, Marx held that merchants played a decisive, independent role: 'Today, industrial supremacy brings with it commercial supremacy. In the period of manufacture it is the reverse: commercial supremacy produces industrial predominance' (1890, p. 918). Of course market growth need not stimulate either industry or wage-labour; it led to the development of grainproducing serfdom in Poland and slave sugar and tobacco plantations in much of the Americas. But even these might have contributed to capitalist development if trade with peripheral areas using these labour forms financed industrial production in England (Wallerstein 1976; cf. Brenner 1977).

Merchants could foster primitive accumulation by expanding markets, by providing employment, or by investing profits. While Marx emphasizes domestic causes of proletarianization, he focuses primarily on international commerce in accounting for the genesis of the industrial capitalist (1890, ch. 31). This interpretation stresses the forcefulness and unevenness of primitive accumulation; it was through servile labour in the colonies, the slave trade, and commercial wars that the English prospered and replaced the Dutch as the dominant mercantile power by 1700.

No doubt international commerce had a central role in industrial expansion. Growing exports stimulated domestic output; particularly for the textile industries, something like half the output of which was exported. In most of the eighteenth century, industrial exports grew more rapidly than industrial output, increasing their share of that output from about a fifth to a third from 1700 to 1800. Imports of industrial raw materials, like silk, cotton, dyestuffs and iron, also supported English industry. Marx's stress on the colonial system is warranted by the expansion of the share of domestic exports shipped to the American colonies from 11 per cent in 1700 to 37 per cent in 1772, as well as by its growing significance for imports and reexports (Davis 1962; Minchinton 1969; Cole 1981).

Merchant services and profits also stimulated domestic output. The ascendency of British merchants in world trade led to the expansion of the ports. Commerce was the principal factor in London's growth, and consumption spending by merchants, related professionals, and labourers fostered both industrial and agricultural expansion in much of England. Lesser ports had similar effects. Purchases of ships, armaments and connected products likewise supported industry. While large and growing, the reinvested profits of the international merchant community remained principally in the same lines of business and, except for a few industries in the ports, offered little industrial financing.

Marx's stress on international commerce is surely one-sided; others, including Lenin (1908), have shifted the focus to the home market. For this market, which in England regularly consumed some nine-tenths of the national product, grew with the perhaps 80 per cent increase of that product from 1700 to 1780.

But the home market had significance beyond its share of national output. As Hobsbawm argues (1954), capitalism involves production for a mass market, and the combination of traditional local and export markets could not supply the necessary scale. During the manufacturing period, an integrated, mass market was born. This transformation was not of course confined to the home market; Hobsbawm underscores the importance of new markets in the colonies. But the home market was primary. It became much more spatially integrated. For food, fuel and many industrial products, the great expansion of London was central to this process. Expanding national markets were accompanied by growing regional specialization of production. The mass market was supported by the emerging class structure, especially the prosperous middle class of farmers, modest merchants, manufacturers, and some professionals and tradesmen. Particularly in times of falling agricultural prices, workers added to this market. Finally, a series of new commodities spread through sections of the home market, including the new textiles, stockings, new tools, and a host of housewares made of metal, pottery and glass. For most of these, the home market was decisive (Eversley 1967: Thirsk 1978).

The reinvested profits of domestic merchants, like their international counterparts, remained preponderantly within the commercial sphere. They expanded their working capital, deepened their wholesale marketing network, and helped form the clearing-house and billdiscounting mechanisms through which the market worked. They were the principal investors in transportation improvements like the expansion of coastal shipping, turnpike construction, river deepening, and, from the second half of the eighteenth century, canal construction. Domestic merchants could also finance industry, but even if they did not, their investment created conditions where others would.

The Birth of Industrial Capital

In his well-known discussion of paths to capitalism, Marx identified two ways that industrial capitalists were formed; producers could become capitalists and merchants, or merchants could enter production and employ wage-labourers (1894, ch. 20: see also Dobb 1947). At stake is not just the genesis of industrial capital but also its dynamic. For Marx, the merchant path separates the worker from ownership of the product but retains inherited techniques and social organization of production. It is ultimately conservative; 'however frequently this occurs as a historical transition . . . it cannot bring about the overthrow of the old mode of production by itself, but rather preserves it and retains it as its own precondition' (1894, p. 452). By contrast, producers-turned-capitalists comprise 'the really revolutionary way' since they grow by transforming the organization and techniques of production.

Two quite different kinds of wholesale capitalist production were formed: manufacturing in the narrow sense and domestic industry. Manufacturing had the more innovative organization of the production process. It grouped craft workers specializing by task in the capitalist's workshop and often entailed economies of scale and significant capital costs. It was not solely the creation of producers; the funds, organizational abilities and market knowledge of merchants and even landlords also played a part. Manufacturing most commonly arose in industries which were new (alum, gunpowder, glass, cane sugar), used new techniques (salt, pig iron, heavy iron products), or produced for newly integrated markets (coal). Marx is ambiguous about its significance; he calls manufacture) 'a characteristic form of the capitalist process of production' which 'prevails throughout the manufacturing period' yet recognizes that it never dominated the system (1890, pp. 455, 911).

Domestic industry was far more widespread. Born earlier in the textile trades, domestic industry expanded across many industries in the manufacturing stage. Spurred by relatively high wages and inelastic labour supply in the organized urban trades, both merchants and producers put out work to be done in the homes of outworkers. Some domestic industry arose in urban areas, especially London, but more was proto-industrial – household production of wholesale industrial goods by those retaining ties to land and rural communities (Mantoux 1928; Mendels 1972; Kriedte et al. 1981).

This proto-industry had distinctive patterns of development. It generally originated in pastoral regions and declining or large-scale agricultural areas. Over time, outwork by independent producers declined and wage-labour rose. Through the efforts of both merchants and producers, proto-industry spread within and between localities. Immigration and a distinctive proto-industrial family structure which encouraged earlier marriages and rising birth rates gave an elasticity to employment in existing areas, but ties to the land meant that rapid expansion could only be achieved by the geographic spread of industry. Much of this growth was undertaken by the formation of new firms holding advantages of knowledge of and proximity to the local population.

By themselves or with others, producers were instrumental in changing the production process and its products. Both from the Continent and within England, craftsmen diffused techniques to make pig iron, paper, saltpetre and brass and copper products. They also made a few advances in coal mining, iron making and civil engineering. No doubt the division of labour was refined in manufacture and learning in the proto-industrial regions improved skills. But the circumscribed technical knowledge of most crafts and the personal interactions required to transmit skills formed barriers which limited the scope and importance of technical innovations and rendered their diffusion slow and uneven.

Changes in products were far more general. The largest of the rural industries, textiles, maintained its position in the world market by developing the new, lighter fabrics called the new draperies, as well as introducing cotton, fustian, linen and silk. Pots, pans, nails, pins, knives, buttons, stockings, ribbon, lace, glass bottles and earthen pots all developed for the home market in the late sixteenth and early seventeenth centuries (Thirsk 1978). Merchants and craftsmen were both active in developing and diffusing these product innovations.

These changes in techniques and products formed a dynamic in production which gave competitive advantages to innovating firms and regions. The use of these advantages helped replace the inherited pattern of local and external markets by a new kind of market, called by Polanyi the internal market (1944). The products of innovators substituted for imports and also extended the market absolutely, particularly among middle and lower class consumers. The extent of the internal market grew with market integration and the increased per capita income and consumption resulting from productivity increases and transportation improvements. As its share of national product grew, industry came to create more of its own demand. Success in the internal market provided the basis from which some commodities entered export markets. In the international economy, as well as in England, industrial advance was leading to commercial success.

Primitive Accumulation and the Stages of the Capitalist Economy

In England, more than in any country before or since, the manufacturing stage realized the preconditions of capitalist production. This stage also created conditions for the distinctive kind and pace of accumulation characteristic of the stage of large-scale industry. It thus satisfies the criterion that Gerschenkron employed to assess the usefulness of the concept of primitive accumulation: whether this prior accumulation aided the rapid growth associated with the onset of industrialization (1966, pp. 31–51).

Manufacturing did this not so much in the way Gerschenkron stresses, by the transfer of previously accumulated wealth to industrialists. The modest capital requirements of early factories and the primary role of producers in founding industrial firms – Marx's revolutionary path to capitalism – makes it difficult to justify the role of the prior accumulation of wealth in this way (Crouzet 1985). Far more important were marketing and transportation investments, which together with the agricultural revolution developed markets wide enough to warrant the extensive factory investment and the formation of a capital goods sector characteristic of the Industrial Revolution (Hobsbawm 1954). Moreover, the manufacturing period generated the proletariat to work in the factories and – through the development of milling techniques, new products like the clock, the printing press, firearms and the Newcomen engine, and the great expansion of the tool-making sector – supplied agents willing and able to solve the technological problems of industrialization.

But even in England, primitive accumulation was by no means identical to the processes of manufacturing stage. It involved processes prior to this stage, like the growth of towns and the elimination of serfdom. Nor was it completed within the manufacturing stage. For the persisting ties to the land, the structure of income distribution, and the inherited forms of labour limited the supply of labour-power, the extent of the market, and the growth of productivity (Levine 1975). It was left to the dynamic of the next stage to complete the) 'dissolution of the old economic relations of landed property', since 'only with the development of modern industry to a high degree does this dissolution at individual points acquire its totality and extent' (Marx 1973, p. 277).

Still, the extent to which the conditions of capitalist production were created within the stage of manufacturing made England unique. In it alone had the agricultural revolution taken 'the classical form' (Marx 1890, p. 876). The success of its industrialization reinforced its uniqueness by altering the process of primitive accumulation. Growing productivity and falling prices undercut the viability of proto-industrial and town craft producers at home and, through the growth of an export economy, abroad. The steamship and railroad overcame locational limits to competition. Separation from the means of production had become a consequence of the industrial stage of capitalism.

Moreover, for latecomers the prior generation of a supply of money capital and labour-power within their countries had less importance than in England. Primitive accumulation was internationalized; capital and labour-power both migrated more readily. New credit institutions and state policies could supply capital during the course of industrialization (Gerschenkron 1962). On the Continent, large-scale industry was often born while peasantries persisted. More extreme was the United States, which was already a major industrial power at the time its frontier closed, and which, in the absence of widespread separation of agricultural producers from the land, sold principally in the home market.

Capitalism is for Marx a world-historical system, not a set of autarkic national units. There can therefore be no stage of primitive accumulation which uniformly prepares the way for capitalism in each of these units. The very success of the kinds of processes which brought large-scale, industrial capitalism in England changed both the process of primitive accumulation elsewhere and the relation of these processes to capitalist expansion. By tying the concept of primitive accumulation to a periodization of capitalist development, Marx provides insight into both the classical case of the genesis of capitalism and the necessarily different forms this genesis took elsewhere.

An agent is a person who is employed to do an act on behalf of another called the principal, so that as a rule the principal himself becomes bound. That one person can represent another is a doctrine that has developed but slowly. In Roman law it was a general principle that no one could enter into a contract by stipulation on behalf of another, and in the case of mandate the mandatarius or quasi-agent incurred a personal liability towards their parties. The modern principle is that contracts entered into by an agent are regarded as entered into by the principal, provided the contract is within the scope of the agent's authority.

No special form of words is required to appoint an agent, and agency may be inferred from the conduct of the parties. An agent is required to conduct the business entrusted to him with as much skill as is generally possessed by persons engaged in a similar business, to act with reasonable diligence, to display the utmost fidelity, to keep proper accounts, and to pay over all moneys received less any expenses and his own remuneration.

Directors, managers, clerks, and servants, having power to act for their principals or masters, are agents. Besides these, the chief classes of agents are (*a*) factors; (*b*) brokers; (*c*) auctioneers ; and (*d*) ship masters. Each class is subject to the usages of the trade relating to the class. An agent cannot as a rule delegate his powers, but by the custom of certain trades sub-agents may be employed. The relation of principal and agent is terminated by mutual consent, by revocation, by the agent renouncing, by the expiration of the time agreed upon by the completion of the business, by the death or lunacy of either principal or agent, and by the bankruptcy of the principal.

Principal and Agent (ii)

Joseph E. Stiglitz

Abstract

The principal–agent literature is concerned with how the principal (say an employer) can design a compensation system (a contract) which motivates another individual, his agent (say the employee), to act in the principal's interests. A principal–agent problem arises when there is imperfect information concerning what action the agent either has undertaken or should undertake. It arises in insurance and credit relationships because of their intertemporal nature, when it is known as 'moral hazard'. It also arises where opportunities exist for the principal to extract as much rent as possible from the agent.

The principal–agent literature is concerned with how one individual, the principal (say an employer), can design a compensation system (a contract) which motivates another individual, his agent (say the employee), to act in the principal's interests. The term principal–agent problem is due to Ross (1973). Other early contributions to this literature include Mirrlees (1974, 1976) and Stiglitz (1974, 1975).

A principal–agent problem arises when there is imperfect information, either concerning what action the agent has undertaken or should undertake. In many situations, the actions of an individual are not easily observable. It would be very difficult for a landlord to monitor perfectly the weeding activity of his tenant. A bank cannot monitor perfectly the actions of those to whom it lends money. The employer cannot travel on the road with his salesman, to monitor precisely the effort he puts into his salesmanship. In each of these situations, the agent's (tenant's, borrower's, employee's) action affects the principal (landlord, lender, employer). Clearly, if an individual's actions are unobservable, then compensation cannot be based on those actions. In some cases, even if an individual's actions are not directly observable, it may be possible to infer his actions. Thus, if output were a function just of effort [$Q = F(e)$] then even if effort were unobservable, if output were observable, and the relationship between output and effort were known, then effort could be inferred with perfect accuracy.

The principal–agent literature focuses on situations where an individual's actions can neither be observed nor be perfectly inferred on the basis of observable variables; thus, for instance, it is usually assumed that output is a function of effort and an unobservable random variable, $\theta : Q = F(e, \theta)$.

Moreover, in many circumstances, the principal wishes the agent to take actions based on information which is available to the agent, not the principal. Indeed, this is the very reason that individuals delegate responsibility. Because of the asymmetry of information, the principal does not know whether the agent undertook the action the principal would himself have undertaken, in the given circumstances. Hence, even if the principal can observe the action, he may not know whether that action was appropriate.

Since, in general, the pay-offs to the agent will differ from those to the principal, the agent will not in general take the action which the principal would like him to take, or that they would contract for in the presence of perfect information. For instance, the employee may not adjust his effort as the situation requires, or he may engage in too much or too little risk taking.

The principal–agent problem is, then, the central problem of economic incentives.

In spite of the importance attached to *economic incentives*, until recently economic theory had little to say on the matter. In the standard theory, individuals were paid for performing a particular task. If they performed the task, they received their compensation; if they failed to perform the task, they did not. Individuals thus always had an incentive to perform the contracted-for service. Only if the employer were so foolish as to pay the worker whether he performed the task or not would an incentive problem arise.

The standard theory was based on the assumption that what action the 'principal' wished his agent to perform was perfectly known, and that the action could be perfectly and costlessly monitored. Neither assumption is plausible and, indeed, relatively few workers are paid solely on the basis of their observed inputs.

Origins of Principal–Agent Problems

Principal–agent problems arise whenever one individual's actions have an effect on another individual. The question arises, then, why cannot economic relationships be designed to avoid this kind of dependency? Under what circumstances do these interdependencies arise? For instance, if a landlord were to sell or rent his land to his tenant, then the workers' effort would have no effect on him. If an employer were to sell or rent his capital to his worker, then the workers' effort would again have no effect on him. Traditional neoclassical analysis emphasized the symmetry in economic relationships: one could describe the employer–employee relationship as the employee hiring capital just as well as one could describe it as the employer hiring labour. (This Wicksellian description of economic relationships always seemed peculiar to me; it seemed to suggest the absence within neoclassical analysis of certain important aspects of economic relationships; it is those aspects which are the subject of scrutiny here.)

There are three important reasons for the existence of principal–agent problems. Two have to do with the essential intertemporal nature of certain relationships: insurance and credit. When two individuals enter into an insurance contract, one individual *(a)* promises to pay the other (*b*) a certain amount if event A occurs, while the other (*b*) promises to pay *(a)* a certain amount if event B occurs. If there are actions which one of the individuals can undertake between the date of the contract and the event which will affect the outcome, then there is a principal–agent relationship between the two. This particular form of the principal–agent problem is referred to within the insurance literature as the *moral hazard problem* (see Arrow 1965), and, by extension, the term has been applied to the principal–agent problem more generally.

Similarly, in credit relationships, one individual gives another some resource (money), in return for a promise to repay that money at some later date. So long as there is some probability of default, which can be affected by the actions of the borrower, there is a *moral hazard* or *principal–agent* problem (provided that that action cannot be perfectly monitored by the lender).

Many economic relationships have an important element of insurance within them. The landlord–tenant sharecropping relationship can be viewed as if the tenant pays a fixed rent, and then receives an insurance policy from the landlord, in which the landlord agrees to pay the tenant a certain amount if output is low (equal to the difference between his share and the fixed rent); and the tenant agrees to pay a premium equal again to the difference between the share and the fixed rent, when output is high.

Indeed, the credit 'problem' can be viewed as a special form of an insurance relationship: the lender provides an insurance policy, such that if the borrower's resources are less than the amount owed, the lender agrees to pay the borrower the difference (which the borrower then immediately repays to the lender). The premium is the difference between the rate of interest on a perfectly safe loan and the rate of interest charged on this risky loan.

Insurance (spreading and transferring risk) provides one of the explanations of sharecropping; were workers to rent the land, they would have to absorb all the risk associated with output variations. With sharecropping, the risk is shared between the landlord and the tenant. Since the wealth of tenants is usually much less than that of landlords, there is some presumption that the landlords are better able to absorb this risk.

But even if the tenants were risk neutral, there might be a principal–agent problem. We suggested above that if the landlord were to rent his land to the tenant, there would be no principal–agent problem. But this is not quite correct. If the tenant did not have sufficient resources to pay the rent before production, then the landlord would have to lend the tenant the money. (If he receives the rent at the end of the period, then it is as if he is lending the individual the money). And then, if there are actions which the individual can undertake which affect the likelihood of not being able to repay the debt (pay the rent), *then* there is a moral hazard problem.

There is a second reason that renting land might not solve the moral hazard problem. There may be actions which the tenant can take which affect the quality of the land. To the extent that those actions are monitorable, the rental agreement may specify the actions to be undertaken (e.g. concerning what crops are to be grown, or grazing patterns). But these actions are not perfectly monitorable, and thus, even with rental agreements there are important principal–agent problems. (The same issues arise, of course, with the rental of any durable good).

Again, one should ask, cannot these principal–agent problems be alleviated, e.g. by *selling* the asset. But this entails precisely the two problems we identified before as giving rise to principal–agent relationships: The agent (tenant, employee) may not have sufficient capital (and thus must borrow to make the purchase, creating a credit principal–agent problem); and if there is any risk associated with the future value of the land, it imposes a risk on the agent. Any attempt to alleviate those risks (through insurance) again gives rise to a moral hazard problem.

The third major source of principal–agent relationships is rather different. It arises from the attempt of the principal to extract as much *rent* (surplus) from the agent as possible. The employer does not know how difficult the task is that he would like the worker to perform. He could pay the worker the full value of his output, but that would leave him no profits. He might pay much less, but that might result in the worker refusing to work, if the task is in fact quite difficult; and thus he would lose profits that he might otherwise obtain. This rent extraction problem has been particularly well studied in the context of public utilities: the government does not know the minimum amount of compensation required to keep the utility producing. The rent extraction problem may be alleviated within competitive environments by holding auctions: the individual for whom the asset (franchise) is most valuable will bid the most. But there may not be enough bidders to extract all the rents through an auction mechanism; and at least in the case of utilities, the government may care not only about the rents received, but also about the actions undertaken by the franchisee. (In some cases, the rent extraction problem and the insurance problem are closely related: the average value of rents received may be increased if rents can be varied with the weather, the state of nature; again, we can think of decomposing the rent payment into a fixed rent and an insurance payment).

This list of reasons for the origins of principal–agent relations is not meant to be exhaustive; yet many of the other reasons cited may be reduced to one of these explanations. For instance, consider the problem of a production line on which there are many workers; the output of the production line depends on all of their efforts. In the absence of risk aversion and credit problems, the incentive problem could be solved by giving each worker the total value of net output. He would purchase the right to the job by paying a fixed fee. With such a compensation scheme, the worker would have full incentives for maximizing the firm's output. But such a compensation scheme imposes on the worker an intolerable level of risk; and the fixed fee he would be required to pay necessitates his borrowing large amounts of money.

The Basic Principal–Agent Problem

In the standard principal–agent problem, one looks for that contract (compensation scheme) which maximizes the expected utility of the principal, given that (a) the agent will undertake the action(s) which maximizes his expected utility, given the compensation scheme; and (b) given that he must be willing to accept the contract.

The second set of constraints (which are nothing more than the standard reservation utility constraints) are sometimes referred to as the individual rationality constraints.

There are two standard mathematical formulations. One is a direct generalization of the insurance–moral hazard problem. There are a set of observable events, such as whether an accident occurs. The probability that an event *i* occurs is a function of the actions undertaken (effort at accident avoidance):

$$p_i = p_i(\mathbf{e}),$$

where **e** may be a vector. The wealth of the individual in state *i*, in the absence of insurance, is w_i, and with insurance it is y_i. Thus

$$h_i = y_i - w_i$$

is the net payment from (to) the insurance company (the principal) in state *i*. The expected utility of the insured (the agent) is then just

$$U = \sum_i U_i(y_i, \mathbf{e}) p_i(\mathbf{e})$$

while that of the principal is

$$V = \sum_i V_i(h_i) p_i(\mathbf{e}).$$

$\{\mathrm{h_i}\}$ is chosen to maximize V subject to $U \geq \overline{U}$.

Notice that the employer–employee relationship may be cast in this form: the observable events are the levels of output. Assume for simplicity, that we measure outputs in round numbers (say, bushels of wheat). Then state *i* refers to the number of bushels produced. p_i then is the probability that *i* bushels will be produced. Assume that the individual's wealth, apart from this contractual arrangement with his employer, is zero. Then y_{i} is the individual's pay if output is *i*. If the employer is risk neutral,

$$V_{\mathrm{i}}(h_i) = qi - hi = qi - y_i,$$

where q is the price of output (of a bushel of wheat), assumed to be independent of *i*.

Although the employer–employee relationship can be cast in this form, it is more naturally represented by a formulation in which the probabilities of the states (weather) are fixed, where the states are unobservable, but where what is affected by the employee is the output in each state.

We can represent this formally in the following way. Let *S* be a set of state variables (like weather) observable to the agent. Let *Q* be a set of output variables (assumed observable to the principal and agent). And let *A* be a set of inputs (actions) by the agent assumed observable only by the agent.

Then a compensation scheme is a payment from the principal to the agent which is a function of all variables that are observable to both the agent and principal.

$$Y = \varphi(Q)$$

The agent chooses his actions to maximize his expected utility which depends both on his income and his actions, given

$$\max \; EU(Y, A, S)$$

where outputs (actions), *A*, are related to the inputs by a production function

$$Q = Q(A, S)$$

We denote the solution to this by

$$A = H(S).$$

Finally, we can calculate the expected utility of the principal; his utility depends on the agent's actions, the payments he makes to the agent, and his state (the actions may affect the principal either directly, or via their effect on outputs, or via their effects on payments).

$$EV = EV(\varphi(Q), Q, A, S).$$

The principal's problem is to choose φ to maximize his expected utility

$$\max \; EV$$

recognizing the dependence of the agent's action on φ and recognizing that he must pay the agent enough to induce him to accept the job

$$EU \geq \overline{U} \qquad \text{(RU)}$$

Pooling Versus Separating Equilibrium

Much of the literature has focused on situations where the principal wishes to induce the agent to take different actions in different states. That is, in the simplest case where only output is observable by the principal, if $A^*(S)$ is the action desired in state S, then the compensation scheme must be such that

$$EU[\varphi(Q(A^*, S)), A^*, S] > EU[(Q\text{-}(A, S)), A, S] \quad \text{for all feasible } A.$$

These constraints are referred to as the self-selection or incentive compatibility constraints.

When the individual takes actions in two different states, so that the observable variables are the same, i.e. so that the principal cannot distinguish which of the two states has occurred, we say that there is a *pooling* equilibrium. When the individual takes actions so that the principal can identify which state has occurred, we say that there is a *separating* equilibrium. (This terminology was introduced within the context of the adverse selection literature by Rothschild and Stiglitz (1976)). A basic result of the principal–agent literature establishes conditions under which the optimal contract involves complete or partial separation.

Adverse Selection

The variable S can be thought of as a characteristic of an individual, rather than as the state of nature. Then the self-selection constraint says that individuals of type S prefer action $A(S)$ to any other feasible action. If the self-selection constraints are satisfied, we can identify who is of what type. The action may consist of nothing more than making a choice. In the adverse selection interpretations of the model, the constraint (RU) needs to be replaced by the set of constraints,

$$U(\varphi(Q(A,S)),A,S) \geq \overline{U}(S), \quad \text{for all } S$$

that is, there is a reservation utility level for each individual (an individual rationality constraint for each type). (Note that a similar set of constraints is relevant if the contractual arrangement between the principal and agent is not binding, i.e. the individual can quit after he sees what the state of nature is).

Some examples follow.

i. *The partially discriminating monopoly* (see, e.g. Salop 1977; Stiglitz 1977). The firm knows that different individuals have different indifference curves between the good he sells and other goods, and different reservation utility levels, but he does not know who is of which type. Q may be the quantity of some commodity chosen by an individual, in which case φ (Q) can be interpreted as the payment to the monopolist. (If one individual unambiguously has stronger preferences for the good, in the sense that at any quantity and payment, the extra amount he is willing to pay for a marginal unit is greater, then some separation is always desirable; this property is called the single crossing property).
ii. *Optimal tax structures* (Mirrlees 1971). The government wishes to impose differential taxation on different individuals; it may want to impose a higher tax on the more able, but cannot tell who is the more able. Neither the individual's productivity nor the number of hours a week he works is observable, but his income is observable. The income tax schedule specifies a level of consumption corresponding to each level of income. The individual chooses (by the amount of work he undertakes) a point on that schedule. A schedule which results in the more able earning (choosing) higher incomes is one which separates. This will be desirable if the indifference curves between consumption and income are flatter for the more able – they require less of an increase in consumption to compensate for an increase in income. This will be true, for instance, if the underlying indifference curves between hours worked and consumption are the same for all individuals.
iii. *Pareto efficient tax structures* (Stiglitz 1982a). In the previous problem, the government maximized the sum of utilities, subject to the self-selection constraints, the revenue constraints, and the individual rationality constraints (which simply required that the individual desire to work). The revenue constraint was equivalent, in this problem, to the profits

(revenues) of the landlord; that is, while in the landlord problem we maximize the revenue, subject to the expected utility of the individual satisfying a certain constraint, here the dual of this problem is analysed. The 'sum of utilities' is equivalent to 'expected utility' – where the probability of each state S is identical. We can directly generalize this by imposing constraints on the level of utility attained by all individuals other than the first; we then maximize the first individual's utility subject to these constraints (and subject to the self-selection constraints, and the revenue constraints). This is the problem of Pareto efficient taxation. It is equivalent to the problem of maximizing a weighted sum of individuals' utilities.

iv. *Implicit contracts with asymmetric information*. (For surveys, see Hart 1983; Stiglitz 1986; Azariadis and Stiglitz 1983). With perfect information, the employer would provide insurance to the employee, to stabilize the employee's income. If, for instance, the workers' utility function was separable between hours worked, l, and income y

$$U = u(y) - v(l),$$

then with complete information, and risk neutral firms, y will be the same in all states, but l will be higher in states where labour productivity is higher. Thus, if the employer knew the state, but the worker did not, the employer would have an incentive always to say that it was a good state (since what he paid the worker was the same, but workers are required to work more in good states). The optimal contract will induce the employer to announce that it is bad when it is in fact bad, i.e. it will separate (at least partially).

Qualitative Results

It is clear that many economic relationships fall within the scope of the 'principal–agent' model. Many of the basic qualitative results emerge from a detailed analysis of the insurance model:

(a) There is a risk-incentive trade-off; since the risks undertaken will be a function of the quantity of insurance purchased, if the latter is observable, the premium will depend on it, and in equilibrium, there will be quantity rationing, i.e., the individual would like to purchase more insurance, at the going benefit premium ratio (Pauly 1968). The amount of insurance will be greater, the more risk averse the individual.

(b) Indifference curves (between benefits and premia) are not generally quasi-concave, nor feasibility sets (the set of insurance premia satisfying the nonnegative profit constraint) convex; this has important consequences for the existence of competitive equilibria. The amount of insurance purchased may not be a continuous function of the price of insurance; and the level of effort may not be a continuous function of the amount of insurance purchased.

(c) Competitive equilibrium, when it exists, will not in general be Pareto efficient (Arnott and Stiglitz 1986; Greenwald and Stiglitz 1986); the profits of one insurance firm are affected both by the terms at which other firms offer insurance contracts (whether for similar accidents or not), and by the prices at which goods (whether complements or substitutes for accident avoidance or accident inducing activities) are sold; there exist a set of Pareto improving subsidies and taxes. In some instances, firms may attempt to internalize some of these 'externalities.' This leads to interlinkage of markets, both across time (the same insurance firm insures the individual over time), and at the same time (the same insurance firm insures the individual for many different risks) (Braverman and Stiglitz 1982). The frequently observed interlinkage between credit and land markets in less developed countries has been interpreted in this light.

Variants of the General Model

Further results have been obtained for various variants of the general model. We discuss a few of the more important versions below:

i. Adverse selection model. The major qualitative results of this model (other than the specification of the conditions under which pooling or separation occurs, discussed above) entail an analysis of the distortions (relative to perfect information) engendered by the self-selection constraints; in the optimal income tax, the reduction in work (income) of the less able (associated with a positive marginal tax rate); in the asymmetric information implicit contract model, in the existence of overemployment in good states (with the separable utility function and risk neutral firms), or underemployment in bad states (with very risk averse firms). To discriminate among individuals, firms may engage in socially wasteful activities, such as random pricing or long queues. Generally, one group in the population (the most risk averse in the insurance model, the highest ability in the optimal income tax model) chooses a contract which does not distort its behaviour.

ii. Incentive model with actions taken before state is known. When the random elements have bounded support, then a first best can be achieved simply by imposing a large enough penalty for performances below a given threshold. The individual will exert enough effort to avoid this. (See Mirrlees 1974; Stiglitz 1975).

iii. Theory of contests. If the output of others performing similar tasks in similar situations is observable, then one will employ compensation schemes based on relative performance; these will do better than individualistic compensation schemes. If there are enough individuals, simple schemes, based only on individuals' rankings, can approximate the first-best outcomes.

iv. Models in which the utility constraint is not binding. In some cases, when the principal maximizes his expected utility, subject to the workers' reservation utility constraint, the latter constraint will not be binding. Such models give rise to unemployment. A particularly important variant of these models is described next.

v. Models in which quality is affected by price. If the probability of default increases with the rate of interest charged (either because individuals undertake more risks when the interest rate is higher, or because those who are less risky stop applying for loans at high interest rates), then banks may not raise interest rates, even in the presence of an excess demand for loans. Similarly, if the productivity of a worker increases with the wage paid (either because individuals exert greater effort at higher wages or because those who are recruited at higher wages are more productive), then firms may not lower wages, even in the presence of an excess supply of labour.

vi. Terminations. In multiperiod models, it has been shown that the optimal contract may entail the termination of a relationship when performance is unsatisfactory; this is shown to be preferable to the imposition of other penalties. (See Stiglitz and Weiss 1983).

vii. Infinite period models. Long-term relationships may ameliorate some of the incentive problems (see Radner 1981). Over an infinite lifetime, the principal (insurer) can make good inferences concerning the actions of the agent (insured); the relative frequency of accidents will converge to the accident probability corresponding to the individual's effort level. Not surprisingly, then, with low enough discount rates, incentive schemes can be designed which approximate the first best outcomes. The interpretation of this result is, however, subject to some controversy. Since with low discount rates, the change in lifetime income which would be associated with the individual bearing the full risk of the outcome for any period is negligible, it is as if the individual is risk neutral; and with risk neutrality we know that first best optimum can be obtained (if bankruptcy is ignored).

The Set of Admissible Contracts

One of the important and general results to emerge from the principal–agent literature is that the nature of the equilibrium contract depends on the set of admissible contracts. Contracts can depend only on the available information; typically, it is desirable to use all of the available information, though in practice, many variables which ought to be relevant (have information value) are not included within the compensation scheme.

Similarly, if one could costlessly implement a non-linear incentive scheme, such schemes would, in general, be preferable to linear schemes. Though in practice, again, most observed schemes seem relatively simple (linear, piece-wise linear, etc.), much of the literature has been concerned with characterizing in admittedly simple situations the optimal non-linear scheme.

In a variety of situations, if one could make pay a stochastic function, it would be desirable to do so, even with risk averse individuals. (Arnott and Stiglitz (1988) and Holmstrom (1979) show that with separable utility functions, this will not happen). The intuition behind this, in the case when actions have to be taken prior to the agent obtaining information about the state is that the possibility that he receives a low compensation so induces him to work hard that the employer (landlord) can reduce the dependence (on average) of pay on output, and thus reduce the variability of income.

Though optimal schemes may thus appear to be fairly complex, in practice most schemes employed are relatively simple. There is an ongoing controversy between those who seek to consider increasingly complex schedules, dismissing work which has analysed simple linear schedules as ad hoc; and those who seek to explain the kinds of compensation schedules actually employed; these dismiss the complex solutions as being irrelevant. They would argue that efforts should be devoted to understanding why actually employed schemes take on the form they do.

One possible explanation of the use of simple schedules is that they may be more *robust*. That is, as technology changes or the probability distribution of states changes (the exogenous parameters in the principal–agent problem) the optimal compensation scheme changes. But in practice, revisions to compensation schemes are costly, and one must find a scheme that works under a variety of situations. Simple, linear schemes may possess this property of robustness.

Another important characteristic of the set of admissible schemes relates to commitments. Can, for instance, the worker commit himself not to leave, or can the employer commit himself not to terminate the relationship?

A closely related issue is the set of punishments (rewards) which are admissible. It makes a great deal of difference if there are limits on the negative compensations that can be provided in the presence of bad outcomes.

We have noted the role of observability in the design of contracts. In some cases an important distinction may arise between observability and verifiability. The question is associated with how a contract is to be enforced. If the contract is to be enforced through the courts, it must be the case that any violation can be verified by an outside third party. Both the principal and the agent might know that the contract has been violated i.e. they both may observe the S (and not S') has occurred, and therefore that the payment should be that corresponding to S (and not S'). But unless it can be proved, the principal might attempt to cheat the agent. Knowing this, the agent would refuse to sign a contract based on unverifiable variables.

On the other hand, if the contract is enforced by a reputation mechanism, good behaviour may be enforced so long as the state is observable by both parties.

Concluding Remark

We have focused here on a discussion of general principles. It should be emphasized, however, that the principal–agent model has provided important insights into the nature of a variety of economic relationships, in labour, land, credit, and product markets. These detailed applications of the general theory represent an important area of on-going research.

Principal Components

T. Kloek

The principal components of a set of m variables are m artificially constructed variables with the following properties. The first component 'explains' as much as possible of the total variance of the original variables. The second has the same property under the additional condition that it is uncorrelated with the first, and so on. It often happens that a few principal components account for a large part of the total variance of the original variables. In such a case one may omit the remaining components. The effect is a substantial reduction of the dimension of the problem. The method is used to explore the relations present in a set of data or to combat the problems created by multicollinearity.

As in linear regression, several approaches are possible. One may view the principal components as the solution to a simple mathematical plane fitting problem, or one may assume a statistical model with an unknown covariance matrix, which is to be estimated. A normality assumption may (but need not) be added, with the consequence that the method of maximum likelihood is available.

If we have a statistical model with an m-vector of random variables ε with covariance matrix Σ the kth principal component can be defined as $\pi_k = \varepsilon' a_k$ where a_k is the eigenvector (characteristic vector) of Σ that corresponds to the kth eigenvalue (characteristic root, latent root), the eigenvalues λ_k being arranged in descending order

$$\lambda_1 \geqslant \lambda_2 \ldots \geqslant \lambda_m. \tag{1}$$

If Σ is estimated by S the same operations of taking eigenvectors and eigenvalues are carried out with respect to S. The mathematics of this approach is explained in almost every book on multivariate statistical analysis. A classic in this field is Anderson (1958). In the econometrics literature a detailed account is given in Dhrymes (1970).

A descriptive approach starts with an $n \times m$ matrix X consisting of n observations on each of m variables. Then the principal components are the columns of $P = XA$, where A is the matrix of eigenvectors of $X' X$. As in (1) the eigenvectors are always arranged according to the descending order of the eigenvalues. The first principal component $p1$ may also be obtained as the result of minimizing the sum of the squares of the residuals E defined as

$$E = X - pa' \tag{2}$$

where p is an n-vector and a an m-vector. This approach to the subject is described in detail by Theil (1971, 1983).

Since both p and a are unknown we need an additional constraint in order to obtain unique results. Most authors choose $a' \ a = 1$ some $p' \ p = 1$. The choice is arbitrary and a matter of convenience. Here, it is henceforth assumed that $A' \ A = I$ and more generally that $A' \ A = I$. Another consequence of the fact that both p and a are unknown is that our problem does not have the simple linear structure of least squares regression. Hence the resulting A and P depend (in a non-trivial way) on the origin and scale of the original variables. In the statistical approach the variables are usually measured from their means, in the descriptive approach this is not always the case. If all variables are measured in the same units, there is a natural solution of the problem of the units of measurement. If this is not the case one often chooses the solution to take correlations rather than covariances. (This holds for Σ and S in the statistical approach but it may also be applied to $X' X$ in the descriptive approach.)

Geometrically, the principal components transformation is equivalent to rotating the scatter (in the descriptive approach) or the density (in the statistical approach). Consider the case $m = 2$ and suppose that the scatter has the form of an ellipse. Then the principal components transformation is equivalent to rotating the ellipse in such a way that the principal axes of the ellipse coincide with the axes of the coordinate system. Equivalently, one might rotate the coordinate axes in such a way that they coincide with the principal axes of the ellipse. More details on the geometry of principal components are given by Fomby et al. (1984, pp. 287–93).

The main purpose of applying principal components is *reduction of the dimension* of a data set. The idea originated with Hotelling (1933) and in the present author's opinion it can be interpreted as a mathematician's reaction on Thurstone's (1931) paper on factor analysis. Indeed, Hotelling applies his approach to psychological test scores. It was precisely for this type of data the psychologists developed factor analysis.

The main difference between factor analysis and principal components can be given as follows. In factor analysis it is assumed that Σ can be decomposed as:

$$\Sigma = CC' + D$$

where C is an $m \times h$ matrix and D a diagonal matrix of order $m \times m$. If

$$h < \frac{1}{2}\left[2m + 1 - \surd(8\mathrm{m} + 1)\right]$$

this assumption implies restrictions on the elements of Σ, while the principal components approach does not impose any restrictions on Σ.

A well-known economic example of dimension reduction was given by Stone (1947), who took 17 time-series from the US national accounts in the period 1922–38. They describe several income and expenditure aggregates relating to consumers, producers and the government. It appeared that in this period the first three principal components accounted for more than 97 per cent of the total variance of these 17 series (the first 80.8 per cent, the second 10.6 per cent, the third 6.1 per cent). The first principal component appears to be highly correlated with total income, the second with the annual change in income, the third with time. It should be emphasized that usually such simple interpretations are not available. More details are given by Stone (1947); also by Theil (1971).

Dimension reduction may also be desirable in the so-called *undersized sample* problem. Consider a (linear) simultaneous equation model. Suppose one wants to estimate the parameters of a simple structural equation by means of two-stage least-squares or a similar method. Then the first step requires the regressions of the current endogenous variables at the right hand side of the equation on the total set of predetermined variables. This is impossible if $n < m$ (the number of predetermined variables), but it may also have undesirable properties if $n < 2.5\ m$, say. In large models, but even in models of medium size, these rules may be violated. Kloek and Mennes (1960) proposed to tackle this problem by replacing the m predetermined variables by a limited number of principal components. For a further discussion and modifications, see Amemiya (1966). The limitations of this approach were discussed by Fisher (1965).

Dimension reduction may also be desirable in more general regressions with *multicollinear* explanatory variables. The principal components of these variables can play a very useful role in clarifying the consequences of multicollinearity for the estimates of the regression parameters and their estimated covariance matrix. The case where one eigenvalue (λ_m) is relatively very small is particularly simple. Consider the linear regression model

$$y = x\beta + \epsilon$$

where y is an n-vector containing the observations on the variable to be explained, X and $n \times m$ matrix, as before, containing n observations on each of m explanatory variables, β a vector of unknown parameters to be estimated and $\in$ a vector of disturbances, with zero means and covariance matrix $\sigma^2 I$. Let A denote the matrix of eigenvectors of $X' X$ and A the diagonal matrix containing the corresponding eigenvalues, then we have $X' X = A\ A\ A'$ with $A'\ A = I$. Then the inverse satisfies $(X' X)^{-1} = A\ A^{-1}\ A'$ and v_{ii}, the ith diagonal element of the covariance matrix $V = \sigma^2 (X' X)^{-1}$ can be written as

$$\upsilon_{ii} = \sigma^2 \sum_j a_{ij}^2 (1/\lambda_j)$$

where a_{ij} is the typical element of A. So v_{ii} is small if the a_{ij}^2 that correspond to small values of λ_j are small and large in the opposite case. This knowledge is helpful in understanding the problem of multicollinearity. Fomby et al. (1984) give a more extensive treatment and more references.

The next question is whether the relationship between principal components and multicollinearity can be exploited in order to solve the problems created by multicollinearity. It has been suggested that one might delete a number of principal components. Since the possibility exists that some of the principal components with small variances have a strong influence on the variable to be explained, it cannot be guaranteed that deleting these is a good choice. This may be decided by means of a preliminary test.

When applying the principal components method we transform a set of variables into linear combinations that are uncorrelated. Theil (1976) extends this approach in the context of the Rotterdam model of consumer demand. He constructs linear combinations of commodities that are *preference independent* and, hence, have a diagonal matrix of price coefficients in his demand system. In an example (p. 287) he transforms beef, pork and chicken into artificial preference independent commodities called inexpensive meat, beef/pork contrast and antichicken. He also gives an example containing clothing, footwear and other goods. His discussion on pages 311 and 312 is illustrative for the interpretation problems that may arise.

In general, one may say that principal components have elegant mathematical properties, but that their interpretation in applications is often far from simple.

Prisoner's Dilemma

Anatol Rapoport

The game nicknamed 'prisoner's dilemma' by A.W. Tucker has attracted wide attention, doubtless because it has raised doubts about the universal applicability of the so called Surething Principle as a principle of rational decision.

The game is illustrated by the following anecdote. Two men, caught with stolen goods, are suspected of burglary, but there is not enough evidence to convict them of that crime, unless one or both confess. They could, however, be convicted of possession of stolen goods, a lesser offence.

The prisoners are not permitted to communicate. The situation is explained to each separately. If both confess, both will be convicted of burglary and sentenced to two years in prison. If neither confesses, they will be convicted of possession of stolen goods and given a sixmonth prison sentence. If only one confesses, he will go scot-free, while the other, convicted on the strength of his partner's testimony, will get the maximum sentence of five years.

It is in the interest of each prisoner to confess. For if the other confesses, confession results in a two-year sentence, while holding out results in a five-year sentence. If the other does not confess, holding out results in a six-month sentence, while confession leads to freedom. Thus, 'to confess' is a *dominating strategy*, one that results in a preferred outcome regardless of the strategy used by the partner. A dominating strategy can be said to be dictated by the Sure-thing Principle. Nevertheless, if both, guided by the Sure-thing Principle, confess, both are worse off (with a two-year sentence) than if they had not confessed and had got a six-month sentence.

In this way, Prisoner's Dilemma is seen as an illustration of the divergence between individual and collective rationality. Decisions that are rational from the point of view of each individual may be defective from the point of view of both or, more generally, all individuals in decision situations where each participant's decision affects all participants.

Generalized to more than two participants (players), Prisoner's Dilemma becomes a version of the so called Tragedy of the Commons (Hardin 1968) It is in each farmer's interest to add a cow to his herd grazing on a communal pasture. But if each farmer follows his individual interest, the land may be overgrazed to everyone's disadvantage. Over-harvesting in pursuit of profit by each nation engaged in commercial fishing is essentially Tragedy of the Commons in modern garb.

Many social situations are characterized by a similar bifurcation between decisions prescribed by individual and collective rationality. Price wars and arms races are conspicuous examples. In the context of Prisoner's Dilemma, holding out would be regarded as an act of cooperation (with the partner, of course, not with the authorities); confession with noncooperation or defection.

Because the prescriptions of individual and collective rationality are contradictory, a normative theory of decision in situations of this sort becomes ambivalent. Attention naturally turns to the problem of developing a *descriptive* theory, one which would purport to describe (or to predict, if possible) how people, faced with dilemmas of this sort, actually decide under a variety of conditions.

As experimental social psychology was going through a rapid development in the 1950s, Prisoner's Dilemma became a favourite experimental tool. It enabled investigators to gather large masses of data with relatively little effort. Moreover, the data were all 'hard', since the dichotomy between a cooperative choice in a Prisoner's Dilemma game (C) and a defecting one (D) is unambiguous. Frequencies of these choices became the principal dependent variables in experiments on decision-making involving choices between acting in individual or collective interest. As for the independent variables, these ranged over the personal characteristics of the players (sex, occupation, nationality, personality profile), conditions under which the decisions were made (previous experience, opportunities for communication), characteristics or behaviour of partner, the payoffs associated with the outcomes of the game, etc. (cf. Rapoport et al. 1976, chs 9, 15, 18, 19).

Prisoner's Dilemma is usually presented to experimental subjects in the form of a 2 × 2 matrix, whose rows, C_1 and D_1, represent one player's choices, while the columns, C_2 and D_2 represent the choices of the other. The choices are usually made independently. Thus, the four cells of the matrix correspond to the four possible outcomes of the game: C_1C_2, C_1D_2, D_1C_2 and D_1D_2. Each cell displays two numbers, the first being the payoff to Row, the player choosing between C_1

and D_1, the second the payoff to Column, who chooses between C_2 and D_2. The magnitudes of the payoffs are such that strategy (choice) D of each player dominates strategy C. The decision problem is seen as a dilemma, because both players prefer outcome C_1C_2 to D_1D_2; yet to choose C entails forgoing taking advantage of the other player, should he choose C, or getting the worst of the four payoffs, should he choose D.

The experiments are usually conducted in one of three formats: (1) single play, where each player makes only one decision; (2) iterated play, in which several simultaneous sequential decisions are made by a pair of players; (3) iterated play against a programmed player, where the subject's co-player's choices are determined in a prescribed way, usually dependent on the subject's choices.

The purpose of a single play is to see how different subjects will choose when there is no opportunity of interacting with the other player. The purpose of iterated play with two bona fide subjects is to study the effects of interaction between the successive choices. The purpose of play against a programmed player is to see how different (controlled) strategies of iterated plays influence the behaviour of the subject, whether, for example, cooperation is reciprocated or exploited, whether punishing defections has 'deterrent' effect, etc. For an extensive review of experiments with a programmed player, see Oskamp 1971.

The findings generated by experiments with Prisoner's Dilemma are of various degrees of interest. Some are little more than confirmations of common sense expectations. For example, frequencies of cooperative choices in iterated plays vary as expected with the payoffs associated with the outcomes. The larger the rewards associated with reciprocated cooperation or the larger the punishments associated with double defection, the more frequent are the cooperative choices. The larger the punishment associated with unreciprocated cooperation, the more frequent are the defecting choices, and so on. As expected, opportunities to communicate with the partner enhance cooperation; inducing a competitive orientation in the subjects inhibits it.

Of greater interest are the dynamics of iterated play. Typically, the frequency of cooperative choices averaged over large numbers of subjects at first decreases, suggesting disappointment with unsuccessful attempts to establish cooperation. If the play continues long enough, average frequency of cooperation eventually increases, suggesting establishment of a tacit agreement between the players. The asymptotically approached frequency of cooperation represents only the mean and not the mode. Typically, the players) 'lock in' either on the C_1C_2 or on the D_1D_2 outcome (Rapoport and Chammah 1965).

Bimodality is observed also in iterated plays against a programmed player who cooperates unconditionally. Roughly one half of the subjects have been observed to reciprocate this cooperation fully, while one half have been observed to exploit it throughout, obtaining the largest payoff.

Comparison of the effects of various programmed strategies in iterated play showed that the so called Tit-for-tat strategy was the most effective in eliciting cooperation from the subjects. This strategy starts with C and thereafter duplicates the co-player's choice on the previous play. Of some psychological interest is the finding that the subjects are almost never aware that they are actually playing against their own mirror image one play removed. In a way, this finding is a demonstration of the difficulty of recognizing that others' behaviour towards one may be largely a reflection of one's behaviour towards them. Escalation of mutual hostility in various situations may well be a consequence of this deficiency.

Perhaps the most interesting result of Prisoner's Dilemma experiments with iterated play is that even if the number of iterations to be played is known to both subjects, nevertheless a tacit agreement to cooperate is often achieved. This finding is interesting because it illustrates dramatically the deficiency of prescriptions based on fully rigorous strategic reasoning.

At first thought, it seems that a tacit agreement to cooperate is rational in iterated play, because a defection can be expected to be followed by a retaliatory defection in 'self defence', so to say, by the other player with the view of avoiding the worst payoff associated with unreciprocated cooperation. However, this argument does not apply to the play known to be the last, because no retaliation can follow. Thus, D dominates C on the last play, and according to the Sure-Thing Principle, D_1D_2 is a foregone conclusion. This turns attention to the next-to-thelast play, which now is in effect, the 'last play', to which the same reasoning applies. And so on. Thus, rigorous strategic analysis shows that the strategy consisting of D's throughout the iterated play is the only 'rational one', regardless of the length of the series.

The backward induction cannot be made if the number of iterations is infinite or unknown or determined probabilistically. In those cases, provided the probability of termination is not too large, the 100 per cent D strategy is not necessarily dictated by individual rationality. The question naturally arises about the relative merit of various strategies in iterated play of Prisoner's Dilemma. This question was approached empirically by Axelrod (1984).

Persons interested in this problem were invited to submit programmes for playing iterated Prisoner's Dilemma 200 times. Each programme was to be matched with every other programme submitted, including itself. The programme with the largest cumulated payoff was to be declared the winner of the contest.

Fifteen programmes were submitted, Tit-for-tat among them. It obtained the highest score. A second contest was announced, this time with probabilistic termination, 200 iterations being the expected number. The results of the first contest together with complete descriptions of the programmes submitted were publicized with the invitation to the second contest. This time 63 programmes were submitted from six countries. Tit-for-tat was again among them (submitted by the same contestant and by no other) and again obtained the highest score.

The interesting feature of this result was the fact that Tit-for-tat did not 'beat' a single programme against which it was pitted. In fact, it cannot beat any programme, since the only way to get a higher score than the co-player is to play more D's than he, and this, by definition, Tit-for-tat cannot do. It can only either tie or lose, to be sure by no more than one play. It follows that Tit-for-tat obtained the highest score, because other programmes, presumably designed to beat their opponents, reduced each other's scores when pitted against each other, including themselves. The results of these contests can be interpreted as further evidence of the deficiency of strategies based on attempts to maximize one's individual gains in situations where both cooperative and competitive strategies are possible. Moreover, the superiority of cooperative strategies does not necessarily depend on opportunities for explicit agreements.

Support for the latter conjecture came from a somewhat unexpected source, namely, applications of game-theoretic concepts in the theory of evolution (Maynard Smith 1982; Rapoport 1985). Until recently, game-theoretic models used in theoretical biology were so called games against nature (e.g. Lewontin 1961). A 'choice of strategy' was represented by the appearance of a particular genotype in a population immersed in a stochastic environment. Degree of adaptation to the environment was reflected in relative reproductive success of the genotype, i.e. statistically expected numbers of progeny surviving the reproductive age. In this way, the population evolved towards the best adapted genotype.

In this model, adaptation depends only on the probability distribution of the states of nature occurring in the environment (e.g. wet or dry seasons) but not on the fraction of the population that has adopted a given strategy. When this dependence is introduced, the model becomes a genuine game-theoretic model with more than one bona fide player.

The model suggested by Prisoner's Dilemma appeared in theoretical biology in connection with combats between members of the same species, for example over mates or territories. Assuming for simplicity two modes of fighting, fierce and mild, we can see the connection to Prisoner's Dilemma by examining the likely result of evolution. In an encounter between a fierce and a mild fighter, the former wins, the latter loses. However, an encounter between two fierce fighters may impose more severe losses on both than an encounter between two mild fighters. With proper rank ordering or payoffs (relative reproductive success), the model becomes a Prisoner's Dilemma. Development of non-lethal weapons, such as backward curved horns or behavioural inhibitions may have been results of natural selection which made lethal combats between members of the same species rare.

Iterated combats suggest comparison of the effectiveness of strategies in iterated play. Maynard Smith and Price (1973) observed a computer-simulated population of iterated Prisoner's Dilemma players, using different strategies, whereby the payoffs were translated into differential reproduction rates of the players using the respective strategies. In this way, the) 'evolution' of the population could be observed. Eventually, the 'Retaliators', essentially Tit-for-tat players, replaced all others.

A central concept in game-theoretic models of evolution is that of the evolutionarily stable strategy (ESS). It is stable in the sense that a population consisting of genotypes representing that strategy cannot be 'invaded' by isolated mutants or immigrants, since such invaders will be disadvantaged with respect to their reproductive success. It has been shown by computer simulation that a population represented by programmes submitted to the above-mentioned contests evolved towards Tit-for-tat as an evolutionarily stable strategy. It was, however, shown subsequently that it is not the only such strategy.

In sum, the lively interest among behavioural scientists and lately many biologists in Prisoner's Dilemma can be attributed to the new ideas generated by the analysis of that game and by results of experiments with it. The different prescriptions of decisions based on individual and collective rationality in some conflict situations cast doubt on the very meaningfulness of the facile definition of 'rationality' as effective maximization of one's own expected gains, a definition implicit in all manners of strategic thinking, specifically in economic, political, and military milieus. Models derived from Prisoner's Dilemma point to a clear refutation of a basic assumption of classical economics, according to which pursuit of self-interest under free competition results in collectively optimal equilibria. These models also expose the fallacies inherent in assuming the) 'worst case' in conflict situations. The assumption is fully justified in the context of two-person zero sum games but not in more general forms of conflict, where interests of participants partly conflict and partly coincide. Most conflicts outside the purely military sphere are of this sort.

Finally, Prisoner's Dilemma and its generalization, the Tragedy of the Commons, provide a rigorous rationale for Kant's Categorical Imperative: act in the way you wish others to act. Acting on this principle reflects more than altruism. It reflects a form of rationality, which takes into account the circumstance that the effectiveness of a strategy may depend crucially on how many others adopt it and the fact that a strategy initially successful may become self-defeating *because* its success leads others to imitate it. Thus, defectors in Prisoner's Dilemma may be initially successful in a population of cooperators. But if this success leads to an increase of defectors and a decrease of cooperators, success turns to failure. Insights of this sort are of obvious relevance to many forms of human conflict.

Abstract

The increasing digitalization of the economy and advances in data processing have drawn economists' attention to the role of personal data in markets. The economics of privacy aims to analyze how individuals, firms and policymakers interact in markets where personal data play a key role. The complexity of these markets is challenging for academics who rely on different disciplines and methods to investigate privacy issues, including field experiments. In this entry, we review this literature, and point out the need to take account of the complex interactions between the different economic agents, and highlight specific strategies regarding privacy issues. First, individuals might face a puzzling tradeoff between sharing data in order to access customized services and, on the other hand, protecting their personal data against potential data misuses. Second, industrial organizations and the literature of marketing study how firms can fit personal data into their strategies, and how this can spur new business models. Third, privacy regulation is being challenged as it aims both at protecting individuals' privacy while preserving firms' capacity to innovate. In this context, the main difficulty for policymakers is to shape a clear framework for both individuals and firms. Lastly, we bring attention to the need for further research to investigate the role of privacy as a business differentiator: in other words to establish a clear link between consumers' demand and firms' offer.

Introduction

The role of personal data in economics has been spurred on by the increasing digitalization of the economy, as it is now possible to collect, store and process huge amounts of data. In the economics literature, the concealing of individuals' personal information was first supposed to lead to information asymmetries between employee and employer, insured and insurer, etc., and thus, to possible market inefficiencies (see Stigler 1980; Posner 1981). However, especially in the context of internet economics, little is known about what might be the right balance for individuals between disclosure and protection of their personal information. For example, individuals might know (or not know) that firms may exploit their data for marketing purposes, or for discrimination in the job market. Recently, large parts of the economics and marketing literature have begun focusing on individual behaviours in different contexts (Acquisti et al. 2012), and in particular, it is investigating the effectiveness of firms' personalized advertising (Lambrecht and Tucker 2013) and the impact of privacy regulation (Campbell et al. 2015).

The literature provides numerous definitions and conceptions of privacy. For instance, Hirshleifer (1980) considers that privacy is the individual capability to act autonomously and independently of other individuals' control. In the same way, Westin (1967) defines privacy as the ability of individuals to control access to, and use of, their personal data, which would appear more relevant in the context of the internet. From an economics perspective, personal data have the characteristics of an information good that is non-rivalrous and non-excludable. Consequently, the secondary use of individual personal data by companies can occur without the individual's awareness. This can lead to possible negative externalities, particularly in the internet era. While the exploitation of personal data enables companies to propose better offers to users by reducing their search costs, it can also lead to discrimination or unwanted and inappropriate solicitations. The economics of privacy examines the policy implications related to the interactions between individuals' decisions to disclose personal data and firms' strategies to implement innovation using these data. The pervasiveness of internet economics (including the internet of things) in various sectors and industries has increased the importance of data to any kind of business activity, and in particular, in the health sector and when dealing with vulnerable populations such as children or people with disabilities.

The economics of privacy encompasses a range of disciplines such as industrial organization, marketing, behavioural economics, information systems, health economics, computer science and law. This strand of literature largely relies on the use of field experiments to study behaviours of both individuals and firms as it allows the assessment of causal inferences. Considering the contributions made by these disciplines, the present entry analyzes the emergence of new forms of complex interactions between the agents in the online market, namely consumers, firms and policymakers. The entry is organized as follows. Section "Individuals' Privacy Behaviours" investigates individuals' behaviours and individual awareness about privacy matters and identifies the role of information asymmetry between individuals and firms. It focuses on research in marketing and behavioural economics. Section "How Firms Use Personal Data" focuses on the market for privacy and firms' strategies (discrimination, hidden market, etc.). The data collected by companies can be used in different contexts, for example to inform individuals during advertising campaigns (e.g. of the best price at your favourite store) or conversely to discriminate against them during a job search. Section "Regulation and Policy Intervention" deals with the regulation of privacy, and it delves into analysis of the factors influencing the adoption of new modes of regulation, such as the spread of privacy-enhancing services. It also demonstrates how policymakers' analysis of privacy regulation is crucial since it provides the instruments to influence firms' strategies and to disseminate information (addressed) to individuals (Goldfarb and Tucker 2012b). It considers recent literature which suggests that major events such as Edward Snowden's revelations about possible misuses of personal data by firms drew the attention of individuals to privacy issues.

Individuals' Privacy Behaviours

The advent of the internet and the increasing adoption of connected devices mean that individuals currently face many more privacy issues than before. Understanding individuals' privacy concerns is crucial since they can hamper the diffusion of online services and, more generally, the growth of ICTs. Above all, there is an obvious tradeoff for users between sharing and protecting their personal data. On the one hand, sharing can be beneficial as it allows users access to personalized services. Individuals can also benefit from the externalities from other individuals' data disclosures. For instance, the (good or bad) recommendations about a product on a website, which reveal people's preferences, can benefit other users who have access to this information. On the other hand, users need to consider possible misuses of their data (Acquisti et al. 2016). Disclosing personal information is not the only way for individuals to have their data collected, since firms can use activity, behavioural or locational data to find out individuals' characteristics. As an example, Facebook Likes can help to predict a range of highly sensitive personal data, like political views or sexual orientation (Kosinski et al. 2013). Consequently, the rationale adopted by users to privacy issues is interesting from an economic point of view. From the perspective of a market for privacy, users may be aware that their personal traits and attributes (age, address, gender, revealed preferences via social media or purchases, comments, etc.) have an economic value for firms.

By default, many existing theoretical models consider users as having complete information about firms' strategies; in other words, they suppose that individuals know how firms might use their personal data, and how to react to these strategies. In fact, these models are related closely to the acceptance of the internet model by users. They deal with how markets would be affected where individuals are reluctant to share their data, and with the effectiveness of privacy protection strategies. While the earliest theoretical approaches consider hiding personal information to be a suspicious strategy, which may be inefficient from a social perspective (Hirshleifer 1980; Stigler 1980; Posner 1981), later models are more realistic and consider that this might be a rational strategy for consumers. Thus, Varian (1997) admits that individuals might find it beneficial not to reveal private information and introduces the idea that individuals may consider secondary usage in their privacy strategies. Within a Coasian perspective, Kahn et al. (2000) take into account explicitly the awareness of consumers able to "deal" in their private information, and able to evaluate the costs and benefits of their privacy choices. Subsequent models provide evidence of consumer strategies which firms need to consider in markets. Indeed, Fudenberg and Tirole (1998) show that a monopoly selling durable goods may employ different strategies according to the type of good, that is the type of consumer – anonymous, semi-anonymous or identified. In a duopoly setting, Villas-Boas (1999) provides evidence that consumers have an interest in revealing their preferences to competitors and to be patient, that is they care about the future, in order to get lower prices from competitors who try to attract them. Thus, theoretical models show that consumers' preferences drive the strategies of firms whose business models are based on the disclosure of personal data by users. In some way, these approaches question the consequences of the existence of asymmetric information between users and firms about firms' privacy strategies. Indeed, the literature points out that individuals may not know what firms or third parties intend to do with their data, and for that reason, may be reluctant to disclose them.

In order to capture the issue of information asymmetry, which is highlighted in theoretical models, and, more broadly, the way individuals reason about privacy, researchers propose empirical approaches and field experiments. The literature tries to understand the diversity of privacy behaviours and to provide evidence of biases which might influence privacy decision making.

Empirical research is interested in estimating users' privacy concerns by emphasizing the motivations and conditions which lead individuals to disclose (or not) personal information. Through an interdisciplinary review, Smith et al. (2011) identify five main factors that might explain an individual's level of concern about online privacy: privacy experience, privacy awareness, personality, demographics and culture. In the case of online services, consumers tend to disclose personal information to access personalized services (Chellappa and Sin 2005). Nevertheless, the literature provides evidence of a privacy paradox, or an inconsistency between what is said and what is done. These differences in privacy choices can be context dependent (Nissenbaum 2004) or can be due to intrinsic characteristics, that is individual preferences or cognitive biases. Field experiments show that personal data disclosure can be explained by access to immediate gratification, by incomplete information and by individuals' bounded rationality (Acquisti 2004; Acquisti and Grossklags 2005). Through a series of diverse field experiments, Acquisti et al. (2012) show that survey respondents disclose more personal data if other respondents do so – the herd effect – and that the level of disclosure increases if the questions progress from more to less intrusive. In a study of people's interactions, Forman et al. (2008) find that consumer-generated product reviews containing identity-descriptive information are rated more positively by community members and are associated with an increase in product sales. Moreover, information disclosure tends to become the norm and to lead other reviewers of a product to do the same.

The literature has underlined that individuals' privacy concerns increase once consumers have, or have heard about, bad privacy experiences, such as identity theft or unwanted secondary uses (Smith et al. 1996). The extent of their concern over privacy depends also on an individual's awareness of firms' privacy practices (Malhotra et al. 2004). In a field experiment, Marreiros et al. (2016) test whether privacy actions and attitudes can be influenced by exposure to information about the advantages and disadvantages associated with disclosing personal information online. The results suggest that privacy concerns emerge once users are asked to think about privacy issues.

From a market perspective, individuals' awareness of the potential risks associated with privacy abuses can have an impact on the demand for privacy. In a field experiment designed on a shopping search engine interface, Tsai et al. (2011) show that individuals' purchasing intentions increase if online retailers display salient information about privacy protection clearly. Acquisti et al. (2013) disentangle the issue of privacy valuations by suggesting that individuals value privacy more when they have it than when they do not. In other words, they highlight the existence of an endowment effect. Using a large dataset, Goldfarb and Tucker (2012b) use a refusal to disclose personal information (here individual income) to measure demand for privacy. They show that, overall, there is an increasing percentage of individuals who do not disclose personal data and that there is a generational pattern: younger individuals disclose more compared to older people.

Open Research Questions

Regarding individuals' privacy behaviours, there are several open research questions. For example, knowing the differing privacy concerns among users is essential in order to conceive adequate privacy regulation. A regulation aimed at users who are not concerned about privacy is likely to be ineffective. For this reason, it is of interest to investigate the younger generation's privacy concerns, and especially the privacy concerns of teenagers. Demand for privacy appears also to be an important feature, and there is a need to design field experiments to estimate the demand for privacy, that is if users find a good or a service with privacy characteristics more attractive.

How Firms Use Personal Data

The marketing and industrial organization literatures mostly investigate how companies exploit personal data, and how personal data can spur new business models and, thus, generate innovation. Big data, data analysis and progress in business analytics permit data to be retrieved and analyzed at an unprecedented level (Acquisti 2014). In a seminal contribution, Varian (1997) distinguishes between first and "second usage" of personal information by internet companies: first usage facilitates firms' interactions with customers, and second usage occurs when the firms pass on information to one or more other firms – "third parties" – better able to exploit personal data. This distinction defines a primary market involving customers and internet companies, and a secondary market involving internet companies and third parties.

In the primary market involving internet companies and customers, personal data is first used to design more effective advertising campaigns aimed at individuals and to set prices that are close to individuals' willingness to pay. Second, both the exploitation of clickstream data that provide detailed information on how individuals interact with websites and advertising and the increased importance of algorithms in internet economics help speed up the pace of innovation.

According to price discrimination theory, the link between firms' strategies and personal information, and thus privacy, is central (Taylor 2004). Exploiting personal information could facilitate first degree price discrimination or, more realistically, third degree discrimination as these data permit a company to identify an individual's reservation price. Consistent with a positive effect of discrimination for users, a recent theoretical work by Belleflamme and Vergote (2016) suggests that the use of technologies to conceal personal information might reduce consumer surplus.

For most online firms, personal ad revenue is a major source of income (Martin and Murphy 2016). However, empirical works based on large field experiments provide some puzzling results regarding the effectiveness of personalized ads. In particular, in a field experiment on a popular social media website, Tucker (2014) shows that the effectiveness of an ad increases if individuals have more control over their personal data. In another field experiment, Lambrecht and Tucker (2013) show that dynamic ad retargeting is, on average, less efficient than generic ads. Dynamic retargeting effectiveness increases once individuals have more information related to the products they want to buy. In addition to price discrimination, other forms of discrimination can arise, in particular, in the labour market where recruiters can discriminate among candidates on the basis of information available on social media (Acquisti and Fong 2015; Manant et al. 2016). The article by Lambrecht and Tucker (2016) adds to this literature the role of social media algorithms which reproduce offline discrimination of individuals and particularly, that of women. Overall, these articles highlight how firms can exploit personal data which users leave online.

Data exploitation strategies suppose that firms can access individuals' personal data. This is why the theoretical literature highlights the need for firms to take account of individuals' privacy concerns. Taylor (2004) shows that firms can employ different strategies depending on the privacy regulation and consumers' expectations: firms prefer a disclosure regime if consumers are naïve and a confidential regime if consumers expect that their personal data will be used by firms. Acquisti and Varian (2005) provide similar results – that is that firms' strategies rely on consumers' preferences for personalized services. This need to take account of consumers' strategies to protect their privacy is confirmed by dynamic approaches (Villas-Boas 2004; Armstrong and Zhou 2010). Internet companies largely rely on the distribution of services or goods in exchange for users' registration. The effectiveness of these practices is not straightforward. In a theoretical model, Morath and Münster (2017) show that a monopoly firm can benefit from ex-ante registration requirements, in particular, if future purchases are considered. To influence consumers' decisions to register, consumer discounts seem appropriate and allow consumer surplus to be increased.

In the market involving internet companies and third parties, firms can also exploit personal data by selling it. While there are many marketing companies such as BlueKai and Avarto which specialize in data management, there is a need to understand the functioning of personal data markets and the role of the companies in these markets. Secondary use of personal information arises if data are sent to third parties or data brokers, that is to data aggregators, advertisers, or, more broadly, to competent departments within a firm (Akçura and Srinivasan 2005). Third party use and secondary use of personal data within the same firm seem to be less legitimate if personal data are sent without the awareness of the user. Taylor (2004) considers that this behaviour is welfare-diminishing for consumers. Using a theoretical model, Akçura and Srinivasan (2005) also show that this secondary market can result in a dramatic decrease in consumer welfare. The existence of the market for personal data implicitly questions the value of data to firms (Spiekermann et al. 2015). From this perspective, industrial organization scholars first may have to assess whether personal data are a good per se. Farrell (2012) contributes to this discussion by showing that personal data can be considered as a good and that privacy protection can be seen as a strategic parameter for profit maximizing firms. In this context, the contribution by Kummer and Schulte (2016) is relevant since it delves into the business models of smartphone applications by highlighting a tradeoff between price and personal data for both the market's supply and the demand side, seeing personal data as an alternative business model for free services. An OECD (2013) report provides details of different methods to evaluate personal data and offers some insights into the firms operating in the market involving internet companies and third parties.

Open Research Questions

There remain various research questions related to the industry structure of the personal data market and the extent to which personal data are part of the business models of internet companies. This is particularly relevant in the market for smartphone applications, where an increasing number of free applications are available. An important issue is to see if privacy can be a business differentiator.

Regulation and Policy Intervention

The emergence of new businesses based on personal data drew the regulators' attention to the need to find the right balance between protecting privacy and promoting data sharing to encourage innovation and improve services. Formulating public intervention in privacy is a complex issue. First, the innovation in sectors where personal data play a key role is challenging and competition among players is high. Second, the design of privacy regulation can affect the behaviours of both individuals and firms. Indeed, market interactions, namely those between firms and consumers, but also between firms and third party companies, can lead to unexpected consequences, which can trigger the effectiveness and the evaluation of the policy. Moreover, while privacy regulation is directed towards consumers and firms, it can also have indirect consequences on market structure. All in all, the direction and the size of these effects are unclear. While regulation helps to create the premise of a clear framework for companies, there is a need to understand the overall role of personal data on the markets. For this reason, we focus here on the principles that govern privacy regulation and on theoretical and empirical evidence of the impact of this regulation on the markets, but also on how privacy-enhancing technologies and data breaches can shape these markets.

Regulation and Self-Regulation

Focusing on the instruments used by the regulatory authorities helps understand how privacy regulation can intervene in the markets. In the USA where the Federal Trade Commission (FTC) provides guidelines at the sectoral level, self-regulation prevails. The main goal of self-regulation is to stimulate "competition on privacy," and then alleviate market failures. This approach considers both sides of the market by assuming that consumers can make decisions to enact their privacy preferences, and that companies are supposed to respect a principle of transparency and control over privacy issues, for example, by giving detailed information on data collection as well as on the use of data. In this perspective, privacy policies rely on a "notice-and-consent" principle where individuals are supposed to read privacy policies and consent or not to the terms of service (Cranor 2012). Privacy policies are expected to provide information to individuals on firms' practices about how their personal data are gathered, used, shared and secured (Marotta-Wurgler 2016). However, empirical evidence shows that those policies are too long to read and too complex to understand for a non-practitioner (McDonald and Cranor 2008). In line with the self-regulation approach, FTC policy has also encouraged the creation of third party certification services and online seals such as TRUSTes and BBBs to help decrease individuals' cognitive costs of assessing the eventuality of potential privacy threats. Nevertheless, adverse selection can emerge with such private seals. In particular, empirical research has shown that websites certified by TRUSTe are more than twice as likely to be untrustworthy as uncertified sites (Edelman 2011). In terms of policy implications, it suggests that regulatory intervention is necessary to ensure the quality of private seals.

In Europe, the regulatory approach is focused more on providing a general framework to protect consumers across sectors, which is substantially different from the self-regulation approach. Regulation aims at alleviating the adverse selection problem by ensuring more guarantees for individuals and a stringent environment for companies. The current debate was triggered in 2016 by the publication of the Data Protection Directive updating the previous Data Protection Directive 95/46/EC Directive and ePrivacy 02/58/EC Directive. This new framework allows individuals access to more information about how their data are processed by companies and gives individuals the right to have their data forgotten – that is, they can ask for deletion or modification of their data by the data holders. The Directive promotes the use of "privacy by design" which aims to embed privacy in the very early phases of the development of a product or a service, as well as throughout its development. Overall, while the European approach is supposed to bring more transparency and stronger protection for individuals than in the USA, it must also be more costly for firms that comply with, since it imposes stronger obligations on them.

The evolving practices of regulation dealing with privacy issues have also had an impact on the commercial relations between the USA and Europe. As an illustration, Snowden's revelations of mass surveillance programs have encouraged the replacement of the previous US-EU Safe Harbor Agreement by the EU-US Privacy Shield, which took effect in July 2016. This agreement pushes for more cooperation between US and European Data Protection Authorities. This obliges US companies to ensure transparency about trans-frontier transfers of personal data and stronger protection of personal data.

Impacts of Privacy Regulation

Since privacy regulation affects both individuals and firms, the literature has identified different levels of impact of this regulation, that is, the impact on agents' behaviours, but also on market structure.

First, the literature shows that the different principles of privacy regulation have direct effects on individuals' choices. Looking at the variation in US State genetics privacy laws over time, Miller and Tucker (2015) show that giving individuals control over the redisclosure of their genetic tests by hospitals encouraged the diffusion of this practice, while requiring informed consent deterred individuals from undertaking genetic testing services. In a large-scale field experiment, Goldfarb and Tucker (2011) study how the enactment of the European privacy regulation has impacted the effectiveness of banner ads on individual behaviours. They show that the intention to buy has decreased since EU regulation restricted the use of data related to customers' past browsing behaviours.

The increased use of open data and mass data collection can also influence consumer behaviours and have potential commercial outcomes. Marthews and Tucker (2015) show that Edward Snowden's revelations about the US government surveillance changed the type of requests conducted on Google Search. The result suggests that this event has affected individual behaviours by increasing the demand for privacy.

Second, while privacy regulation is directed towards consumers and firms, it can also have indirect consequences on the market structure. Campbell et al. (2015) propose a theoretical model to show that a consent-based approach, even if it deters consumers and imposes costs on all firms, may disproportionately benefit generalist firms that offer a large scope of services, rather than specialist firms. This regulation regime thus affects the competitive structure of the market. In the context of the impact of sectoral privacy regulation on organizations' activities, there is a large literature studying the impact of health regulation in the USA on the diffusion of hospital information technologies. Exploiting the variation in State privacy legislation in the USA, Miller and Tucker (2009) show that privacy protection can hamper the adoption of these technologies by hospitals if they are unable to take advantage of patient information from other hospitals. US privacy law restricts cases where hospitals can exchange patient data. The regulation can also have an impact on the location of internet companies. Using a sample of the most visited websites worldwide, Rochelandet and Tai (2016) demonstrate empirically that internet firms prefer to be located in countries where data collection and exploitation are less regulated. Inversely, tax instruments can help reduce data collection by internet platforms, while an opting-out option, where users can access the platform with no data collection, induces the platform to raise the level of data exploitation (Bloch and Demange 2016).

The increased importance of data has also stimulated mergers and acquisitions aiming to increase their competitive advantages. These practices might radically change the structure of the market. On the one hand, they can counterbalance the internet giants currently in place, and on the other hand, they can create the conditions for anti-competitive data-driven strategies once these operations aim to prevent rivals from accessing data or hamper the access of consumers to competitors' platforms (Goldfarb and Tucker 2012a). As an example, the Google/DoubleClick merger has illustrated how the standard tools of competition policy cannot really assess consumer privacy issues since privacy issues are related to non-price attributes. In this respect, the role of data brokers can be central. In a theoretical model, Clavorà Braulin and Valletti (2016) show that it is possible to achieve first best allocation only when data are sold non-exclusively. When a data broker sells the data exclusively, this creates inefficient allocations.

Privacy-Enhancing Services: Privacy as a "Business Differentiator"

The increasing level of individuals' privacy awareness can have an impact on demand for privacy, which then generates conditions conducive to the adoption of privacy-enhancing services. After the Snowden revelations, the number of DuckDuckGo service users, a search engine that does not register users' IP addresses, sharply increased by about 600% (Wired 2017). In January 2017, it had more than 14 million searches. In this respect, the protection of personal data can represent a differentiation strategy for internet companies, "pushing to the top" the most privacy respectful firms. In such a case, the decrease in personal data collection would offset the increase in the number of consumers becoming more confident. An important contribution in this respect is the theoretical model of Casadesus-Masanell and Hervas-Drane (2015) showing that higher competition intensity in the marketplace need not improve privacy when consumers exhibit low willingness to pay. However, so far there is no clear evidence that people do understand the current model of free internet services in which they give personal data in exchange for free services, and that they might be better off paying for it and protecting their privacy. Privacy-enhancing services can remain a niche market if demand for these services does not increase, which Farrell (2012) defines as a "dysfunctional equilibrium". In this respect, moving from free services to paid services is a major challenge in the future for privacy-enhancing services. Nowadays, the large majority of these services are freely available (examples are blogs, website contents or smartphone applications). The main sources of income of these internet services are advertising, e-shopping and personal data (Lambrecht et al. 2014). The advance of services that help block advertising, as well as the increase of individuals' privacy concerns, might challenge the model of free web services (e.g. Adblock Plus, Google Contributor). In particular, the demand for privacy can influence the willingness to pay for services which are respectful of privacy.

Open Research Question

With the "internet of things" generating huge amounts of data ("big data"), and then the proliferation of algorithms that implement artificial intelligence and machine learning, many choices can be suggested to individuals. This could have a positive or negative impact on social welfare. Potential discrimination due to these technologies will require special attention from the regulator but also innovations on their part.

Further Developments

We identify the existence of a privacy market linking users' demand for privacy. Looking at the drawbacks of privacy policy, privacy-enhancing technologies (PET) can be seen as an alternative. An example was the P3P project (Platform for Privacy Preferences Project) which was dedicated to the creation of machine-readable privacy policies, aimed to normalize privacy policies and help users to better understand them and increase individuals' trust. However, these solutions have also failed, due partly to their complexity. More advanced solutions, such as encryption, differential privacy or decentralized personal data systems, based on the blockchain technology, have been suggested to help build a market for personal data, but these technologies do not yet guarantee a possible re-identification of the personal data owner (Zyskind et al. 2015).

Starting from these weaknesses, and by simplifying the signal to its maximum, behavioural economists and psychologists suggest that information related to privacy issues should be conveyed in a simple and standardized manner in order to ensure that consumers understand it (Bhargava and Loewenstein 2015). Nudging privacy seems to be a promising practice that is complementary to effective regulation and individuals' empowerment (Lazer et al. 2009).

As a summary, it appears to be particularly complicated to achieve an appropriate balance between information sharing and information hiding. Therefore, there is no single way to reduce information asymmetry. Regulation, market-based or technologies-based solutions can be seen as complementary. In this perspective, privacy protection as a business differentiator "pushing to the top" the most privacy respectful firms deserves consideration, although it depends *in fine* on consumers' preferences for privacy.

Privatization

John Vickers

Abstract

Privatization is the transfer from government to private parties of the ownership of firms. Privatization programmes have been carried out worldwide since the mid-1980s, with important consequences for economic efficiency, public finance, and distribution. In competitive industries privatization generally has positive effects on incentives and performance. The economic consequences of privatizing firms with market power depend on the effectiveness of regulation and competition policy. These points are illustrated by experience in Britain, a leading exponent of privatization policies.

'Privatization' is defined here as the transfer from government to private parties of the ownership of firms. This definition is not so broad as to embrace, for example, the sale of publicly owned housing and natural resources, contracting out the supply of publicly financed services, or the introduction of user charges for services previously provided at public expense. However, some of the economic principles for privatizing firms apply more generally.

This article is in two parts. The first part addresses some economic and financial principles of privatization, beginning with the basic question: how does ownership matter for economic efficiency? It is concluded that, at least for firms with significant market power, this question must be addressed in conjunction with the framework of regulation and competition that accompanies public or private ownership. The second part examines some aspects of privatization in practice, particularly in Britain, the leading exponent of the policy in the 1980s.

Privatization: Principles

Ownership and Economic Efficiency

If privatization is defined as the transfer of ownership, the first question is: what is ownership? According to the incomplete contracts view of the firm (see Hart 1995), ownership of an asset is to be identified with residual rights of control – rights to make decisions in the domain not already subject to contractual obligations. No such rights would exist in a world of complete contracts, where ownership, and hence privatization, would therefore be irrelevant.

The ultimate owners of sizable firms typically delegate the exercise of residual control rights to professional managers (whose identity may or may not be affected by privatization). Privatization affects principal–agent relationships between owners and managers by changing (*a*) the principals and hence their objectives, (*b*) the means of monitoring and giving incentives to the agents, and (*c*) the scope and incentives for action by the former public principals.

As to (*a*), a limitation to the economic theory of privatization is that there is no definitive theory of the firm under public ownership. In some sense the ultimate owners are the general public, but, even if their preferences could satisfactorily be aggregated into a welfare measure, it would be pious to suppose that government ministers or bureaucrats would necessarily exercise their authority over public firms to maximize welfare, avoiding distraction by political considerations, influence by well-organized vested interests, and so on. With private firms the usual assumption that owners seek to maximize profit or share value seems a tolerable approximation for present purposes, except perhaps if workers or consumers have large ownership stakes.

Since private, unlike public, ownership claims are generally tradable, privatization can alter the monitoring and incentives of managers by changing information conditions. For example, managers' rewards can be related to share price performance. In so far as share prices reflect the value of the firm, managers can thereby be given incentives to enhance firm value. Stock market investment analysts become a new source of managerial monitoring. However, free-rider considerations imply that monitoring by private owners might be limited, especially if share ownership is diffuse.

The tradability of ownership claims also means that privatized firms, unless they are given special protection, are potentially open to takeover threats, whereas publicly owned firms obviously are not. It is a matter for debate whether such threats from the market for corporate control are effective in disciplining managers of private firms to act in shareholder interests. Private firms also face the possibility of bankruptcy, in which case residual control rights shift to debt-holders.

Privatization changes the relationship between government and the firm. Thus public officials may lose power to intervene in the running of the firm. Moreover, and perhaps most important, the credibility of government commitment not to intervene may be enhanced by privatization so that, for example, managers face harder budget constraints and hence stronger incentives (see Schmidt 1996).

Nevertheless, privatization might not make government commitment not to intervene completely credible, especially if the firm remains subject to regulation or dependent on public subsidy. In any event, the government retains powers of taxation, and ultimately there is the possibility that privatization might be reversed, possibly on terms disadvantageous to private owners. To the extent that these factors give rise to risk of more or less subtle expropriation by government, private investment incentives may be adversely affected.

From the considerations above it follows that the consequences of privatization are likely to be influenced by the extent of market power enjoyed by the firm in question. For a firm that operates in competitive conditions, the shift from 'public' to profit objectives raises no concerns about the exercise of market power, and, since no special apparatus to regulate market power is required, opportunities for expropriation are limited. In these circumstances one may expect private ownership to be superior to public ownership in terms of economic efficiency, and indeed that is what the empirical evidence shows.

For a firm with market power, however, it may be desirable for reasons of allocative efficiency, and inevitable for political reasons, for privatization to be accompanied by monopoly regulation. But regulation risks blunting the very incentives – for example, for cost reduction and efficient investment – that privatization is usually intended to sharpen.

A complementary approach to the problem of privatized (and in principle also nationalized) market power is liberalization – the removal of legal and other barriers to competition, and accompanying measures to contain anti-competitive behaviour by the incumbent firm. Among other things, liberalization may expose and undermine patterns of cross-subsidy practised under public monopoly.

Therefore, in contrast to the competitive market case, it would appear that no general claim can be made as to the economic desirability of privatizing firms with market power. The accompanying regimes of regulation and competition policy are crucial determinants of the consequences of their privatization.

Privatization and Public Finance

In addition to microeconomic efficiency, considerations of public finance have motivated privatization policies in a number of countries, including Britain. By raising government revenue, privatization reduces the immediate need for public sector borrowing. It may also release firms from financial constraints resulting from government macroeconomic policy commitments. But the economic, as distinct from public accounting, significance of these points is unclear.

Selling public firms indeed raises government revenue, but the same is true of selling government bonds: in both cases the public sector receives a lump sum in return for a stream of future profit or interest payments. The deeper question is how privatization differs from government bond issue in terms of its effect on the net worth of the public sector.

If privatization leads to economic efficiency gains (which would not otherwise have been achieved) – or to greater exercise of monopoly power, which is akin to a tax increase in public finance terms – then the firm's profits are greater with privatization than in the public sector. If the firm is sold at a fair price, then the public sector captures the net present value of the profit gain (less the transactions costs of privatization, which are likely to exceed those of bonds). If, however, the firm is underpriced, then any gain to the net worth of the public sector is reduced by the extent of underpricing. Competition among potential buyers and a pre-existing market for the firm's shares are factors likely to assist more accurate pricing of privatization share issues.

Privatization can also affect the net worth of the public sector, compared with selling government bonds, if risk-adjusted discount rates differ. For example, a government with poor inflationary credibility may have to cede a large interest rate premium when selling bonds. Shares in privatized firms are not so vulnerable to expropriation via inflation (neither are index-linked bonds). However, as discussed above in relation to regulatory credibility, some privatized firms, especially those with monopoly power, may face serious risks of expropriation via regulation or even renationalization. The relative sizes of these risks of default on debt and of 'default on equity' are likely to vary by industry as well as by country. The nature of the private shareholders – for example, their nationality or whether they are small individual investors – might also be an influence upon the probability of expropriation.

Self-imposed public finance constraints by government can provide efficiency rationales for privatization if they prevent publicly owned firms from making desirable investments. In macroeconomic terms, it ought to matter little whether a firm is in public or private ownership when it does a given amount of borrowing; it appears, however, that governments seeking to adhere to public borrowing commitments may view matters differently.

Privatization and Distribution

Privatization, and the financial and industrial policies that accompany it, can have large distributional consequences. First, if public firms are sold to private investors for less than their market value – for example as part of a plan to promote 'wider share ownership' – then, relative to the situation with more accurate pricing, wealth is redistributed away from the general taxpayer to the investors who succeed in getting shares. Employees and managers of privatized firms gain from such redistribution if, as has often happened, they are allocated shares on favourable terms. Managers may benefit also from share option schemes and from being released from public sector pay constraints.

Second, if privatization hardens the firm's budget constraint, then it may diminish rents enjoyed by those within the firm to the benefit of the general taxpayer. Third, widespread cross-subsidy – for example, of small customers by large customers, and/or of suppliers of certain inputs – is a common feature of publicly owned monopoly. Privatization entails redistribution in so far as it undoes such cross-subsidies, but, here as elsewhere, the accompanying regime of regulation and competition is likely to be more important. Thus liberalization tends to be a more potent enemy of cross-subsidy than privatization itself, and, in the case of privatized monopoly, regulation can be a major determinant of the extent of redistribution among consumer groups as well as between consumers and shareholders.

Finally, it has been suggested (see Biais and Perotti 2002) that privatization policies may be designed in part so that their distributional consequences alter political preferences – in particular by giving voters a stake in the avoidance of political parties whose policies would undermine the value of shares in privatized firms.

Privatization in Practice

Privatization Worldwide

Principally since the mid-1980s, privatization policies have been pursued, to varying degrees, around the world – for example in Argentina, Brazil, Chile, France, Germany, Jamaica, Japan, Malaysia, Mexico, the Philippines, Singapore, Spain, the formerly Communist countries of central and eastern Europe and the former Soviet Union. Privatization sales proceeds worldwide are estimated to have exceeded a trillion dollars. The extensive survey by Megginson and Netter (2001) concludes that the state-owned enterprise share of global output fell from more than ten per cent in 1979 to below six per cent by 2000.

The following account concentrates on Britain, which was a leader of the worldwide privatization movement in terms of both the scale of its programme and its embrace of monopoly industries. Further details may be found in Vickers and Yarrow (1988) and Newbery (2000).

Privatization in Britain

Nationalization by the post-war Labour government and subsequently had led to a situation in 1979 where the public sector in Britain dominated the supply of energy (gas, electricity, coal and some oil), transport (air, rail and bus), communications (post and telecommunications) and water, and also had substantial interests in manufacturing (for example, in aircraft, shipbuilding, steel and cars).

In the 18 years of Conservative government from 1979 to 1997, the proportion of GDP accounted for by state-owned firms fell from 11 per cent to below two per cent. At the peak of the privatization programme, between the mid-1980s and the early 1990s, sales proceeds typically exceeded one per cent of GDP and were sometimes of the order of three per cent of public expenditure.

The watershed in the British privatization programme was the sale of British Telecom (BT) in 1984, an event motivated in good part by a desire to free BT from macro-economic policy restrictions on public sector borrowing. Before that, privatization policies were relatively modest in scale and confined to firms in more or less competitive industries such as oil and manufacturing. By extending the programme to utility monopolies, the sale of BT marked a key shift in the nature, as well as the scale, of the British privatization programme. In particular, it required the development of a system for regulating private monopoly.

Privatization – with accompanying regulation – was subsequently extended to gas (1986), airports (1987), water in England and Wales (1989), electricity (1990–91) and the railways (1996). By 1997, when the Labour Party returned to power (having abandoned its traditional commitment to public ownership), the main activities remaining in the public sector were the Royal Mail, the BBC, London Underground, British Nuclear Fuels, Air Traffic Control, and the water industry in Scotland. In 2001 National Air Traffic Services was partly privatized as a public–private partnership (PPP). London Underground remains in public ownership but since 2003 infrastructure renewal and maintenance has been procured under long-term PPP contracts.

Methods of Sale

The main ways of privatizing a firm are (*a*) offer for sale of shares to the general public, (*b*) sale to another firm, and (*c*) management/employee buyout. The third method was used in parts of the transport sector, including road haulage, some bus companies, and rail rolling stock leasing companies. The Rover car group was an example of privatization by sale to another firm (British Aerospace, which later sold Rover to BMW). However, by far the most important method used in Britain was offer for sale to the general public.

With this method, questions include (*a*) whether to sell the firm in two or more stages, or all at once; (*b*) whether the share price is set administratively or by competitive tendering among prospective purchasers of the shares; and (*c*) whether incentives and bonus schemes are created to encourage small investors to buy (and hold) privatization shares. Before the BT sale, privatizations were mostly in stages (as was BT's), use was often made of competitive tendering, and no great inducements to wider share ownership were given. These methods are conducive to reasonably accurate share pricing. Thus selling a firm's shares in stages enables accurate pricing after the first stage because the market value of the shares is known.

In the latter part of the 1980s, however, some large firms (such as British Gas) were sold in one go, tendering methods were eschewed, and there were strong incentives for small investors to buy shares. This pattern suggests that wider share ownership was a primary objective of privatization policy. In the 1990s tendering methods came back into use, albeit with discounts for small investors, thus combining the objectives of revenue maximization and wider share ownership to some extent. However, Railtrack, the railway infrastructure company, was floated on the stock market in one go in 1996.

Even judged relative to the discounts that are typical with private initial public offerings, the government revenue forgone in pursuit of the objective of wider share ownership appears to have been very large. The number of British individuals directly owning shares rose sharply but the proportion of the stock market owned directly by individuals has continued its long-run decline. If it is thought to be an appropriate policy goal, wider share ownership might be better pursued by reforms to the taxation of saving and investment generally rather than by privatization policies.

Regulation

The regulatory framework for the privatized BT was established by the Telecommunications Act 1984. A similar framework was subsequently adopted for gas, electricity, water and railways. Regulatory powers and duties were divided between the government minister, who granted licences containing regulatory provisions; an industry-specific regulator (for example, the Director General for Telecommunications), who enforced and reviewed licence conditions; and the Monopolies and Mergers Commission, which considered disputes about licence modification.

This regulatory model developed over time. Powers were transferred from individual directors general to boards, and some regulatory bodies were combined. Thus the Utilities Act 2000 created the Gas and Electricity Markets Authority, and under the Communications Act 2003 a new body, Ofcom, took over the roles of several regulators including the Director General for Telecommunications. The regulators gained powers under new UK competition law (see below). And the wider European context grew in importance, with EC directives for the liberalization of network industries such as telecommunications and energy.

For firms with market power, perhaps the most important aspect of regulation concerns price control. When it embarked on the privatization of BT the British government was anxious to avoid perceived deficiencies of rate-of-return regulation. Instead, following the report of Professor Stephen Littlechild (1983), it adopted the form of price cap regulation known as 'RPI minus *X*', which requires an index of the firm's regulated prices to fall by *X* per cent per annum in real terms (that is, relative to the retail price index) for a period of years. This was intended to be 'regulation with a light hand' and to wither away over time. However, price regulation in several industries at first became tighter and more detailed, and rate-of-return considerations were soon seen to be of prime importance at points of regulatory review. Nevertheless, even if RPI minus *X* price cap regulation is akin to rate-of-return regulation with long lags, this may well have substantial advantages over rate-of-return regulation as traditionally practised. After a time, as competition took hold after liberalization, some price controls were lifted, notably from domestic energy retail prices in 2002 (though transmission and distribution remain regulated) and from BT's retail prices in 2006.

Industry Restructuring

Restructuring is an important instrument of competition policy when firms with market power are privatized. (Forced restructuring after privatization may seriously jeopardize regulatory credibility.) Both BT and British Gas were privatized without restructuring as vertically integrated firms with nationwide dominance. However, after a decade of competition problems arising from the vertical integration of British Gas, and, in view of accelerated liberalization of retail supply, the company divided itself into separate pipeline and supply companies in 1997.

By contrast, the government radically restructured the electricity and railway industries before privatization. In 1990 the Central

Electricity Generating Board in England and Wales was divided into a transmission company (National Grid) and three generators (National Power and PowerGen; and Nuclear Electric, which was eventually privatized as British Energy in 1996). Vertical separation meant that a new mechanism had to be devised to coordinate transmission and generation, and a wholesale auction market, the Pool, was established (and later reformed by the introduction of New Electricity Trading Arrangements in 2001). In all, 12 Regional Electricity Companies (RECs) were privatized with responsibility for distribution and retail supply, which was progressively liberalized in the late 1990s and finally deregulated in 2002.

Major restructuring and ownership changes have occurred in the energy sector since privatization. The generators, National Power and PowerGen, had to divest substantial generation capacity following concerns about their market power, which was largely due to the concentrated structure for generation chosen by government in an unsuccessful effort to privatize nuclear power at the outset. Initially National Grid was jointly owned by the RECs but it became an independent company in 1995, and in 2002 merged with the gas pipeline company. After the lifting of takeover protections in the mid-1990s, most RECs were acquired, and ten years later six companies, supplying both gas and electricity (often in combined deals), accounted for nearly all energy supply – British Gas and five electricity suppliers, of which one is French- and two are German-owned. Thus, depending on merger policy, industry structure and ownership can alter substantially after privatization.

British Rail was restructured before privatization to separate network infrastructure from train operation. Railtrack, which took over network infrastructure, including track and stations, was privatized in 1996. The company went into administration in 2001 and its assets were acquired by Network Rail, a company limited by guarantee that has no shareholders. Three rolling stock leasing companies were also privatized in 1996 (and soon resold at a profit). Private train operating companies run train services under franchises. Large public subsidy to rail services continues in the privatized regime.

Liberalization of Competition

Statutory monopoly typically accompanied public ownership in the utility industries. Among other things this served to facilitate extensive cross-subsidy between groups of customers, and sometimes of input suppliers – for example, the nationalized electricity industry effectively subsidized British Coal. The removal of statutory barriers to entry in telecommunications, gas and electricity began in the early 1980s, before privatization policies were adopted, but then had little competitive effect. Liberalization has generally gone further since privatization – as illustrated above by the energy sector – and over time more attention has been given to economic, as well as legal, barriers to entry.

In telecommunications, liberalization of apparatus supply and value-added services began in 1981, when BT was split from the Post Office, and in 1982 Mercury was licensed as a competing network operator. However, for the rest of the decade the government adopted a ‘duopoly policy’ of allowing no further entry into fixed-link network operation. A parallel duopoly policy applied to mobile telecommunications.

When the duopoly policy was ended in 1991, the interconnection question – on what terms can rivals gain access to BT’s local network? – became and has remained a focus of controversy. On the one hand it was argued that rivals could inefficiently ‘cream-skim’ BT’s more profitable business while BT remained restricted by controls on its tariff structure and universal service obligations. On the other hand, it was argued that rivals faced entry barriers. These tensions eased somewhat over time as tariff rebalancing diminished cross-subsidies in BT’s pricing structure, and as entry barriers (such as the lack of number portability) were tackled directly by the regulator. But the advent of broadband, with BT still an integrated incumbent operator, brought the interconnection question back into sharp focus. Faced with the prospect of an investigation under competition law, BT agreed in 2005, 20 years after privatization, to operational separation of its local access infrastructure.

A major weakness of UK policy towards privatized firms with market power had been the absence of effective competition law against anti-competitive agreements and abuse of dominance. However, that gap was filled in March 2000 when the Competition Act 1998 – which mirrors Articles 81 and 82 of the EC Treaty – came into force and was followed by the Enterprise Act 2002. The regulators can now apply (non-merger) competition law in their sectors. Over time, then, following the shift from state monopoly to regulated private monopoly, there has been increasing availability of competition policy instruments to address market power in historically monopolized industries such as energy and telecommunications in Britain. Nevertheless, the regulatory regimes have remained the principal means of controlling market power.

The Performance of Privatization

Privatization policies have undoubtedly had major economic and financial effects. Have they generally been positive? Answering this question properly requires the specification of evaluation criteria, performance measures, statistical methods and the counterfactual: what would have happened without privatization?

Megginson and Netter (2001, section 5) review 38 empirical studies of privatization covering both developed market economies and transition economies. Privatized firms are generally found to become more efficient and profitable, and to invest more. There are mixed results on employment effects, though job cuts appear to be associated with corresponding productivity gains. Direct evidence on effects on consumers is limited. In their survey of studies of transition economies, Djankov and Murrell (2002) conclude that privatization, especially to outside investors as distinct from managers and workers, is robustly associated with enterprise restructuring and growth, and that competition has a significant positive effect on enterprise performance.

In competitive industries, improvements in the corporate performance of privatized firms imply overall economic gain, and there is ample evidence that privatization has been a success. For firms with market power, however, corporate performance can improve at the expense of the public as well as by enhanced efficiency. Moreover, it is hard to isolate the effects of privatization in hitherto monopolized industries from those of accompanying regulatory and competitive reforms. In Britain, methods of privatization and regulatory reform have at times been seriously flawed. But privatization was probably necessary for liberalization and for the creation of a system of independent economic regulation, augmented in time by effective competition policy. Though far from perfect, these are major improvements upon the nationalized monopoly of old.

Privatization Impacts in Transition Economies

Saul Estrin

Abstract

This article addresses the large-scale privatization processes in central and eastern Europe. It explains why reformers placed such emphasis on privatization and the practical problems posed by the scale of state ownership under communism, leading to the widespread use of mass privatization. As a result ownership changes were huge and extremely rapid but the improvement in corporate governance was more questionable. The empirical findings about the impact on enterprise performance are patchy, though on balance the effect has been positive, especially in countries with stronger institutions or where the new owners have been foreigners.

Privatization is the process whereby the ownership of the state's productive assets, often utilities or large industrial enterprises, is transferred into private hands. This has been a major activity for governments in both the developed and the developing worlds since Prime Minister Thatcher's first modern privatization programme in the UK between 1979 and 1984. The cumulative revenues raised from the process globally probably exceeds $1.25 trillion dollars, while the role of state-owned enterprises in the economies of high income countries has declined from around 8.5% GDP on average in 1984 to around 6% in 1991 and probably below 5% in 2005 (see Megginson 2005). The reduction in state ownership has probably been even more dramatic in less developed countries, from around 16% GDP in 1981 to around 5% in 2004. Privatization is intended to improve corporate efficiency and generate revenues for the state, and there is now probably sufficient experience in different economic and institutional environments to evaluate its impact relative to expectations.

Privatization has been a particularly important phenomenon in the transition process in central and eastern Europe from planning to a market system. This is because Communist regimes had placed almost all the productive assets of the economy in state hands for ideological reasons, and to facilitate the planning process. As a result, countries like Czechoslovakia and the Soviet Union contained virtually no private sector at all – typically in excess of 90% of assets were state owned and even in countries with slightly larger private sectors, like Poland or Hungary, private ownership was concentrated in agricultural and handicraft activities; industrial firms were all in state hands. This meant that privatization was a central aspect of building a market economy in all the transition economies. Indeed, to quote Dusan Triska in 1992, 'privatization is not just one of the many items on the economic program. It is the transformation itself' (see Estrin 2002).

This article addresses the privatization process in central and eastern Europe, focusing on the objectives, the methods and, most importantly, the impact of the ownership changes. Privatization always had some ideological content in the transition economies, especially in the early years, when the reformers wished to create a 'capitalist class' supporting the radical changes that were required to build a market economy. But the fundamental objective of privatization in transition economies, as in developed and developing ones, has been to enhance company performance. We enquire whether privatization has succeeded in this objective in the remainder of this article.

Why Privatize?

We begin by identifying why reformers in the transition economies placed such emphasis on privatization. Transforming state-owned assets into private hands can improve corporate efficiency (see Vickers and Yarrow 1985), and, particularly with the privatization of infrastructure, the benefits can spill over to the rest of the economy. To understand why, one must compare company objectives and corporate governance under state and private ownership. It is normally argued that the fundamental difference between state-owned and private firms rests in their objectives: the latter focus exclusively on profit, which generates close attention to costs and to the demands of customers. State-owned firms may be interested in profits too, but they will almost certainly be expected by their owners to satisfy other objectives as well, for example, politically determined targets such as creating or maintaining employment in economically depressed regions or holding prices below average costs for redistributive reasons. In this situation, profits become a secondary criterion, or indeed an irrelevance, and business decisions become politicized. Inefficiencies can thrive because they are not a central concern of the owner, and managers can exploit the lack of clarity in company objectives to ensure an easy life for themselves and employees (see Shleifer and Vishny 1994).

Therefore, an important motive for privatization is to focus attention on profits as the sole objective for the enterprise sector. But the problems of state ownership go beyond just diffuse and non-commercial objectives. In a socialist economy, the system of administered prices also means that privatization and market liberalization are needed to reveal opportunity costs. Moreover, even in a market economy, when a public-sector firm operates in a competitive market and the government tries to enforce an objective of profit maximization on its management, weaknesses in corporate governance can still cause inferior performance to what might be achieved under private ownership. The problem is centred on the asymmetry of information held by managers and owners; outside owners – private or state – can never have full access to the information about corporate performance that is in the hands of managers. Thus, it is hard for them to establish whether poor results are a consequence of unforeseen circumstances or managers exploiting firm profits for their own purposes. Whenever ownership and control are separated, firm-specific rents can be used to satisfy management's aim – for example, lower effort or managerial power, via the size of the firm – rather than profits. However, a private ownership system places more effective limits than does state ownership on their discretionary behaviour, via external constraints from product and capital markets which largely operate through the market for corporate control, and through the internal constraints imposed via statutes and monitoring by the owners themselves (see Estrin and Perotin 1991).

In Anglo-Saxon countries, the constraints on managerial discretion in large part derive from stock markets (see Megginson 2005). The quality of managerial decision-making and the extent of managerial discretion are an input in the choices of traders in equity markets, whose judgement on company performance is summarized in the share price. If the managerial team is thought to be incompetent or inefficient, the share prices will be reduced, putting pressure on managers to improve their performance. A persistently poor showing by a quoted company may also generate external pressure by encouraging a takeover bid. In this case, the stock market can be viewed as a market for corporate control, with alternative teams vying for the right to manage the enterprise. However, the effectiveness of these disciplines relies to some extent on the concentration of ownership. If ownership is highly dispersed, each individual owner has only a slight incentive to monitor effectively, and as there is a free rider problem monitoring may be inadequate.

Governance also comes from the way that the managerial market operates, with managerial performance, pay and job prospects assessed by movements in share prices. Payment mechanisms such as management stock option schemes can also be put in place to align the incentives of owners and managers. In countries such as Japan or Germany, however, the mechanisms can be different, with less reliance on an adversarial market for corporate control and more extensive use of internal governance constraints. Ownership is typically highly concentrated in the hands of banks, funds or families who are granted board representation and undertake close monitoring of managerial performance directly, and use the managerial market and management incentive schemes.

Either way, it is hard for the state to imitate these market-based constraints. State-owned firms are not subject to private capital market disciplines, so neither the competitively driven informational structure nor the market-based governance mechanisms can be substituted for in full. State employees are usually civil servants and do not compete in the wider managerial market, though Western governments have recently tried to reduce the labour market segmentation between the public and private sectors. Moreover, though the government's ownership stake is concentrated, the state is rarely directly represented on the boards of public sector companies and usually does not have the capacity in the supervisory ministries to undertake the necessary scale and quality of monitoring (see Vickers and Yarrow 1985).

These arguments have particular resonance in the transition economies of central and eastern Europe. The economic problems of the socialist system were largely a result of the impact of state ownership and planning on investment allocation, incentives and efficiency (see Gregory and Stuart 2004). Firms did not attempt to maximize profits, and productive efficiency was a low priority. Instead, weak monitoring of managers by the state as owner and the absence of external constraints gave management almost total discretion to follow their own objectives – rent absorption, asset stripping, employment, social targets. The softness of budget constraints (Kornai 1990) that goes with the political determination of resource allocation was a further source of incentive problems, since managers did not have to bear the consequences of their own actions. Mistakes were condoned and losses were subsidized.

Methods of Privatization in Transition Economies

It is therefore clear why privatization was so important in the transition process. Nonetheless, reforming governments might in principle have left privatization until the track records of particular firms in the market environment had become firmly established and until the stock of domestic savings in private hands was sufficient to ensure the success of a competitive bidding process for the assets. But the state was probably not able to manage its assets effectively in the intervening period, and managers and workers began very rapidly to steal the assets (Canning and Hare 1994). The collapse of communism had left state-owned firms with limited internal structure to handle the new requirements of the marketplace and no mechanisms to monitor or enforce governance on state-owned firms (see Blanchard et al. 1991). The authorities had either quickly to create structures whereby the state as owner could control enterprise decisions or face a gradual dissipation of the net worth of the enterprise sector by consumption, waste or theft. These stark alternatives persuaded many reforming governments and their Western advisors to consider rapid privatization. (Boycko et al. 1995 – the first of these an insider to Russia policymaking at the time – make a similar point concerning Russia. They argue that Russia had to undertake a massive and speedy ownership change in order to break the tradition of rent-seeking behaviour and the long-standing links between the state and the enterprise sector. They argue that, in order to gain political support for the privatization process, substantial stakes had to be given to insiders – the managers and workers in firms – so that they did not block the process.)

The sheer scale of privatization required in the transition economies posed considerable practical problems. As we have seen, the Communist heritage meant that the majority of firms in the economy needed to be privatized. At the aggregate level, the stock of domestic private savings in these countries was too small to purchase the assets being offered. This led the reformers to innovate with privatization methods.

For selected firms, many transition economies used auction or public tender, as have been the norm in the West. Such sales could in principle be to domestic or foreign purchasers but, in practice, only Hungary and Estonia were willing or able to sell an appreciable share of former state-owned assets to foreigners. Foreign capital ended up purchasing about 20% of the privatized assets in Hungary and up to 50% in Estonia, but even in these countries the preponderance of foreign ownership gave rise to public disquiet. Moreover, foreign direct investment flows to the transition economies were modest in the early years, when privatization was taking place, and were highly concentrated towards the Czech Republic, Hungary and Poland (United Nations 2004; Meyer 1998). In practice, sales of state-owned enterprises have mainly been to a country's own citizens: either to external capital owners or to insider management–employee buyouts. Managers and employees were the more common initial buyers, perhaps because they had insider knowledge about their company's business prospects. Some governments, such as in Romania, actively encouraged the emergence of insider-owned firms.

Some countries also experimented with restitution to former owners; the former East Germany, Hungary, the former Czechoslovakia and Bulgaria are prominent examples. Restitution has the advantage that it immediately creates a property-owning middle class and re-establishes 'real ownership'. However, the process of restitution entails legal complexities. For example, suppose that a factory has been built on a plot of land formerly owned by a noble. Does the noble receive the land back, and therefore rental for the factory? Or should the noble be compensated for the value of the property at the time of its seizure and, if so, how is such an evaluation to be made some 80 years later? Restitution also raises the deep question of how the assets accumulated during the Communist era, when consumption levels were held down for national capital accumulation, should be distributed. Since the burden of lower consumption was imposed on everyone, the argument that the distribution of the resulting assets should be egalitarian has been a powerful one.

To increase the pace of privatization, a number of transition countries began to experiment with 'mass privatization'. This entails placing into private hands nominal assets of a value sufficient to purchase the state firms to be privatized. To avoid the inflationary consequences of such wide-scale 'money' creation, the new assets must be non-transferable and not valid for any transaction other than the purchase of state assets. This was largely achieved using the instrument of privatization vouchers or certificates. It was hoped that any deficiencies in the resulting corporate governance mechanism arising from the fact that the ownership structure was initially diffuse would be addressed by capital market pressures leading to increased ownership concentration (Boycko et al. 1995).

Mass privatization has been carried out in a number of different ways, but the differences can be summarized around two issues. The first was whether the vouchers or certificates were distributed on an egalitarian basis to the population as a whole or whether, as in Russia and many other countries of the former Soviet Union, management and employee groups received many of the shares, perhaps to diffuse potential opposition to privatization. Second, policymakers needed to determine whether vouchers were intended to be exchanged directly for shares in companies, or whether the vouchers should be in funds that own a number of different companies. In the Czech and Slovak republics and in Russia, vouchers were exchanged directly for shares, although financial intermediaries soon developed in the market. In the Polish scheme, vouchers were exchanged for shares in government-created funds that jointly owned former state-owned enterprises.

Every country used a variety of privatization methods and everywhere different sorts of firms were sold in different ways. For example, in most transition economies small firms were usually sold to the highest bidder, and utilities were often floated on stock markets. However, it was possible by the time the bulk of privatization was completed in the late 1990s to discern the predominant method used in each country, and we report the most widely used summary in Table 1 from the EBRD's *Transition Repor*t, 1998. Mass privatization was the most common privatization method across the transition economies; 19 of the 25 countries listed used some form of mass privatization as either a primary or secondary method. Moreover, management–employee buyouts (MEBOs) also proved important, perhaps because transition governments sometimes did not have the authority to take on entrenched insiders in firms. Thus, nine countries used MEBOs as their primary method, and six as their secondary method. Most transition economies therefore eschewed the conventional method of privatization, by direct sale. In fact, only five countries used this as their primary privatization method, though these were among the most developed transitional economies.

The Scale of Privatization

There was an extremely speedy ownership change in most transition economies. Few countries had contained a private sector of any significance in

1990. Exceptions were Hungary and Poland, where there had been long-standing private firms in agriculture and crafts, and the private sector already represented over 30% of GDP (see Estrin 1994). But in the transition economies as a whole the private sector contribution to GDP was usually less than 20%. The growth in the private sector share during the 1990s, reported in Table 2, is extraordinary. As early as 1995, the private sector share was above 50% in nine countries, though in eight former republics of the Soviet Union it remained below 30%. By 2002, the private sector in 13 additional nations had reached at least 50% of GDP and in only two laggards, Belarus and Turkmenistan, was private sector activity still below 25% of GDP. Thus the privatization process in the transition economies was in many countries effective in transferring the bulk of economic activity from state to private hands in the space of hardly more than a decade.

This remarkable performance should not conceal real concerns raised at the time about the quality of privatization, and therefore about its consequences for enterprise restructuring. First, there are questions about how real the privatization has been. In many transition economies, the state continued to own golden shares or significant shareholdings in companies. For example, the Russian state retained more than a 20% share in 37% of privatized firms, and kept more than a

40% share in 14% of the firms that it privatized. Only in half of privatized firms did the Russian government sell its entire holding. Thus, the clean break between the state as owner and the enterprise sector has perhaps been more notional than real. In a survey of privatized firms undertaken by the EBRD in 1999, reported in Table 3, we show that in 20 of the 23 countries the state has retained some shares post-privatization. On average, the state retained some shares in around 20% of privatized firms, with more than a 20% shareholding in around 12% of the firms. It is suggestive that retained state shareholdings are negligible in some of the leading transition economies – for example, the Czech Republic, Hungary and Latvia – but the state has tended to keep a larger share in less advanced transition economies: more than 15% of privatized firms in Albania, Belarus, Georgia, Lithuania, Poland, Romania, Russia and Ukraine, and more than 30% of privatized firms in Bulgaria, Croatia, Slovenia and Uzbekistan. State ownership has also been retained in many developed OECD economies, including via the use of 'golden shares'. According to Bortolotti and Faccio (2006), governments were actually the largest stakeholder or held special control powers (golden shares) in 62.4% of privatized OECD companies.

But widespread retained state ownership is not the only indication that privatization may not have ensured the establishment of effective corporate governance mechanisms in transition economies. The long 'agency chains' implicit in mass privatization may not provide appropriate incentives for corporate governance. Voucher privatization led to ownership structures that were highly dispersed (Coffee 1996). Typically the entire adult population of the country, or all insiders to each firm, were allocated vouchers with which to purchase the shares of the company. The desire for equitable and politically acceptable outcomes dominated the need to create concentrated external owners who would have a large enough stake to be motivated to maintain oversight of management. However, it was possible that financial intermediaries could aggregate individual voucher holdings and carry out effective monitoring of management, and in Czech Republic, Poland, Slovenia and Slovakia some effort was made to ensure such concentrated intermediate agents did emerge. This was often associated with fraud and the outright theft of assets by managers to avoid their use by the new owners – so-called 'tunnelling' (Johnson et al. 2000).

The way that mass privatization was carried out in many countries also sometimes led to majority ownership that was not best suited to accelerate restructuring, for example by insiders. This was probably largely for political reasons, especially in countries where the pro-reform forces were politically weak. According to Earle et al. (1996), insiders held a majority shareholding in 75% of firms in Russia immediately post-privatization (1994) and outsiders only 9%. Insider ownership was predominantly in the hands of workers. However, this created little problem for management because worker ownership was so highly dispersed. Indeed Blasi et al. (1997) argue that control was effectively in the hands of management in Russian employee-owned firms. Outsider ownership is also typically highly dispersed, with much of it in the hands of banks, suppliers, other firms and an assortment of investment funds. In Russia, it appears from a variety of studies (see Estrin and Wright 1999, for a survey) that outside shareholding has increased at the expense of the state and insiders during the 1990s, but ownership is also becoming increasingly dispersed and the greater degree of outside ownership may largely represent the fact that former insider voucher owners have left the firm but retained their shares.

This pattern of extensive employee ownership seems broadly consistent with the evidence for other CIS countries. In Ukraine, insiders owned 51% of shares in all privatized firms in 1997 – managers 8% and workers 43% – while outsiders held 38% and the state residue share was 11%. In Ukraine, insiders have actually increased their shareholdings, while managers have been buying shares from workers. Thus, rather than evolving towards the structure of firms owned by a concentrated group of outsiders, as was hoped by reformers, enterprises in the CIS appear to have remained primarily owned by dispersed groups of employees or outsiders. However, the situation appears to have been somewhat different in central Europe, where many of the most important firms in the economies are now quoted on the relevant national stock exchanges or owned by large foreign firms – for example, Skoda and Volkswagen. As we have seen, foreign ownership was predominant in Hungary, ownership by new entrepreneurs was common in Poland, while investment-fund ownership predominated in the Czech Republic.

The Impact of Privatization

In this section, we analyse the impact of privatization on economic and company performance in the transition economies. This can be considered from the macro-economic and the microeconomic sides, and we provide some information on both. We start by considering the effects on government resources, and exploring the relationship between private sector shares, privatization methods and revenues and economic growth. We then summarize the findings of the very large literature about the effects of privatization on company performance.

In Table 4, we present the cumulative revenues from privatization in each of the transition economies, from 1995 to 2002. The sums were relatively modest in most countries in 1995; cumulative revenues were less than 2% of GDP in 15 countries of the 23 covered, and exceeded 20% in only one country, namely, Hungary. The situation had changed appreciably by 2002. Cumulative revenues from privatization exceeded 5% of GDP in 14 countries, exceeded 10% of GDP in eight and were greater than 30% in Hungary and Slovakia. Thus, even in countries which used mass privatization the selling of state assets proved to be a significant source of government revenue through the financially demanding period of early transition, and may therefore have

contributed to macro-stability and growth. However, there is no empirical evidence linking growth to the private sector share. Bennett et al. (2007) explore the impact of privatization on growth, but, while they identify a positive effect from the use of the mass privatization method, they do not find any significant relationship between growth and the private sector share. There is a limited amount of academic work for other economies, which explores the impact of privatization on growth rates. In an early study, Plane (1997) looks at the effects of divestiture on growth in a sample of 35 developing countries. He also controls for the problem of reverse causality by identifying separately the factors that determine a successful privatization programme. He finds that the impact of privatization on economic growth is indeed positive, and is strengthened when privatization occurs in infrastructure or in industrial sectors. Zinnes et al. (2001) use a fairly short sample period to undertake an aggregate growth study for the transition economies. They conclude that, while privatization does not actually increase growth, there is a positive impact when the privatization process is accompanied by institutional reforms.

To turn to the microeconomic evidence, there have been a large number of studies of how privatization affects the performance of firms in transition economies. The most complete of these is by Djankov and Murrell (2002), which surveys the findings of more than 100 empirical studies of transition economies and uses a meta-analysis of the results to draw conclusions. Despite the plethora of material, the overall findings remain ambiguous. This is partly because the studies employ a variety of data-sets, measurements and methods which produce contradictory results. For example, there are many ways of measuring company performance, including profitability, productivity, sales growth, export growth, and restructuring; and their findings differ. To begin with productivity, there is a wide variance in results across countries and samples, with private ownership found to yield positive, zero or negative effects. There is, however, convincing evidence that sale to foreign owners yields a positive effect, and that privatization is more likely to improve performance in central Europe than in the former Soviet Union. More recent literature strongly confirms the results with respect to foreign direct investment (for example, Sabirianova et al. 2005). However, it is harder to discern positive effects from privatization when profitability is the performance measure, though once again some studies find a positive impact when the firm is sold to a foreign owner, and very few studies isolate a positive significant effect of privatization on revenues. There are fewer studies of the impact of privatization on exports, and these tend to be positive, especially when foreigners take over the former state-owned firm, and restructuring activity seems to have been significant in privatized firms in central Europe, but not in Russia, Ukraine and other countries of the former Soviet Union.

The variation in results is not merely a consequence of the wide variety of measures and countries with which the effects of privatization have been tested. Some serious methodological problems bedevil work of this sort, most importantly that of selection. This is the situation when firms with particular characteristics – for example, superior performance – were systematically chosen for privatization. In such a case, while one observes what appears to be superior performance among firms that have been privatized, the correct interpretation is not that privatization enhances performance but that it was the better firms that were chosen for privatization. The converse applies if the state chooses to keep the best firms for itself and to sell only the less productive ones; in this case, privatization will appear to lead to worse performance. Unfortunately, very few studies of privatization in the transition economies have been able to do much to address this problem of reverse causality. The data-sets upon which the empirical work has been based have been small and usually derived from sample survey questionnaires that did not contain sufficient information to control for the selection problem.

Even so, Djankov and Murrell (2002) conclude on the basis of the weight of the evidence that the impact of privatization on company performance has probably been positive and significant, though not in every circumstance. Two factors are usually cited as being particularly influential in determining whether privatization acts to enhance company performance. The first is the nature and characteristics of the new private owners. We noted that foreign owners lead to an improvement on most measures of performance. There is also some evidence, though it is less convincing, that sale to domestic private owners also improves performance, though it can be important for the ownership shares to be concentrated. However, there is almost no evidence that company performance is improved when firms are sold to insiders, either managers or workers. This is probably because insiders have exploited their control to resist the changes in behaviour required to make firms competitive in the market environment, rather than to promote them. We observed above that insider ownership was a fairly common phenomenon, especially in the former Soviet Union, and this probably goes some way to explain why economic performance in many of those countries was weaker than in, for example, much of central Europe, such as Hungary, Poland and the Czech Republic, where foreign direct investment flows were much greater.

The second factor is the institutional and business environment in which privatization takes place. We noted above that privatization relies on improved corporate governance, but that in turn depends on a competitive market environment and the enforcement of property rights. In countries where the legal system is not functioning effectively, and businesses face high level of corruption and weak standards of financial discipline, it is hard to imagine how private ownership on its own might be expected to improve company performance. For example, sharper performance is meant to come from tighter financial disciplines to eradicate waste and reduce cost, but these will not bind in situations when budget constraints remain soft, as occurred post-privatization in many countries of the former Soviet Union, with firms financing their deficits not through direct government subsidies but by not paying their bills, especially to their workers, to the government in taxes, and to the state-owned utility companies.

These two limiting factors affect some privatizations in all transition economies, but on average have been more likely to pertain in the economies of the former Soviet Union than those of central and eastern Europe. Thus while the macroeconomic work suggests a clear positive impact from privatization on economic growth, the results from the microeconomic literature are more modulated. The positive effects from privatization are found not to be automatic. They depend on to whom the firm was sold – foreigners, outsiders or insiders – and on the broader business environment in which the firm operates. The latter in particular tends to be better in central Europe and especially in the new accession economies to the European Union. Privatization methods may also have played an important role (see Bennett et al. 2007).

Conclusion

The most impressive feature of privatization in the transition economies has been the speed and scale at which it occurred. The reforming governments of the late 1980s and early 1990s managed successfully to transfer the huge state-owned sector into largely private hands in a time period of hardly more than a decade, and to do so they had to use innovative privatization methods. However, this led them to introduce private ownership into situations where other crucial aspects of the business environment were not yet sufficiently developed to support the private economy. We find that privatization appears to have provided governments with much-needed revenues. However, at the enterprise level the results on performance are more patchy, though on balance the effects of privatization have probably been positive, especially when the new owners were foreigners. The most serious problem for privatization as a policy has been its use in a weak legal and institutional environment. In such cases, it rarely appears to have improved company performance.

Probability

Ian Hacking

Probability denotes a family of ideas that originally centred on the notion of credibility, or reasonable belief falling short of certainty. There have arisen two quite distinct uses of this group of ideas, namely in the modelling of physical or social processes, and in drawing inferences from, or making decisions on the basis of, inconclusive data.

Modelling

We imply the most elementary of probability models when we say that a roulette is fair, meaning that the probability of the ball settling in any one segment of the wheel is equal to that of its settling in any other. Talk of fair coins or biased dice is represented in a model that is typically used to predict the relative frequency with which the possible outcomes will occur. More formal models arise from a natural abstraction and generalization of this ancient idea. In proposing a probability model for some phenomenon, one is making a claim about how some aspect of the natural, social or human world is arranged and how it behaves. Such assertions are contingent propositions that should be susceptible of empirical test. In economic theory they are typically embedded in models employing other theoretical constructs, such as utility, but the present entry is restricted to probability itself.

Inference

Probability is also used for drawing inferences from inadequate information. When combined with an assessment of utilities, it is also used for deciding what to do in the face of uncertainty. Probability is here a tool for reasoning from data and for adjusting one's beliefs or actions in the light of new evidence. Such use in reasoning is more akin to logic than to the empirical science of which probability modelling is a part.

Evidently modelling and inference are tools that need not conflict. Often they are complementary, for methods of inference or decision are often required to choose among competing models. Conversely, a probability model may, in suitable circumstances, be invaluable for drawing probable inferences and making decisions. Despite the compatibility of inference and modelling; there has been a great deal of controversy about the foundations of probability and statistics, partly but only partly arising from confusing these two distinct uses to which probability ideas can be put. The present entry will describe these foundational and conceptual issues, leaving the applications of probability to special topics treated elsewhere in these volumes.

Frequency Conceptions of Probability

It has often been urged, in order to diminish controversy, that there are two distinct and compatible conceptions of probability that perhaps deserve to be called by different names.

One idea derives from our experience of the fairly stable relative frequency of some kinds of events in repeated trials. We appear to be familiar with such phenomena, not only in manmade gambling devices, but also in nature, ranging from radioactivity to the relative frequency of births of the two sexes. A precise definition is, however, elusive.

Some writers propose that we should represent this idea in terms of an infinite sequence of trials. If the relative frequency of event *A* in a countably infinite series tends in the limit to *p*, and certain other conditions are met, then the probability of *A* is *p*. The chief additional condition is that the relative frequency of *A* should also tend to *p* in all sub-sequences that can be picked out in advance. This requirement makes a) 'gambling system' impossible (von Mises 1928); for a precise analysis of such randomness in terms of complexity see work reported in Fine (1973, ch. V).

It is often objected that limiting frequencies are too much of an idealization. Coins are seldom tossed very often, and they wear out unevenly. A chief alternative to limits is that of propensity (Popper 1959). Here a probability is taken to apply to a physical or social system, and is the tendency or disposition of the system to deliver event *A* on a single trial This may manifest itself in a stable relative frequency if sufficiently many trials are made, but the propensity is thought of as a property of the system itself. A comparison would be with the malleability of a piece of copper, taken to be a fact about the structure of the mental. It is often objected that there has never been a lucid analysis of any kind of propensity, tendency or disposition, and that talk of propensities is obscurantism. The American philosopher C.S. Peirce (1839–1914) held each idea in succession, first favouring the limiting frequency view (Peirce 1878, II, 651) and later the dispositional account (Peirce 1910, II, 664). In fact it may not be necessary to take a position on these matters. Although talk of limiting frequencies and of tendencies plays an important heuristic role in forming intuitive ideas of probability, it is not of final importance. The substantial connection between probability and frequency is provided by the limiting theorems of §8 below.

Degrees of Belief

Here the paradigm is a statement such as, 'The probability that it will be warm and sunny tomorrow is 80 %'. Of itself this cannot express a relative frequency (even if meteorological frequencies are part of the evidence for the statement), because tomorrow comes but once. The statement expresses the credibility of the thought that it will be a nice day tomorrow. There are two ways to explicate it.

First, the oldest, is the idea of rational confidence: the extent to which it is rational to be confident of hypothesis *A* (a fine day) in the light of available evidence *B*. This approach has often been called subjective, because its early proponents spoke of probability being relative in part to our ignorance and in part to our knowledge (Laplace 1795). However, it is now generally agreed that the term is misleading, for one is concerned with an objective relation between the hypothesis *A* and the evidence *B*, a probability relation analogous to the deductive relations of logic (Keynes 1921). One is concerned with reasonable degrees of belief relative to evidence, and this theory is best called a *rationalist* one.

The label 'subjective theory' should be avoided; when used, it should be applied to another account that starts with the following observation by F.P. Ramsey: a 'fundamental criticism of Mr Keynes' views,. . . is the obvious one that there really do not seem to be any such things as the probability relations that he describes' (Ramsey 1926, p. 2). This scepticism led Ramsey, B. de Finetti (1937) and L.J. Savage (1954) to develop what Savage called a theory of personal probability. Here a statement of probability is the speaker's own assessment of the extent to which he or she is confident of a proposition. It is remarkable that a seemingly subjective idea like this is arguably constrained by exactly the same mathematical rules as govern the frequency conception of probability. It is to these rules that we must now turn.

Mathematical Probability

Probability theory is a branch of the mathematical discipline known as measure theory, with the further condition that all measures are normalized, i.e. lie in the interval [0, 1]. The formal theory is open to numerous interpretations, including those mentioned in the two preceding sections.

In what follows, $P(A)$ is read as the probability of A. In the frequency interpretation, A will be an event of some kind, while in a belief interpretation, A is a proposition or hypothesis. This proposition/event nomenclature is of little moment, for we can speak of the proposition that an event occurred, or of the event that a proposition is true. In the event reading, events are represented by sets and we are concerned with an algebra of sets closed under union ($\cup$) and complementation. Intersection is denoted ($\cap$). In a propositional algebra, these correspond to disjunction, negation and conjunction. Ω denotes the sure event or certain proposition, the union of all events (or disjunction of all propositions) in the algebra.

Informally the basic laws of probability for an algebra of finitely many events (such as the six possible outcomes of a die, closed under union and complementation) are as follows:

(1) Normalization. $P(\Omega) = 1$.
(2) Non-negativity. For all events A, $P(A) = 1$.
(3) Additivity. For disjoint A, B, $P(A \cup B) = P(A) + P(B)$.

Two fundamental concepts, conditional probability and independence, may then be defined. Conditional probability is denoted by $P(A/B)$. In a frequency interpretation this is the relative frequency with which A occurs among trials on which B occurs. In a personal belief interpretation, this may be understood as the rate at which a person would make a conditional bet on A – all bets being cancelled unless condition B is satisfied. Note that in the rational belief interpretation, all probability statements are implicitly statements of conditional probability, and an axiomatization will be couched in terms of conditional probabilities.

(4) Conditional probability.

$$P(A/B) = \frac{P(A \cap B)}{P(B)} \text{for } P(B) \neq 0.$$

Finally the notion of an independent event is vital in frequency applications. Intuitively A is independent of b if the occurrence of B makes no difference to whether A occurs or not, so we expect that $P(A/B) = P(A)$. In virtue of (4), this is equivalent to:

(5) Independence. A and B are pairwise independent if and only if

$$P(A \cap B) = P(A)P(B)$$

Mutual independence of a class of n events is defined analogously.

From the very earliest days of probability calculations, speculators and gamblers were preoccupied by the fair price for a stake in a game or other transaction, such as the purchase of an annuity. Expectation, or expected value, is the formalization of this idea. Let there be a quantity X with possible values $x_1, x_2, \ldots, x_n$, and let $P(x_i)$ be the probability that X has the value x_i. In the historical origins, the x_i would be payoffs from a game and the $P(x_i)$ would be the chances of getting payoff x_i. The expectation is then defined:

(6) Expectation. $\Sigma(X) = \Sigma x_i P(x_i)$. The expectation is also called the mean value of X. The usual measure of the 'average deviation' from the mean μ is the standard deviation σ whose square σ^2 is called the variance.
(7) Variance. $\sigma^2 = E(X - \mu)^2 = \Sigma(x_i - \mu)^2 P(x_i)$.

The concepts present in (1)–(6) are clearly set forth in Huygens (1657), which takes expectation rather than probability as the primitive idea. The classic formulation of these ideas as part of measure theory is due to Kolmogorov (1933). Here a probability space is a triple $(\Omega, \mathscr{F}, P)$.

Ω: a space of mutually exclusive and jointly exhaustive events.

$\mathscr{F}$: a countable algebra of suitable subsets of Ω, that is, an algebra closed under countably infinite union and complementation.

Corresponding to (1)–(3) above we have Normalization, Non-negativity and:

(3^*) Countable additivity. For any countable sequence A_1, A_2, . . . of pairwise disjoint elements of $\mathscr{F}$,

$$P(UA_i) = \Sigma P(A_i)$$

Conditional probability, independence, expectation and variance are explained by measure theoretic generalizations of (4)–(7).

Personal Degrees of Belief and the Axioms

It is evident that both finite and limiting relative frequencies will satisfy the probability axioms. It is obscure why propensities should do so. This question is seldom addressed by those who favour that approach, but see Suppes (1973). This may be because of deeper connections between the frequency idea and the mathematical formalism; see §8 below. Here we indicate the ground for the more surprising result that, arguably, personal degrees of belief should satisfy the probability axioms.

There are two parts of the argument. (*i*) Construe degrees of belief as betting rates. (*ii*) Establish reasonable constraints on a person's set of betting rates. The best introductory exposition of these ideas is the first place they were proposed (Ramsey 1926).

Ramsey thought of a probability space as a representation of psychological states of belief. $P(A)$ stands for a person's degree of confidence in A. It is to be evaluated behaviourally by determining the least favourable rate at which this individual would take a bet on A. If the least favourable odds are, for example, 3:1, then that person's probability is $P(A) = 3/4$. Conditional probability may be explained in terms of conditional bets. Thus suppose one bets on horse A winning a race, on condition B that the horse completes the course, all bets being off if the condition B fails and the horse drops out. If a person bets 2:1 on A winning, conditional on B, then that person's conditional probability is 2/3. Ramsey was well aware that one should not expect that real betting rates should be measured to 'too many places of decimals'.

Betting is all very well, but is hardly a general psychological test, for many people go out of their way to seek or to avoid gambling, and this irrelevant factor will distort or render impossible measures of belief by betting behaviour. To get around this, imagine that a man is offered the choice of one of the two following options, at no cost to himself:

(a) He gets $1 if A occurs.

(b) He gets $1 if B occurs. If he is indifferent between the two, they are equally probable for him, while if he prefers (a) to (b), then for his personal probabilities $P(A) > P(B)$. Now if this man can generate large sets of equally probable events we can measure his probabilities to any realistic degree of precision. Suppose for example that he acts as if he thought a coin is fair, and regards any sequence of 10 outcomes of heads and tails as as probable as any other. Then he has 10! equally probable disjoint events. He can be asked about options such as:

    (a) $1 if A occurs.

    (b) $1 if heads occurs on the next two consecutive tosses. Preference for (a) indicates that his $P(A) > 3/4$; for (b), $P(A) < 3/4$, while indifference indicates that his $P(A) = 3/4$. Repeated uses of this 'risk free' technique can refine the measurement of his probabilities without any recourse to outright gambling. Suppose, then, that it makes sense to attach betting rates to a person's beliefs. Why should they satisfy the probability axioms? Why call betting rates) 'probabilities' at all? The deepest justification jointly develops probability and utility, and hence is

> outside the scope of this entry. That was the method of Ramsey (1926), which uses a perspicuous zig-zag exposition. That is, first a constraint is placed upon degrees of belief. This is used to place a constraint on utilities. This in turn is fed back into degrees of belief in the form of a further constraint. The upshot of Ramsey's paper is a full axiomatization of probability and utility. A more sophisticated version of such an approach is given in Savage (1954).

There is, however, a less compelling but easy to follow argument suggested in a throwaway phrase in Ramsey (1926), and independently developed in detail in de Finetti (1937).

De Finetti urged that a set of betting rates should be *coherent* in the following sense. It would be unreasonable or) 'incoherent' to offer betting rates on a schedule of propositions such that a clever gambler could make a profit by betting with you no matter what transpires. For a trivial example, let A = Australia retains the *America*'s cup in the next competition. Suppose a person is willing to bet on A at odds 7:3, and on the opposite, $\bar{A}$ at odds of 3:2, then the personal probabilities are $P(A) = 0.7$ and $P(\bar{A}) + 0.6$ That violates the additivity law that requires $P(A) = P(\bar{A}) = 1$.

Suppose that a gambler bets against this person on A with a stake of \$75, and against him on $\bar{A}$ with a stake of \$100. The gambler stakes \$175 and gets back \$250, regardless of who wins the next *America*'s cup. The pair of betting rates 7:3 and 3:2 are *incoherent*. A coherent set of betting rates is such that it is impossible to place a bet against them in such a way as to make a guaranteed profit in the above sense.

De Finetti proved that the necessary and sufficient conditions that a set of betting rates be coherent, is that they satisfy the probability axioms and conditional probability rule, (1)–(4) of §5 above. He does not extend this result to a fully countably additive algebra of events, because he is rigorous in his construal of personal probability. A person cannot realistically be supposed to have a structure of beliefs over such an algebra of events. However, de Finetti does extend his theory so as to allow for example for integration, in ways reminiscent of intuitionist and constructive approaches to the foundations of mathematical analysis.

De Finetti also gave a personal equivalent of independence, defined as (5) in §5 above. This was particularly important for him, because he held that in nature there are no independent trials or stable frequencies; there are only our beliefs about what will happen on individual trials. Since 'independence' is of great heuristic and mathematical power, de Finetti wished a personal surrogate for it. Corresponding to statistical independence he proposed what he called *exchangeability*. The core idea is that events that may occur in a sequence are exchangeable (in a person's belief structure) if the person is indifferent between all sequences in which the proportions of events of given kinds which occur are the same, regardless of the order in which they occur. Thus a person is indifferent between any *ABBBB, BABBB, BBABB, BBBAB* and *BBBBA;* indifferent between any of the 10 sequences containing 2 A and 3B, and so forth. Natural generalizations of this idea lead to a powerful theory of exchangeability (Diaconis and Freedman 1980).

Bayesianism

The probability axioms have an immediate consequence much used in the theory of personal probability. Let $A_1, \ldots, A_n$ be a set of mutually exclusive and jointly exhaustive events. By (4) of §5, for each $i \leq n$,

$$P(B)\,P(A_i/B) = P(A_i)P(B/A_i).$$

Since

$$B = \cup\left(A_j \cap B\right)$$
$$P(B) = \sum P\left(A_j \cap B\right) = \sum P\left(A_j\right)P(B/A_i).$$

The first and third lines imply that

$$P(A_i/B) = \frac{P(A_i)P(B/A_i)}{\sum P(A_j)P(B/A_j)}. \qquad (8)$$

(8) is often called Bayes' theorem, due to its tenuous connection with Bayes (1763). As it is a trivial deduction it is better called Bayes' rule. It is of course valid in any interpretation, but it is of serious interest only from a belief point of view. For suppose that the partition $A_1, \ldots, A_n$ is an exhaustive set of mutually exclusive hypotheses of interest, and that B is evidence bearing on the hypotheses. Suppose further that a person has, in the light of prior knowledge, a distribution of belief over the A_i, represented by $P(A_i)$ for each i. Call this the *prior* probability distribution. Let the A's be of such a sort that for each A_i, $P(B/A_i)$ is defined. This is called the *likelihood* of getting B, if A_i is true. For example, let A_1 state that the outcomes of a die are equiprobable, and A_2, that there is bias with $P(6) = 0.3$. Then the likelihood of 6 on A_1 is 1/6, and A_2 is 0.3.

Now we may ask, in order to be coherent, how should a person incorporate a new piece of evidence B into a prior probability distribution over the hypotheses A_i? A plausible answer following Bayes' rule is that the 'posterior distribution' (in the light of B) should be the same as the (prior) conditional probability distribution $P(A_i/B)$. Schematically,

Posterior probability ∝ prior probability × likelihood

The constant of proportionality is as in (8) above.

It is argued that this provides a model of reasonable learning for experience. A person at some stage has a purely personal prior probability distribution over some range of possibilities. This is subject only to the constraint of coherence. However, it is urged, coherence entails a uniquely reasonable way to adjust one's probabilities in the light of new information. On learning new B, one should move from prior probabilities $P(A_i)$ to posterior probabilities equivalent to $P(A_i/B)$. If we spoke of personal probabilities at a time, indicated by a superscript t, and if between t and t' we learn just: B, then

$$P^{t'}(A_j) \text{ should be } P^t(A_i/B). \qquad (9)$$

This is an additional postulate that does not follow from the probability axioms, and which is peculiar to the personal interpretation of probability. Nothing in the coherence argument entails that probabilities should be adjusted across time in accord with (9). Attempts to justify statements such as (9) have been interesting but inconclusive (Diaconis and Zabell 1982). Assertion (9) should be regarded as a pragmatic postulate for the use of personal probabilities. No one has proposed a significantly different and seriously better general rule for personal learning from experience.

Every interpretation of probability appears to require a pragmatic postulate, although what is required is different in each case. Consider the theory of rational belief, in which the conditional probability $P(A/B)$ is interpreted as a logical relation between B and A. This is supposed to be a unique constant determined by something analogous to deductive logic. Here there is no need for a time-spanning postulate such as (9), for in a theory of rational belief, all probabilities are conditional and are held to be uniquely defined. How can such purely logical relations serve as 'the very guide of life' (Butler 1736, Introduction) that one expects from an applied theory of probability? How can a collection of logical relations help with predictions and decisions? One cannot reply that if the total available evidence bearing on A is B, then the rational probability of A is $P(A/B)$, because on the theory of rational probability, 'the probability of A' makes no sense, all probabilities being relative.

One requires a pragmatic postulate similar to what has been called *the requirement of total evidence* (Carnap 1950, p. 211). Let $A_1, \ldots, A_n$ be a partition of states of affairs, and B a further proposition. Let $P(A_i/B)$ be a rational probability function defined for fixed B. Let U_i be the value or utility if A_i obtains. Then the rational expectation on B is, following (6) of §5,

$$\sum U_i P(A_i/B).$$

A pragmatic posultate would state: if B is the total available evidence relevant to members of the partition Ai, then act so as to maximize the rational expectation on B. Since it is doubtful whether there exist rational probability functions, and since the notion of total available evidence is utterly obscure, such a postulate is of purely academic interest, intended to illustrate a feature of some traditional reflections on probability.

The term Bayesian is at present commonly used for a personal theory of probability that makes heavy use of Bayes' rule and (implicitly) a pragmatic postulate. But is should also include rationalist approaches such as those of Jeffreys (1939) which also make extensive use of Bayes' rule.

Limit Theorems

Bayes' rule is a theorem valid under any interpretation of probability but whose interest is largely confined to degree of belief approaches. We now turn to a fundamental body of work whose immediate application is more evident for frequency approaches. Arguably this work, which results in a series of limit theorems, establishes the essential connection between probability and finite relative frequencies. It begins with a result proved by Jacob Bernoulli around 1695 (Bernoulli 1713).

Bernoulli intended his investigations to contribute to an understanding of statistical inference, but they are also important for the very conception of probability.

Regardless of the glosses of §3 above, in terms of limiting frequency or propensity, the intuition underlying an abstract frequency conception of probability is this: if A occurs k times in n independent and 'identical' trials, then, if n is large, k/n should be close to the probability p to A. This is the content of Bernoulli's theorem. In its weak form it states that for any small 'error' ϵ,

$$P\left(\left|\frac{k}{n}-p\right|<\varepsilon\right)\rightarrow 1 \text{ as } n\rightarrow\infty. \qquad (10)$$

A stronger form asserts that for any error ϵ and small probability δ there is a number N such that for $n > N$,

$$P\left(\left|\frac{k}{n}-p\right|<\varepsilon\right)\rightarrow 1-\delta. \qquad (11)$$

This applies only to 'identical' trials on which the probability is $P(A) = p$ for each trial. S.-D. Poisson coined the term 'law of large numbers' for a generalization (Poisson 1837). Suppose that the probability of A on successive trials is not constant, but only that there is a suitable regular probability distribution for values of $P(A)$. In Poisson's examples, one would have a sequence of urns, each with a different proportion of black as opposed to white balls. $P(A)$ would be the probability of drawing a black ball from a given urn, and there would be a probability distribution over the proportions of balls in successive urns. Poisson established that a result analogous to (11) holds, in which p is replaced by the mean probability of $P(A)$. The term 'law of large numbers' is now widely used to apply to all results of this type, including Bernoulli's original (10).

A continuation of this result began with work by A. de Moivre in 1732 and fully developed by P.S. Laplace and C.F. Gauss around 1800 (Stigler 1986). It is the beginning of the well known Gaussian or Normal probability distribution with its familiar 'bell shaped curve' once known simply as *the* curve of probability.

Bernoulli had been able to place crude upper bounds on the probability that on n trials the proportion of A occurring should be within ϵ of p. De Moivre addressed the more general question of the form of the histogram of k/n (for $k = 0, \ldots, k = n$) as n grows without bound. Let $\Phi(x)$ be a cumulative probability distribution for a real-valued variable x: thus $\Phi(x)$ is the probability of the variable taking a value less than or equal to x. The Normal distribution with mean zero and variance 1 is

$$\Phi(x)=\frac{1}{\sqrt{(2\pi)}}=\int_{-\infty}^{x}\exp\left(-\frac{1}{2}y^2\right)\mathrm{d}y.$$

In repeated independent trials with fixed probability $P(A) = p$, the following holds. For any fixed $a < b$, as $n \to \infty$,

$$P\left\{a \leq \left|\frac{k}{n} - p\right| \left[\frac{n}{p(1-p)}\right]^{1/2} \leq b\right\} \\ \to \Phi(b) - \Phi(a). \qquad (12)$$

This establishes with greater precision the connection between probability and stable long-run frequency. It also shows how the probability distribution associated with the simplest chance device, namely coin tossing, relates to the Normal distribution which, for mean μ and variance σ^2 is:

$$\frac{1}{\sqrt{(2\pi)}\sigma}\int_{-\infty}^{x} \exp\left[-(y-\mu)^2/2\sigma_2\right] \mathrm{d}y.$$

Proofs of (12) and increasingly general theorems of that type were developed by the Petersburg school of mathematicians in the latter part of the nineteenth century: P.L. Chebyshev, A.A. Markov and A.M. Lyapunov (see Maistrov 1967). Lyapunov gave one form of the *central limit theorem*. Consider a sequence of mutually independent variables $x_1, \ldots, x_r$ with a common distribution. Suppose that the mean and variance of x_i exist, and are μ and σ^2. Let $k = x_1 + \ldots + x_n$. Then for every fixed ϵ as $n \to \infty$,

$$P\left\{\left|\frac{k}{n} - \mu\right| \left(\frac{n}{\sigma}\right)^{1/2} < \varepsilon\right\} \to \Phi(\varepsilon). \qquad (13)$$

From a conceptual point of view, central limit theorems should be regarded as a culmination of a series of results that explicate the fundamental frequency conception of probability. They also illustrate the power of the probability axioms.

Application of Such Probabilities

Although the limit theorems lay bare the intuitive connection between probability and frequency, there remains a question of application to a single and unique event, such as the next outcome of a roll of a die. If we think of probability in terms of relative frequencies, how can it bear on a particular toss? We may believe that the probability of 6 with a die is 1/6, and believe, thanks to the limit theorems, that in a long run the relative frequency of sixes will usually be close to 1/6. But if we are to judge only the next outcome, for example for purposes of making a bet, why should the fraction 1/6 be of special interest? Once again it appears that, just as for a personal probability interpretation, we require a pragmatic postulate, this time in order to decide what to do *next*, in other words, once again in order to make probability 'a very guide of life'. This has in effect been proposed by many writers, for example by Reichenbach (1949, §72), who speaks of single case 'posits' in connection with individual cases.

There is, however, an additional problem, often called the problem of the reference class. A particular future event may be a member of several classes, each of which is associated with a stable relative frequency. A man may be both a heavy smoker and a jogger. Probabilities of living to the age of 60 may be known for smokers of his age, and for joggers of his age, but neither in itself tells us what to expect of this individual. It is commonly proposed that an individual case should be referred to the smallest discernible class for which a frequency is known. Then a pragmatic postulate would instruct one to act so as to maximize expectations relative to smallest discernible reference classes.

This postulate is curiously similar, in certain respects, to the pragmatic postulate needed for Bayesian learning from experience. Even if expectation may seem a good guide in life in situations where one is to make a series of successive decisions or take a series of successive gambles, there is no compelling reason for employing expectations in a particular case. All the same (just as with (9), the temporal use of Bayes' rule) no alternative yet proposed has, in general, any desirable features at all.

Non-Quantitative Probability

The classical approach to probability from Huygens (1657) to the present has measured probabilities by rational fractions or real numbers.

A minority of workers has rejected this as unrealistic. Thus Keynes supposed that comparisons of probability are often feasible when quantitative measures are not (Keynes 1921). He had the rationality approach, in which all probabilities are conditional, and he held that the fundamental form of probability statements is:

$$P(A/B) \leq P(C/D).$$

This gives rise to a lattice of partially ordered probabilities that has proved attractive from various points of view. Some personalists hold that we can usually only compare our personal degrees of confidence, not measure them. A few frequentists have held that stabilities in nature are seldom secure enough to guarantee quantitative long-run frequencies, but that we have many comparisons furnished by nature. For a survey of these approaches, see Fine (1973, ch. II).

Inference and Modelling

We now return to the chief uses of probability stated in §§1, 2, namely inference and modelling. It might seem as if inference would naturally employ a belief-oriented conception of probability, and that modelling would be via frequency or propensity. This would imply a quite eclectic approach to interpretations of probability, as is common among day-to-day consumers of probability mathematics. However, a majority of workers on foundations have been dogmatic, arguing that we should use one and only one interpretation of probability for all purposes of interest.

Thus a majority of authors who present theories of statistical inference favour a frequency interpretation. They hold that the only legitimate tool for objective public discussion must be a frequency oriented idea. An account of personal probability is too subjective for scientific inference or public decision making.

Conversely, many adherents to a degree of belief approach hold that there just do not exist any objective propensities or frequencies in macroscopic nature. (Some but not all admit a place for them in microphysics.) Such writers try to re-express everything valuable in a frequency approach in terms of personal belief. De Finetti's exchangeability of §4 above was intended to provide a subjective surrogate for the notion of objective independence (which de Finetti thinks does not exist in nature).

Such dogmatic personalism precludes any use of modelling of natural processes by frequency-like structures, and reduces all reasoning about nature, where we have incomplete information, to operations with coherent personal probabilities. Inference, on the other hand, is no problem for the personalist, who augments the probability axioms with a (usually implicit) pragmatic postulate (9) as in §5 above. All inference is by Bayes' rule or by a more sophisticated version of that.

Conversely, the dogmatic frequentist has no problem with modelling natural processes by probability structures interpreted in terms of stable frequencies or propensities. But whereas in a sense the personalist has no theory of statistical inference (all inference being by Bayes' rule), the frequentist has not one but several competing theories of considerable conceptual difficulty. These will now be briefly described.

Inferring by Frequency

There has evolved an enormous battery of techniques for testing statistical hypotheses, estimating statistical parameters, designing experiments and making decisions. There is less agreement on the foundations for these techniques. From 1920 until his death in 1962, R.A. Fisher was a prolific source of such fundamental ideas as significance tests, maximum likelihood estimators, randomized experimental design, sufficient statistics, information, and a host of others. In part because he favoured many different and non-equivalent uses of probability, it is not possible to give a brief simple account of what he took to be the basics. The opposite is the case for a later and influential pair of workers, Jerzy Neyman and E.S. Pearson, whose theory will be sketched first.

Neyman was a dogmatic frequentist who held that it is never possible to make a probability statement about a particular event or hypothesis.

Inductive *inference* is, he said, impossible, and is to be replaced by a theory of inductive *behaviour*. We can at best choose a policy that has desirable ‘operating characteristics’. In the case of testing one statistical hypothesis H against a family of others, we require a method that seldom rejects H if it is true, (say 1 per cent of the time), and, given that constraint, usually rejects H if it is false. In most practical situations this goal cannot be uniformly achieved, but Neyman and Pearson introduce other operating constraints so as to design unique tests. Likewise in estimating that an unknown parameter lies in a certain interval on the real line, one requires that on repeated experiments the method of estimation would yield an interval that includes the true parameter most of the time. A 99 per cent confidence interval is derived by a method that is correct 99 per cent of the time (and is subject to other constraints to ensure uniqueness). In a particular case one *cannot* assert that there is 0.99 probability that the unknown parameter is within the bounds of the estimate. One can say only that the interval was derived by a method that is usually right.

Fisher regarded statistical inference as primarily a procedure for data analysis, for maximizing information obtained from experiment, and for producing intelligible informationpreserving summations of data that would otherwise be too complex to understand. He thought of the various significance levels (analogous to confidence levels) as convenient standards by means of which experimental workers could judge each others’ results. Thus in considering a treatment (of a field with fertilizer, of patients with medicine, of an economy with a rise in interest rates) one wants to know if the treatment is efficacious. Thus one tests the ‘null hypothesis’ by making a probability model of the hypothesis of no effect. The result of an experiment is significant at the 1 per cent level if, on the model of the null hypothesis, an effect at least as large as that observed would occur with probability less than or equal to 0.01. Otherwise the result is judged not to be significant at the 1 per cent level. In the event that the treatment is judged significant, one is not obliged to reject the null hypothesis. The result of a significance test is always of the following logical form: either something very unusual has occurred by chance, as will from time to time happen, or else the null hypothesis is false and the treatment is efficacious (Fisher 1956, ch. III).

Such a piecemeal approach, in which a statistical report summarizes a situation and leaves other experimenters to make up their own minds, is in apparent contrast with the regimented policies derived by the Neyman–Pearson theory. For Fisher’s chief papers, see Fisher (1950); for the joint work of Neyman and Pearson, see Neyman and Pearson (1967).

Most ordinary practitioners do not draw firm lines between the two approaches. There remain significant practical differences. For example, in certain Fisherian analyses based on likelihood (see definition in §5 above) it makes no difference whether the length of an experiment has been determined in advance, or whether the experimenter decides in the course of the experiment when to quit. On the Neyman theory, such optional stopping completely changes the analysis of the data. Likewise there are striking contrasts between frequency theories on the one hand – be they those of Fisher or Neyman – and Bayesian belief theories on the other. The former not only regularly incorporate randomization into the design of experiments, but hold it to be an essential procedure for increasing the amount of information derived from an experiment. On a Bayesian account, however, randomization is of no value and may actually lead to a loss of information. It remains the case that almost all experimenters favour randomization, and in the case of human subjects, urge double blind experimentation when practicable.

Probability and Economics

Expectation, defined in terms of utility and probability, is an economic concept. The first book on the probability calculus, one which set the pace in the early days, defined probability in terms of expectation (Huygens, 1657), and this practice continued until at least the time of Bayes (1763). Hence one would anticipate a longstanding relationship between probability and economics. This has not been the case. French pre-revolutionary physiocrats thought that probability should play a central role in ‘moral science’, which would include what we now call economics. However, this had little direct influence, even if through the mediation of the Marquis de Condorcet it aroused the early interests of that greatest of probability mathematicians, Laplace.

Only during the 19th century did probability become a working tool of a sizable number of sciences, disciplines and practices. The complete assimilation of probability to almost every topic has occurred only very recently. (For cross-disciplinary studies, suggesting the differential adoption of probability tools and techniques, see Daston et al. 1987.) Despite the fact that maximization of utility has long been an economic adage or even tautology, economics has been one of the slower disciplines to be penetrated by probabilistic thinking.

Economists have usually been eclectic in their use of probability. F.Y. Edgeworth, author of the article *Probability* in the original *Palgrave*, noted in his longer essay for the *Encyclopaedia Britannica* that a belief approach to probability might be rejected on the ground that it was ‘merely psychological’. He goes on to mention a limiting frequency approach. But, he continues, ‘these views are not so diametrically opposed as might at first appear’ (Edgeworth 1911, p. 377). Many economists would echo his words today.

Some, however, have strongly favoured only one approach to probability. The most notable example is Keynes. Although he became less dogmatic about probability later in life, at the time of his major contribution to the field (Keynes 1921) he provided the classic statement of the rationalist approach to probability, and also was far ahead of his time in urging that comparative probabilities are fundamental. F.P. Ramsey, who in his very short life had commenced important contributions to economic theory, is of course the founder of the modern personalist approach, and he was the first to see how probability and utility can be jointly axiomatized as concepts that are integrally and necessarily connected.

The theory of games and economic behaviour, set forth in its modern form by von Neumann in a work with that title, settles on the ‘perfectly well founded interpretation of probability as frequency in long runs’ (Von Neumann and Morgenstern 1944, p. 19). In a footnote it is said that one may instead axiomatize probability and preference jointly. This was done explicitly by L.J. Savage (1954), who had been one of von Neumann’s wartime assistants, and who has provided us with the standard exposition of personal probability, one which has, as one of its consequences, von Neumann’s theory of utility. The present entry has emphasized controversies about the interpretation and application of probability ideas; it must conclude by stating that despite differences in foundation, a great many divergences are washed away in the routine of day-to-day application and derivation.

Procurement

Yeon-Koo Che

Abstract

Firms and government agencies rely increasingly on goods and services procured from outside suppliers. How to assure desired quality at a minimal cost in the procurement is often challenging and warrants carefully devised contracting policies. This article reviews several problems arising in procurement and policies designed to remedy them.

Keywords

Adverse selection; Auction contests; Auctions; Collusion; Corruption; Cost-plus contracts; Fixed-price contracts; Mechanism design; Option contracts; Outsourcing; Procurement; Quality assurance; Reputation; Risk aversion; Risk sharing; Scoring auctions; Virtual cost

D6

Virtually all businesses, both public and private, rely on procurement of numerous goods and services, ranging from such routine jobs as food and custodial services to the complex job of building high-tech fighter jets and high-speed train systems. Rapid progress of communication technologies – most notably the emergence of the Internet – has made outsourcing both cheaper and more efficient, thus altering the traditional boundaries of 'make-or-buy' decisions by many firms and government agencies in favour of more outsourcing. Thus, designing efficient mechanisms for procuring goods and services has become ever more important.

Procurement of standardized parts and services is relatively straightforward as a competitive market or standard bidding would produce an efficient outcome. In many procurement settings, however, the quality of the procured job is an important concern, and it is not easy to assure the desired level of quality, since a high-quality job may entail a cost that is unknown or privately known by the supplier or require his special effort that is not observable to the buyer, or the quality of the job provided is not easy to verify or is simply unobservable to the buyer. The present article reviews some of the answers economics research has provided for optimal responses to these procurement problems.

Contractible Quality

When quality is verifiable, the terms of the contract can be made contingent on the quality of the system. If the cost associated with delivering the job is unobservable, it presents two problems. First, ensuring the supplier's participation may require paying more than the true cost, that is, information rents to elicit the cost, so the quality level must be decided based on the overall cost paid to the supplier. Second, the buyer must identify the supplier who can deliver the good at the minimal cost to her. We sketch the method for finding the optimal mechanism that deals with these issues.

To begin, suppose a buyer derives utility of $v(q) - t$ when she procures a job of quality $q \in \mathbb{R}_+$ and pays $t \in \mathbb{R}_+$, where the gross surplus function, $v : \mathbb{R}_+ \mapsto \mathbb{R}_+$, is strictly increasing, differentiable and strictly concave. Suppose there are $n \geq 1$ potential suppliers. Suppl ier $i \in N := \{1,\ldots,n\}$ can deliver quality at unit cost of θ_i, which is drawn from $\left[\underline{\theta}, \overline{\theta}\right] =: \Theta$ according to the cumulative distribution function $F_i(\cdot)$ which has a positive density over $\left(\underline{\theta}, \overline{\theta}\right)$. Assume also that $\theta + \frac{F_i(\theta)}{f_i(\theta)}$ is non-decreasing in θ. A supplier i receives t - $\theta_i q$ from a contract that pays him t for delivering q.

If the suppliers' costs are observable, then the procurer's decision will be straightforward. She can pick the most efficient one, $i = \arg\min_{i \in N} \{\theta_i\}$, and have him deliver the job at cost, so she will pick the first-best quality, $q_i^{**}(\theta_i) \in \arg\max_{q \in \mathbb{R}_+} v(q) - \theta_i q$.

When the suppliers' costs are unobservable, it is not possible to procure at the actual cost, since suppliers can pretend to have higher than actual cost. Nor is it easy or necessarily desirable to pick the least-cost supplier, as will be seen. To illustrate the optimal procurement decision, suppose first there is only one potential supplier, $n = 1$. By the revelation principle, there is no loss in restricting attention to a direct revelation contract that determines the quality and the payment, $\{(q_i(\theta), t_i(\theta))\}_{\theta \in \Theta}$, as a function of the cost reported by the supplier.

The optimal contract $\left(q_i^*(\cdot), t_i^*(\cdot)\right)$ must solve

$$\max_{(q_i(\cdot),\, t_i(\cdot))} \int_{\underline{\theta}}^{\overline{\theta}} [v(q_i(\theta)) - t_i(\theta)] dF_i(\theta) \qquad ()$$

subject to

$$U_i(\theta) := t_i(\theta) - q_i(\theta) \geq 0, \forall \theta \in \Theta \qquad \text{(IR)}$$

$$U_i(\theta) \geq t_i\left(\widetilde{\theta}\right) - \theta q_i\left(\widetilde{\theta}\right), \forall \theta, \widetilde{\theta} \in \Theta, \qquad \text{(IC)}$$

where (IR) and (IC) ensure, respectively, the supplier's participation and his incentive to report truthfully his type.

By the well-known method, (IR) and (IC) constraints can be simplified to a pair of conditions:

$$q(\cdot)\,\text{is}\,\text{non}-\text{increasing}. \qquad \text{(M)}$$

and

$$U_i(\theta) = \int_{\theta}^{\overline{\theta}} q\left(\widetilde{\theta}\right) d\widetilde{\theta}, \qquad \text{(Env)}$$

or equivalently

$$t_i(\theta) = \theta q_i(\theta) + \int_{\theta}^{\overline{\theta}} q\left(\widetilde{\theta}\right) d\widetilde{\theta}. \qquad \text{(Env}'\text{)}$$

The constraint (M) will be seen not to bind, so it can be ignored. Substituting (Env′) into the objective function of [P] and switching the order of expectations yield

$$\int_{\underline{\theta}}^{\overline{\theta}} [v(q_i(\theta)) - J_i(\theta) q_i(\theta)] dF_i(\theta),$$

where $J_i(\theta) := \theta + \frac{F_i(\theta)}{f_i(\theta)}$ is the so-called 'virtual' cost. The additional cost $\frac{F_i(\theta)}{f_i(\theta)}$ reflects the additional rents that must be given away to the types more efficient than θ when its quality is raised marginally. To see this more intuitively, suppose the quality for type θ is raised by Δq towards the efficient level. Then, there is an efficiency gain (to be captured by the procurer) of $[v'(q) - \theta]\Delta q f(\theta)$. At the same time, the raising of quality enables each type $\theta' < \theta$ to command extra rents of Δq by mimicking (or choosing the contract intended for) type θ, so the same amount must be given to them to dissuade them from doing so. Since the measure of those types is $F(\theta)$, the marginal cost of quality increase is $F(\theta)\Delta q$. The optimal quality $q_i^*(\theta)$ balances these two marginal effects, so $v'(q) - \theta \frac{F_i(\theta)}{f_i(\theta)}$ if $q_i^*(\theta) > 0$, or more generally

$$q_i^*(\theta) \in \arg \max_{q \in \mathbb{R}_+} [v(q) - J_i(\theta)q].$$

Clearly, $q_i^*(\theta) < q_i^{**}(\theta)$, for $\theta > \underline{\theta}$, whenever $q_i^{**}(\theta) > 0$. In other words, it is optimal for the buyer to choose less than the first-best quality. In particular, the buyer may not procure at all even though procuring is socially efficient, for instance when $\theta < v'(0) < J_i(\theta)$. In practice, the optimal procurement policy can be implemented by a *menu* of quality-transfer pairs, $\left(q_i^*(\theta), t_i(\theta)\right)$, or by a *nonlinear pricing scheme* $\tau(q) := t_i\left(q_i^* - 1(q)\right)$.

Now suppose $n \geq 2$ so there are multiple candidate suppliers. The selection of the supplier, which can be studied using the same mechanism design approach (see Myerson 1981; Laffont and Tirole 1987; McAfee and McMillan 1987; Riordan and Sappington 1987), extends the above insight naturally. What ultimately matter to the buyer are suppliers' virtual costs, not their actual costs. Hence, the supplier with the lowest virtual cost, $i \in \arg\min_{j \in N}\{J_j(\theta_j)\}$, must be selected, and the selected supplier must choose the 'downward distorted' quality level, $q_i^*(\theta)$. If supplier i has *ex ante* higher cost than j, say in terms of conditional stochastic dominance: $\frac{F_i}{f_i} < \frac{F_j}{f_j}$, then the optimal selection rule favours i. Favouring the 'underdog' can be seen as a way of *handicapping* the top dog to make him compete more aggressively.

When the suppliers are *ex ante* symmetric, that is, $F_i = F_j$ for $i \neq j$, then the optimal selection is also efficient, and the optimal procurement policy can be implemented by the so-called *scoring auction* (see Che 1993). Specifically, there is a quasi-linear scoring function,

$$S(q, t) := v(q) - \varDelta(q) - t,$$

for some $\varDelta(\cdot)$ increasing, that implements the optimal outcome if the suppliers are asked to make two-dimensional bids, (q, t), and the supplier who achieves the highest score according to $S(q, t)$ is selected to produce his proposed quality and receive his payment. The term $\Delta(q)$ serves as a penalty against 'quality bid' so as to implement the downward distortion feature of the optimal contract. The scoring auction resembles the procedures used in the procurement of weapons, transportation, construction, and a multitude of other goods and services. *Quasi-linear scoring auctions* are analytically tractable and can implement a broad range of outcomes, even when the quality is multidimensional (so q is a vector of attributes) and the suppliers may have heterogeneous costs with these attributes (Asker and Cantillon 2004). (A quasi-linear scoring auction may not implement the optimal direct revelation mechanism for the buyer if the suppliers have multidimensional costs, but it does implement the socially efficient quality mix. See Asker and Cantillon 2005.)

In many procurement settings, the monetary expenditures are observable, but the suppliers' inherent capabilities as well as their effort to reduce the cost may not be observable. In this case, how a supplier's cost should be reimbursed becomes an important issue. A *fixed-price contract* that pays the same price to the supplier regardless of his realized cost provides a strong incentive for cost-reduction but requires the supplier to bear the risk of cost shocks. By contrast, a *cost-plus contract*, which reimburses the supplier's cost fully, provides weak incentives for cost-reduction effort but imposes no risk on the part of the supplier. McAfee and McMillan (1986) show a mixture of the two contract forms — that is, a *partial reimbursement rule* — to optimally balance the trade-offs between the cost reduction incentive, adverse selection and risk sharing. (Laffont and Tirole 1986, obtained a similar result without risk aversion of the agent.) Bajari and Tadelis (2001) focus on the trade-off between the cost reduction incentive and *ex post* renegotiation inefficiencies, and study how the complexity of the procurement job affects the choice of contract form. They argue that fixed-price contracts are optimal for standard jobs, whereas cost-plus contracts are optimal for complex projects. Empirical findings on the contract choice appear consistent with this latter finding (Crocker and Reynolds 1993; Corts and Singh 2004; Bajari et al. 2002).

Uncontractable Quality

Often the quality enjoyed by the buyer is unobservable to the supplier and/or unverifiable to the court, so it is difficult to contract on it *ex ante*. Book publishing, advertising, film production, development of new (such as pharmaceutical) technologies, procurement of new weapons systems and hiring new talents all involve some difficulty in specifying the quality of jobs. While *ex post* signals about quality are often available after the procurement (for example, sale of a book or of an advertised product), the fixed cost associated with procurement may be so high that quality assurance is needed before full-scale production begins. We discuss several methods for assuring quality.

To illustrate, suppose a buyer values the good at q if a supplier makes an effort $c(q)=\frac{1}{2}q^2$. It would be ideal for the buyer to obtain the quality $q^*=1$ at the price of $c(q^*)=\frac{1}{2}$. If quality is unverifiable, it would be difficult to specify contractually the level of quality. The buyer would argue that the quality provided is lower than specified, and the supplier would argue the opposite. In any case, the supplier would have little incentive to provide high quality, since there would be little reward for it.

A simple *option contract* can solve the problem of unverifiable quality. Suppose the buyer signs a contract that requires the supplier to pay a (non-refundable) upfront fee of q^* - $c(q^*)$=$\frac{1}{2}$ to the buyer and gives the buyer an option either to accept the good at the price of $p=q^*=1$ or to reject it at no penalty. If the supplier produces quality of q, then the buyer would receive $q-\frac{1}{2}$ from accepting the good and $\frac{1}{2}$ from rejecting the good. Hence, the buyer will purchase the good if and only if $q-\frac{1}{2}\geq\frac{1}{2}$, or the quality is at least $q^*=1$. Knowing this, the supplier will produce $q^*=1$. The supplier has the incentive to provide adequate quality since the buyer has an option to reject the good if the quality is not to his liking. These option contracts, known by such names as *purchase upon approval* and *delivery-contingent* contracts, are common in situations where quality assurance is important (Taylor 1993; Che and Hausch 1999). For instance, advertising agencies must often develop acceptable pilot campaigns before they are paid in full; real estate agencies and other brokers are typically not paid until they find an acceptable match between buyers and sellers; book publishers often reserve the right to recover an advance in the event that they find the book unacceptable. The *up-or-out* contracts well-known for academic tenure and law partnerships are a form of an option contract, presumably motivated to deal with the 'unverifiable quality' problem (Kahn and Huberman 1988).

A problem with the option contract is that it requires the supplier to pay an upfront fee, that is, to buy in. Often, suppliers have limited liability or are liquidity constrained, which can make the option contract infeasible. In the above example, for instance, if the supplier cannot be induced to 'buy in', the buyer will receive zero net surplus. (This is attributable to the deterministic nature of quality. If quality is stochastic, the quality accepted will generally exceed the option price. Even with stochastic quality, however, the option contract will be of limited value to the buyer if the suppliers cannot buy in.) This problem can be solved by a *pilot/research contest*, that is, by having multiple suppliers compete for a reward. To be concrete, suppose the buyer invites two suppliers, each with the same technology described 25 above, and suppose the buyer promises a fixed prize $P=\frac{8}{25}$ (which turns out to be the optimal level) for the supplier who offers the higher quality. It is then equilibrium behaviour for each supplier to randomize quality over $[0, 4/5]$ according to the CDF, $F(q) = \frac{25}{16}q^2$, yielding a surplus of $\frac{8}{25}$ to the buyer. (If the other supplier follows the randomization strategy, a given supplier receives a payoff of $F(q)P - c(q) = \frac{1}{2}q^2 - \frac{1}{2}q^2 = 0$, when choosing $q \in [0, 4/5]$, so randomizing according to F is a best response.)

Fixed-prize contests have been used for developing new innovations, some historically important, such as the *longitude technology* and the *steam engine design*. But recent procurement contests have allowed suppliers some freedom in specifying their own rewards. For instance, most of the defence procurement competitions as well as grant competitions allow suppliers to adjust the size of their prizes and compete along that dimension as well. Such *auction contests* can in fact be justified, as a contest that allows suppliers to bid on their reward is optimal (see Che and Gale 2003). Suppose the buyer in the above example lets suppliers bid prices for their innovations and then procures from the one offering the highest net surplus (the difference between the quality offered and payment demanded). This auction contest induces each supplier to randomize over q uniformly from [0,1] and to bid $\frac{1}{2}q$ for his prize, yielding a net expected surplus of $\frac{1}{3}\left(> \frac{8}{25}\right)$ to the buyer.

The purpose of employing competition here is not to select a supplier efficiently (recall both suppliers are equally efficient *ex ante*) but rather to provide incentives for unverifiable quality. The buyer has an incentive to select the supplier that offers the best value (quality minus payment), and this option to select from suppliers – just like the option to reject in the option contract – creates incentives for quality from the suppliers, and assures the surplus for the buyer even without supplier buy-in. Such incentives come at the expense of duplicative investment, however, since the buyer procures from only one supplier. This suggests that limiting the number of competitors – often to two – is optimal (see Che and Gale 2003; Taylor 1995; Fullerton and McAfee 1999). If the quality of the innovation/good is stochastic, competition will serve the additional purpose of identifying an efficient supplier.

The non-verifiable quality problem can be overcome if the buyer procures the good repeatedly. In such a situation, a *reputation* – more specifically, the promise of granting rents in exchange for an agreed-upon quality – combined with the threat of terminating a relationship for a sub-par quality, can create the supplier's incentives for quality (Klein and Leffler 1981). For instance, in the above example the buyer and a supplier can make an implicit agreement such that the latter provides the quality of $q^* = 1$ in exchange for a payment $p \in \left(\frac{1}{2}, 1\right)$ from the former, as long as both honour the agreement; if one deviates unilaterally, both terminate the relationship. The threat of termination is credible, since it is a Nash equilibrium in each round for the supplier to provide zero quality and for the buyer to pay nothing. If nobody deviates, the buyer and the supplier would obtain $\frac{1-p}{1-\delta}$ and $\frac{p-0.5}{1-\delta}$ respectively, where $\delta \in [0, 1)$ is a common discount factor. The two parties can get at most 1 and p, respectively, from a unilateral deviation. If $\delta \geq \left\{p, \frac{1}{2p}\right\}$, then the first-best quality can be implemented in a subgame perfect equilibrium.

So far, we have assumed that quality of procurement is observable to the buyer (albeit non-verifiable to the court). Often, the quality of good supplied may not be observable to the buyer at the time she procures from a supplier. Development of new weapons or transportation systems are subject to this problem, as the quality of new features is learned long after the procurement. If the buyer is unsure about the quality supplied, a standard auction based solely on price performs poorly (and unobservability of quality precludes the use of multi-dimensional competition such as scoring auctions). In such a case, it may be socially optimal for the buyer to bargain with one of many potential suppliers, instead of inviting them to compete for a job. To illustrate, suppose there are two potential suppliers, each with cost c drawn independently and uniformly from [0,1]. A supplier with c can deliver a good with quality $v(c) = 3c$ to the buyer, so the quality is not only unknown to the buyer but also positively correlated with the supplier's cost. In this case, competition based only on price will result in the selection of the low quality, with the buyer obtaining only $\frac{1}{3}$ in expectation. By contrast, if the buyer selects a supplier at random and makes a *take-it-or-leave-it offer* of price 1, then the offer will be accepted, and the buyer will enjoy an expected surplus of $\frac{1}{2}$. Notice that bargaining dominates competition also in social surplus in this case (see Manelli and Vincent 1995).

Procurement Irregularities

The difficulty with verifying quality may require a buyer to hire agents with special expertise to evaluate the proposals. This added bureaucracy can introduce agency costs to the procurement. In particular, there is a potential for the agents evaluating proposals to favour a certain supplier in exchange for a bribe or kickback. *Corruption* is a serious problem in both public and private procurement, particularly across national borders. (Between 1994 and 1999, bribery was allegedly a factor in the awarding of nearly 300 contracts worldwide worth $145 billion and caused US firms to lose as many as 77 contracts worth $24 billion.) Burguet and Che (2004) analyse this problem via a scoring-auction model where quality score is measured imperfectly and is manipulable by the procurement agent in exchange for a bribe, and show that bribery competition – unlike standard auction competition – leads to allocational inefficiencies (see also Celentani and Ganuza 2002; Burguet and Perry 2002; Compte et al. 2005).

Another type of procurement irregularity is *collusion* among bidders in procurement competition. Bidding cartels in procurement auctions account for a significant portion of antitrust cases. McAfee and McMillan (1992) show that standard auctions are vulnerable to collusion but that the outcome will depend crucially on whether the cartel can exchange transfers. If the cartel members can exchange transfers, they can organize a ‘knock-out’ auction to achieve an efficient allocation, whereas if transfers cannot be used (for fear of detection, say) a member will be chosen randomly to win without any competition, meaning that allocation will be inefficient. Subsequent work has shown that repeated interaction allows asymmetrically informed cartel members to sustain collusion via a ‘bid rotation’-type scheme, and that the scheme can be refined to attain a degree of allocational efficiency (see, for example, Aoyagi 2003; Athey and Bagwell 2001; Athey et al. 2004; Blume and Heidhues 2002; Skrzypacz and Hopenhayn 2004). To what extent inefficiencies result from procurement irregularities and how they can be remedied by procurement policies remain open questions. (For some promising lead for the latter question, see Che and Kim 2006a; 2006b; Dequiedt 2005; Marshall and Marx 2003; Pavlov 2006).

Producers' Markets

Harrison C. White and Robert G. Eccles

Any market is a social formation which decouples sellers from buyers exactly by turning the particular persons into occupants of roles. These roles form a transposable structure, which also translates items of offer into roles as commodities. Other varieties of such social formations are, for example, ritual prestation cycles of gifts, in which status and purity are computed via regularized offerings and receptions (such as Strathern's *The Rope of Moka*, 1971). But all markets are decentralizing; they dissolve the global structure of flows in prestation institutions into locally accountable flows.

The product market is by any account the predominant modern form. It is peculiarly concerned with asymmetry. Producers' markets generate and guarantee continuing flows of production from dedicated producers, but they exhibit flexibility and variety with respect to the sorts of buyers and their organizational forms. Producers' markets evolved historically from *verlager, kaufman*, and putting-out systems of early modern times (Kriedte et al. 1981) in which production became increasingly rationalized and concentrated within more and more formal organization. Interchangeable sellers and buyers of markets became specialized into producer/seller and buyer.

Production Markets as Role Structures

Asymmetry is problematic for role structures, because asymmetry can only be maintained between roles when they are explicitly articulated into a global structure such as the Rope of Moka. Role structures are more flexible and effective and translatable when they define roles as parallel, as structurally equivalent in relation to the ongoing processes (White et al. 1976). Competition is an important example. Those who compete are *a fortiori* similar; they can be compared and are comparable one to another.

A producers' market organizes producers into an array of parallel roles whose primary focus is each other. The producers' market exists to remove the need for attention to individual roles on the 'other side' of the market from producers who develop roles with respect to each other. In common business parlance, these roles are articulated as the producer's *strategy*, which details the role the producer hopes to occupy in the market in terms of volume, cost structure, and quality. It is revealing to recognize that these expressions of strategy, which can as easily be made *post hoc* as *a priori*, are rarely made solely in absolute terms. Instead they are made with respect to other producers with whom one is competing. These others are, in turn, attempting to do the same thing and so a certain recursive element is introduced. Each producer defines its role in terms of the similarities and differences it has with respect to other producers.

Markets vary in the accuracy of their producers' ability to make these comparisons. In some markets these perceptions fairly closely reflect underlying economic realities and buyers' perceptions. This contributes to the reproducibility of the social structure. When producers' perceptions are inaccurate, such as when each producer thinks of itself as different from all the others each of whom thinks it is different from all the others in exactly the same way, roles are ambiguous and the resulting market is unstable.

The substance of a producers' market as a social formation is the frame or schedule for terms-of-trade. These are perceived as objectively binding by the actors deciding within them; yet their basis is exactly the choices just made by producers. A producers' market is a tangible social construction, an interface which can only be maintained through the reproduction of its own assumptions in the very course of acting in terms of it. This requires accurate perceptions and the willingness of each producer to act in the future similarly to how it has acted in the past or, at a minimum, to change its actions in predictable ways. Nothing wreaks as much havoc in a producers' market as unanticipated actions by one or more producers. A particularly salient example is producers' prices. Businessmen often comment that nothing is worse than a competitor who prices 'irrationally', i.e., unpredictably. Thus, while producers' roles are defined in terms of their competitive relationships with each other, the existence of a market requires some form of tacit cooperation to continue to play by the established rules of the game.

There are two fixed sides and there also are two sorts of flows, physical volumes and value transfers, in a producers' market. Producers are the shapers of deals, the actors who offer terms of trade. Thus they can attempt to optimize outcomes for themselves, within the objective constraints of the terms of trade. In producers' markets buyers are sayers of yea/or/nay. Buyers refuse any deal which is not as good as other deals. In that way buyers enforce discipline on the terms of trade.

Producers' markets as social mechanisms presume and require small numbers of producers: the social mechanisms cannot work otherwise. Since role definition depends upon interproducer comparisons, the complexity of making these comparisons grows geometrically as the number of producers grows arithmetically. There are obvious limitations to how many producers any given producer can be sufficiently knowledgeable about in order to define its role with respect to these others. Consequently, there are limitations to how many actors can sustain the kinds of competitive and cooperative efforts that are necessary in order for a market to exist. A rough rule of thumb is that stable markets cannot contain more than a dozen or so producers.

Terms-of-trade seen by any producer are the revenues received for the various volumes shipped. These are the observables. They are easily extrapolated into a schedule of how revenue may change with volume. Everyone knows that producers differ in qualities and in cost structures, as well as in volumes shipped and revenues received, but only the latter are easily observable. Everyone also knows that buyers do discriminate among producers in ways summed up as quality, but no one can quantify this in advance or independent of volumes shipped. Instead producers recognize that responses to quality underlie and shape the observed schedule of terms-of-trade.

Evidence that the importance of quality differences to structuring the terms-of-trade is recognized by producers is seen from the expense and effort expended in market surveys, conducted by the producer itself or through retaining the services of a market research firm. An entire industry has emerged to help producers better understand how buyers perceive their quality and the quality of their competitors. This contributes to accurate role definitions (i.e. strategies) and thus to the reproducibility of the market. Of course, these surveys are not totally passive information gathering exercises. The execution of them contributes in a major way to the shaping of quality perceptions on the buyer side by defining the terms on which the elusive but very real notion of quality can be evaluated.

Similarly, an entire industry has emerged to provide information to producers on the cost structures of their competitors. The firms in what is often referred to as the 'strategy consulting industry' use a variety of information gathering mechanisms in order to estimate the cost structures of participants in a market. This information is obtained from both the producers themselves and from buyers. However, unlike the market research firms where the real value of the activity lies in shaping the buyers' perceptions of quality, information on cost structures is of relatively greater importance to producers. This is not to say that buyers are uninterested in the relationship between cost and price of their suppliers.

Pricing and Differentiation

Pricing is nonlinear with volume in production markets, reflecting differences in volumes shipped by producers of different quality. The price schedule tends to be monotonic and continuous, since buyers exert continuing discipline for deals of equal value, through which the schedule is extrapolated. The schedule will reproduce itself if each producer chooses again the production level of before. Given the perceived terms-of-trade, the producer will choose the volume at which revenue has the greatest margin over cost of production. An interesting consequence of the conditions for reproducibility is that producers must differ in profits and profitability in order to maintain the dispersion which sustains the market. While it may be true that eventually all profits become equal across firms and even across industries as capital seeks its best use, one of the strongest empirical findings of those who study actual markets is that profits and profitability differ substantially among them and between the firms within them. What actually *is* needs to be explained as much as what *will* (may) *be*.

A producers' market can be seen as a device for segmenting producers. Producer choices reflect off buyer gainsaying, which sorts out producers by volume in reflection of quality. A producers' market is not set up by – it does not come from – some pre-existing product. Rather, what a 'product' is emerges from successful evolution of producers' markets as self-reproducing schedules. The product defines the market and vice versa. Little is known of how new markets actually evolve – how often they are variants of pre-existing ones and how often they are new.

The driving force behind the evolution of markets is the effort of each producer to differentiate its offering from those of the other producers. In doing so it seeks to appeal to a specific segment of the buyer side. At the limit each producer would have its own set of customers which did not purchase from any other producer – markets of one firm. At the other extreme all buyers would purchase from any producer of a given product resulting in markets of dozens of producers. The creation of a self-reproducing social structure requires a market between these two extremes. This is achieved by a process that determines which producers will constitute the market, thereby defining the product, and which producers will be outside of the market and therefore members of a different one. Although this is difficult to determine analytically, it happens in business life all of the time.

Participants in a market know quite clearly who their competitors are (from the perspective of the producer) or who the available suppliers are (from the perspective of the customer). A product is defined in terms of the offerings made by the producers who constitute this market. The offerings of the producers in the market are considered more similar to each other than they are to offerings of producers not in the market.

Thus, markets require differentiation in two forms. The first is that which distinguishes market members from non-market members. The second distinguishes market members from each other in terms of their respective roles. As producers enter and leave the market, the product is constantly being redefined. One of the great competitive struggles in business life is between members of a market who seek to keep new entrants out and these potential new members who want in. Member cooperation supersedes member competition vis à vis non-members.

A basic implication is that producers' markets have arbitrary levels of 'supply and demand'. A market schedule is labile in the sense that buyers can only discipline the shape of the schedule, not the absolute levels of revenue and volume. A producers' market sorts out producers with respect to one another, but that regulates only their relative performance, not the absolutes. The ranges of price and volume within which a given market can and does emerge depends on historical circumstance.

Another important market characteristic which depends on historical circumstance is the pricing conventions used. Pricing conventions are a significant determinant of overall profitability levels. These pricing conventions include the units for which prices are established, the extent and nature of quantity discounts, how bundled or unbundled the pricing is of related products or services, returns policy, and the conditions in which prices can be renegotiated.

Prices are not something that mysteriously emerge from 'the market'. They are part of the terms-of-trade and are socially constructed by the actors involved in the exchange.

On the Nature of Markets

To sum up, a producers' market depends on and reflects the *dispersons* of producers and not their averages on costs and qualities. Producers necessarily need to differ in profits in order to reproduce the dispersion which sustains the market.

The market terms-of-trade is an interface which decouples producers from the buyer side. This permits the evolution observed into networks of markets with products of one being inputs to producers in many others as well as to ultimate consumers.

A major and heretofore unrecognized puzzle is resolved by this model of producers' markets as role structures: Why is it so rare to see two producers with equal shares in their market? Existing theories assume away the problem by hypothesizing a strict ordering of producers by market shares. Yet existing theory, on any plausible computation from the combinatorics of constituent firm characteristics, should expect to find equal shares a common phenomenon. The sociological view of production markets as role structures makes the missing equality possible.

Specific computations are necessary to bring this view of producers' markets to bear on specific current markets and to guide tests by comparison across a set of markets. Elsewhere (White 1981a,

b, 1987; Leifer 1985; Leifer and White 1987) particular families of Cobb–Douglas functions have been used to frame such computations. By analytic continuity the main features of these results can be extended to less specific assumptions on cost and taste structure.

Figure 1 shows a state space consistent with the cited computations. The exact number and characteristics of producers are passed over. Instead two sensitivity ratios are used to identify possible states of a production market. The abscissa is sensitivity of taste to quality spread among producers, measured as a ratio, to the sensitivity of cost structures of producers to quality spread. This axis measures net differentiation among producers seen across the market. The ordinate is parallel, but sensitivities are to volume from a producer. This other axis can be seen as a measure of dependence which reflects tendency to concentrate purchase on a particular producer.

Existence is the crucial property to report: can producers' markets exist stably in that state? Since market schedules are labile, if a producers' market can exist for given sensitivity ratios it may exist with a range of particular terms-of-trade schedules. Detailed computations show that the answer depends in some states upon the range of producers included, but not in general. Only in one extreme limit is there no range of schedules possible and no limitation upon the spread of producers involved: this is the zero differentiation limit, on the left, corresponding to 'perfect competition'. Several results stand out:

1. Only when volume sensitivity is greater than quality sensitivity are robust markets common.
2. When volume sensitivity becomes large, markets collapse as production is concentrated in a single producer; yet there *is* a range of markets in states exhibiting some degree of increasing returns to scale.
3. In states yielding markets with increasing returns to scale, the addition of new producers to a market tends to decrease the total size of the market in gross revenue.
4. Dispersion in market share among producers tends to be less the more nearly equal the two sensitivity ratios are; as this equality is approached in the state space, markets are less stable and furthermore the dispersion in profitability declines, and average profitability increases.

This sociological perspective on markets is not without precedent in economics. It takes up again the realist stance opened up a half-century ago by Chamberlin but subsequently abandoned under the influence of P.A. Samuelson. Much of the technical apparatus underlying Fig. 1 is adapted from Spence's 1974 study of market 'signalling'. Various aspects are akin to themes in the economics literature, for example Sanderson (1974) on ‘demand’, Spulbur (1981) on nonlinear pricing, Telser (1981) on futures markets, and the economies-of-scope literature surveyed in Bailey and Friedlander (1982). But this role theory explains producers’ markets endogenously as social mechanisms rather than exogenously from boundary conditions.

Product Cycle

Raymond Vernon

No one will deny that products come into existence, change in character, and eventually disappear or become altered out of all recognition. Archaeologists, historians, businessmen and ordinary people have no difficulty in recognizing that fact. Economists, at least since David Hume, have occasionally acknowledged the phenomenon. But until a decade or two ago, the disposition of economists to use that process as a basis for formal inductive or deductive analysis has been extraordinarily limited. The ideas have surfaced from time to time in the works of John Williams (1947), Donald MacDougall (1957) and Michael Posner (1961) among many others, only to slip back into limbo. When economists have found it difficult to disregard innovation and product change in any formal analysis, they have usually assumed that the economic effects of innovation could be captured through its consequences for increased productivity, hence through a change in production costs. The appearance of the railroad, the automobile and the commercial aircraft, therefore, was usually thought to have been captured by referring to a decline in the cost of transportation; the appearance of nylon was treated as the equivalent of a decline in the cost of thread.

Meanwhile, businessmen and business schools came to speak of products as going through a life cycle. During the course of that cycle, predictable changes were thought to occur in product characteristics, hence in production technique and production location. Equally predictable changes were seen in the nature of the market during the life cycle of a product, including changes in the prevalence of competition and in the character of demand.

In their early stages, new products tended to be unstandardized in character, as suppliers experimented with different inputs, different production processes, and different designs of the final product. This was a stage, therefore, in which suppliers could not readily determine an optimum location, production scale or sale price, and in which product differentiation among suppliers was relatively high. In a later stage, the number of suppliers would increase, the product would become more standardized, production and location decisions would be made with less uncertainty, and the price elasticity of demand – both in the aggregate and for the output of the individual supplier – would increase. Thereafter, some producers might elect to attempt some degree of product differentiation, using trade names, advertising and minor variations in product; but price elasticities at the firm level would still be quite high, demanding close attention to production costs.

These ideas, which have formed the basis of a large literature about product life cycles or product cycles over the past few decades, would ordinarily be assigned by any economist who took note of them to the microeconomics of imperfect markets. In the two or three decades immediately following World War II, however, some economists professed to see such considerable strength in the product cycle factor as to help explain the macroeconomic performance of some countries, notably, the foreign trade patterns and foreign direct investment patterns of the US economy.

In brief, the product cycle was thought to be greatly influencing the performance of the US economy as a whole because of some highly distinctive features of that country. For many decades, the United States had recorded the highest per capita incomes in the world, along with high hourly labour costs, low capital costs and low costs of raw materials. That configuration, according to the argument, had placed a distinctive cast on US innovation. US innovators specialized in generating new products that responded to the emerging demands of a mass market of high-income consumers, as well as to the desires of producers for devices that could produce goods and services with less labour.

Fortuitously, according to the argument, the US pattern of innovations created a stream of products during much of the twentieth century that subsequently would be appropriate for other countries as well. That outcome was a result of the fact that during this period, the per capita incomes and labour costs of other countries were also rising, albeit from a lower level, while the capital costs and raw material costs of these countries were declining in relative terms; hence the products that had been generated for the US economy in 1950 became increasingly appropriate for other economies in the succeeding years.

These asserted relationships, supported by numerous empirical studies, were thought to provide an important part of the explanation for the strong showing of the US economy in the exportation of manufactured products, especially in high-technology goods, along with the heavy investments of US firms in subsidiaries in foreign markets devoted to the manufacture of such products.

By the 1970s, however, it was evident that the performance of US firms in both exports and direct investment was changing. At the same time, the product cycle factors that were thought to have produced the strong international performance of the US economy up to that time also were seen as considerably altered. For one thing, the per capita incomes of Western Europe and Japan were rapidly rising to the US level. Moreover, the distinctiveness in the profile of US factor costs was being obliterated, as the global costs of capital and raw materials came to be reflected increasingly within US markets. As a result, Europe-based and Japan-based innovators, responding mainly to the conditions of their own home markets, were found to be challenging US innovators with similar products.

Moreover, the 1970s interrupted the long-time global trends that had created markets for US innovations. Income growth was interrupted; capital costs and material costs rose more rapidly than labour costs. Now it was the turn of the European and Japanese innovators, with their long-time emphasis on the conservation of materials, the improvement of product performance, and the paring of costs. As a consequence, the United States found itself importing on a large scale products in which such characteristics had come to matter, such as steel, electronics and automobiles.

The power of the product cycle concept as an explicator of the export and investment behaviour of the US economy accordingly declined in the 1970s. As US products matured in world markets, US producers were pressed increasingly to concern themselves with the costs and prices of those products. Moreover, once the US firms had established their multinational networks, the existence of those networks gradually altered the perceptions and calculations of some US-based firms. Some began to respond to conditions in foreign markets, as well as the home market, to provide the stimuli for their innovations. Some began to think in terms of world models for their products, with production facilities for component parts established in any country in the world where factor cost considerations might indicate. Trends of this sort reduced the relevance of the nationality of the parent in determining the direction of the firm's innovations and in determining the patterns of its imports and exports.

Still, the product cycle concept continues to have some considerable utility. Most producing firms continue to produce within a single national economy, even though the relative output of such firms is considerably smaller than their relative numbers. Moreover, national economies continue to retain some distinctive national characteristics, a fact that may lead their entrepreneurs to generate distinctive new products. Thus, US and Israeli producers operate in economies that are heavy producers of military goods; Argentine and Indian producers in economies in which they are challenged to overcome the handicaps imposed by unreliable supplies of power or transportation; Singapore producers in a national economy so small that it cannot provide the basis for scale economies. These different conditions will tend to push innovations in somewhat different directions, creating fertile grounds for theorizing about the trade and investment patterns that these differences will eventually produce.

Product Differentiation

Simon P. Anderson

Abstract

Product differentiation is pervasive in markets. It is at the heart of structural empiricism and it smoothes jagged behaviour that causes paradoxical outcomes in several theoretical models. Firms differentiate their products to avoid ruinous price competition. Representative consumer, discrete choice and location models are not necessarily inconsistent, but performance depends crucially on the degree of localization of competition. With (symmetric) global competition, rents are typically small and market variety near optimal. With local competition, profits may be protected because entrants must find profitable niches. These rents lead firms to competitively dissipative them, and performance may be poor.

Overview

Consumer goods are available in a variety of styles and brands. Product differentiation refers to such variations within a product class that (some) consumers view as imperfect substitutes. The store Foods of all Nations in Charlottesville, Virginia, USA (area population 120,000) carries 118 varieties of hot pepper sauce, 41 balsamic vinegars and 121 different olive oils (these figures include variations such as flavourings and different package sizes from the same manufacturer). There are 82 other retail grocers listed in the area. Charlottesville is served by 23 rated radio stations which differ by format choices (18 are commercially operated).

Product differentiation offers firms market power. This enables them to transcend the Bertrand paradox for pricing homogeneous products. In the Bertrand paradox, two or more firms sell goods that consumers perceive as identical, so goods are perfect substitutes. Assume that marginal costs are common and constant, and market demand has a finite price intercept. Then one good cannot carry a price premium over another while retaining positive sales. Any lowest price above marginal cost would then profitably be undercut. This logic impels us to marginal cost pricing as the only equilibrium under Bertrand competition.

Product differentiation resolves the paradox naturally. When products are imperfect substitutes, a price-cutting firm cannot take all its rivals' customers with an infinitesimally small price cut. This means that firms have some market power (due to the special features that distinguish them from their rivals' products); they can set prices without a completely elastic response by consumers. It also means that the product itself becomes a choice variable and firms differentiate to avoid the Bertrand outcome.

However, many models of product differentiation do not treat this choice explicitly, and instead assume a framework (representative consumer, discrete choice, and symmetric location models) that generates a demand system. It is not so much the framework used but rather the structure of product differentiation that is critical to the predictions and results. Indeed, common models of one type may be recast within another framework and be formally equivalent. Instead, the important feature for performance is whether each product is equally substitutable with all others or if each has only few close substitutes which are chain-linked to other products in the industry. Equal substitutability describes *global competition* where each firm competes with each other firm. Chain-linking corresponds to *local competition*. Local competition models naturally apply in geographical space since nearby stores are closer substitutes for consumers than distant ones. Likewise, in a characteristics setting, a consumer with a sweet tooth will find sugary products closer substitutes for any sweet product than for a saltier one.

The next section describes models of product location (in geographical space or its characteristics analogue) and distinguishes horizontal from vertical differentiation. Section "Modelling (Horizontal) Product Differentiation" compares the common approaches to product differentiation used to analyse the market provision of variety. In these models, product decisions are suppressed and product selection is determined by entry. Section "Monopolistic Competition and Optimal Variety" describes how the market variety diverges from the equilibrium one. Section "Localized Competition" elaborates on this theme for local competition. Section "Further Applications" indicates how product differentiation is used elsewhere in economics.

Product Choice

Hotelling (1929) wrote the seminal paper treating the product specification as endogenous.

Applications beyond industrial organization include marketing, economic geography (spatial competition), political science (the 'Hotelling–Downs' model), and media economics. The basic paradigm is that consumers are differentiated by their locations ('addresses') and dislike distance. Products, too, are locations in this space (geographic, characteristics and so on). When products are priced at marginal cost, consumers differ by which they like best, a situation known as *horizontal differentiation.* The simplest version of the model has two ice-cream sellers locating on a beach (with fixed prices). The Nash equilibrium is back-to-back pairing at the median of the consumer distribution, a result christened the *principle of minimum differentiation.* It has been used to explain striking similarities in colas, petrol station location, political parties' platforms and the timing of television programmes.

However, the principle dissolves when firms locate in rational expectation of ensuing equilibrium prices (that is, seeking a subgame perfect equilibrium to a two-stage price-then-location game). Indeed, if two products were collocated, Bertrand competition would drive prices to marginal cost. Firms will avoid this ruinous result by differentiating to retain market power attributable to location advantage. The equilibrium trades off two opposing factors. Getting closer to a rival provokes more intense price competition, so firms differentiate in order to relax price competition, but getting close to a rival attracts more customers.

The equilibrium locations are outside the optimum ones (which are at the quartiles for a uniform consumer density) for the central case of quadratic distance disutility costs, but otherwise there is no fundamental reason for excessive market differentiation. More elaborate models can rapidly become quite intractable and are hamstrung by non-existence of (pure-strategy) price equilibria due to fundamental failure of quasi-concavity of the profit functions in prices.

The case above of horizontal differentiation has consumers with fundamental preference differences across different varieties. In *vertical differentiation,* all consumers have the same preference ordering (when goods are priced at marginal cost). More preferred goods are often described as having higher 'quality' (with different individuals having different willingness to pay for quality). In vertical differentiation models, firms are to choose their product qualities. Choosing the same quality is avoided because of ruinous price competition, and the same trade-off operates as under horizontal differentiation. Under vertical differentiation though, the firm producing a higher-quality product earns more profit than a firm with lower quality. This result is an extension of the Bertrand paradox. One firm differentiates itself by a low quality, but this puts it at a disadvantage. Indeed, it may not be able to escape the shadow of the high-quality firm and earn a positive profit in equilibrium. This result implies the finiteness property that only a finite number of firms can survive in equilibrium even as fixed costs become arbitrarily small. By contrast, in a horizontal model, a firm may always find a niche between existing firms that gives it an advantage over some consumers (so that finiteness cannot hold). Finally, if the costs of improving quality are mainly sunk, a firm may invest more heavily in quality in a larger market because the benefit accrues over a larger consumer base (so sunk costs are endogenous).

Quite similar in spirit to the above approaches, Lancaster's (1966) model of *characteristics* was a quite revolutionary approach to consumer theory. It posited that consumers care about the characteristics intrinsic to goods and purchase goods because they deliver the desired characteristic mix, adjusting appropriately for prices. Lancaster's theory answers the question of why goods are desirable by formulating fundamental preferences over characteristics. The approach is intuitively appealing and is at the heart of hedonic models in econometrics, state preference and mean variance models in portfolio choice problems in finance, and structural econometric work in industrial organization. However, the approach is rather cumbersome for generating much theoretical insight into firms' location decisions, that is, the choice of which characteristics to embody in products.

Modelling (Horizontal) Product Differentiation

There are three basic families of product differentiation models that are typically used for modelling equilibrium with free entry and comparing optimal to equilibrium diversity.

Representative consumer models start by positing a utility function intended to portray aggregate preferences. This preference ordering generates the demand system for differentiated products and it measures welfare for the optimality analysis. Such functions typically embody global competition insofar as demands for varieties of the differentiated product are symmetric substitutes. Models in this class include the often-used constant elasticity of substitution (CES) preference formulation and the quadratic utility that gives rise to a linear demand system. These are parameterized utility functional forms that embody taste for variety in that more variety raises welfare even when total consumption is fixed.

The *discrete choice approach* is founded in econometric and probabilistic models of consumer behaviour. Each individual has an idiosyncratic taste (or ‘match value’) for each product. Aggregating individual choices yields the demand function and aggregating the surpluses yields the welfare function. Any i.i.d. tastes yield global competition in that products are symmetric substitutes (for example, the logit model).

Discrete choice models are not constrained to symmetric substitutability among variants. Models such as the nested logit embody closer substitutability between products within the same nest and the general probit model embodies quite elaborate substitutability patterns through the variance–covariance matrix of the match terms. These models are commonly used in the new structural empirical industrial organization literature.

Location models explicitly describe product specifications and consumer preferences as addresses and assume that consumers dislike distance ‘travelled’ between ideal type and product. Location models may also be viewed as discrete choice models because individuals make discrete choices and have idiosyncratic match values. There is a difference in interpretation: location models typically assume the population of consumers to be given and deterministic, while discrete choice models suppose that an individual’s taste is a realization from a probability distribution.

In models such as the circle model, the emphasis is on the number of products produced in equilibrium and exogenous symmetric locations are effectively imposed: however, the standard symmetric location pattern can be proved to be a location equilibrium under some circumstances.

One major benefit of discrete choice and location models is that the explicit micro foundations indicate how to introduce some economic phenomenon of interest. For example, network externalities may be incorporated into consumer utility and a consistent set of demands is then generated. Representative consumer models are less satisfactory since they do not start with a population of differentiated individuals.

The different approaches are not necessarily inconsistent with or substitutes for each other. Rather, they may frequently be twinned and one approach may be reinterpreted within the setting of the others. The CES model is a variant of the logit model, and a representative consumer exists for the circle model and for probabilistic discrete choice models. Indeed, although global competition is typically generated from models such as the CES representative consumer or models of discrete choice with i.i.d. errors, it can also be derived from a spatial model if there are sufficiently many dimensions (so that each good can be a ‘neighbour’ to each other).

These models are also useful for comparative static analysis of changing patterns in industries in response to structural changes in cost structures, population growth, transport costs and consumer tastes. These descriptions are useful for urban economics, industrial organization, international trade, and economic geography.

Monopolistic Competition and Optimal Variety

In Chamberlin’s (1933) monopolistic competition model, products have downward sloping individual demands, yet there are so many firms that a free entry condition reasonably applies. With increasing returns to scale in production, there is a social trade-off between the benefits from variety and the costs of producing further varieties. The market equilibrium roughly embodies the same type of trade-off in so far as more firms enter if fixed costs are lower. Chamberlin concluded (although without explicit analysis) that the market equilibrium would reach ‘a sort of ideal’.

Under symmetric global competition, each entrant carves out its market share equally from established firms. Then, the number is the largest whole number at which profits are positive. This number of firms is tied down uniquely and zero profit is a reasonable approximation. Strategic behaviour by firms is scarcely relevant since there are virtually no profits to be had.

Later work showed Chamberlin to be right that the market would settle on the same amount of product diversity as the (zero-profit constrained) optimum in the central case of CES preferences (and for the logit model). Other discrete choice models lead to over-entry: this is exacerbated with asymmetric product qualities. The market may also bias against products with high fixed costs and inelastic demands. Multi-product firms choose inefficiently narrow product ranges in order to relax price competition: this effect exacerbates excessive entry of firms.

Although the symmetric CES/logit results (asymmetries aside) suggest that product differentiation is not much cause for performance concern, the alternative framework of the circle model typically generates substantial over-entry of firms.

The divergence between equilibrium and optimum product variety depends on the balance between two opposing forces. When a firm chooses to enter, it does not consider that its entry will benefit consumers. This *non-appropriation of consumer surplus* is therefore a positive externality that the firm does not internalize insofar that it cannot capture this surplus in its revenue. This force favours insufficient entry into the marketplace. It is the only force governing a multiproduct monopolist’s choice of how many products to introduce, so it provides too few products. However, in a competitive setting, a firm’s entry can also reduce the profits of existing firms. This *business stealing* is also not accounted for by the firm in its entry calculus because other firms’ profits do not affect its own bottom line. This negative externality encourages too many firms in equilibrium. For the CES model, these two forces exactly cancel out. For the circle model of localized competition, business stealing dominates and so there are too many firms. Loosely, prices fall quite slowly with entry in the circle model, meaning that too many firms are attracted.

Localized Competition

Vickrey (1964) can be credited with developing several important themes of spatial competition. He formulated the circle model, finding over-entry at the equilibrium, and noting that there may be multiple equilibria under localized competition because a new entrant must fit in a niche between existing firms. An entrant’s expected market space is substantially smaller than an incumbent’s. This effect is exacerbated because entrants rationally expect incumbent firms will react to new entry (in a new Bertrand–Nash price equilibrium) by cutting prices. Incumbents may earn substantially higher gross profits than the cost of entry that would be incurred by an entrant. There are then multiple equilibria. These range from the tightest packing at which incumbents just earn zero profits (and so are not induced to exit), to a loosest packing at which incumbents earn substantial profits (and entrants will not wish to set up).

The normative economics are very sensitive to the particular equilibrium selected. Typically, the equilibrium where the incumbents just make zero profits involves too many firms, while the loosest packing equilibrium involves too few firms. It is therefore crucial to determine which equilibrium is the reasonable description. The possibility of positive profits is also very important for market conduct because firms will strive to capture the rents attributable to advantageous locations. The deadweight losses due to rent seeking should be added to any inefficiency in location choice per se. Firms may commit capital early to a market that is growing over time in order to stake claim to locations that will later be profitable. Such capacity may be sunk before it is economically viable in terms of flow profit. The equilibrium locations are those of minimum packing (maximal spacing). However, a subsidy to encourage more entry might simply raise the amount of rents that are dissipated.

Thus, while performance under global competition may not generate much cause for concern, there may be substantial welfare losses in situations characterized by a strong degree of localized competition.

Further Applications

Product differentiation explains and resolves some other paradoxical results that obtain when products are assumed to be perfect substitutes. The *Diamond paradox* holds that the monopoly price prevails in the presence of small search costs even with many firms. Suppose consumers expected the monopoly price to be charged everywhere. Any firm pricing lower can raise its price and not lose consumers: a lower price attracts no consumers from other firms because a lower price is not expected. Any (rationally expected) price below the monopoly one is not an equilibrium because a firm can raise its price by an amount up to the search cost without losing any consumer who encounters it first. There is thus a striking discontinuity between the Bertrand and Diamond paradoxes as the search costs go from zero to a small positive value. Product differentiation smoothes the transition by allowing the consumers to shop for attributes other than purely price. A consumer may indeed find the price she expected at the first store sampled but still search further if she expects to find a better match. Her continued searching effectively brings firms into competition with each other. Firms therefore reduce prices to retain consumers who search for better matches.

The existence of a (pure strategy) price equilibrium in the original Hotelling model can be restored (through restoring profit function quasiconcavity) if there is sufficient non-locational product differentiation (through idiosyncratic preferences for products). This mechanism can restore the principle of minimum differentiation in locations, even with endogenous prices.

The standard Bertrand–Edgeworth pricing problem treats capacity constraints and, with homogenous products, has only mixed strategy equilibria. With sufficient product heterogeneity, pure strategy equilibria re-emerge since the benefits from undercutting are reduced. Likewise, standard models of positive network externalities typically exhibit multiple equilibria or no pure strategy equilibria. Unique pure strategy equilibria result with enough differentiation of products.

In international trade, product differentiation explains the empirical paradox of intra-industry trade; much bilateral trade is in the same product class. Furthermore, product differentiation is a source of gains from trade (in addition to the traditional comparative advantage in production and factor difference reasons) because of access to larger markets supporting more variety. Endogenous growth theory relies on product differentiation (typically with CES preferences or ‘quality ladders’ based on vertical differentiation) to rationalize continued research and development of new varieties. It is also a predominant feature as an agglomerative force in recent models of new economic geography. In macroeconomics, product differentiation models have been used to introduce imperfect competition. This is useful for providing micro-underpinnings to New Keynesian analysis. For example, in conjunction with ‘menu costs’ of switching prices, it gives rise to real effects to monetary policy.

Product Life Cycle

Steven Klepper

Abstract

The product life cycle connotes the idea that, comparable to humans and other organisms, new industries evolve through distinct and predictable stages. When industries are young, they are subject to high product innovation, rapid output growth, a build-up in the number of producers, and flux in firm market shares. As industries age, product innovation gives way to process innovation, output growth declines, the number of producers goes through a shakeout, and firm market shares stabilize. Evidence supporting this characterization is discussed and three alternative theoretical accounts of it are reviewed.

Keywords
Innovation; Market share; Product life cycle

The product life cycle (PLC) connotes the idea that industries evolve through distinct and predictable cycles, similar to the way humans and other organisms pass through distinct stages in their lives. Originally, the idea of a PLC was proposed in the marketing literature (Levitt 1965). Subsequently it became a rallying point for how a number of disciplines view the evolution of new industries, especially ones with rich opportunities for product and process innovation.

Typically, three stages of evolution are distinguished in the PLC (see Williamson 1975, pp. 215–16; Clark 1985; and Drew 1987, for prototypical depictions). In the first stage, uncertainty about user tastes and the means to satisfy them is high, product design is primitive, unspecialized machinery is used in production, and the volume of production is low. Many firms enter and compete on the basis of product innovation, offering different variants of the industry's product. In the next stage, output growth is high, the design of the product begins to stabilize, product innovation declines, specialized machinery is substituted for labour, and the production process becomes more refined. Entry slows and exit exceeds entry, leading to a shakeout of producers. In the final stage, the industry becomes mature. Output growth slows, product innovation becomes less significant, diversity in product offerings declines, firm market shares stabilize, entry remains low and the number of firms may continue to decline, and management, marketing and manufacturing techniques become more refined. The firms that are left in the market disproportionately tend to be those that entered early.

Industries

This conceptualization of the PLC has been heavily influenced by the history of the US automobile industry, which is summarized in Klepper and Simons (1997). Commercial production of automobiles in the United States began in 1895. By 1904 annual sales were only 22,800 cars, but from 1909 to 1919 the average annual growth in the number of automobiles sold was 25.8%, and well over a million cars were sold in 1919. Subsequently annual growth slowed to 11.5% through 1929 and then declined to lower levels after the Second World War and the recovery from the Great Depression. Entry initially was slow but then rose steadily through 1907, when it peaked at 82 firms. Two years later the number of firms peaked at 272. Subsequently entry declined precipitously, the number of firms steadily fell, and by 1941 only nine firms were left in the industry. Counts of product and process innovations indicate that product innovation peaked early in 1905 but process innovation increased steadily into the 1930s, with innovations such as the moving assembly line revolutionizing the production process. Firm market shares initially fluctuated greatly, but after 1910 the industry was dominated by Ford and General Motors. Based on data for 1895–1966 (Klepper 2002), early entry provided a decided advantage. Thirteen of the 219 entrants from 1895 to 1904 survived at least 30 years, as against 3 of the 271 entrants from 1905 to 1909 and none of the subsequent 275 entrants from 1910 through 1966.

The shakeout of producers in automobiles was extreme, but Klepper and Simons (1997) document similarly severe shakeouts in tyres, television receivers and penicillin. All experienced rapid initial output growth that subsided over time. All experienced considerable entry that eventually became negligible, after which the number of firms declined for many years. In all three products firm market shares stabilized over time and the long-term survival rate was decidedly greater for earlier entrants (Klepper 2002). The record of innovation in the three products is less well documented than in autos (Klepper and Simons 1997). Trends in product and process innovation in tyres were similar to autos. In televisions there were only two major product innovations, both of which occurred early, but labour productivity grew steadily, suggesting no decline over time in process innovation. In penicillin process preceded product innovation, but this was largely due to a government orchestrated war effort to reduce the cost of production of penicillin rather than market forces.

These three products were part of a larger sample of 46 new products studied by Gort and Klepper (1982) and later by Klepper and Graddy (1990), Agarwal and Gort (1996), and Agarwal (1998). The products were typically characterized by high initial growth in output that declined over time. Pronounced shakeouts were common in a majority of the 46 products. Agarwal and Gort (1996) found that early entrants had greater survival rates, although this was also true of very late entrants. No systematic evidence was compiled on product and process innovation, but Agarwal's (1998) findings suggest that products subject to greater technological change were more likely to experience shakeouts.

Theory

Numerous theories have been proposed to explain 'excessive entry' and shakeouts, but three stand out in their emphasis on technological change and thus their ability to address all aspects of the PLC.

Jovanovic and MacDonald (1994) develop a model of a new industry that is created by a major invention. Initially firms enter to develop the invention until expected profits are driven to zero. Subsequently another major invention occurs that opens up the possibility of an increase in the minimum efficient scale of production. It may induce immediate entry, but entrants are at a disadvantage relative to incumbents in developing the invention because of their lack of experience. Successful innovators expand their output to the new minimum efficient scale, pushing down the price of the product until non-innovators are forced to exit, which triggers a shakeout.

Utterback and Suarez (1993) envision that firms enter a new industry based on innovative designs for the industry's product. Eventually consumers and producers coalesce around a particular design for the industry's product that becomes a de facto product standard known as a dominant design. Product innovation is limited to incremental improvements in the dominant design, which makes entry more difficult. Process innovation increases because firms become less fearful that product innovation will make investments in the production process obsolete. Firms less successful at process innovation, which tend to be later entrants with less experience, exit. Coupled with the decline in entry, this gives rise to a shakeout.

Klepper (1996) develops a model of the evolution of a new industry in which firm growth is costly and firm size conditions the returns from process R&D. This imparts a competitive advantage to earlier entrants. Over time, entry and incumbent expansion causes industry output to rise and price to fall. Eventually this renders entry unprofitable and it ceases. Continued decreases in price compromise the profitability of the latest entrants, forcing them to exit, giving rise to a steady decline in the number of producers. As incumbents expand, they increase their expenditures on process R&D, causing a rise in process relative to product innovation. Firm price–cost margins also get compressed, which diminishes the incentives of firms to grow, causing firm market shares to become more stable and industry output growth to decline.

Testing of alternative accounts of the PLC is in its incipiency. Klepper and Simons (2005) found that in autos, tyres, televisions and penicillin, innovation was dominated by the leading firms and was a key determinant of firm survival, as predicted by all three theories. During the shakeouts in the four products, exit rates of early and late entrants generally did not converge, which is not consistent with the first two theories.

Variations

Not all technologically progressive industries follow the PLC (Klepper 1997). Notably, some industries have not experienced any sign of a shakeout after 35 years and show no sign of the decline in entry that is characteristic of shakeout industries. Two examples that were in Gort and Klepper's (1982) sample of 46 new products are styrene, which is a petrochemical, and lasers. In both industries firms have ended up specializing either vertically (styrene) or horizontally (lasers). In other industries, technological developments led to turnover in the leading firms, undermining the advantages of early entry. This occurred in the disk drive industry before it went through a shakeout (Christensen 1993). It also occurred in autos, tyres and televisions well after their shakeouts had begun, with long-time US leaders displaced by Japanese and European firms that capitalized on small cars, radial tyres and the use of semiconductors in televisions.

These examples make clear that the PLC is a composite that only describes the prototypical evolutionary path followed by new industries. It will be an ongoing challenge to document systematic departures from the PLC and to understand the forces that contribute to them. This process is just beginning.

Production and Cost Functions

Melvyn A. Fuss

The traditional starting point of production theory is a set of physical technological possibilities, often represented by a production or transformation function. The development of the theory parallels the firm's objective (cost minimization or profit maximization) and leads to input demands (and output supplies in the case of profit maximization) constructed from an explicit consideration of the underlying technology (i.e. derived directly from the production function).

An alternative approach to production theory is to start directly from observed economic data generated by markets – supplies, demands, costs and profits. In this case economic theory can be formulated in terms of the causal economic behaviour which is presumed to hold (cost minimization, profit maximization, revenue maximization, etc.), without the intervening constructive steps required in the traditional theory. The main advantage of such an approach is tractability. A direct approach to modelling the behavioural responses embodied in demand and supply functions simplifies the development of basic theoretical relationships and permits the specification and estimation of more complex production processes than is typically possible using the traditional, production function-based approach to production theory. This latter advantage is responsible for the virtual explosion of econometric estimation studies of production structures which have appeared in the last fifteen years based on the specification of economic behavioural relationships such as cost and profit functions.

It might appear that an approach to production theory based on economic observables such as cost would be less fundamental than one based on direct physical relationships. However, the theory of production duality establishes that, conditional on the optimizing behavioural response, the two approaches are equally fundamental and provide the same information about the production process. Using duality, any required characteristic of the underlying physical relationship can be uncovered from the observed economic variables.

In this entry I will concentrate on the duality between cost and production, although an analogous conceptual framework can be developed linking profit and production. Section "The Theory of Cost and Production Duality" presents the basic duality theorems which link cost and production functions as alternative, equally fundamental descriptions of the production technology. Section "History" provides a history of the development of the cost function approach to production theory. In section "Applications of Cost Functions" I survey several of the applications of the cost function approach which have appeared in the economic literature. The final section offers some concluding remarks.

The Theory of Cost and Production Duality

The *cost function* $C(\mathbf{y}, \mathbf{p}, \mathbf{z})$ is the *minimum* cost of producing a vector of outputs $\mathbf{y} = (y_1, \dots, y_M)$, when the firm faces a vector of exogenous input prices $\mathbf{p} = (p_1, \ \ldots, p_N)$, conditional on a set of exogenous characteristics of the production process $\mathbf{z} = (z_1, \ \ldots, z_R)$. The vector **z** represents a set of variables (other than outputs) over which the cost minimizing production unit (e.g. a firm) does not optimize. Examples include an index of technological change (usually a time trend) or the level of a fixed factor of production in a Marshallian short-run analysis. If the firm produces a single output *y*, and **p, z** are taken as fixed constants, then $C(\mathbf{y}, \mathbf{p}, \mathbf{z})$ reduces to the cost curve $C(y)$, a basic concept in elementary economic analysis.

Define the *production possibility set L.* to be the set of feasible input–output combinations **(x, y)** conditional on **z**. The boundary of *L.* can be represented by the *transformation function* ($F(\mathbf{y}, \mathbf{x}, \mathbf{z})$, where efficient production implies $F(\mathbf{y}, \mathbf{x}, \mathbf{z}) = 0$. In the case of a single output *y, F* = 0 can be solved for the *production function* $y = f(\mathbf{x}, \mathbf{z})$. The *input requirement set* $V(\mathbf{y}, \mathbf{z})$ is the set of all input bundles which can produce **y**, given **z**. The input requirement set corresponds to the conventional notion of an isoquant, but is well-defined for single or multiple output technologies. From the point of view of duality theory, it is convenient to represent the technology by the input requirement set rather than the production possibility set.

Duality theory between cost and production is based on the fact that if *V* or *F* possess certain properties, then *C* will possess a corresponding set of properties and vice versa. Consider the following set of regularity conditions on *V* and *F.* Suppose, conditional on **Z, V** is a nonempty closed, convex set characterized by free disposal of **x** or **y** (monotonicity). Alternatively, suppose (again conditional on **z**), that $F(\mathbf{y}, \mathbf{x}, \mathbf{z})$ is a real-valued continuous function which is monotone (increasing in **y** and decreasing in **x**) and quasi-convex in **y** and **x**. In the case of a single output *y,* the assumed properties of *F* imply that the production function $f(\mathbf{x}, \mathbf{z})$ will be, conditional on **z**, a real-valued continuous function which is monotone (increasing in **x**) and quasi-concave in **x**.

The Shephard (1953)–Uzawa (1964) duality theorems state that if *V* or *F* possess the above respective properties, then there will exist a cost function $C(\mathbf{y}, \mathbf{p}, \mathbf{z})$ with the following properties (contained on **z**):

(1) *C* is a positive real-valued function defined for all positive prices **p** and all positive producible outputs. In addition, $C(0, \mathbf{p}, \mathbf{z}) = 0$.
(2) *C* is non-decreasing in outputs and factor prices.
(3) *C* is a continuous function in y and **p**.
(4) *C* is a concave function in **p**.
(5) *C* is a linear homogeneous function in **p**.

The properties of the cost function with respect to **z** can be determined once one has knowledge of the nature of **z**. For example, in the case where **z** is a vector of fixed inputs, so *C* is a short-run variable (or restricted) cost function, *C* will be non-increasing, continuous and convex in **Z**.

The main force of the duality theorems is contained in the implication that, if we can specify a cost function possessing the regularity conditions enumerated in (1–5), then that cost function is guaranteed to embody a technology with the regularity properties specified above for *V, F* or *f.* In the words of McFadden (1978), p. 4), the duality between the cost function and the underlying production possibilities ‘establishes the cost function as a ‘sufficient statistic’ for all economically relevant characteristics of the underlying technology’.

While the duality theorems do not require differentiability for their validity, differentiability is almost always assumed in applications. Hence from this point on I will assume that *F* is twice differentiable in **(y, z)**, *f* is twice differentiable in **x**, and *C* is twice differentiable in **(p, y)**. Given differentiability, the cost function possesses two additional important properties:

(6) A derivative property known as Shephard’s (1953) Lemma, i.e.

$\frac{\partial C}{\partial p_i} = x_i,$

the cost-minimizing demand for the *i*th input, $x_i(\mathbf{p}, \mathbf{y}, \mathbf{z})$.
(7) A symmetry property analogous to the symmetry of the Slutsky matrix of consumer demand theory, i.e.

$$\frac{\partial^2 C}{\partial p_i \partial p_j} = \frac{\partial^2 C}{\partial p_j \partial p_i} \text{ or } \frac{\partial x_i}{\partial p_j} = \frac{\partial x_j}{\partial p_i}.$$

Shephard's Lemma can be used to derive systems of cost-minimizing input demand functions from arbitrarily specified cost functions possessing properties (1–5). The symmetry property can provide a test of the underlying cost minimization assumption or can be used to reduce the number of parameters which must be estimated in an econometric application, thus preserving degrees of freedom.

History

While the cost curve has a long history in economics, the cost and production functions literature is of relatively recent origin. Development of the literature had to await the understanding that an underlying production technology could be equivalently represented in either commodity or price space. Probably the first systematic approach to cost and production duality appears in two papers by Hotelling (1932, 1935). Hotelling analysed the problem of minimizing consumer expenditure subject to a utility level constraint, which is mathematically equivalent to the problem of minimizing cost subject to an output level constraint. He recognized the existence of a cost (expenditure) function concave in prices, introduced the profit function, and derived for the profit function a derivative property (Hotelling's Lemma) analogous to Shephard's Lemma. Hotelling also derived the symmetry conditions for the profit function which are analogous to those discussed above for the cost function.

The properties of expenditure functions were developed further by Roy (1942) and McKenzie (1957). The cost function and its properties were discussed in Samuelson (1947). Many of the developments in the modern theory and applications of cost and production functions have their origin in Shephard's (1953) pioneering book. Shephard exploited the theory of convex sets to establish rigorously the duality between cost and production functions. He also anticipated a number of the subsequent practical uses of duality theory: (1) as an aid in comparative statics analysis, (2) in econometric studies of production when cost and price data are more easily obtained than input data, and (3) as an aid in the analysis and use of aggregation conditions.

Additional early contributions to the duality theorems between *f* (or *F*) and *C* include McFadden (1978), Hanoch (1970, 1978) and Diewert (1971). Duality theorems between *V* (or *L*) and *C* have been proven by, among others, Uzawa (1964), McFadden (1966, 1978), Shephard (1970) and Diewert (1971).

The usefulness of cost functions and other dual functional forms (e.g. profit functions) in econometric applications was not recognized until Nerlove (1963) employed the Cobb–Douglas cost function in a study of returns to scale in the supply of electricity. The major impetus to empirical applications of cost functions occurred when Diewert (1969a, b) realized that cost functions representing more general production processes than the production functions then available for empirical analysis (e.g. Cobb–Douglas, C.E.S.) could be specified and easily estimated. From that realization came the popular Generalized Leontief (Diewert 1969a, b, 1971) and Translog (Christensen et al. 1970; 1973) functional forms. Later additions to the class of cost functions amenable to econometric estimation include: the normalized quadratic (Lau 1976), the Box-Cox (or generalized translog) (Brown et al. 1979), Berndt and Khaled 1979), and the Generalized McFadden (Diewert and Wales 1987).

In recent years there has been an enormous number of econometric applications of cost functions; far too many to list. Early applications which illustrated the advantages of the cost function approach for empirical analysis include Diewert (1969a), Fuss (1970, 1977b), Parks (1971), Burgess (1974) and Berndt and Wood (1975).

The duality approach of cost and production functions has begun to appear in the textbook literature. Textbooks currently in use which contain this method of analysis include Baumol (1977) and Varian (1984).

Applications of Cost Functions

In this section I will discuss two of the main applications of the cost function dual approach – to comparative statics and the specification of the characteristics of the production technology.

The Cost Function Approach to Comparative Statics

Suppose the cost function $C(\mathbf{y}, \mathbf{p}, \mathbf{z})$ is twice differentiable with respect to $\mathbf{p}$. Then since C is concave, the matrix of second order partial derivatives $\nabla^2_{pp}C$ is negative semi-definite, where

$$\nabla^2_{pp}C = \begin{bmatrix} \frac{\partial^2 C}{\partial p_1^2}, \frac{\partial^2 C}{\partial p_1 \partial p_2}, \ldots, \frac{\partial^2 C}{\partial p_1 \partial p_N} \\ \frac{\partial^2 C}{\partial p_2 \partial p_1} \\ \vdots \\ \frac{\partial^2 C}{\partial p_N \partial p_1}, \frac{\partial^2 C}{\partial p_N \partial p_2}, \ldots, \frac{\partial^2 C}{\partial p_N^2} \end{bmatrix} \qquad (1)$$

$$= \begin{bmatrix} \frac{\partial x_1}{\partial p_1}, \frac{\partial x_1}{\partial p_2}, \ldots, \frac{\partial x_1}{\partial p_N} \\ \frac{\partial x_2}{\partial p_1} \\ \vdots \\ \frac{\partial x_N}{\partial p_1}, \frac{\partial x_N}{\partial p_2}, \ldots, \frac{\partial x_N}{\partial p_N} \end{bmatrix}$$

The derivatives are to be interpreted as being evaluated at a particular cost-minimizing input bundle $x^*(\mathbf{p}^*, \mathbf{y}^*, \mathbf{z}^*)$, and to represent a small perturbation from $\mathbf{p}^*$. In particular, from the concavity property we have

$$\frac{\partial x_i}{\partial p_i} \leq 0, i = 1, \ldots, N \qquad (2)$$

which is known as the fundamental law of demand (input demand curves cannot slope upwards). Using Euler's theorem and the linear homogeneity of C yields the following restrictions on the derivatives of the input demand functions:

$$\left[\nabla^2_{pp}C\right] \cdot \mathbf{p} = \left[\nabla_p \mathbf{x}\right] \cdot p = 0. \qquad (3)$$

Finally we have (as before) the symmetry property of the second order partial derivatives of C, which implies a corresponding symmetry property for the derivatives of the input demand functions:

$$\frac{\partial^2 C}{\partial p_i \partial p_j} = \frac{\partial x_i}{\partial p_j} = \frac{\partial^2 C}{\partial p_j \partial p_i} = \frac{\partial x_j}{\partial p_i}. \qquad (4)$$

Cost-minimizing input demand functions must satisfy the comparative statics properties (2, 3, 4). One of the advantages of the cost function approach to production theory is the simplicity by which comparative statics can be analysed, in contrast with the original derivations (Hicks 1946; Samuelson 1947) which require the manipulation of bordered Hessian determinants.

A second type of comparative statics analysis which is facilitated by the cost function approach is the Marshallian short run–long run, or temporary equilibrium, approach to production modelling. Suppose $\mathbf{z}$ is now a vector of quasi-fixed inputs, fixed in the short run but variable in the long run. Examples of elements of $\mathbf{z}$ are capital plant and equipment and overhead labour. The cost function $C(\mathbf{p}, \mathbf{y}, \mathbf{z}) = C^s(\mathbf{p}, \mathbf{y}, \mathbf{z})$ is now a variable, or restricted, cost function and is interpreted as the minimum variable cost (in the short run) of producing $\mathbf{y}$, conditional on the level of quasi-fixed factors $\mathbf{z}$. The short-run input demand functions are obtained by applying Shephard's Lemma to C^s (i.e. differentiating C^s with respect to the prices of the variable factors p^i). Comparative statics in the short run is accomplished by applying to C^s the analysis contained in section "Applications of Cost Functions". The relationship between the short- and long-run cost functions and costminimizing input demand functions is obtained by noting that in long-run equilibrium the shadow values of the quasi-fixed factors, $-\nabla_z C^S$, must be equal to the market prices of these factors $\mathbf{q}$, i.e.

$$-\frac{\partial C^s}{\partial z_i} = q_i, i = 1, \ldots, R \qquad (5)$$

since the total cost of producing **y**,

$$\text{Totalcost} = C^s(\mathbf{p}, \mathbf{y}, \mathbf{z}) + \mathbf{q} \cdot \mathbf{z} \tag{6}$$

will be minimized with respect to **z** in the long run. Solving (5) for the long-run cost-minimizing levels of the quasi-fixed factors $\mathbf{z} = \mathbf{z}(\mathbf{p}, \mathbf{q}, \mathbf{y})$ and substituting in (6) provides the link between the long-run cost function $C^L(\mathbf{p}, \mathbf{q}, \mathbf{y})$ and the short-run cost function $C^s(\mathbf{p}, \mathbf{y}, \mathbf{z})$:

$$C^L(\mathbf{p}, \mathbf{q}, \mathbf{y}) = C^s[\mathbf{p}, \mathbf{q}, \mathbf{z}(\mathbf{p}, \mathbf{q}, \mathbf{y})] + \mathbf{q} \cdot \mathbf{z}(\mathbf{p}, \mathbf{q}, \mathbf{y}) \tag{7}$$

Differentiation of both sides of (7) with respect to elements of **p** or **y** provides the relationship between long-run and short-run comparative statics. For example,

$$\begin{aligned} \frac{\partial C^L}{\partial y_i} &= \frac{\partial C^s}{\partial y_i} + \sum_j \frac{\partial C^s}{\partial z_j} \cdot \frac{\partial z_j}{\partial y_i} + \sum_j q_j \frac{\partial z_j}{\partial y_i} \\ &= \frac{\partial C^s}{\partial y_i} + \sum_j \left[\frac{\partial C^s}{\partial z_j} + q_j \right] \cdot \frac{\partial z_j}{\partial y_i}. \end{aligned} \tag{8}$$

Equation (8) provides the relationship between long-run and short-run marginal costs. If the firm is in long-run equilibrium, then (5) holds and (8) reduces to the well-known equilibrium result that long-run and short-run marginal costs are equal.

The short run-long run illustration of temporary equilibrium analysis provides another example of the usefulness of the cost function methodology. Berndt and Fuss (1986) provide additional examples of the cost function approach to issues in temporary equilibrium. The ability to specify the cost function directly leads to important simplifications in analysing complex production processes.

The Specification of the Characteristics of Production

Economic effects such as scale, distribution, substitutability and technical change can be quantified in terms of the production function or the cost function and the first and second order derivatives of the respective function. Consider an n input production function $y = f(\mathbf{x}, t)$, where $\mathbf{x} = (x_1, \ldots, x_n)$ is a vector of inputs and t is an index of disembodied technical change. The corresponding cost function is $C = C(\mathbf{p}, y, t)$ where $\mathbf{p} = (p_1, \ldots, p_n)$. Table 1 contains a summary of the economic effects in terms of the production or cost function. The table contains $(n + 2)(n + 3)/2$ distinct effects which characterize the usual comparative statics properties of a production technology at a point in the input–output or input price–output space. The production function

Production and Cost Functions, Table 1 Economic effects and their relation to the production or cost function

Economic effect	Production function formula	Cost function formula	Number of distinct effects
Output or cost level	$y = f(x)$	$C = C(p, y, t)$	1
Returns to scale	$\mu = (\sum x_i f_i)/f$	$\mu = \frac{C}{y}/C_y$	1
Distributive share	$s_i = x_i f_i / \sum_1^n x_i f_i$	$s_i = C_i \cdot \frac{p_i}{C}$	$n - 1$
Own 'price' elasticity	$\varepsilon_i = x_i f_{ii}/f_i$	$\varepsilon_i = p_i C_{ii}/C_i$	n
Elasticity of substitution	$\sigma_{ij} = \frac{\left[-f_{ii}/f_i^2 + 2\left(f_{ij}/f_i f_j\right) - f_{jj}/f_j^2\right]}{\left[1/x_i f_i + 1/x_j f_j\right]}$	$\sigma_{ij} = \frac{C \cdot C_{ij}}{C_i C_j}$	$\frac{n(n-1)}{2}$
Rate of technical change	$T = f_t\ .\ /f$	$T = \ - C_t/C$	1
Acceleration of technical change	$\dot{T} = (f_{tt}/f) - (f_t/f)^2$	$\dot{T} = (C_t/C)^2 - (C_{tt}/C)$	1
Bias of technical change			
(i) rate of change of marginal products	$\dot{m}_i/m_i = f_{it}/f_i$		n
(ii) rate of change of cost shares		$\frac{\dot{s}_i}{s_i} = C_{it}/C_i - C_i/C$	n

Source: adapted from Fuss et al. (1978)

and its first two derivatives in (**x**, t) also comprise (n + 2)(n + 3)/2 distinct quantities; thus the production function formulae can be inverted to determine the function value and the first and second derivatives at a point in terms of economic effects. Since the cost function has n + 2 arguments in contrast to the n + 1 arguments of the production function, it may appear to permit a larger number of distinct effects involving first and second order derivatives. However, the restrictions on comparative static effects (from section "Applications of Cost Functions")

$$\sum_{i=1}^{n} p_i C_{ij} = 0, j = 1, \ldots, n \tag{9}$$

along with the additional restrictions

$$\sum_{i=1}^{n} p_i C_{yi} = c_y \tag{10}$$

$$\sum_{i=1}^{n} p_i C_{ti} = c_t \tag{11}$$

provide (n + 3) restrictions on the cost function and its derivatives. Therefore the number of distinct cost function conditions is

$$\frac{(n+3)(n+4)}{2} - (n+3) = \frac{(n+2)(n+3)}{2},$$

identical to the case of the production function. As before, the cost function formulae can be inverted to determine the function value and the first and second derivatives at a point.

The term *flexible functional form* has been applied to a production or cost function which has sufficient parameters to reproduce the (n + 2)(n + 3)/2 comparative statics effects at a point without imposing restrictions across these effects (Diewert 1974). The minimal number of parameters necessary for a functional form to be 'flexible' is (n + 2)(n + 3)/2, if unrestricted reproduction of the economic effects in Table 1 is to occur. Lau (1974) noted that a Taylor's series expansion to the second order would satisfy this criterion. For this reason cost functions which can be interpreted as second order approximations to an arbitrary cost function have become widely used in the empirical literature to estimate economic effects (or characteristics of the production structure). For example, the popular translog cost function (Berndt and Wood 1975; Fuss 1977a) approximates the logarithm of C(**p**, y, t) as a second order (quadratic) approximation in the logarithms of (**p**, y, t):

$$\begin{aligned}\log C &= \alpha_0 + \sum_{i=1}^{n} \alpha_i \log p_i + \alpha_y \log y + \alpha_t \log t \\ &+ \frac{1}{2}\left[\sum_i \alpha_{ii} (\log p_i)^2 + \alpha_{yy} (\log y)^2 + \alpha_{tt} (\log t)^2\right] \\ &+ \sum_i \sum_{\substack{j \\ i \neq j}} \alpha_{ij} \log p_i \log p_j + \sum_i \alpha_{iy} \log p_i \log y \\ &+ \sum_i \alpha_{it} \log p_i \log t + \alpha_{yt} \log y \log t\end{aligned} \tag{12}$$

The parameters of the cost function are

$$\alpha_0, \alpha_i, \alpha_y, \alpha_t, \alpha_{yy}, \alpha_{tt}, \alpha_{ij}, \alpha_{iy}, \alpha_{it}, \alpha_{yt}; \\ -\frac{(n+3)(n+4)}{2}$$

in number. The linear homogeneity regularity condition required of a cost function implies the following constraints on the parameters:

$$\begin{aligned}&\sum_i \alpha_i = 1; \sum_j \alpha_{ij} = 0, i = 1, \ldots, n; \\ &\sum_i \alpha_{iy} = 0; \sum_i \alpha_{it} = 0.\end{aligned} \tag{13}$$

Restrictions (13) imply (n + 3) parameter constraints; so that the number of free parameters of the translog cost function is

$$\frac{(n+3)(n+4)}{2} - (n+3) = \frac{(n+2)(n+3)}{2},$$

the minimal number required of a flexible functional form. The translog cost function formulae corresponding to the economic effects of Table 1 are set out in Table 2. One important characteristic of the translog cost function which is readily

Production and Cost Functions, Table 2 Economic effects and the translog cost function

Economic effect	Translog cost function formula
Cost level	$logC = logC(\log\mathbf{p}, logy, logt)$ as in (12)
Returns to scale	$\mu = \left[\alpha_y + \alpha_{yy}\log y + \sum_i \alpha_{iy}\log p_i + \alpha_{yt}\log t\right]^{-1}$
Distributive share	$s_i = \alpha_i + \sum_j \alpha_{ij}\log p_j + \alpha_{iy}\log y + \alpha_{it}\log t$
Own price elasticity	$\varepsilon_i = \left(\alpha_{ii} + s_i^2 - s_i\right)/s_i$
Elasticity of substitution	$\sigma_{ij} = (\alpha_{ij} + s_i s_j)/s_i s_j$
Rate of technical change	$T = -\frac{1}{t}\left[\alpha_t + \alpha_{tt}\log t + \sum_i \alpha_{it}\log p_i + \alpha_{yt}\log y\right]$
Acceleration of technical change	$y = f(x)$
Bias of technical change	$\frac{\dot{s}_i}{s_i} = \frac{1}{t}\left(\alpha_{it}/s_i\right)$

apparent from Table 2 is that the share equations s_i are linear in the parameters of the function. This fact means that the parameters of a system of input demand equations represented by $(n - 1)$ share equations (one equation is redundant since $\Sigma s_i = 1$) can be estimated using standard multivariate econometric estimation techniques. The addition of the cost function to the system does not complicate the estimation technique. This addition is necessary if all the economic effects listed in Table 2 are to be estimated.

Concluding Remarks

This entry has presented the theoretical rationale for the cost function approach to production theory – that, conditional on cost minimizing behaviour, production characteristics can be represented equivalently by production functions or cost functions. Since the cost function approach is often a simpler, more direct approach to production theory, this equivalence has led to an explosion of applications of the cost function methodology in the last fifteen years. This entry has only scratched the surface of the range of topics where the cost function approach has been exploited. Important applications include aggregation theory, the economic theory of index numbers, general equilibrium theory – especially as applied in the international trade literature, public finance topics such as optimal taxation, and industrial organization topics such as the existence of natural monopoly. More information concerning the above topics and detailed discussions of duality theory can be found in Fuss and McFadden (1978) and the survey articles Diewert (1974), (Diewert 1982), Nadiri (1982) and Jorgenson (1986).

Production as Indirect Exchange

Trout Rader

Relative to classical doctrines, neoclassical economics was distinguished early on by the addition of utility to the arsenal of theoretical tools, especially with respect to mathematical methods (e.g. Jevons (1871); Marshall (1890) and Walras (1874–7) as a supplement to such as Adam Smith (1776), Ricardo (1817) and Cournot (1838). In his *Éléments*, Walras conjectured that grouping or *tâtonnement* led to general equilibrium where supply equalled demand for each, even in a manycommodity, many-dimensioned world. Also utility was shown to be equivalent to abstract properties of preferences on bundles of consumer goods (Hicks and Allen 1934). For example, not only was choice by rational agents expostulated but, consistent with modern psychoanalysis or its milder variants, many non-rationalities were permitted Sonnenschein 1971 and Shafer 1974). Thereby application of economics was greatly expanded to cover non-transitive preferences.) However, the story did not end there.

Induced Preferences on Trade

With my thesis on Edgeworth's *Mathematical Psychics* (1881) I began a long study of the foundations of trade. Along these lines the tool from economic theory of interest is that which, on the basis of the underlying preferences and production technology, imputes consumer wellbeing to trades with properties in common usage by theorists (Rader 1963; 1964). The basic problem then is to evaluate feasible *trade* vectors, $T = \{t: t \in W + Y\}$, where Y is the *general* production possibility set (positive coordinates for outputs, negative for inputs) and W the initial endowments. The induced preference ordering is $s \succ_i$ t, i.e. agent i prefers proposed exchange s to trade t, if given s, the optimal attainable final consumption is preferred to all attainable consumptions given t. In turn for this to be sensible we should know that the optimum exists for all s (and t as well), which is known if the relevant set of trades is compact and either

(1) $\succ_i$ is transitive and irreflexive and the complement of $P_i(S) = \{t: t \succ_i S\}$ is open or, unexpectedly,
(2) Y is convex, compact, $\succ_i$ is irreflexive and complete (i.e. total) and $P_i(x)$ is convex, $P_i(s)$ is open as is its complement (Sonnenschein 1971).

Condition (1) follows for a consumer who evaluates final consumption by an upper semicontinuous, quasi-concave utility function. For instance, not only condition (1) but a relevant part of (2) is implied by the strong property of a concave utility function. However (2) applies much more widely, even to whole economies with social preferences where the properties except for transitivity are sometimes canonical (as will be seen), or perhaps more bizarrely even to political preferences based on such as majority rule which is well known to be intransitive (cf. Kramer 1972). By this construction there is a transparent derivation of induced preferences, with or without transitivity depending on which case (1) or (2) applies (Rader 1978a). In effect, *for every economy with exchange, there are preferences on trades whereupon given convexity and such, we can theorize for the whole as though there were only pure exchange*. The construction is such that basic ordering, continuity, and convexity properties can be derived and results known for exchange economies go over even if production is applied. Consequently many results of welfare economies of pure exchange are imputed to production – exchange economies by the foregoing *Principle of Equivalence*, e.g. implied is the old Fundamental Theorem of Welfare Economics that shows the equivalence of equilibrium with Pareto optimality (Gale and Mas-Colell 1977 or the newer result, Edgeworth's conjecture stated in his *Mathematical Psychics* to the effect that equilibrium is exactly that state for a large economy which does no worse for a subgroup than the group's best in autarky (Scarf 1962; Aumann 1964; Debreu and Scarf 1963). As such the Equivalence is a unification of otherwise apparently disparate materials.

Application to Hedonic Theory

This and the next three sections present applications. First, induced preferences can be applied in a Lancaster (1966) set-up where goods are demanded not for their own sake but for their underlying characteristics. Then preferences on goods are not inherent but in turn, induced. Therefore there is the sequence,

$$\text{production} + \text{initial wealth} \rightarrow \text{characteristics} \rightarrow \text{consumption},$$

and preferences are (potentially) defined in reverse at each stage. Furthermore at each stage, properties are inherited from those preceding. Mathematically, except for elementary and straightforward (if at times unexpected) syllogisms, the main relevant tools are those of the theory of linear topological spaces and more commonly finite dimensional vector spaces. This involves among other things the generalized matrix inverse used in statistics (Graybill 1969), and the formal equality of algebraic internality and topological interiority (Kelley and Namioka 1963).

Pairwise Optimality

In the case of bilateral trade, the achievement of optimality among pairs, *pairwise optimality*, often implies Pareto or consumer efficiency. By our analysis, this will apply to consumerproducers as well as those with fixed endowments. The basic requirement is interconnectedness of potential trade gains and quasi-concavity of induced utility, ore more generally convexity of induced preferences (see Rader 1968; also Polterovich 1970; and Goldman and Starr 1982, or such as ensured by the existence of a 'money good' always of use to all consumers (cf. Feldman 1973). (A unified treatment using Helly's theorem for sets was offered by Madden in 1975.) In cases of non-convexity there will still be mutual tangency of indifference hypersurfaces. By smoothness of underlying preferences, the induced preferences are smooth and by definition, there the tangent hyperplane is uniquely determined, a property inherited from the earlier stages (Rader 1976). The normal to this hyperplane defines prices and for optimality they must be equal for different consumers (since otherwise there would be exploited gains to supplementary trade). However, there is nothing to ensure that the consequent value of final consumption does or even can equal the value of initial wealth. Hence optimal trades may entail Pareto superior gifts, a subject of current research interest especially with regard to inter-country transfers, such as reparations or foreign aid (J.M. Keynes 1919; Leontief 1936; Samuelson 1952, 1954).

World Trade and Transfers

A direct application is to countries in international commerce, following Meade (1955) or Chipman (1979), each with community preferences of his own. Under a regime of free trade not only are prices equalized of final goods between countries but often so are per-unit factor costs, even for those that are immobile, so called factor price equalization (Rader 1977, 1978b; (I now prefer the phrase factor cost equalization). Therefore results for distribution of factor shares are implied as well.

The theory described above is at a relatively general level. However, there are cases of special interest. For example, if all consumers have gross substitutable demand so that an increase in one price always increases excess demand for the other goods then, even though not social utility maximizing, the economy's excess demand locally satisfies the weak law of revealed preference,

$$\delta P \Delta e < 0$$

where $e =$ excess demand and $p =$ generalized price (the vector p includes not only prices of manufactured goods but also unit costs of productive factors.)

Suppose e is chosen at p, $\bar{e}$ at $\overline{p}$. Then the weak axiom of revealed preference (WA) is that e affordable at $\overline{p}$ implies $\bar{e}$ is too expensive at p ($p\bar{e} > 0 = pe$).

Specifically, suppose the economy is partitioned into two sectors, one for consumers with gross substitutable demand and the other consisting of profit maximizing firms, then *near any equilibrium* (WA) *holds*, as stated in Rader (1972). Furthermore in this instance (WA) is easily verified for all other p near equilibrium. Also the weak law (WA) follows if consumer-traders of a given taste class are distributed with respect to expenditures over a line interval beginning at zero *expense* and ending at zero *frequency*, the frequency always non-increasing (Hildenbrand 1983). In still another case, the economy behaves as if it were one transitive consumer. It is required that all traders are homothetic and that expenditures are in constant proportions, one to the other, and the strong law (SA) is said to hold (Chipman 1974).

In these various instances, the whole economy acts like a single representative consumer with various rationality properties. The Marshallian idealization where marginal utility of income or money is assumed constant so that the whole acts like a single consumer is more than metaphor that permits aggregation of consumer demand. The 'offer' curve is indeed the result of social optimization and also choice is still the intersection of the community feasibility set with a social indifference hypersurface. It is only that disjoint surfaces may intersect, reflecting the absence of transitivity.

Transaction Costs

One particular technology which was mentioned in Debreu (1959, ch. 7) has, evidently independently, received much attention and continues to have prospects, namely that of the technology of transferring a good from one location to another or more generally, transaction costs (cf. Coase 1960). Since the conditions sufficient for induced preferences to be upper-semi continuous are very weak, the set of Pareto optima is very likely non-empty. However, if the technical possibilities do not form a convex set, whence induced preferences on trades may not be convex even when those for direct consumption are, then the welfare equivalence between optimality and equilibrium may not be, whence non-competition may be appropriate.

Production Functions

Dale W. Jorgenson

Abstract

Traditionally, the production function was assumed to be additive and homogeneous. The constant elasticity of substitution (CES) production function adds flexibility by treating the elasticity of substitution as an unknown parameter, but retains the assumptions of additivity and homogeneity and imposes very stringent limitations on patterns of substitution. The dual formulation of production theory characterizes the production function by means of a dual representation such as a price or cost function, and generates explicit demand and supply functions as derivatives of the price or cost function.

Introduction

The economic theory of production – as presented in such classic treatises as Hicks's *Value and Capital* (1946) and Samuelson's *Foundations of Economic Analysis* (1983) – is based on the maximization of profit, subject to a production function. The objective of this theory is to characterize demand and supply functions, using only the restrictions on producer behaviour that arise from optimization. The principal analytical tool employed for this purpose is the implicit function theorem.

The traditional approach to economic modelling of producer behaviour begins with the assumption that the production function is additive and homogeneous.

Under these restrictions demand and supply functions can be derived explicitly from the production function and the necessary conditions for producer equilibrium. However, this approach has the disadvantage of imposing constraints on patterns of producer behaviour – thereby frustrating the objective of determining these patterns empirically.

The traditional approach was originated by Cobb and Douglas (1928) and was employed in empirical research by Douglas (1948, 1967, 1976) and his associates for almost two decades. The limitations of this approach were made strikingly apparent by Arrow et al. (1961, henceforward ACMS), who pointed out that the Cobb–Douglas production function imposes a priori restrictions on patterns of substitution among inputs. In particular, elasticities of substitution among all inputs must be equal to unity.

The constant elasticity of substitution (CES) production function introduced by ACMS adds flexibility to the traditional approach by treating the elasticity of substitution as an unknown parameter. However, the CES production function retains the assumptions of additivity and homogeneity and imposes very stringent limitations on patterns of substitution. McFadden (1963) and Uzawa (1962) have shown, essentially, that elasticities of substitution among all inputs must be the same.

The dual formulation of production theory has made it possible to overcome the limitations of the traditional approach to econometric modelling. This formulation was introduced by Hotelling (1932) and later revived and extended by Samuelson (1953, 1960) and Shephard (1953, 1970). The key features of the dual formulation are, first, to characterize the production function by means of a dual representation such as a price or cost function, and second, to generate explicit demand and supply functions as derivatives of the price or cost function.

Patterns of producer behaviour can be described most usefully in terms of the behaviour of the derivatives of demand and supply functions. For example, measures of substitution can be specified in terms of the response of demand patterns to changes in input prices. Similarly, measures of technical change can be specified in terms of the response of these patterns to changes in technology. The classic formulation of production theory at this level of specificity can be found in Hicks's *Theory of Wages* (1963).

Hicks (1963) introduced the elasticity of substitution as a measure of substitutability. The elasticity of substitution is the proportional change in the ratio of two inputs with respect to a proportional change in their relative price. Similarly, Hicks introduced the bias of technical change as a measure of the impact of changes in technology on patterns of demand for inputs. The bias of technical change is the response of the share of an input in the value of output to a change in the level of technology.

By treating measures of substitution and technical change as fixed parameters the system of demand and supply functions can be generated by integration. Provided that the resulting functions are themselves integrable, the underlying price or cost function can be obtained by a second integration. As we have already pointed out, Hicks's elasticity of substitution is unsatisfactory for this purpose, since it leads to arbitrary restrictions on patterns of producer behaviour.

The introduction of a new measure of substitution, the share elasticity, by Christensen et al. (1971, 1973) and Samuelson (1973) has made it possible to overcome the limitations of parametric forms based on constant elasticities of substitution. Share elasticities, like biases of technical change, can be defined in terms of shares of inputs in the value of output. The share elasticity of a given input is the response of the share of that input to a proportional change in the price of an input.

Models of Producer Behaviour

The purpose of this section is to present the simplest form of the economic theory of production. We base this theory on a production function with constant returns to scale. Producer equilibrium implies the existence of a price function, giving the price of output as a function of the prices of inputs and the level of technology. The price function is dual to the production function and provides an alternative and equivalent description of technology.

An econometric model of producer behaviour takes the form of a system of simultaneous equations, determining the distributive shares of the inputs and the rate of technical change as functions of the input prices and the level of technology. Measures of substitution and technical change give the responses of the distributive shares and the rate of technical change to changes in prices and technology. To generate an econometric model of producer behaviour we treat these measures as unknown parameters to be estimated.

In order to present the theory of production we first require some notation. We denote the quantity of output by y and the quantities of J inputs by $x_j(j = 1, 2, \ldots, J)$. Similarly, we denote the price of output by q and the prices of the J inputs by $p_j(j = 1, 2, \ldots, J)$. We find it convenient to employ vector notation for the input quantities and prices:

$x = (x_1, x_2, \ldots, x_J)$ – vector of input quantities.

$p = (p_1, p_2, \ldots, p_J)$ – vector of input prices.

We assume that the technology can be represented by a *production* function, say *F*, where:

$$y = F(x, t), \tag{1}$$

and t is an index of the level of technology. In the analysis of time series data for a single producing unit the level of technology can be represented by time. In the analysis of cross-section data for different producing units the level of technology can be represented by one-zero dummy variables corresponding to the different units. We can define the *shares* of inputs in the value of output by:

$$v_j = \frac{p_j x_j}{qy}, (j = 1, 2, \ldots, J).$$

Under competitive markets for output and all inputs the necessary conditions for producer equilibrium are given by equalities between the share of each input in the value of output and the elasticity of output with respect to that input:

$$v = \frac{\partial \ln y(x, t)}{\partial \ln x}, \tag{2}$$

where:

$v = (v_1, v_2, \ldots, v_J)$ – vector of value shares.

$\ln x = (\ln x_1, \ln x_2, \ldots, \ln x_J)$ – vector of logarithms of input quantities.

Under constant returns to scale the elasticities and the value shares for all inputs sum to unity:

$$i'v = i' \frac{\partial \ln y}{\partial \ln x} = 1,$$

where i is a vector of ones. The value of output is equal to the sum of the values of the inputs.

Finally, we can define the *rate of technical change*, say v_t, as the rate of growth of the quantity of output holding all inputs constant:

$$v_t = \frac{\partial \ln y(x, t)}{\partial t}. \tag{3}$$

It is important to note that this definition does not impose any restriction on patterns of substitution among inputs.

Given the identity between the value of output and the value of all inputs and given equalities between the value share of each input and the elasticity of output with respect to that input, we can express the price of output as a function, say *Q,* of the prices of all inputs and the level of technology:

$$q = Q(p, t). \tag{4}$$

We refer to this as the *price* function for the producing unit.

The price function Q is dual to the production function F and provides an alternative and equivalent description of the technology of the producing unit. We can formalize this description in terms of the following properties of the price function:

(1) *Positivity.* The price function is positive for positive input prices.
(2) *Homogeneity.* The price function is homogeneous of degree one in the input prices.
(3) *Monotonicity.* The price function is increasing in the input prices.
(4) *Concavity.* The price function is concave in the input prices.

Given differentiability of the price function, we can express the value shares of all inputs as elasticities of the price function with respect to the input prices:

$$v = \frac{\partial \ln q(p, t)}{\partial \ln p}, \tag{5}$$

where:

ln p = (lnp$_1$, lnp$_2$, lnp$_J$) – vector of logarithms of input prices.

Since the price function is increasing in the input prices the value shares must be non-negative.

We can express the negative of the rate of technical change as the rate of growth of the price of output, holding the prices of all inputs constant:

$$-v_t = \frac{\partial \ln q(p, t)}{\partial t}. \tag{6}$$

Since the price function Q is homogeneous of degree one in the input prices, the value shares and the rate of technical change are homogeneous of degree zero and the value shares sum to unity.

We have represented the value shares of all inputs and the rate of technical change as functions of the input prices and the level of technology. We can introduce measures of substitution and technical change to characterize these functions in detail. For this purpose we differentiate the logarithm of the price function twice with respect to the logarithms of input prices to obtain measures of substitution:

$$U_{pp} = \frac{\partial^2 \ln q(p, t)}{\partial \ln p^2} = \frac{\partial v(p, t)}{\partial \ln p}. \tag{7}$$

We refer to the measures of substitution (7) as *share elasticities,* since they give the response of the value shares of all inputs to proportional changes in the input prices. If a share elasticity is positive, the corresponding value share increases with the input price. If a share elasticity is negative, the value share decreases with the input price. Finally, if a share elasticity is zero, the value share is independent of the price.

Second, we can differentiate the logarithm of the price function twice with respect to the logarithms of input prices and the level of technology to obtain measures of technical change:

$$u_{pt} = \frac{\partial^2 \ln q(p, t)}{\partial \ln p \partial t} = \frac{\partial v}{\partial t} = -\frac{\partial v_t(p, t)}{\partial \ln p}. \tag{8}$$

We refer to these measures as *biases of technical change.* If a bias of technical change is positive, the corresponding value share increases with a change in the level of technology and we say that technical change is *input-using.* If a bias of technical change is negative, the value share decreases with a change in technology and technical change is *input-saving.* Finally, if a bias is zero, the value share is independent of technology; in this case we say that technical change is *neutral* (in the sense of Hicks).

Alternatively, the vector of biases of technical change u_{pt} can be employed to derive the implications of changes in input prices for the rate of technical change. If a bias of technical change is positive, the rate of technical change decreases with the input price. If a bias is negative, the rate of technical change increases with the input price. Finally, if a bias is zero so that technical change is neutral, the rate of technical change is independent of the price.

To complete the description of technical change we can differentiate the logarithm of the price function twice with respect to the level of technology:

$$u_{tt} = \frac{\partial^2 \ln q(p,t)}{\partial t^2} = -\frac{\partial v_t(p,t)}{\partial t} \tag{9}$$

We refer to this measure as the *deceleration* of technical change, since it is the negative of rate of change of the rate of technical change. If the deceleration is positive, negative, or zero, the rate of technical change is decreasing, increasing, or independent of the level of technology.

The matrix of second-order logarithmic derivatives of the logarithm of the price function Q must be symmetric. This matrix includes the matrix of share elasticities U_{pp}, the vector of biases of technical changes u_{pt}, and the deceleration of technical change u_{tt}. Concavity of the price function in the input prices implies that the matrix of second-order derivatives, say H, is nonpositive definite, so that the matrix $U_{pp} + vv' - V$ is nonpositive definite, where:

$$\frac{1}{q} N \cdot H \cdot N = U_{pp} + vv' - V;$$

the price of output q is positive and the matrices N and V are diagonal:

$$N = \begin{bmatrix} p_1 & 0 & \ldots & 0 \\ 0 & p_2 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \ldots & p_J \end{bmatrix}, \quad V = \begin{bmatrix} \upsilon_1 & 0 & \ldots & 0 \\ 0 & \upsilon_2 & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \cdots & \upsilon_J \end{bmatrix}$$

We can define substitution and complementarity of inputs in terms of the matrix of share elasticities U_{pp} and the vector of value shares v. We say that two inputs are *substitutes* if the corresponding element of the matrix $U_{pp} + vv' - V$ is negative. Similarly, we say that two inputs are *complements* if the corresponding element of this matrix is positive. If the element of this matrix corresponding to the two inputs is zero, we say that the inputs are *independent.* The definition of substitution and complementarity is symmetric in the two inputs, reflecting the symmetry of the matrix $U_{pp} + vv' - V$. If there are only two inputs, nonpositive definiteness of this matrix implies that the inputs cannot be complements.

To generate an econometric model of producer behaviour a natural approach is to treat the measures of substitution and technical change as unknown parameters to be estimated. For this purpose we introduce the parameters:

$$B_{pp} = U_{pp}, \beta_{pt} = u_{pt}, \beta_{tt} = u_{tt}, \tag{10}$$

where B_{pp} is a matrix of constant share elasticities, β_{pt} is a vector of constant biases of technical changes, and β_{tt} is a constant deceleration of technical change.

We can regard the matrix of share elasticities, the vector of biases of technical change, and the deceleration of technical change as a system of second-order partial differential equations. We can integrate this system to obtain a system of first-order partial differential equations:

$$\begin{aligned} v &= \alpha_p + B_{pp} \ln p + \beta_{pt} \cdot t, \\ -v_t &= \alpha_t + \beta'_{pt} \ln p + \beta_{tt} \cdot t, \end{aligned} \tag{11}$$

where the parameters –α_p, α– are constants of integration.

To provide an interpretation of the parameters – α_p, α_t – we first normalize the input prices. We can set the prices equal to unity where the level of technology t is equal to zero. This represents a choice of origin for measuring the level of technology and a choice of scale for measuring the quantities and prices of inputs. The vector of parameters α_p is the vector of value shares and the parameter α_t is the negative of the rate of technical change where the level of technology t is zero.

Similarly, we can integrate the system of first-order partial differential equations (11) to obtain the price function:

$$\ln p = \alpha_0 + \alpha_p' \ln p + \alpha_t \cdot t + \frac{1}{2} \ln p' B_{pp} \ln p \\ + \ln p' \beta_{pt} \cdot t + \frac{1}{2} \beta_{tt} \cdot t^2, \qquad (12)$$

where the parameter α_0 is a constant of integration. Normalizing the price of output so that it is equal to unity where t is zero, we can set this parameter equal to zero. This represents a choice of scale for measuring the quantity and price of output.

For the price function (12) the price of output is a transcendental or, more specifically, an exponential function of the logarithms of the input prices. We refer to this form as the *transcendental logarithmic* price function or, more simply, the translog price function, indicating the role of the variables. We can also characterize this price function as the *constant share elasticity* or CSE price function, indicating the role of the fixed parameters. In this representation the scalars – α_t, β_{tt} – the vectors – α_p, β_{pt} – and the matrix B_{pp} are constant parameters that reflect the underlying technology. Differences in levels of technology among time periods for a given producing unit or among producing units at a given point of time are represented by differences in the level of technology t.

Economies of Scale

In section "Models of Producer Behaviour" we have considered producer behaviour under constant returns to scale. In this section we consider producer behaviour under increasing returns to scale. Under increasing returns and competitive markets for output and all inputs, producer equilibrium is not defined by profit maximization, since no maximum of profit exists. However, in regulated industries the price of output is set by regulatory authority. Given demand for output as a function of the regulated price, the level of output is exogenous to the producing unit.

With output fixed from the point of view of the producer, necessary conditions for equilibrium can be derived from cost minimization. Where total cost is defined as the sum of expenditures on all inputs, the minimum value of cost can be expressed as a function of the level of output and the prices of all inputs. We refer to this function as the cost function. We have described the theory of production under constant returns to scale in terms of properties of the price function (3); similarly, we can describe the theory under increasing returns in terms of properties of the cost function.

Utilizing the notation of section "Models of Producer Behaviour", we can define total cost, say c, as the sum of expenditures on all inputs:

$$c = \sum_{j=1}^{J} p_j x_j.$$

We next define the shares of inputs in total cost by:

$$v_j = \frac{p_j x_j}{c}, (j = 1, 2, \ldots, J).$$

With output fixed from the point of view of the producing unit and competitive markets for all inputs, the necessary conditions for producer equilibrium are given by equalities between the shares of each input in total cost and the ratio of the elasticity of output with respect to that input and the sum of all such elasticities:

$$v = \frac{\dfrac{\partial \ln y}{\partial \ln x}}{i' \dfrac{\partial \ln y}{\partial \ln x}}, \qquad (13)$$

where i is a vector of ones and:

$$v = (v_1, v_2, \ldots, v_J) - \text{vector of cost shares.}$$

Given the definition of total cost and the necessary conditions for producer equilibrium, we can express total cost, say c, as a function of the prices of all inputs and the level of output:

$$c = C(p, y). \qquad (14)$$

We refer to this as the *cost* function. The cost function C is dual to the production function F and provides an alternative and equivalent description of the technology of the producing unit.

We can formalize the theory of production in terms of the following properties of the cost function:

(1) *Positivity.* The cost function is positive for positive input prices and a positive level of output.
(2) *Homogeneity.* The cost function is homogeneous of degree one in the input prices.
(3) *Monotonicity.* The cost function is increasing in the input prices and in the level of output.
(4) *Concavity.* The cost function is concave in the input prices.

Given differentiability of the cost function, we can express the cost shares of all inputs as elasticities of the cost function with respect to the input prices:

$$v = \frac{\partial \ln c(p, y)}{\partial \ln p}. \tag{15}$$

Since the cost function is increasing in the input prices, the cost shares must be nonnegative.

We can define an index of returns to scale as the elasticity of the cost function with respect to the level of output:

$$v_y = \frac{\partial \ln c}{\partial \ln y}(p, y). \tag{16}$$

Following Frisch (1965), we can refer to this elasticity as the *cost flexibility.* The cost function is increasing in the level of output, so that the cost flexibility is positive. Since the cost function C is homogeneous of degree one in the input prices, the cost shares and the cost flexibility are homogeneous of degree zero and the cost shares sum to unity.

The cost flexibility v_y is the reciprocal of the *degree of returns to scale*, defined as the elasticity of output with respect to a proportional increase in all inputs:

$$v_y = \frac{1}{i' \dfrac{\partial \ln y}{\partial \ln x}}. \tag{17}$$

If output increases more than in proportion to the increase in inputs, cost increases less than in proportion to the increase in output.

We have represented the cost shares of all inputs and the cost flexibility as functions of the input prices and the level of output. We can characterize these functions in terms of measures of substitution and economies of scale. We obtain *share elasticities* by differentiating the logarithm of the cost function twice with respect to the logarithms of input prices:

$$U_{pp} = \frac{\partial^2 \ln c(p, y)}{\partial \ln p^2} = \frac{\partial v(p, y)}{\partial \ln p}. \tag{18}$$

These measures of substitution give the response of the cost shares of all inputs to proportional changes in the input prices.

Second, we can differentiate the logarithm of the cost function twice with respect to the logarithms of the input prices and the level of output to obtain measures of economies of scale:

$$\begin{aligned} u_{py} &= \frac{\partial^2 \ln c(p, y)}{\partial \ln p \partial \ln y} = \frac{\partial v(p, v)}{\partial \ln y} \\ &= -\frac{\partial v_y(p, y)}{\partial \ln p}. \end{aligned} \tag{19}$$

We refer to these measures as *biases of scale.* The vector of biases of scale u_{py} can be employed to derive the implications of economies of scale for the relative distribution of total cost among inputs. Alternatively, this vector can be employed to derive the implications of changes in input prices for the cost flexibility. To complete the description of economies of scale we can differentiate the logarithm of the cost function twice with respect to the level of output:

$$u_{yy} = \frac{\partial^2 \ln c(p, y)}{\partial \ln y^2} = \frac{\partial v_y(p, y)}{\partial \ln y}. \tag{20}$$

The matrix of second-order logarithmic derivatives of the logarithms of the cost function C must be symmetric. This matrix includes the matrix of share elasticities U_{pp}, the vector of biases of scale u_{py}, and the derivative of the cost flexibility with respect to the logarithm of output u_{yy}. Concavity of the cost function in the input prices implies that the matrix of second-order derivatives, say H, is nonpositive definite, so that the matrix $U_{pp} + vv' - V$ is nonpositive definite, where:

$$\frac{1}{c} N \cdot H \cdot N = U_{pp} + vv' - V.$$

Total cost c is positive and the diagonal matrices N and V are defined in terms of the input prices p and the cost shares v, as in section "Models of Producer Behaviour".

We say that the cost function C is *homothetic* if and only if the cost function is separable in the prices of all J inputs $\{p_1, p_2, \ldots, p_J\}$, so that:

$$c = C[P(p_1, p_2, \ldots, p_J), y], \tag{21}$$

where the function P is homogeneous of degree one and independent of the level of output y. The cost function is homothetic if and only if the production function is *homothetic,* where:

$$y = F[G(x_1, x_2, \ldots, x_J)], \tag{22}$$

where the function G is homogeneous of degree one.

Since the cost function is homogeneous of degree one in the input prices, it is homogeneous of degree one in the function P, which can be interpreted as the price index for a single aggregate input; the function G is the corresponding quantity index. Furthermore, the cost function can be represented as the product of the price index of aggregate input P and a function, say H, of the level of output:

$$c = P(p_1, p_2, \ldots, p_J) \cdot H(y). \tag{23}$$

Under homotheticity, the cost flexibility v_y is independent of the input prices:

$$v_y = \frac{\partial \ln H}{\partial \ln y}(y). \tag{24}$$

If the cost flexibility is also independent of the level of output, the cost function is homogeneous in the level of output and the production function is homogeneous in the quantity index of aggregate input G. The degree of homogeneity of the production function is the degree of returns to scale and is equal to the reciprocal of the cost flexibility. Under constant returns to scale the degree of returns to scale and the cost flexibility are equal to unity.

We can generate an econometric model of cost and production by introducing the parameters:

$$B_{pp} = U_{pp}, \beta_{py} = u_{py}, \beta_{yy} = u_{yy}, \tag{25}$$

where B_{pp} is a matrix of constant share elasticities, β_{py} is a vector of constant biases of scale, and β_{yy} is a constant derivative of the cost flexibility with respect to the logarithm of output. We can treat the matrix of constant parameters as a system of second-order partial differential equations, obtaining:

$$\begin{aligned} v = \alpha_p + B_{pp} \ln p + \beta_{py} \ln y,\ v_y \\ = \alpha_y + \beta'_{py} \ln p + \beta_{yy} \ln y, \end{aligned} \tag{26}$$

where the parameters – α_p, α_y – are constants of integration.

We can integrate the system (26) to obtain the cost function:

$$\begin{aligned} \ln c = \alpha_0 + \alpha_p \ln p + \alpha_y + \frac{1}{2} \ln p' B_{pp} \ln p \\ + \ln p' \beta_{py} \ln y + \frac{1}{2} \beta_{yy} (\ln y)^2, \end{aligned} \tag{27}$$

where the parameter $-\alpha_0$ is a constant of integration. We can refer to this form as the translog cost function, indicating the role of the variables, or the constant share elasticity (CSE) cost function, indicating the role of the parameters.

Under homotheticity the cost flexibility is independent of the input prices. A necessary and sufficient condition for homotheticity is given by:

$$\beta_{py} = 0; \tag{28}$$

the vector of biases of scale is equal to zero. Under homogeneity the cost flexibility is also independent of output, so that:

$$\beta_{yy} = 0;$$

the derivative of the flexibility with respect to the logarithm of output is zero. Finally, under constant returns to scale, the cost flexibility is equal to unity; given the restrictions implied by homotheticity, constant returns requires:

$$\alpha_y = 1. \qquad (29)$$

Summary and Conclusion

The econometric modelling of producer behaviour requires parametric forms for demand and supply functions. Patterns of production can be represented in terms of unknown parameters that specify the responses of demands and supplies to changes in prices, technology and scale. New measures of substitution, technical change and economies of scale have provided greater flexibility in the empirical determination of production patterns. These innovations have arisen from the dual formulation of the theory of production.

We can conclude by suggesting possible directions for future research. The primary focus of our discussion has been on the characterization of technology for individual producing units. Application of the results typically involves models for both demand and supply of a given commodity. The ultimate objective of econometric modelling of production is to construct general equilibrium models encompassing demands and supplies for a wide range of products and factors of production, along the lines suggested by Jorgenson (1983).

Our exposition of the theory of production has emphasized models where the econometric methodology has crystallized. An important area for future research is the implementation of dynamic models of technology. These models are based on substitution possibilities among outputs and inputs at different points of time. The simplest intertemporal model of production is based on capital as a factor of production. This model is treated in a companion paper by Jorgenson (1986).

A number of promising avenues for further investigation have been suggested in the literature on the theory of production summarized in the entry on vintages.

Production: Neoclassical Theories

M. Ishaq Nadiri

The economic theory of production is concerned with the characterization of the input demand and output supply functions based on a theory of profit maximization subject to a production function. Two sets of issues are involved: one is the technical constraint that describes the range of production processes available to the firm, and the other is the make-up of the markets where the firm's transactions take place. There is a substantial literature on the latter, which cannot be addressed here: we adopt the admittedly unrealistic assumption of 'perfect competition' in both commodity and factor markets. Our purpose is to discuss the properties of the production technology in the context of the neoclassical theory of the multiple-product and multiple-input firm, identify the specific forms of the production function which are proposed in the literature, and discuss the duality principles as well as some of the new dynamic factor demand model analyses.

Neoclassical Theory of Production

Consider a firm that produces n products and employs m inputs; its objective is to maximize profits given as:

$$\Pi = \sum_{i=1}^{m+n} p_i y_i = \sum_{i=1}^{n} p_i y_i + \sum_{i=n+1}^{m} p_i y_i \qquad (1)$$

where $y_i(i = 1,\ldots, n)$ are the outputs and p_i $(i = \mathrm{n} + 1, \ldots, m)$ are output prices: $\mathrm{y}_{n+1} = x_i(i = 1,\ldots,m)$ are the inputs, and $p_{n+1}(i = 1,\ldots, m)$ are the input prices. Profit, Π, is maximized subject to the production function

$$f(y_1, y_2, \ldots, y_n, y_{n+1}, \ldots, y_{m+n}) = 0. \qquad (2)$$

$y_1, y_2, \ldots, y_{m+n}$ are often called *net outputs;* they have positive signs for outputs and negative signs for inputs.

Assuming that the production function $f(\cdot)$ is (1) twice differentiable, i.e.

$$\partial f/\partial y_i = f_i \text{ and } \partial^2 f/\partial y_i \partial y_j = f_{ij}, (i,j = 1, \ldots, m + n),$$

exist; (2) increasing in the *net* outputs, i.e. the derivatives, f_i are always positive; and (3) convex (subject to the condition $f(\cdot) = 0$, the function is *strictly* convex); the optimal production plan of the firm can be stated using the familiar Lagrangian function:

$$\begin{aligned} L(y_1, y_2, \ldots, y_{m+n}; \lambda) &= \Pi + \lambda f(y_i, y_2, \ldots, y_{m+n}) \\ &= \sum_{i=1}^{m+n} p_i y_i + \lambda f(y_1, y_2, \ldots, y_{m+n}), \end{aligned} \qquad (3)$$

where λ is a Lagrange multiplier associated with the constraint $f(\cdot) = 0$.

There are $m + n$ first-order conditions that can be interpreted as equality between the marginal profitability of each net output and its revenue or cost. The Lagrange multiplier is the change in profit made by the firm with respect to a change in its production plan. Manipulating these equalities, we obtain familiar expressions such as the marginal transformation among commodities and inputs, the marginal rate of technical substitution among inputs and the expansion path of inputs. It follows that the profit-maximizing output and input levels, $\bar{y}_i(i = 1,\ldots, m + n)$, and the

Lagrange multiplier, $\overline{\lambda}$ are functions of the prices $p_i(i = 1,\ldots, m + n)$. That is:

$$\overline{\lambda} = \overline{\lambda}(p_1, \ldots, p_{m+n})$$

and

$$\overline{y}_i = s^i(p_1, \ldots, p_{m+n}), \quad (i = 1, \ldots, m + n). \tag{4}$$

$\overline{\lambda}(\cdot)$ is homogeneous of degree one, while s^i $(\cdot)$ is homogeneous of degree zero. $\overline{y}_i$ are the *net supply functions*. For outputs, the equations i y are the usual supply functions; for inputs, they are the negative of the demand functions. Thus net supply functions exist provided that the marginal profitability conditions are satisfied and that the production function has the appropriate properties.

Production: Neoclassical Theories, Table 1 A partial list of economic effects related to the production function

Output level	$y = f(x, t)$
Returns to scale	$\mu = \left(\sum_{i=1}^{n} x_i f_i\right)/f$
Distributive share	$s_1 = x_1 f_i / \sum_{i=1}^{n} x_i f_i$
Own ‘price’ elasticity	$\epsilon_i = x_i f_{ii}/f_i$
Elasticity of substitution	$\sigma_{ij} = \frac{\left(f_{ii}/f_i^2 + f_{ij}/f_i f_j - f_{jj}/f_j^2\right)}{\left(1/x_i f_i + 1/x_j f_j\right)}$
Disembodied technological change:	
(1) Rate of technical change	$T = f_t/f$
(2) Acceleration of technical change	$\dot{T} = (f_{tt}/f) - (f_t/f)^2$
(3) Rate of change of marginal products	$\dot{m}_t/m_t = f_{it}/f_i$

Properties and Form of the Production Functions

The characterization of the input demand and output supply functions depends on the specific properties of the production function. A number of studies have tried to specify these properties and discover more flexible functional forms to accommodate various economic effects often imbedded in the production process. Some economic concepts of interest are listed below. Though the concepts shown in Table 1 are defined in terms of a single-output production function, they can easily be extended to multiple-output production functions. Given the production function $y = f(x, t)$, where x is a vector of inputs and t the index of technological change, it is possible to deduce expressions shown in Table 1 for returns to scale, shares of factors of production, price elasticity and elasticity of substitution, as well as various indices of disembodied technical change. Other effects such as indices of *embodied* technical change can also be derived. By imposing specific restrictions across these effects, different functional forms of the production function can be obtained. Of this array of economic effects, those associated with returns to scale, degree of substitution among inputs and the type and nature of technological change, have received prominent attention in the literature.

These economic effects arise from the inherent nature of the underlying production process, and the specific form of the production function is therefore critical in determining the existence and magnitude of these effects. These properties of the production function – homogeneity, additivity and separability – have played an important role in the derivation of input demand and output supply functions. A homogeneous production function of degree k is defined as:

$$f(\lambda x_1, \ldots, \lambda x_n) = \lambda^k f(x_1, \ldots, x_n); \quad \lambda > 0$$

and a monotonic transformation of a homogeneous production function yields a homothetic production function in $y = g[f(x_1,\ldots,x_n)]$. This family of production functions is characterized by straight-line expansion paths through the origin. Additivity may take the form:

$$f^1(\lambda y_1) + \cdots f^n(\lambda y_n) = f^2(y_1), \ldots, f^n(y_n) = 0 \quad \text{for any} \ \lambda > 0$$

where y_i represents net output of ith commodity, some of which are inputs to the production process. If the function f^i is either homogeneous of some degree, or logarithmic, the additivity condition holds.

Most of the theoretical formulations of the production functions described in the literature implicitly assume that separability conditions prevail. The $f(x)$ is *weakly separable* with respect to partition R when the marginal rate of substitution (MRS) between any two inputs x_i and x_j from any subset $N_{s,}$ $s = 1, \ldots, r$, is independent of the quantities outside N_s (Leontief 1947; Green 1964; Berndt and Christensen 1973) or $\partial(f_i/f_i)/\partial x_k = 0$. *Strong separability*, on the other hand, exists when MRS between any two inputs inside N_s and N_t does not depend on the quantities outside N_s and N_t or $f_i f_{ik} - f_i f_{jk} = 0$.

Functional separability plays an important role in aggregating heterogeneous inputs and outputs, deriving value-added functions and estimating production functions. It also opens up the possibility of consistent multi-stage estimation, which may be the only feasible procedure when large numbers of inputs and outputs are involved in the production activities of highly complex organizations.

A major preoccupation in the literature for empirical estimation of production functions has been to find flexible functional forms. Well-known functions (e.g. the Leontief and Cobb–Douglas production functions) impose restrictions of zero and one, respectively, on the elasticity of substitution, σ while for CES production functions, σ is an arbitrary constant to be estimated. Attempts to relax this stringent requirement have led to the development of the variable elasticity of substitution functions (VES) where σ is dependent on economic variables such as input mix (Liu and Hildebrand 1965; Kadiyala 1972). Efforts to relax the homogeneity property have led to the development of a number of homothetic production functions that make the returns to scale depend on output and/or input mix (Zellner and Revankar 1969; Färe et al. 1978). A major advance has been the formulation of non-homothetic functions by Christensen et al. (1973), who formulated the translog production function, which does not *a priori* impose restrictive constraints such as homotheticity, constancy of σ additivity, and so on.

Technical Progress

Technical progress deals with the process and consequences of shifts in the production function due to the adoption of new techniques which either have a neutral effect on the production process or change the input–output relationships. Neutrality of technical progress can be measured by its effect on *certain* economic variables such as capital–output, output–labour and capital–labour ratios, which should remain invariant under technical change. Several definitions of technical progress have been proposed, such as (1) product-augmenting, (2) labour- or capitalaugmenting, and (3) input-decreasing and factor-augmenting, amongst others (Beckmann et al. 1972). However, the most familiar definitions are the Hicks, Harrod, and Solow forms of technical progress.

Part of technical change can be endogenous and would be determined by the firm to maximize its long-run profit. Technical knowledge is expensive to produce but, once produced, its transmission cost is almost zero, giving rise to the ‘indivisibility’ and ‘inappropriability’ characteristics of inventions. Attempts have been made to incorporate R&D as an input in the neoclassical production and cost functions, to estimate its contributions to the firm’s productivity growth and cost behaviour, and to measure its spillover effects on other firms or industries (Nordhaus 1969; Griliches 1979.) The results indicate substantial private and social rates of return to R&D (Mansfield 1969). Changes in relative prices and output not only affect endogenous technical change but also the rate of factor productivity and the bias of technical change, which will in turn alter the structure of the production process (Jorgenson and Fraumeni 1981).

Duality

A major advance in the economic theory of production has been the dual formulation of production theory (Shephard 1953; Diewert 1974; Fuss and McFadden 1978). The main features of this approach is to recover through indirect functions – that is, by means of a dual representation such as profit or cost functions – the

Production: Neoclassical Theories, Table 2 Comparison of the properties on the transformation function and its dual cost function

Property A on the transformation function $F(y, x)$	Property B on the cost function $C(y, p)$
1 Non-increasing in y	Non-decreasing y
2 Uniformly decreasing in y	Uniformly increasing in y
3 Strongly upper semi-continuous in (y, x)	Strongly lower semi-continuous in (y, p)
4 Strongly lower semi-continuous in (y, x)	Strongly upper semi-continuous in (y, p)
5 Strongly continuous in (y, x)	Strongly continuous in (y, p)
6 Strictly quasi-concave from below in x	Continuously differentiable in positive p
7 Continuously differentiable in positive x	Strictly quasi-concave from below p
8 Twice continuously differentiable strictly differentiably quasi-concave from below in x	Twice continuously differentiable and strictly differentiably quasi-concave from below in p

properties of the underlying production function. The dual approach not only contributes important insights of its own but also offers more immediate empirical applications. A mapping of the characteristics of the transformation function and its dual cost function is indicated in Table 2.

The cost formulation is used extensively in econometric studies. This approach has two main advantages: (1) demand and supply functions can be derived as explicit functions of relative price and output without imposing arbitrary constraints on production patterns required in the traditional methodology; (2) cost and profit functions are computationally simple and permit testing of a wider class of hypotheses by utilizing economic variables (Nadiri 1982).

Dynamic Factor Demand Models

These types of production functions emphasize the intertemporal aspect of the production process by focusing on the movement from one equilibrium state to another. The models incorporate costs of adjustment that are incurred in order to change the level of quasi-fixed inputs, costs which can take two forms. The first type is external: as the firm adjusts its quasifixed factors it must face either a higher purchase price for these factors (Lucas 1967; Gould 1968) or a higher financing cost for the accumulation of these inputs (Steigum 1983). The second type is internal and reflects the fact that firms must make the trade-off between producing current output and diverting some of the resources from current production to accumulate capital for future production (Treadway 1974).

Suppose the firm maximizes its present value:

$$V = \int_0^\infty \{Py - WL - rK - G\dot{K}\}\, \mathrm{e}^{-\rho t}\mathrm{d}t$$

subject to the production function $f(y,L,\dot{K},K) = 0$ and the initial condition $K(0) = K_0$. P is the price of output, y is the level of output, W is the nominal wage, r is the user cost of capital, G is the purchase price of investment, K is a vector of capital inputs, L is labour, and $\dot{K}$ is net investment. $\dot{K}$ is introduced in production on the assumption that firms produce essentially two types of outputs: y, to sell, and $\dot{K}$ the internally accumulated capital which will be used in future production. K is assumed to be neither perfectly fixed nor perfectly variable. Suppose, in addition, that the production function is characterized by the relation $y + C(\dot{K}) - g(K,L) = 0$, where C and g are continuous and the marginal products of f_L and f_K are positive and diminishing.

From the necessary conditions, it follows that for perfectly variable inputs its marginal product must equal its price, while for the quasi-fixed inputs the discounted sum of future net values of its marginal product must equal the sum of the purchase price of investment and the marginal value of real product foregone as a consequence of expansion at the rate $\dot{K}$. The basic problem in this type of model is to deal with expectations about future prices of inputs and outputs. A simple and often-used approach to the problem is to assume static expectations, but that begs the question. Uncertainty about future prices are handled in two ways, either by approximating optimization under uncertainty with certainty equivalence, which requires a quadratic objective function and linear constraint (Hansen and Sargent 1981) or by making adjustment costs a function of the level of the quasi-fixed inputs, which exploits the expectations of future prices that are contained at the quasi-fixed input levels.

There is a fairly large and growing theoretical and empirical literature using the dynamic production function or its duals, dynamic profit or cost functions. The main result of these models is that, because of the existence of adjustment costs, substitution possibilities and technological biases may be limited in the short run, and the effects of prices and tax changes on factor demands may be quite different from their effects in the long run.

Economies of Scale and Scope

An important extension of the theory of the firm has been the production and pricing behaviour of a multi-product firm when economies of scale prevail. To derive the net supply functions, the necessary conditions for equilibrium noted earlier break down when increasing returns or declining long-run average costs prevail. In such cases, monopolistic organization of an industry may offer cost advantages over production by a multiplicity of firms. An interesting and important question is what are the necessary and sufficient conditions for a multi-product firm to be a natural monopoly and for it to be sustainable against entry (Baumol 1977). The condition for natural monopoly is that a cost function be *strictly and globally subadditive* in the set of commodities $C(y^1 + \bullet \bullet + y^m) < C\ (y^1) + \bullet\ \bullet + C(y^m)$, which means that it is always cheaper to have a single firm produce whatever combinations of output is supplied to the market. If the output vectors are restricted to be orthogonal, then the production function exhibits *economies of scope*. The natural monopoly is a sustainable set of products set at prices that do not attract rivals into the industry (Baumol et al. 1977). Even if rivals are attracted, the monopoly may be able to protect itself from entry by changing its prices. But, by definition, only a sustainable vector of prices can prevent entry and yet remain stationary. The conditions necessary for sustainability are (1) the products are weak gross substitutes; (2) the cost function exhibits strictly decreasing ray average costs; and (3) the cost function is also transray convex. Ramsey prices often ensure sustainability under specified circumstances.

Productive and Unproductive Consumption

Mark Blaug

The terms ‘productive’ and ‘unproductive’ consumption were introduced into economics by John Stuart Mill in Book I, chapter 3, of his *Principles of Political Economy* (1848), although the distinction (without the terminology) first appeared in the closing pages of the new chapter on machinery in the third edition of Ricardo’s *Principles* (1821), where he argued that workers have a personal interest in the pattern of luxury spending by the rich because spending on ‘menial servants’ increases the demand for labour by more than the equivalent amount of spending on physical goods. Mill’s distinction between the two kinds of consumption is a direct application of Smith’s distinction between ‘productive’ and ‘unproductive’ labour; according to Mill, the only productive consumers are productive labourers, but not all consumption by productive labourers is productive consumption: ‘that alone is productive consumption’, Mill observes, ‘which goes to maintain and increase the productive powers of the community’.

The basic idea behind the distinction between productive and unproductive consumption goes back to the writings of the physiocrats. It is the notion that a certain quantity of the consumer goods produced in an economy (i.e. wage goods) enters as necessary inputs into the production of manpower itself in the household sector. Productive consumption is simply an input necessary to maintain human capital intact. If wages are at subsistence, the whole of the wages bill is required for productive consumption. Mill concedes, however, that workers do consume some ‘luxuries’, and in that sense a portion of wages is consumed unproductively. The fact remains that consistent classical income accounting consistent with the subsistence theory of wages implies deducting all productive consumption from the gross national product to arrive at the true net national product, which consists simply of profits plus rent; this net product is created entirely by productive labour and is spent entirely on investment and *true* consumption goods, that is, non-wage goods. The logic of this argument is impeccable, although the statistical difficulty of segregating wages into its productive and unproductive components might be unsurmountable. The point is, however, that only a society bent on maximizing capital accumulation, come what may to current living standards, would want to adopt this kind of accounting. But

Mill, unlike Adam Smith, was not at all sure that a higher rate of economic growth was really desirable. Thus the only practical use that Mill made of the distinction between productive and unproductive consumption was to convert Ricardo's thesis that the volume of employment depends on the pattern of unproductive consumption into the paradoxical proposition that 'demand for commodities is not demand for labour'.

The dozen or so pages explaining this proposition in Mill's *Principles* (Book I, ch. 5, para. 3) are among the most tortuous ever to have been penned by a great economist, and the secondary literature commenting on Mill's discussion is almost entirely negative (Thompson 1975). Nevertheless, it is possible to catch the drift of Mill's meaning, which was that the volume of employment in an economy is a direct function of the rate of capital accumulation, so that consumers' demand, while it clearly determines the allocation of labour between different industries, influences total employment only at one remove. Since the decision whether the proceeds of sales will be used to reconstitute the 'wages fund' for a new bout of production rests with employers, demand for commodities is not *necessarily* demand for labour. Having made the decision to save a certain portion of his income, the only way in which an individual can directly influence the demand for labour is by substituting labour services for commodities in his own consumption. This is Ricardo's old argument that the interest of labour is best served by the most labour-intensive kind of spending on personal consumption.

Unfortunately, Ricardo had applied his argument to a situation in which some labour has become unemployed owing to the sudden introduction of labour saving machinery, from which it follows that demand for commodities *is* demand for labour. Mill, however, seems to be assuming full employment by affirming that an increased demand for labour in one industry must draw labour out of another. In that case it seems to follow tautologically that an increased demand for consumer goods cannot increase the demand for labour. But Mill's object was to argue the stronger thesis that the demand for labour will in fact fall off under full employment when resources are shifted into the manufacture of additional consumer goods: an increase in consumption means a decrease in investment, and investment under the wages fund doctrine can only mean advancing more wage goods to labour in subsequent periods. Given the rigid discontinuity of production implied in the wages fund doctrine, it is perfectly true that an increase in aggregate consumption demand under full employment impairs the wages fund and so leads to a decline in the amount of employment demanded at any given wage rate. In short, Mill's proposition that 'demand for commodities is not demand for labour' holds only insofar as the wages fund doctrine itself.

With the demise of the wages fund doctrine, the distinction between productive and unproductive consumption disappeared from the literature of economics. Marshall (1890, p. 67) included the distinction in his *Principles* but made absolutely no use of it and added characteristically in a footnote: 'All the distinctions in which the word "productive" is used are very thin and have a certain air of unreality. It would be hardly worthwhile to introduce them now: but they have a long history; and it is probably better that they should dwindle gradually out of use, rather than be suddenly discarded.' The reason for the disappearance of the Millian distinction is obviously connected with the declining interest after Mill in the fundamental question raised by any such distinction; namely, what is it that determines the volume of employment? Thus Marshall and many other neoclassical economists of the post-1870 period retained an interest in the distinction between different types of consumption as between) 'necessities', 'convenience' and 'luxuries' in terms of their different price elasticities of demand rather than the volume of employment generated by the pattern of expenditure on different categories of consumer goods.

Productive and Unproductive Labour

Guido Montani

According to Schumpeter the debate on productive and unproductive labour was nothing but a 'dusty museum piece' (Schumpeter 1954, p. 628). And indeed, after the achievement of marginal utility theory, there was no need to distinguish between productive and unproductive labour, because all labour producing 'useful and scarce' things was to be considered as productive. So the meaning of 'productive' covers the whole field of economic goods. Albeit cautiously, Marshall suggested dropping this kind of terminology. 'Whenever we use the word Productive of itself [says Marshall] it is to be understood to mean *productive of the means of production, and of durable sources of enjoyment*. But it is a slippery term, and should not be used where precision is needed. If ever we want to use it in a different sense, we must say so: for instance we may speak of labour as *productive of necessaries, etc*.' (Marshall 1890, p. 56).

Nevertheless, in classical economics the distinction between the two kinds of labour seems to be a very useful one, since it makes it possible to know whether a certain expenditure of money can engender a new income (in which case it is to be considered an investment) or whether it engenders only enjoyment or waste (in which case it is to be considered consumption). At the very beginning of the *Wealth of Nations* Adam Smith says that the nation will be better or worse off according to 'the proportion between the number of those who are employed in useful labour, and that of those who are not so employed' (Smith 1776, p. 1). This distinction raised innumerable disputes during the last century, but, in a different way, the problem is not at all avoidable in contemporary economics. Take for instance the question of including civil service expenses in national accounting or not. Should we consider expenses for higher education as consumption, as investment or as a demonstration of affluence? And the defence budget? Is the national income increased or decreased when more nuclear weapons are produced and stored in underground silos? There is no clear-cut reply. As Marshall warned, if we take a certain expense as consumption or investment according to its capacity to 'produce' only utility (enjoyment) or new income as a means of production, a nuclear weapon is neither a consumption nor an investment good.

Here the difficulty is raised by the fact that a certain activity is considered 'useful' or not for political reasons, social welfare policies, etc., that is, criteria not based on market evaluations. Therefore, we can say that a certain State expenditure, for instance, in the defence or education sector, is *indirectly useful* to the production of national income, since without State administration the very existence of a free market is impossible.

Even if we tie ourselves to market produced commodities some problems still arise. Take, for instance, Sraffa's modern reconstruction of the classical theory of value and distribution.

Sraffa does not take into consideration the distinction between productive and unproductive labour. But when he comes to examine the case of production with surplus, he states that) 'one effect of the emergence of a surplus' is that 'there is room for a new class of "luxury" products which are not used, whether as instruments of production or as articles of subsistence, in the production of others. These products have no part in the determination of the system. Their role is purely passive' (Sraffa 1960, p. 7). Therefore, if we define all the labour employed in sectors which contribute directly or indirectly to the production of the social surplus as productive, the labour employed in the 'luxury' sectors ought to be considered as unproductive. If we eliminate, during a certain year, the activities relating to 'luxury' productions 'the price-relations of the other products and the rate of profits would remain unaffected'. The following year, the production cycle can start anew on the same scale and the same quantities of 'non-luxury' (basic) commodities can be produced.

Nevertheless, there is no perfect match between the notion of luxury and unproductive sectors. Take, for example, commerce, which was considered by Marx as unproductive (see *Capital*, vol. II). The whole economy is divided into two sectors: industry, where commodities are produced and brought at the end of the year to the wholesale market, and commerce, where the surplus is sold on the retail market during the year. Therefore, the commerce sector does not produce any physical new product. Its function is to transfer the commodities required by consumers to other places and to store them up during the year. The rate of profits, if wages are given, is determined only inside the industrial sector. Merchants are able to get a rate of profits equal to the industrial one if they sell commodities at a retail price higher than the price paid to industries on the wholesale market.

From a formal point of view, commerce should be considered as a luxury sector, because all commodities sold on the retail market do not enter, directly or indirectly, into the industrial sector as means of production. But two more observations should be considered: (a) commodities are bought on the retail market mostly by workers and therefore, as wage goods, they enter industrial production; (b) the existence of a commercial sector side by side with the industrial one means that a better division of labour is possible (as compared with the case where commerce does not exist) and that consumers can buy commodities at a cheaper price. If it were not so, consumers would find it convenient to go directly to the factory to buy commodities. Therefore, we must say that the commercial sector is 'productive', because, if we do away with it, it would be impossible for the economy to reproduce the same quantities of commodities the following year with the given quantity of the work-force previously employed (of course, no technological change is considered here).

So far, we have worked with a concept of productive labour in a simple reproduction economy, that is, an economy which reproduces itself every year on the same scale. This concept does not change even if we consider the case of expanded reproduction, that is, accumulation. Accumulation means only an enlargement of the productive forces already employed, and not a qualitative change in the role played by every sector of the economy in relation to other sectors. In fact, one of the main problems of an expanding economy is the study of the proportion which should exist between sectors, on the one hand, and between production and income, on the other, in order to assure steady and balanced growth.

The case of development is very different. By development we mean the transition from a certain 'mode of production' (to use Marxist terminology) to another one. This approach was typical of classical economists and their followers, but it seems to have been forgotten in contemporary economic analysis. For instance, Adam Smith refers over and over again to 'that early and rude state of society' which preceded the capitalist development and the industrial revolution. It is worthwhile here remembering that a vast literature flourished during the 18th century on the 'four stages of progress' which mankind passed through (Meek 1976).

In the history of economic thought the best treatment of the problem of development is in List's *National System of Political Economy* (1841), where a sketch of a theory of productive forces (or productive powers) can be found. List protested against the tendency to reduce political economy to the theory of value. List stated clearly 'that an independent *theory of the "productive power"* must be considered by the side of a *"theory of values"* in order to explain the economical phenomena' (List 1841, p. 137). Smith's and Say's concept of productive labour, according to List, is very limited because it refers only to the creation of exchangeable values. On the contrary, we should consider all the expenses which produce *productive powers* as productive.

> The errors and contradictions of the prevailing school [says List] can be easily corrected from the standpoint of *the theory of the productive powers*. Certainly those who fatten pigs or prepare pills are productive, but the instructors of youths and of

> adults, virtuosos, musicians, physicians, judges, and administrators, are productive in a much higher degree. The former *produce values of exchange*, and the latter *productive powers* (List 1841, p. 143).

List's concept of productive powers is very useful in contemporary economic analysis. Let us consider a typical problem of underdevelopment. In an agricultural society, public expenses for primary education should be considered as unproductive if our point of view is limited to a selfreproduction economy. But if our aim is the transition towards an industrial society, primary education should be considered as a prerequisite, since industrial production needs a skilful workforce, businessmen, a service sector, etc. In a few words: we need to create productive powers in order to go beyond the agricultural mode of production.

But List's theory of productive powers is very helpful for a second reason: it allows us to consider the *State* as a productive power (or force). In fact, List aimed at the political unification of Germany (a Customs Union) in order to create conditions favourable to German entrepreneurship, which was choked in his day by stronger English industrial competition. In our century, one of the most striking phenomena is the transition of the main industrialized countries (both capitalist and socialist) towards a new mode of production, which should be called 'scientific', given the role played by science as a productive force. But since science, and typically 'big science' which requires huge public investment, can be organized efficiently only by state research programmes, it seems correct to consider all public expenses nowadays devoted to scientific research as 'productive'.

Productivity: Measurement Problems

Zvi Griliches

Productivity is a ratio of some measure of output to some index of input use. The meaning and quality of such a measure depends on the definition and quality of its ingredients and on the particular formula and the associated weights used to aggregate the various components into one output or input index. Economists tend to think of productivity as measuring the current state of technology used in producing the goods and services of an economy (or industry or firm), and want to interpret the changes in such a measure as reflecting) 'technological change', shifts in the production possibilities frontier. For this purpose, it is usual to focus on one or another version of 'multi-factor productivity', where the list of inputs considered extends beyond labour and includes also measures of capital services and also, occasionally the use of materials and other inputs.

Measuring technological change is of interest because, in a sense, it defines our wealth and puts limits on what we can accomplish. Our wealth at any time can be thought of as consisting of three parts: (a) quantities of various resources available to the economy – labour, capital, land, minerals, etc.; (b) the organizational arrangements for using these resources in production; and (c) the currently known ways of converting such resources into outputs desired by the economy. Each one of these can potentially increase, improve, or decline and deteriorate. The range of things covered under the last broad concept – 'technology' – can be thought of as consisting of both the average set of recipes for doing things, embedded in the current range of equipment and in the training of the existing work-force, and the currently known *best* way of doing things. 'Technological change' as measured by productivity type measures, even after allowances have been made for the growth in other resources, for economies of scale, and for errors in measurement, reflects changes in the 'average' technology used by an industry or economy. 'Average' technology can improve because more firms have shifted to the best (or better) technology (this is called diffusion of technology), because some of the poorer firms have gone out of business even though the others have not become any better, and because the 'best' technology itself has improved, the technological frontier having been expanded by science, organized research, learning by doing, and plain serendipity. In the long run, average technology can keep improving only if the best technology is also improving. Ultimately, therefore, since our ability to accumulate additional conventional resources, such as capital or mineral resources, may be limited, the growth of the economy and of per capita income and wealth depends on the rate at which technological knowledge is expanding and on our ability to affect this rate by changing the amount of resources we devote to science and technology and on the institutions that we devise for using them effectively.

The point here is that we are interested in 'productivity' and what is happening to it primarily because we believe that it may tell us something about the ultimately more fundamental process of technological change. But conventional measures of productivity are only a distant and murky reflection of it. Changes in such indexes, especially sharp short-run fluctuations, should be interpreted with great care since they may have little to do with technological change proper.

The list of potential problems is long and overlapping:

1. Coverage issues, definition of the borders of a sector and of the relevant concept of 'output' for it. For example, is illegal activity included? Are pollution damages counted against the 'output' of an industry?
2. The measurement of 'real' output over time. Price) 'deflation' and quality-change problems.
3. The measurement of inputs over time. The changing skill-mix of the labour force, quality change in the machinery and equipment used and the changing utilization of the labour force and of the existing capital stock.
4. The list of inputs to be included in the total input concept. The treatment of research and development and of public infrastructure expenditures.
5. Missing data on hours worked by people and machines and/or specific input use by various industries.
6. Getting the right 'weights'. The divergence of market prices from 'shadow prices' and the impact of various disequilibria.
7. Formula differences. Index number formulae and the unknown shape of the underlying production possibilities frontier. Gross versus net concepts and other variants.
8. The consequences of aggregation over heterogeneous individuals and industries.

The last two topics are treated at length in separate entries (*see* AGGREGATION PROBLEM and INDEX NUMBERS) and will not be considered further here. It may be useful to outline briefly an algebraic–taxonomic framework for organizing the discussion about this range of topics. The conventional measure of residual technical change (TFP) in an industry can be written as

$$\lambda = y - sk - (1 - s)n$$

where *y, k*, and *n* are percentage rates of growth in output, capital, and labour respectively, *s* is the share of capital in total factor payments, and the relevant notion of capital corresponds to an aggregate of actual machine hours weighted by their respective base period (equilibrium) rentals. This procedure assumes that all the variables are measured correctly, that all the relevant variables are included, and that factor prices represent adequately the marginal productivities of the respective inputs. The last assumption is equivalent to the assumption of competitive equilibrium and constant returns to scale. To analyse λ the 'unexplained' part of output growth, it is useful to rewrite it in terms of a more general underlying production function and the 'correct' set of inputs:

$$\begin{aligned}\lambda = {} & s(k^* - k) + (1 - s)(n^* - n) \\ & + (s^* - s)(k^* - n^*) \\ & + h[sk^* + (1 - s^*)n^* - f] + \alpha_z z + u + t\end{aligned}$$

where the starred magnitudes are rates of growth of the correctly measured inputs; $s^* = \alpha_k/(\alpha_k + \alpha_n) = \alpha_k/(1 + h)$ where the α ' s are the true elasticities of output with respect to the specific inputs and $h = \alpha_k + \alpha_n - 1$ is a measure of economies of scale with respect to the conventional inputs k and $n; f$ is the percentage rate of growth in the number of establishments (plants) in the industry; and z is the rate of growth of inputs which affect output but are not included in the standard accounting system. These could be services from the accumulated stock of past private research and development expenditures, or services from the cumulated value of public (external) investments in research and extension in agriculture and other industries, or measurable disturbances such as weather or earthquakes. The last terms, u and t, represent respectively errors in the measurement of output growth and the 'true' rate of growth in the average level of technology. The α coefficients, h, and $s*$ need not be constants. If they are, we have the Cobb–Douglas case. The whole framework could be complicated and generalized by adding square terms in rates of growth as approximations to CES or translog type production functions.

The various terms in this formula can be interpreted as follows: The first term is the effect of the rate of growth in the measurement error of the conventional capital input measure on the estimated 'residual'. The second term reflects errors in the measurement and definition of labour input. The third term reflects errors in assessing the relative contribution of labour and capital to output growth. It would be zero if factor shares were in fact proportional to their respective production function elasticities. The fourth term is the economies of scale term. It would be zero if there are no underlying economies of scale in production ($h = 0$) or if the rate growth in the number of new firms (plants) just equalled the growth in total (weighted) input. The fifth term reflects the contribution of omitted inputs (private or public). The sixth term (u) represents various unspecified errors in the measurement of output growth, while the last term t is the 'pure' residual term – the amount of output growth not accounted for by this expanded list of possible sources.

Turning to a discussion of the potential content of some of these empty boxes, let us start with the penultimate term (u), errors in the measurement of output growth, before turning to the consideration of the input side. As far as the definition and measurement of output is concerned there are serious definitional problems at the aggregate national level about the borders of economic activity (e.g. home production and the investment value of children) and where one should draw the line between final and intermediate consumption activity (e.g. what fraction of education and health expenditures can be thought of as final rather than intermediate 'good' or 'bad'?). There are also difficult measurement problems associated with the existence of the underground economy and the poor coverage of some of the major service sectors. The most serious problem is probably in the measurement of 'real' output in 'constant prices' (at the national or industry level) and the associated growth measures. Since many output measures are derived by dividing ('deflating') current value totals by some price index, the quality of these measures is intimately connected to the quality of the available price data.

Because of this, it is impossible to treat errors of measurement at the aggregate level as independent across price and) 'quantity' measures.

The available price data, even when they are a good indicator of what they purport to measure, may still be inadequate for the task of deflation. For productivity comparisons and for production function estimation the observed prices are supposed to reflect the relevant marginal costs and revenues in a competitive equilibrium. But this is unlikely to be the case in sectors where output or prices are controlled, regulated, subsidized, and sold under various multi-part tariffs. Because the price data are usually based on the pricing of a few selected items in particular markets, they may not correspond well to the average realized price for the industry as a whole during a particular period, both because) 'easily priced' items may not be representative of the average price movements in the industry as a whole and because many transactions are made with a lag, based on long-term contracts. There are also problems associated with getting accurate transaction prices but it is the continued change in the available set of commodities that creates major difficulty: the 'quality change' problem.

'Quality change' is actually a special version of the more general comparability problem, the possibility that similarly named items are not really similar, either across time or individuals. In many cases the source of similarly sounding items is quite different: Employment data may be collected from plants (establishments), companies or households. The answer to the same question may then have a different meaning, depending on the source.

The common notion of quality change relates to the fact that many commodities are changing over time and that often it is impossible to construct appropriate pricing comparisons because the same varieties are not available at different times and in different places. Conceptually one might be able to get around this problem by assuming that the many different varieties of a commodity differ only along a smaller number of relevant dimensions (characteristics, specifications), estimate the price–characteristics relationship econometrically and use the resulting estimates to impute a price to the missing model or variety in the relevant comparison period. This has become known as the 'hedonic' approach to price measurement. The data requirements for the application of this approach are quite severe and there are very few official price indexes which incorporate it into their construction procedures.

While there have been significant improvements in data collection and processing procedures over time, it is fair to note that much still remains to be done. In the US GNP deflation procedures, until recently the price of computers had been kept constant since the early 1960s, for lack of agreement on what to do about it, resulting in a significant underestimate in the growth of real GNP during the last two decades. There are more such horror stories to be told but the point here is not that a particular price index is biased in one or another direction, rather that one cannot take a particular published price or 'real output' index series and interpret it as measuring adequately the underlying notion of price or output change for a well-specified, unchanging commodity or service being transacted under identical conditions and terms in different periods. The particular time series may indeed be quite a good measure, or at least better than the available alternatives, but each case requires a serious examination of whether the actual procedures used to generate the series do lead to a variable that is close enough to the concept envisioned by the model to be estimated, or by the theory under test.

The issues discussed above affect also the construction and use of various 'capital' measures in the analysis of productivity growth. Besides the usual theoretical issues of aggregation connected with the 'existence' of any unambiguous capital concept, the available measures suffer from potential quality change problems, since they are usually based on some cumulated function of past investment expenditures deflated by some combination of available price indexes. In addition, they are also based on rather arbitrary assumptions about the time pattern of both the survival of the machines themselves and the deterioration in their flows of services. The available information on the reasonableness of such assumptions is very sparse, ancient and flimsy. In some contexts it is possible to estimate the appropriate pattern from the data rather than impose them a priori, but very little of that has been incorporated into the conventional estimates.

From the production function point of view, what is needed is a measure of the flow of services of capital in constant prices. A central problem in constructing such a measure is what to assume about how the services of a given machine behave as it ages. It is usually assumed that they decline rapidly with age, as evidenced by the undoubted fact that the price of a used machine falls rapidly with its age. But the value of an old machine declines because its expected worklife is falling, because new and better machines are becoming available, and because the quality of the services it renders deteriorates with its age. Only the last factor is a legitimate deduction to be made from a service-oriented measure of capital. Admittedly, there is less life left in the old machine; but that does not imply that its current product is any the worse for that. Of course, the availability of better machines will result in capital loss for the owners of the old machine; but that does not make the old one any worse, only the new one better.

Even if capital services were in fact proportional to their stock measure (if, say, they did not deteriorate with age – the one-hoss shay – or declined exponentially) this property would not continue to hold if one added together machines with different lengths of life. A $100 machine that will last five years will have roughly twice as large an *annual* flow of services (in dollars) as another $100 machine whose expected length of life is ten years. Thus, the shorter the life expectancy, the higher is the ratio of services to stock. In manufacturing we can identify two major components of capital formation: equipment and structures. Structures have a much longer life than equipment and hence should be given a lower weight in compiling an index of capital *services*. Since the stock of equipment has been growing more rapidly, this adjustment makes a substantial difference to our measurement of the growth in the total level of capital services.

The other major problem with the measurement of capital is the lack of good data on its rate of utilization. Ideally, the relevant measure of capital services is one that is close to the number of machine-hours worked, weighted by their respective rental rates. Business cycle fluctuations and errors in forecasting demand result in large fluctuations in the rate of utilization of installed capacity. Such fluctuations are relevant for ‘efficiency’ measures of productivity, since they tell us how well we are utilizing our existing resources but are misleading as far as ‘technological change’ measures are concerned. It is very difficult, however, to find or design good capital utilization measures. Most of the existing measures are based on deviations of output from trend or previous peaks and contain essentially no independent information on this question.

Similar issues arise also with respect to the third term in this formula, the measurement of the contribution of labour input and associated variables: hours of work, unemployment, and wage rates; both at the macro and micro levels. At the macro level the questions turn on the appropriate weighting to be given to different types of labour: young–old, male–female, educated versus uneducated, and so forth. The direct answer here as elsewhere is that they should be weighted by their appropriate marginal prices; but whether the observed prices actually reflect correctly the underlying differences in their respective marginal productivities is one of the more hotly debated topics in labour economics.

It is also difficult to find relevant labour quantities and prices. The usual data sources report average annual, weekly, or hourly earnings which do not represent adequately either the marginal cost to the employer or the marginal return to a worker of an additional hour of work. Both are affected by the existence of overtime premia, fringe benefits, training costs, and transportation costs. Only recently has an employment cost index been developed in the United States. From an individual worker’s point of view the existence of non-proportional tax schedules introduces another source of discrepancy between the observed wage rate and the unobserved marginal after-tax net return from working. In addition, there are serious problems associated with the measurement of the number of hours worked rather than just hours paid for.

The fourth term is a wrong relative weights or disequilibrium term. It comes into play when the underlying elasticities of the production relation are not well approximated by the respective factor shares and the different inputs are not growing at the same rate. It could be of importance in agriculture in some periods, if capital use is growing while labour use is declining, while at the same time the observed relative prices underestimate the discrepancy in their marginal products.

The fifth term reflects the impact of economies of scale. It depends both on the degree of homogeneity of the production function and the amount of growth in average plant size that occurred during the period in question.

The sixth term reflects the contribution of ‘unconventional’ inputs, inputs that should have been, but have not been included in the standard accounting framework, either through error or because they are ‘external’ to the units being analysed (e.g. the resources used in the construction and maintenance of airports and air-traffic control systems as an input into the production function of the air-transport industry).

Because some of these inputs are not marketed directly and hence have no price attached to them which could be used to approximate their marginal product, and because the previous two terms (wrong weights and economies of scale) also imply a divergence of true productivity from observed market data, one cannot learn about them from an examination of conventional accounting data. Econometric estimation of production functions is required to assess the importance of economies of scale, to test the divergence of estimated coefficients from observed factor shares, to estimate the contribution of excluded and public inputs such as research and development expenditures, and to validate suggested quality adjustments for particular inputs (such as the measurement of the quality of labour by wage-weighted education per man indexes). Production (or cost) function based approaches to the measurement of technical change raise many difficult problems of their own, but they are the only way of testing our notions of what is the ‘right’ way of measuring certain inputs and their contribution to overall output growth.

It is hard to single out one factor or measurement problem as more important than another. Their import differs across countries, industries, and time. In the recent past, the major problems (or villains) have been the measurement of real output and real input growth, i.e. the correct measurement of prices and the associated adjustment for quality change and, in the context of shorter-run comparisons, the treatment of capacity utilization fluctuations. Over a longer historical view, the growing quality of the labour force and the discovery (and exhaustion) of new resource pools have probably been both the major source of true productivity growth and the major source of its mismeasurement, or at least misinterpretation.

Produit Net

G. Vaggi

The French Physiocrats defined the net product, *produit net*, as the difference between the gross output of agriculture and the overall expenses involved in production (Mirabeau 1764, vol. 1, p. 337; Quesnay 1768, p. 979). The *produit net*, or revenue as they often called it, is that part of annual output which is left over after the deduction of the means of production which have been consumed. It is a great merit of Quesnay to have provided the first clear distinction between gross and net product.

The Physiocratic concept of *produit net* has two characteristics; it can be expressed in physical terms as a surplus of agricultural output over its inputs. But the Physiocrats measured the net product also in terms of value, as the difference between the value of agricultural product and the overall value of the expenses incurred in its production. It was a peculiar opinion of the Physiocrats that only agriculture and the other activities directly linked to nature could give rise to a net revenue over costs. According to them the value of industrial output was just equal to that of its costs of production. Of course, from the works of Turgot and Smith onwards industry was considered productive as well as agriculture, and the net product then included capitalists' profits and not only rent (Smith 1776, vol. 1, pp. 330 ff.).

The contention that only the primary sector gives rise to a *produit net* is the cornerstone of Physiocratic economic policy. The net product is the only part of the output which is freely disposable without jeopardizing further production (Quesnay 1766a, p. 869). Thus the concept of *produit net* provides the basis for the Physiocratic theory of taxation; only a single tax on rent does not damage agricultural production, and hence the whole economy. Commercial policies must favour the profitable sale of the products of land in order to sustain their prices and the net product. For the same reason the landlords must spend most of their revenue in the purchase of agricultural goods rather than in that of manufactured commodities.

The Physiocratic notion of *produit net* is important because it originates that stream of thought that since Marx has been called 'theories of surplus' (Marx 1963, vol. 1, p. 44). This approach, which is based on the separation between surplus and capital, is still influential on present-day economic theory (see Sraffa 1960; Pasinetti 1977; Leontief 1941). Quesnay's distinction between productive and sterile activities is based on the criterion of whether or not they yield a *produit net*, a point of view which has also been accepted by Smith. Ricardo and Marx too distinguished productive and unproductive labour.

In Physiocracy the existence of surplus in agriculture was sometimes justified in terms of the benevolence of nature (see Weulersse 1910, vol. II, p. 112–115). But Quesnay defended his view of the exclusive productivity of agriculture with much stronger arguments than the idea of a 'gift of nature'. He linked the existence of a *produit net* to the availability of a large stock of advances in agricultural production, and to the favourable market conditions for the products of French soil (see Quesnay 1767, pp. 960–961; Quesnay 1766b, p. 911; Meek 1962, p. 387). The fact that only agriculture yielded a *produit net* led the Physiocrats to identify the largest part of the net product with the rent of the landlords. But part of the annual revenue of cultivation also goes to the King as taxes.

A theory of profit should address itself to at least three questions – about the size (volume) of profit, its share in total income and about the rate of profit on capital invested. Each of these three issues (size, share, rate, hereafter) can be examined at three separate levels of aggregation, the firm, the industry or the economy.

Theories of profits of size, share or rate can be classified as to whether they treat profits as an equilibrium or as a disequilibrium phenomenon, and of course as to whether the equilibrium is a static or a dynamic one. Theories then deal with the role of profits, that is, the effects of the size, share or rate on other economic variables, and the source of profits, that is, the variables which cause profits to be what they are. An issue related to the cause of profits is the moral justification of the claimant to profits. This issue though prominent in the classical and Marxian economics, disappears in neoclassical economics with the triumph of the marginal productivity theory of distribution. But the issue reappeared during the controversy surrounding capital theory in the 1960s.

Before we go into these issues, we have to ask whether profit is a pure category in economics since a theory presumes the existence, in the abstract at least, of a definable category to which the theory is addressed. With profits, there has been a frequent problem of conflating it with interest and rent.

One class of theories have taken profits as synonymous with interest. Theories have failed to distinguish consistently between profits and interest as categories of non-labour income. Thus, theories for the existence of positive rates of interest are often thought of as theories of profit rate. The abstinence theory of profits, attributed to Nassau Senior, is as much a theory of interest as of profits. In early classical writing, in Adam Smith for example, profits and interest do not appear as separate income categories. Wages, rent and profits are the three divisions of total income. When the interest rate does make its separate appearance, it is as the limit to which the rate of profit can fall. The ambiguous relationship between the two reappears in the marginal productivity theory where the return to capital (real rental on capital) is not sufficiently distinguished from interest to be a separate category of income.

There are also other conventions which lead to a loose definition of profits. Profits are sometimes used as synonymous with all non-labour income, subsuming rent and interest incomes. This is very much a Marxian tradition which has come down into modern-day Cambridge growth theory via Kalecki's theory of distribution. Alternatively, Marshallian theories subsume profits under a general category of quasi-rent. This leads to the further distinctions made between normal and supernormal profits or pure profits.

Neoclassical Theory

In neoclassical theory, the competitive firm (the entrepreneur) maximizes the quantity of profits to decide the level of output and inputs. This gives the price equal marginal cost condition. In equilibrium, the *size* of profits is indeterminate as are the *rate* and *share*. In long-run competitive equilibrium of the industry (if such an equilibrium can be shown to exist) the firm has zero (actual or if there is uncertainty, expected) profits; price equals average cost and the output is produced at the lowest point of the U-shaped average cost curve. Thus, zero profit is an equilibrium condition and also a signal that output is produced under efficient conditions. This zero profit condition is often qualified by adding that this does not rule out 'normal' profits. This not only leaves normal profits indeterminate in size but could easily lead to the condition of zero profits being a tautology. In this paradigm, non-zero profits are an indication of (long-run) disequilibrium or of non-competitive conditions (for example, barriers to entry). A third alternative is that in the presence of uncertainty any observed non-zero profits may be the random deviation of actual from expected profits. The zero profit condition is best thought of not as a descriptive prediction but as a rule to check for consistency in any model that assumes competitive behaviour.

In terms of the *rate of profit* the condition for competitive equilibrium is that the rate of profit be equal in all activities (industries, sectors, and so on). Here again the rate of profit is itself indeterminate but it is the interindustrial differential in the rate which needs to be zero in equilibrium. Again in analogy with the size of profits, a persisting non-zero differential indicates either disequilibrium or imperfectly competitive elements.

Normal non-zero level of profits or persisting differential in a particular firm or industry can be reconciled with competitive equilibrium by an appeal to Marshall's doctrine of quasi-rent. Ricardo's theory of rent compels the marginal land to have zero rent but supramarginal lands to earn positive rent. Marshall extends this logic to other factor incomes with the doctrine of quasi-rent relying on restrictions on elasticity of factor supply in the particular case where differential rates of return or non-zero surplus incomes are found. Normal non-zero profits could then be a quasi-rent.

But if so, what is the factor of production whose income is profit (as quasi-rent)? This raises the contentious question of the moral and economic basis of profit as income. Is profit the return to capital or is it the remuneration of the capitalist as a manager/entrepreneur? Attempts to provide a justification for profits as income invoke the abstinence doctrine, or the 'residual claimant' argument in the 19th century. But abstinence could provide a theory of reward for savings, that is, a theory of the interest rate but not for a reward for capital unless all savers are also capitalists. The residual claimant theory, that is, profits are what is left over after every other input has been paid its due, is hardly a theory. It needs to be supplemented by a theory of how all other inputs are rewarded, that is, how the residual is determined.

It was the achievement of J.B. Clark's marginal productivity theory of distribution to provide such a link by an attempt to integrate production and distribution via the marginal principle. Clark's theory claimed to explain distribution at each of the three levels of aggregation. The equating of the marginal value product of a factor to its unit price is a principle which treats labour and non-labour inputs symmetrically. In this theory, capital appears as equipment and its marginal revenue product is equated to its unit price. If one could further identify the profit per unit of capital with the unit price of capital, then the return to the capitalist (profits) is the reward of the productivity of capital (the rental for the factor). This brings profits in an analogous relation with rent. The capitalist is one who owns the factor of production capital. It is the structure of property rights as well as the productivity of capital which combine to make the owner of capital the recipient of its fruits.

In equilibrium, the price of the capital equipment will be the present value of its future net income stream. This is the contribution of Irving Fisher. Under certain restrictive assumptions – known future income stream, constant relative price of capital and constant and known discount factor – the real rental of capital is equal to the sum of the rate of discount (the rate of interest) and the rate of depreciation of the capital good. The presence of the rate of depreciation in the formula is required only in the case of a physical durable good. The rate of depreciation may of course not be constant but variable; worse, it could be endogenous and dependent on the forces determining the rental on capital (the rate of investment, for example). If, on the other hand, one were to take an infinitely lived capital good, that is, zero depreciation rate, then the real rate of return (the rate of profit) 'degenerates' to the rate of interest. In such a case an infinitely lived capital good becomes like a financial asset – a consol.

This illustrates the difficulty of separating profits from rent or interest. The problem here is that capital can be a physical good (a machine/a building), a financial asset (bond/consol) or an abstract attribute (human capital/skills). The marginal productivity notion relates to capital only when it is a material input to production. This is why the specification of the production function used to explain the rate of profit as arising from the marginal productivity of capital as factor becomes a contentious issue. Once capital is a physical good, its durability and heterogeneity entail an assumption of malleability if we wish to add up the disparate units of capital to arrive at an aggregate capital stock. This aggregate may be at the level of a firm, or an industry, but it is at the highest level of the economy that the problem is serious.

The need to have an aggregate measure arises from the practice of using an aggregate production function in terms of labour and capital, both assumed to be homogeneous aggregates. The use of the aggregate production function had begun in the 1920s and 1930s where on the one hand, Paul Douglas and Charles Cobb had used their well-known function to explain the constancy of the share of labour in total income (Cobb and Douglas 1928; Douglas 1948). Theorists such as Hicks, Harrod and Joan Robinson had also used the device of an aggregate production function to define various measures of technical progress which would reconcile the stylized facts of the constancy of the share labour, with a rising real wage and a trendless rate of profit. Thus it was that technical progress measures such as Hicks-neutral, Harrod-neutral, and so on, were proposed as simple constructions to explain these stylized facts. The theorists' work did not require the Cobb–Douglas form as such but the latter proved a convenient way for expressing these forms explicitly in econometric work in the 1950s when economic growth and technical progress engaged the attention of economists. It was Solow's work both in proving the stability of growth equilibrium and in measuring the contribution of technical progress to economic growth which generated the veneration of the Cobb–Douglas production function (Solow 1956, 1957).

This use of the aggregate production function in neoclassical growth theory in the 1950s accomplished two things. It could link the rate of growth of the economy to the rate of profit; in some cases the two could be equal. At the same time, the Cobb–Douglas form could be used to link the rate of profit to the marginal productivity theory. Thus, a microeconomic firm theoretic proposition – the equality of marginal productivity and factor prices – could be exploited to explain macroeconomic magnitudes of factor shares and growth.

This brilliant device linking the marginal productivity theory of distribution with a macroeconomic growth theory soon ran into difficulties and unravelled itself. The capital theory (or Cambridge–Cambridge) controversy is dealt with elsewhere in this dictionary. For the purpose of this essay, it suffices to note that while the factor prices could be taken as given by the firm, they become endo-genous at the macroeconomic level. The return to capital – the real rental or the profit rate – depends on the rate of investment. To explain the latter in terms of demand for capital in terms of factor–price substitution involves circular reasoning. Further, the existence of an aggregate capital stock presumes the prior existence of equilibrium prices for the heterogeneous capital goods comprising such an aggregate. The aggregate then cannot be used to 'explain' equilibrium profit rate. There seemed to be some insuperable logical problems in the notion of an aggregate capital stock. As an explanation of the profit rate, the macroeconomic theory of distribution proved to be a cul-de-sac.

An alternative treatment of the return to capital would be to abstract from such complications and treat capital as a commodity like any other. Using Debreu's very general definition of a commodity, new capital and old capital become different commodities, heterogeneous capital goods retain their differences and do not need to be aggregated. The task of the theory is then to show that a set of non-negative prices will clear markets for all the commodities. Given the facts of time and uncertainty we create dummy markets for contingent commodities. The price of the commodity 'capital' can then be determined for each time period and each state of nature.

But while the price of capital good can be determined by this method, it has no further link with profits. Profits in the Arrow–Debreu equilibrium are zero. Owners of capital goods will receive the price as their reward but this is not profit. Nor need the price of capital good have any specific connection with the rate of interest; as an intertemporal price the interest rate links the price of any commodity to that of its substitute available at a different date.

The Arrow–Debreu theory invokes a very stylized sort of uncertainty. Going back to a distinction made by Frank Knight between risk and uncertainty, it is risk rather than uncertainty which is involved in the Arrow–Debreu notion of contingent commodities. It assumes that states of nature can be described fully and the probabilities of various outcomes under different states of nature calculated in advance of determining the excess demand functions (or correspondences) for such contingent commodities. Such risk being previsible and insurable against, will yield only such return which cannot be arbitraged away. There can be no pure profit in such an equilibrium.

Classical Theories of Profit (Smith and Ricardo)

In classical economics profits are important as a quantity. Together with rent, they constitute the economic surplus, wages being the *faux frais* of production. The distribution of the surplus as between the owners of stock (capitalists) and the landlords becomes a central issue. This is because the two classes were presumed to have different propensities for productive consumption (accumulation). The division of surplus then had growth consequences.

The Physiocrats regarded land (nature) as the only source of surplus. Profits were only a recycled part of the *produit net*. Adam Smith could be read as regarding a surplus producing agriculture as a necessary but not the sole source of surplus, since productive labour was another source. The productivity of both land and labour depended on constant improvements in the manner of their utilization – agricultural practices and division of labour. Thus behind the 'factors' was the incessant propensity for progress – technical progress in the narrow sense as well as general innovations and improvements in practices.

The size of profits is ambiguous in Smith as there are no clear rules about the division of the surplus between rent and profit. The rate of profit was expected by Smith to fall. The reason for this was not diminishing returns in agriculture, as it was to be for Ricardo. The division of labour and effects of trade could counter the limits imposed by the soil. It was however that the stock of profitable investment opportunities was limited within a country. Smith could see that the fabulous profits made by trading companies were shrinking as merchants began to compete. Profits on industrial activities were on the moderate side. Thus the falling rate of profit hypothesis emerges to recognize an empirical fact though Smith had no reason for believing that technical progress could not stave off the tendency indefinitely.

It is David Ricardo who relates profits and rent antagonistically and has a clear view of the rate of interest as defining the lower limit of the rate of profit. In Ricardo, there is the first rigorous attempt to define the rate of profit, as a pure number which will be free of problems of valuation. By defining a one-good economy, corn, inputs and outputs can be measured in the same commodity. This is done by defining the wage in terms of corn and any equipment as product of labour. Given these two assumptions, the profit rate is defined as the ratio of net surplus – output of corn less inputs defined in terms of corn – to the capital advanced also measured by the inputs defined in terms of corn. But given the conflict in the economy between rent and profits, how was rent to be accounted for?

Ricardo defined the marginal land as zero rent yielding land. Thus the pure rate of profit could be defined on the marginal land free of complications introduced by rent. If we then add that profit rates equalize everywhere, the rent yielding land does so by achieving a superior output–input ratio compared with the marginal land. The difference is rent. Rent is an unearned income accruing to the landlords as a result of the progress of accumulation and the growth of population.

Ricardo integrates the conflict between rent and profit with a theory of growth which gives an explanation of the falling rate of profit. The size of profit as shared out with rent, determines the rate of accumulation since capitalists have a high propensity to accumulate. As accumulation proceeds, there are diminishing returns to land as well as labour. If the real wage were to be taken as constant, then the surplus above wage shrinks due to diminishing productivity of labour. But at the same time, rents rise. Hence profit is squeezed out. The rate of profit falls with accumulation.

But on the zero rent land, profits are antagonistic to wages. Thus any tendency for wages to go up will reduce the rate of profit. The determinants of real wages were accumulation (demand for labour) and growth of population (supply of labour). The Malthusian mechanism to keep real wages constant worked at least in the long run. But even in the short run, although theoretically real wages could rise with the force of accumulation, the empirical facts of population growth since the 1780s and the potentially high participation rate of men, women and children, meant that for the period in which he was writing, Ricardo could easily assume rapid adjustment of the supply of labour to a rise in the real wage rate.

New Classical Theories of Profit (Sraffa, von Neumann)

There are at least two directions in which Sraffa (1960) generalizes Ricardo. First he drops the single-good assumption but defines a standard commodity in terms of which the rate of profit is invariant to relative price changes. He also drops the assumption of a constant subsistence wage. By taking wages and profits as constituting surplus, that is, wages no longer being merely the costs of production but part of value added, the conflict between the rate of profit and the share of wages in total surplus is made explicit. The wage–profit frontier derived from the structure of the input–output information illustrates this conflict.

If we were to take Ricardo's choice of corn as the single good as a substantive and not merely a methodological device, one must attribute a large role to agriculture as the source of surplus. Ricardo is less explicit about the role of technical progress either in generating surplus or in staving off the effects of diminishing returns. By dropping land from the general model altogether as an essential input, Sraffa implicitly takes the technical conditions of production (the matrix of the input coefficients) as guaranteeing that a surplus exists. He does not however pursue the question of the disposal of profits, that is, accumulation.

In a parallel but independent work, von Neumann put forward a linear model of the economy with joint production, in which the timing of input and output was articulated. In this system, there are several processes available for producing a commodity but only those are chosen which at least yield a certain rate of surplus (say g) of the output above the inputs. Labour is one of the inputs. The converse of this proposition is that given the input and output prices, only those activities are chosen which yield the minimum rate of profit (p). If the linear system of production coefficients is indecomposable, from the duality of prices and quantities, it follows that $g = p$. If we now regard g as the rate of growth between this year's inputs and next year's output, we have in von Neumann's model, an equality between the rates of growth and profit. All profits need to be accumulated and wages have to be at subsistence level. The classical lineaments of von Neumann's model are thus clear (von Neumann 1945–1946).

Von Neumann's system leaves the size and share of profits indeterminate while making its rate determinate. It is his device of defining the production process as jointly producing final output and one year older capital goods, that is, the joint production technology that has proved a fertile innovation. In one way this device avoids the problem of heterogeneity as well as of durability of capital. Each item of capital equipment can be defined as a separate commodity and can be given a one period length of life after which it becomes another commodity, albeit a one year older version of itself. The problems of measurement of capital which plague the neoclassical aggregate production function are thus avoided. Also a strict separation is made between price of capital goods and profits. Finally the source of profits is seen as the technology which permits growth.

Technological progress is not endogenized in neoclassical economics, nor in classical economics except in a loose sense in the grand design of Adam Smith. Von Neumann as well as Sraffa leaves the question well alone. It is with Karl Marx that an ambitious model is attempted of a fully endogenous model of growth, accumulation and technological progress.

Profits as Exploitation (Marx)

Marx makes an explanation of the source of profits a central part of his theory. There are two ways of understanding this central role of profit in Marx. The *measure* of economic surplus being labour in the classical theory, an immediate question arose among certain socialist followers of Ricardo as to whether labour was also the *source* of all surplus and hence should be its *sole recipient*. While this is not the case in Smith or Ricardo, for Marx labour becomes a measure of value, and the source of surplus value. Surplus value takes the money form of profits via the mediation of prices, which are formed on the basis of values.

A second motivation of Marx's theory could be seen as extending Ricardo's critique of rent as an unearned income to the category of profits. The scarcity of fertile land is not a natural but a social phenomenon in Ricardo, caused by the progress of accumulation and population. Was the scarcity of capital and the fact that it commanded a surplus equally social? Marx asked.

Marx's theory of profits is that profits are the money form of surplus value produced by labour in the production process but appropriated by the owners of means of production. The capitalist advances capital to buy labour and means of production. But what he buys is labour power, the capacity for work. This is because the labour contract is a voluntary, *ex ante* agreement on the part of the labourer to work a fixed period of time – the length of the working day in return for a wage. The wage is the *exchange value* of the commodity labour power. The *use value* of the labour power is whatever productivity the capitalist can extract from the worker during the working day. There is a gap between the use value and exchange value of labour power but this gap cannot be seized by the sellers of labour power, but only by the buyers. This is because the buyers of labour power, the capitalists, enjoy a class monopoly of ownership of the means of production. Without finding a buyer for the labour power, the labourer cannot reproduce himself, that is, he cannot survive for any length of time with his working capacity intact. Thus, there is an asymmetry in the positions of the workers and the capitalists, as a result of a historical process that has deprived workers of direct access to means of production.

The gap between use value and exchange value present in the case of labour power is not present in the case of capital goods. These are bought and sold by capitalists and hence there is no scope for unrealized gaps to exist for any length of time without being captured by the seller. This is why Marx called the flow of input services from capital goods *constant* (c) capital, i.e. capital which had the same value in the beginning as at the end of the production process. For labour, the flow of input services – the use value realized – was made up of necessary labour measured by the exchange value, i.e. wage and surplus labour which accrued to the capitalist. This is why labour was *variable* (v) capital, it changed value between the time it was bought/paid for and the end of the production process.

The rate of profit, for Marx, was then the ratio of surplus value (s) to the sum of constant and variable capitals $(c + v)$; $[\rho = s/(c + v)]$. All the three terms of the ratio are measured in labour time and are commensurate. Thus, Marx also attempted to arrive at a measure of the rate of profit which would be invariant to relative price changes. But, unlike Ricardo, he did not assume a single good economy. What is needed is that the wage rate can be converted into labour values. The same has to be done about flow of services emanating from the means of production. This requires that the production technology be of a form which makes such conversion of goods into their labour values problem free.

The source of profits in Marx is the exploitation of labour by the capitalists, although it is subsumed that the technology is such as to yield a surplus, that is, a gap between the use value and exchange value of labour power. Positive surplus value is seen as a necessary and sufficient condition for profits to be positive (Okishio 1963; Morishima 1973). Profits are accumulated, and put into ever improving technology as a result of the competition among capitalists. It is in the constant search for higher profits, partly immanent and partly as a response to factors threatening the rate of profit, that the incessant improvement in technology takes place. Capitalists have to find better ways of increasing profits, by any means which can increase the gap between the exchange value and use value of labour power. They may do this by improving working methods (Taylorism), by extending hours of work without increasing the wage (absolute exploitation) or by investing in improved machinery (relative exploitation).

Marx in common with the classical economists also has a theory of the falling rate of profit. The progress of accumulation raises the wage rate and hence with a given technology lowers the ratio of surplus value to variable capital, that is, lowers the rate of surplus value (s/v). In order to stave off this danger, capitalists are compelled to use labour-replacing technology. This raises the organic composition of capital, that is, the share of constant capital in total capital $[c/(c + v)]$. The rate of profit varies directly with the rate of exploitation and inversely with the organic composition of capital. In the pure theoretical model, Marx reasoned that the balance would be such that the rate of profit would fall. He also discussed a number of countervailing tendencies such as the growth of monopolies in particular and a high degree of concentration in the industrial structure which may arrest this tendency of the rate of profit to fall.

Accumulation in Marx proceeds incessantly but not at a constant or equilibrium rate. The search for higher profits drives accumulation and accumulation in turn increases surplus value by being embodied in better techniques. But accumulation acts on a labour force that ultimately even exhausts its reserve army and thus wages threaten to rise. On the other hand, markets have to be found for the larger quantities of goods being produced at prices which will yield a profit, that is, surplus value has to be *realized* in the market, not just extracted from labour. The result is that the accumulation process facing these two limits results in a cyclical growth pattern. This pattern yields cycles around a declining rate of profit.

Marx's attempt to obtain a pure (relative price invariant) measure of the rate of profit has been criticized mainly due to the problem of evaluating the different types of skilled labour used in production. Marx's theory requires that all types of labour be reducible to homogeneous labour. Such reduction cannot be made without a measure of relative value productivity of different types of labour, independently of their market rates of remuneration. Despite much ingenious work, this problem has proved intractable. Another problem arises from the durability of capital. In a joint production formulation, it can be shown that positive surplus value is neither necessary nor sufficient for positive profits. The theoretical formulation has to be amended to rule out non-convexities which lead to the curiosum that negative surplus value can lead to positive profits (Steedman 1976; Morishima 1974). A third problem arises from the fact that an example of accumulation, with balanced growth and a constant rate of profit, was provided by Marx himself in his Scheme for Expanded Reproduction contradicting the necessity of cyclical accumulation or of a falling rate of profit.

Profit as Disequilibrium (Schumpeter, Keynes)

Another ambitious attempt to combine profits and growth was made by Schumpeter. With Schumpeter, profits become a *disequilibrium* phenomenon. He advances a theory of the size of profits, especially the source of profits but none of either the rate or the share of profit. Schumpeter's theory is also the only one where there is a clear link between the monetary system that finances production and the real system that generates profits. Schumpeter's is also the only theory which makes the agency of the profit earner – the entrepreneur – an explicitly central part of the theory.

The source of profits is innovation. Innovations can comprise introduction of a new good, of a new method of production, the opening of a new market, discovery of a new source of supply of raw material, or the carrying out of a new organization of an industry. The economy is supposed to be in a state of stationary or steady-state equilibrium before the innovation occurs. An entrepreneur as a visionary innovates by launching a new product or a new technique, and so on. Such a new product may have a long gestation lag before it earns revenue and, as such, may be risky. Thus in the financing of innovations, credit plays an active role. Such credit will be excess to current goods supply and will cause inflation. Once the innovation appears on the market, the entrepreneur makes monopoly profits. The credit initially created can be liquidated out of profits but the innovation causes further ripples via backward and forward linkages as well as by attracting imitators. Innovations occurring singly or in a cluster set off a long wave, a Kondratieff cycle. In the rising phase, prices, profits and output rise. But eventually the monopoly profits are bid away by competitors and the system returns to equilibrium, with profits tending to zero.

The innovation process is discontinuous and disequilibrating. It is accompanied by a credit boom and a cyclical upturn. Innovations are unanticipated. The economy exists in cycles caused by innovations but tending towards an equilibrium of zero profits, once the innovation has spent itself. The history of capitalism was for Schumpeter made up of successive long waves caused by clusters of innovations.

Thus for Schumpeter the source of profits is the superior productivity achieved by innovations but the agent of change is the entrepreneur. Neither the conventional industrialist nor labour generates profits. Profits are by nature abnormal, disequilibrium phenomena. They do not persist but dissipate in equilibrium.

Schumpeter thus reconciles a zero profit stationary equilibrium with observed facts of profits. But while the theory is an appealing one, it has lacked sufficient analytical detail to prove either a source of further developments in profit theory or a tool for empirical investigation.

While Schumpeter put forward a dynamic theory of the disequilibrium role of profits, his model is sparse in details. Keynes in his *Treatise on Money* also treats profits as disequilibrium and insists that national income calculations exclude profits. The emergence of profits as a disequilibrium category comes from the gap between savings and investment. The famous Fundamental Equations of the *Treatise* describe a two sector model with consumption goods and investment goods. For each sector, the price level is made up of unit labour cost and a disequilibrium item. For the consumption goods sector, this item consists of the cost of production of investment goods less savings. Following a similar procedure for the other sector and aggregating over the two sectors, Keynes gets the result that

$$P = w + \pi \tag{1}$$

$$\pi = (I - S)/Y. \tag{2}$$

P is the overall price level, w earnings per unit of output (unit labour cost) and π is profit per unit of output, that is, the share of profit. This identity becomes an equation only because via the expenditure equations, profits per unit of output are derived as the gap between investment expenditure (I) and savings (s) both per unit of output (Y) as in Eq. (2). In equilibrium, Keynes expects π to be zero and w to include 'normal' profits or remuneration of non-labour inputs as well as labour. When profits are non-zero this is because of investment exceeding savings and in a Wicksellian process this gap drives profits to drive the gap wider still. This process is not sufficiently articulated due to the fact that Keynes concentrates on conditions for price stability rather than on disequilibrium dynamics.

Post-Keynesian Theories of Profit and Growth

Kalecki's theory marks a bridge between Marxian and Keynesian traditions and is the seminal contribution to what is now called the Post-Keynesian or Cambridge theory of income distribution. Paradoxically its points of contact with the *Treatise on Money* have not been sufficiently brought out. Kalecki's route was via Rosa Luxemburg's critique of Marx's Schemes of Expanded Reproduction (SER). The SER is also a two-sector model but of a growing economy. It has a two goods/two class configuration which is similar to the Fundamental Equations of the *Treatise*. While Marx's formulation of the SER make the model an equilibrium one, Luxemburg was seeking to find roots of dynamic disequilibrium within it. There are several strands which Kalecki weaves into this story.

Kalecki has a macroeconomic theory of pricing which yields a determinate share of profits in total output. He does this by exploiting the marginal revenue equals marginal cost conditions of equilibrium for the neoclassical firm. By then exploiting the simple idea that the ratio of price to marginal revenue departs from one to the extent that the price elasticity of demand is below infinity he connects price to marginal cost via the demand elasticity. Thus

$$p = mc\left(1 + \eta^{-1}\right) \tag{3}$$

where mc is the marginal cost and η is the elasticity of demand. The coefficient $(1 + \eta^{-1})$ is called the degree of monopoly. To the extent that η^{-1} departs from zero, the firm is a monopolistic one.

This is a partial equilibrium, microtheoretic derivation of the p/mc ratio and its generalization to a macro-economic level has proved to contain problems (Mitra 1954). The main problem is that if (3) is supposed to refer to a specific firm, its elasticity of demand is not a constant but a function of the firm's own and its rivals' strategies. A determinate and tractable aggregation procedure for many jointly dependent p/mc ratios is not possible. It has however been found possible and empirically fruitful to interpret pricing decision as a mark-up above average cost.

$$p = (1 + k)ac \tag{4}$$

where ac is average cost and k is the mark-up ratio. The similarity of (4) to Keynes's Fundamental Equation in (1) is striking, that is, $\pi = k/(1 + k)$. But while (1) is an identity, (4) could be thought of as an equation where the profits come from producers' price setting behaviour.

But how are these profits sustained or in Marx's terminology realized? This is where the aggregate demand relations become important. It would be through the spending behaviour of the profit receivers that profits can be sustained. This was already clear in Keynes's invocation of the widow's cruse parable whereby a Wicksellian cumulative dynamic process can sustain growing profits as long as capitalists spend (that is, dissave) while keeping up their investment expenditure. By starting with the Marxian SER, Kalecki was able to derive this as an *equilibrium* relation.

Kalecki's macroeconomic theory is best seen in terms of Kaldor's generalization. Kaldor takes the two class/two good model and integrates profits into a theory of growth and distribution. Let R be total profits ($\equiv \pi Y$) and W be the total wage bill ($= wL$). Then

$$Y = R + w \tag{5}$$

$$I = S = s_w W + s_c R. \tag{6}$$

Equation (5) is a national income identity, whereas (6) combines the Saving–investment equality with a decomposition of total savings into workers' savings ($s_w W$) and capitalists' savings ($s_c R$) with the $s_c s_w$ being saving propensities and $s_c > s_w$. From (5) and (6), we can derive

$$\begin{aligned} R/Y &= \pi \\ &= (s_c - s_w)^{-1}(I/Y) - s_w(s_c - s_w)^{-1} \end{aligned} \tag{7a}$$

and

$$\begin{aligned} R/K &= \rho \\ &= (s_c - s_w)^{-1}(I/K) - s_w(s_c - s_w)^{-1}(Y/K). \end{aligned} \tag{7b}$$

Equation (7a) gives the share of profits in terms of the investment income ratio and (7b) gives the rate of profits in terms of the rate of growth of capital stock (I/K) and the output–capital ratio (Y/K). To specialize the equation, set $s_w = 0$, that is, assume workers do not save. Then

$$\pi = {s_c}^{-1}(I/Y) \tag{8a}$$

$$\rho = {s_c}^{-1}(I/K). \tag{8b}$$

These two equations show how the profit share is determined by the capitalists' investment behaviour, i.e. capitalists determine their own profits. If we take the output–capital ratio to be a constant, then the rate of growth of income (g) is equal to the rate of growth of capital stock (I/K). Thus from (8b), we have

$$\rho = {s_c}^{-1} g. \tag{9}$$

If we now put $s_c = 1$, we have the von Neumann result reproduced in the Kalecki–Kaldor models.

The restriction that $s_w = 0$ is of course arbitrary and thus makes the result under (8b) somewhat unrealistic. Pasinetti (1962) generalized the Kaldor argument by allowing workers as well as capitalists to save and own capital. Thus total capital K could be held either by capitalists K_c or by workers K_w but since capitalists make output and investment decisions workers were assumed to have loaned K_w to capitalists. In terms of the distinction we made above, capital as productive equipment is *controlled* by capitalists but capital as a financial asset is *owned* by both workers and capitalists, and capitalists pay workers a rate of interest i on the loaned capital. Thus instead of (7a) and (7b), we get

$$\begin{aligned} R/Y &= \pi \\ &= (s_c - s_w)^{-1}\Big[(I/Y - s_w) + r\Big(s_w s_c (I/K)^{-1} \\ &\quad - s_w (Y/K)^{-1}\Big)\Big] \end{aligned} \tag{9a}$$

$$\begin{aligned} R/K = \rho = (s_c - s_w)^{-1}\Big[&(I/K - s_w(Y/K)) \\ &+ r\Big(s_w s_c (I/K)^{-1} - s_w\Big)\Big] \end{aligned} \tag{9b}$$

If we now put $r = \rho$, (9a) and (9b) degenerate to

$$\pi = {s_c}^{-1}(I/K) \tag{10a}$$

$$\rho = {s_c}^{-1}(I/K). \tag{10b}$$

The only condition needed for this result is that $(I - s_w Y) = 0$. But while (10b) is similar to (8b), now it is independent of whether s_w is zero or not.

The similarity of the Kalecki–Kaldor result to the von Neumann result, as we noted above, is striking. The Pasinetti result seems to reinforce it. It is a one-good model and hence problems of relative price or aggregation or measurement of capital which plague other theories are completely avoided here. It is also not clear as to whether causality proceeds from growth to profits or profits to growth. There is an implicit assumption that the economy must have adequate resources and technology to generate surplus but the source of the surplus is not clear. There is no specification of the production conditions and a neoclassical aggregate production function is deliberately avoided.

The Pasinetti result has been derived by an alternative route by Samuelson and Modigliani (1966) who do use a neoclassical aggregate production function. Their purpose was to point out that the Pasinetti result was a special case of a more general result and that a dual to Pasinetti's theorem – an anti-Pasinetti theorem – could be derived from a slightly alternative formulation. All the assumptions of Pasinetti's theory are retained except that profits and wages are now derived from the marginal productivity conditions and a constant return to scale, two factor production function.

Let the production function be

$$\overline{Y} = f\left(\overline{K}\right) f' > 0, f'' > 0. \tag{11}$$

Here $\overline{Y} = Y/L, \overline{K} = K/L$, that is, output per worker and capital per worker. By the standard rules of marginal productivity theory we have that wage and rate of profit are determined as

$$\rho = f'\left(\overline{K}\right) \tag{12a}$$

$$w = f - \overline{K}f'\left(\overline{K}\right). \tag{12b}$$

In the production function, there is no distinction as to who owns the total capital stock – capitalists or workers. The savings augment the amount of capital owned by workers and capitalists,

$$S_c = \dot{K}_c = S_c\, f'(K)\, K_c \tag{13a}$$

$$S_c = \dot{K}_w = s_w[Y - f'(K)K_c]. \tag{13b}$$

The equilibrium condition in the Samuelson–Modigliani model is that the relative rates of growth of capital stock owned by workers and capitalists be the same, i.e. constancy of shares in productive wealth. This is not an obvious condition for equilibrium but it does have the dramatic consequence that in such an equilibrium (of balanced growth of K_c and K_w), the rate of profit is independent of the saving propensity of the worker. If n is the constant growth rate of the capital stock, we get from the above after some manipulation

$$\dot{K}_w = s_w[f(K) - K_c f'(K)] - nK_w \tag{14a}$$

$$\dot{K}_c = [s_c f'(K) - n]K_c. \tag{14b}$$

In steady state $\dot{}K_c = \dot{}K_w = 0$, so (14b) gives

$$\rho = f'(K) = n/s_c. \tag{15}$$

Thus, the Pasinetti result can be derived from a neoclassical logic. This should not be too surprising though much was made of this paradox at the time (Pasinetti 1966; Kaldor 1966). Neither a condition such as $\rho = r$ (what we have called the degeneracy result) nor that K_c/K_w is a constant tell us very much about the mechanisms by which an economy can arrive at such results. Our economic world is a world of many heterogeneous goods – capital as well as labour, of uncertainty, of financial constraints, of the persistent possibility of technical progress, of mergers and takeovers. There is in these models no decision making agency and time is eliminated in any meaningful sense since no *ex ante* versus *ex post* distinctions can be made. The Kalecki–Kaldor–Samuelson–Modigliani propositions are simple parables of pedagogic value no doubt but they do not tell us much about the origins or the role of profits in a modern economy.

Behavioural Theories of Profit

We can move in the final section of our essay to theories where the behavioural context is much more explicit. The neoclassical firm is a black box, where all the allocative rules could be followed by a computer which can be programmed to equate a derivative to a price. But the modern economy consists of corporations which operate in a world of financial markets and profits and are in this world both a signal of managerial performance and a facilitator for future expansion. It is this cluster of theories which supply the missing dimension in the theories hitherto surveyed.

Entrepreneurial Theories of Profit

In this cluster of theories, the level of aggregation is the firm and the agency of decision making is identified as the entrepreneur. It is assumed that the firm operates in a noncompetitive but stable environment where the entrepreneur has to form expectations about economic variables within his control as well as rivals' strategies. The other set of variables is the macroeconomic one where entrepreneurs may hold similar short run expectations. The level of profit sustained by the firm will depend in the short run on macroeconomic factors, common to all firms but in the long run on the decisions to invest so as to keep rivals at bay (Keirstead 1953).

Knight's definition of uncertainty and Keynes's view of the difficulty of rational calculus in forming long-run expectation have been synthesized by Shackle in a series of works (Shackle 1954, 1969, 1970) which purport to relate investment and *ex ante* profit in a decision theoretic framework. Shackle's decision theory is not however that of von Neumann–Morgenstern. He puts forward the notion of potential surprise and a surprise function relating the 'size' of potential surprise to the profit or loss attached to the project. Along with the surprise functions there is an ascendancy function which relates the entrepreneur's engagement with a project given the size of gain or loss anticipated.

Shackle then describes an optimizing exercise on the part of the entrepreneur, yielding optimal potential surprise. The size of gain or loss attached to the optimal potential surprise is then called primary focus gain or loss. The zero surprise (that is, certainty) equivalent of this primary gain is what Shackle calls profits. Profits are thus an *ex ante* certainty equivalent measure of the likely gain of the optimally chosen investment project. This definition unlike all previous ones makes the subjective and *ex ante* concept of profits clear. The problems with Shackle's theory are that it is determinedly resistant to aggregation even over individuals and while emphasizing the difficulty of using the calculus of subjective probability it assumes that the surprise function and the ascendancy functions are continuous and differentiable enough to define a unique maximum. There is obviously a contradiction here.

Mention should be made in this respect of Lamberton's work (Lamberton 1965). Lamberton prefers a satisficing to a maximizing approach and explicitly introduces the entrepreneur's income–leisure (inactivity) trade-off as determining the choice of investment projects and the associated profit outcome. In later work, amberton rationalizes suboptimizing behaviour in terms of the costs of information gathering and processing. Entrepreneurial activity to maintain or enhance profits is triggered off subject to threshold effects.

A Corporate Theory of Profit

Authors such as Keirstead and Shackle view the firm as a single-owner entity. Modern firms are not by and large individually owned. In terms of share of output, employment or sales, it is the corporation with team management and hierarchical command structures which is the dominant mode of firm organization. It is not surprising therefore that one class of theories deals with profits in the context of corporate or managerial behaviour.

While in general Galbraith can be said to have made economists aware of the corporate form, corporate theories could be said to have benefited from the contribution of the behavioural theory of firm of Simon, Cyert and March, the hypothesis attributed to Baumol that firms maximized sales rather than profits and the notion due to Marris among others that growth of corporate size was the aim of managers of corporations (Baumol 1967; Cyert and March 1963; Galbraith 1967; Marris 1964; Simon 1957). These various developments in industrial economics brought forth a view that managerial behaviour was growth oriented, that operating in monopolistic competitive environments managers could choose profits and growth combination subject to the constraint of external sources of finance.

Wood (1975) presents the most complete theory in this respect. There are no details on the production side in his theory of profits. Profits arise from the need of the corporation to grow. The choice variables are the retention ratio, that is, the proportion of investment financed from external sources and the amount of liquid financial assets desired by the firm to be held as some relation of gross investment expenditure.

The firm is assumed to be facing a convex opportunity frontier between the profit share (profit margin as Wood calls it) and the growth rate of its sales revenue. Its desired (or target) values of the retention ratio (γ) the external finance ratio (λ) and the liquid financial holdings ratio (δ) give a simple relation between profit share (π) and the growth rate g. We have

$$I + \delta I \leq \gamma R + \lambda I. \tag{16}$$

In Eq. (16), the left-hand side represents the uses of funds and the right-hand side the sources of funds. A slight rearrangement gives us

$$R/Y = \pi \geq \gamma^{-1}(1 + \delta - \lambda)\sigma g \tag{17}$$

where $g = \Delta Y/Y$, the growth rate of sales and $\sigma = I/\Delta Y$ is investment to increase in output (or the incremental capital output) ratio. Now if one could accept that the coefficients δ, λ and γ are fixed parameters and σ is also constant, then π and g are linearly related. The firm will start with a desired value of g and seek the appropriate Π and by an iterative process arrive at a Π, g combination which satisfies (17) as an equality rather than an inequity. This Π, g combination will also be on the boundary of the opportunity frontier.

Wood's theory treats the corporation in isolation and with some control over its pricing and revenue situation. The presence of competing monopolistic firms is ignored here as in Kalecki's theory. But his theory does bring out the interrelationship between profits and the financing of investment. Note also that in (16) all the variable are in nominal terms. If the parameters δ, λ and γ were identical across firms, we would aggregate (16) across firms. Since Y is sales revenue in nominal terms Eq. (17) would make sense at an aggregate level though it would be harder to swallow that σ would be a constant.

Conclusion

A satisfactory theory of profits is still elusive. For neoclassical economics, profit is a non problem and the only problem is to assign any observed net income above costs to the category of interest, quasi-rent or managerial wages for risk bearing. But problems persist for other theories as well. The classical theory neglects uncertainty and is vague about the microfoundations of profits. If von Neumann and Sraffa detail the technical conditions of production, neither uncertainty nor demand considerations figure prominently in their theories. Most theories, with the exception of the corporate theories and Schumpeter's, neglect the financial aspects of business operations. The firm is a black box in neoclassical theory whereas for Knight, Keynes and Shackle the individual decision maker's expectations are crucial to business behaviour. To allow for persistent positive profits in a dynamic equilibrium microeconomic model with subjective uncertainty and expectations with the possibility of technical substitution and technical change in production remains a challenge. If such a theory could be cast in terms to allow aggregation over firms to the level of the economy, the puzzle of profits would be solved.

Progressive and Regressive Taxation

William Vickrey and Efe A. Ok

Abstract

Progressive (resp. regressive) taxation refers to a taxation scheme in which the amount of tax paid as a proportion of the tax base rises (resp. declines) with that base. While progressive taxation has been justified in terms of the 'principle of equal sacrifice' and mitigating the inequality of market outcomes, no general political theory of income taxation provides theoretical support for the observed prevalence of progressive taxation schemes. Nor has the theory of optimal income (and consumption) taxation shed any light on the nature of progressive taxation, either normatively or positively.

Progressive (resp. regressive) taxation refers to a taxation scheme (applied to a monetary base such as income, consumption, wealth and so on) in which the amount of tax paid as a proportion of the tax base rises (resp. declines) with that base. As such, characterizing taxes as progressive or regressive according to the relative degree to which they impose burdens on the wealthy and on the poor seems at first blush a fairly straightforward matter. Unfortunately, when one wishes to understand the nature of *effective* progressivity of a taxation scheme, and its redistributive properties thereof, and especially to compare the relative degree of progressivity or regressivity of alternative taxes, a number of problems arise. Before formalizing the notion of progressivity, we thus have a quick look at these issues.

Tax Base

An important and often overlooked question is that of the base to which the tax burden is to be related. Usually the base is taken to be income, which in practice, whenever an attempt is made to produce actual figures, means some version of annual monetary income (which perforce includes salaries, interest and dividends, but which may or may not include capital gains). An alternative basis for evaluating progression would be consumption. This is not often used, and is subject to the same deficiencies as income as a result of omissions of non-monetary items such as imputed incomes from consumer durables (like owned homes).

Tax Burden

There are various difficulties in determining the actual tax burden levied on a taxpayer. First, application of tax rates to incomes that fluctuate (due to, say, the stage of one's life cycle) makes this difficult to measure. As advocated by Vickrey (1947), it appears that some form of income averaging is needed (to serve as a proxy for the expected permanent incomes) but this has been found to be too complicated to administer in practice. Second, it is not obvious how to incorporate family size in the computation of tax burdens. Simply taking the aggregate would misclassify the larger and smaller units relative to their level of welfare or ability to pay, while taking a per capita measure overstates the importance of children relative to their needs. (See Pechman 1987, pp. 78–133, for a careful discussion of these issues and other structural problems with tax assessment in general.) Third, the market mechanism often allows the tax burden to be passed from the taxpayer to other units in the economy, with the eventual consequence that the burden of taxes is not necessarily borne by those upon whom they are levied. In particular, the imposition of taxes on income or sales changes the budget sets of individuals, thereby altering equilibrium prices in the economy. The issue becomes particularly pressing in the case of corporate income tax, as tax incidence in this case varies widely according to fiscal, monetary or activity level changes that are associated with an alteration in the tax. For instance, a tax imposed on firms for hiring labour is more than likely to be 'shifted' to workers through lower wages and to consumers through higher prices, upon the adjustment of employment decisions on the part of the firms. In general, then, the ultimate distribution of the tax burden – the so-called *economic incidence* – is different from *statutory incidence*, that is, the initial distribution of tax liabilities. Unfortunately, it is a highly non-trivial matter, both empirically and theoretically, to determine precisely who bears the tax burden, and ultimately to what extent. It is thus not uncommon in practice to encounter discussions on tax progressivity that ignore tax incidence problems and concentrate instead simply on statutory incidence. (See Musgrave and Musgrave 1989, chs. 12 and 13, for an introductory account of tax incidence analysis, and Kotlikoff and Summers 1989; Atkinson 1994, for advanced treatments.)

It is worth noting that the issues concerning the base and burden of taxes are integral to any sort of fiscal analysis, and are not particular to the analysis of tax progressivity. To flesh out the elements of the latter, therefore, we shall abstract from these difficulties in what follows and assume that a notion of monetary outcome, which we shall simply refer to as *income*, is determined as the arbiter of ability to pay. Moreover, for the most part we shall work under the (uncomfortable) supposition that the amount of tax charged on a given level of income corresponds to the actual tax burden of the taxpayer with that amount of income. At the very least, this will allow us to focus properly on certain facets of the *theory* of progressive taxation.

Progressive (Regressive) Tax Functions

Formally speaking, a *tax function* is a right-differentiable and strictly increasing map $T : \mathbb{R}_+ \to \mathbb{R}_+$ such that $T(0) = 0$ and $T(x) < x$ for all $x \in \mathbb{R}_{++}$, and $0 < T'(x) < 1$ for all $x \in \mathbb{R}_+$. (Here we denote the right-derivative of T by T'.) This formulation maintains that (i) zero income earners do not pay any taxes; (ii) if a person earns positive income, the amount of taxes imposed on her must be less than her taxable income base; (iii) higher-income earners pay a higher level of tax than lower-income earners; and (iv) taxation is non-confiscatory in that the ranking of taxpayers by pretax income and post-tax income is the same. (We rule out here negative taxation to simplify our exposition, and view T as modelling a *statutory* tax scheme.) A tax function T is said to be *progressive* if the map $x \mapsto \frac{T(x)}{x}$ is increasing on $\mathbb{R}_{++}$, that is, if the amount of income tax paid as a proportion of the tax base (say, income) rises with that base. In turn, T is *regressive* if $x \mapsto \frac{T(x)}{x}$ is decreasing on $\mathbb{R}_{++}$. Finally, T is *marginal-rate progressive* (*regressive*) if the tax rate T' is itself an increasing (decreasing) function. In practice, statutory taxes on income and spendings are always progressive – in fact, they are almost always marginal-rate progressive – while payroll and sales taxes possess a flat statutory tax rate (but economic incidence analyses frequently reveal that such taxes are, effectively, regressive).

Normative Basis for Progressivity

The most well-known equity principle – advanced originally by John Stuart Mill – that provides a normative basis for progressive taxation is the *principle of equal sacrifice.* The modern formulation of this principle demands that there be a social norm, represented by a continuous, concave and strictly increasing (social) utility function $U : \mathbb{R}_+ \to \mathbb{R}$ relative to which the income tax T imposes equal sacrifice upon all taxpayers, that is,

$$U(x) - U(x - T(x)) = \text{constant for all } x > 0$$

(see Young 1987, 1990; Ok 1995). We may now ask: does a progressive, or a marginal-rate progressive, tax necessarily satisfy the principle of equal sacrifice? Conversely, does this principle necessitate progressivity?

The answers are, unfortunately, not very clear. First, the good news: it can be shown that a marginal-rate progressive tax function surely satisfies the principle of equal sacrifice. The bad news is that mere progressivity of a tax function is not enough for it to satisfy this principle (Mitra and Ok 1997). To make matters worse, even for some non-progressive taxes T we can find a (social) utility function U that satisfy the properties above, that is, the principle of equal sacrifice need not imply, or be implied by, tax progressivity. At the very least, one needs to assume more about T and U to be able to relate these principles more closely. For instance, if we demand that U be differentiable (at least near the origin), then a piecewise linear tax function T satisfies the principle of equal sacrifice (as we formulated above) *if, and only if*, T is marginal-rate progressive (Mitra and Ok 1996). If one is prepared to accept this set-up, therefore, the principle of equal sacrifice can be thought of as characterizing marginal-rate progressivity of a (statutory) tax function, thereby necessitating its progressivity.

An additional caveat here is, of course, that this account ignores the disincentive effects of taxation. It is partial relief that Berliant and Gouveia (1993) have shown that, when the individual utility functions over income and leisure are additively separable, the link between the principle of equal sacrifice and progressivity would prevail even in the presence of such effects. Unfortunately, little is known about this matter in the (more realistic) non-separable case.

Redistributive Consequences of Progressivity

One of the traditional arguments for progressive taxation is that such schemes redress the highly inegalitarian outcomes of the market system, thereby acting as social insurance against inequality. As colourful as it may be, this argument needs to be formalized properly.

Let us first agree to model an income distribution as a continuous and increasing distribution function $F : \mathbb{R} \to [0, 1]$ with $F(0) = 0$ and $F(1) = 1$. This sort of a specification is, for instance, frequently adopted in macroeconomic models of income distribution. For any such F, we let $\mu_F := \int_0^1 x dF(x)$, which is the total income in the society. (Since incomes are distributed on $[0, 1]$, that is, we effectively concentrate on relative incomes, μ_F also corresponds to the per-capita income in this model.) In what follows we naturally assume that $\mu_F > 0$.

For any such income distribution F, the *pseudo-inverse* of F is defined as the function $F^{-1} : (0, 1) \to \mathbb{R}_+$ with

$$F^{-1}(t) := \inf\{x \geq 0 : F(x) \geq t\}, 0 < t < 1.$$

Intuitively, we may think of $F^{-1}(t)$ as the income level of the person who belongs to the poorest $100t$ per cent in the income distribution. We next define the map $L_F : [0, 1] \to \mathbb{R}$ by

$$L_F(p) := \frac{1}{\mu_F} \int_0^p F^{-1}(t)\, dt, 0 \leq p \leq 1,$$

which corresponds to the cumulative share of income held by the poorest 100 per cent of the population. The graph of the map $p \mapsto L_F(p)$ is called the *Lorenz curve* of the distribution F.

We say that the income distribution F *Lorenz dominates* another income distribution G whenever $L_F(p) \geq L_G(p)$ holds for all $p \in [0, 1]$, with strict inequality for at least one p. It is well known that this happens if, and only if, G can be obtained from F by means of finitely many mean-preserving spreads (Rothschild and Stiglitz 1970). This is one of the reasons why Lorenz dominance is generally accepted as an *unambiguous* method of making ordinal inequality comparisons. Its welfare basis is identified in the seminal works of Kolm (1969) and Atkinson (1970).

Now take any income distribution F. A tax function T applied to this distribution induces the *post-tax income distribution* F^T where $F^T(x){:} = F(x - T(x))$ for any $x \in \mathbb{R}$. A celebrated theorem of public economics – often called the *Jakobsson–Fellman theorem* – maintains that F^T Lorenz dominates F, that is, tax is inequality-reducing, if, and only if, T is progressive (see Fellman 1976; Jakobsson 1976). That is, progressive taxes, *and only progressive taxes*, possess the property of reducing the level of income inequality no matter to which pre-tax income distribution they are applied. (For variations on this theme, see Eichhorn et al. 1984, and Thon 1987.) This shows, in a nutshell, why the progressivity of a taxation scheme may be justified on the basis of desire for inequality reduction.

The Jakobsson–Fellman theorem also leads to a natural method of quantifying the redistributive effect of a tax function T that is applied to an income distribution F. To see this, let us consider the function $R_{F,T} : [0, 1] \to \mathbb{R}$ defined by

$$R_{F,T}(p) := L_{F^T}(p) - L_F(p).$$

In words, $R_{F,T}(p)$ measures the income share of the poorest $100p$ per cent in excess of what they would obtain under an equal yield flat tax. Obviously, the Jakobsson–Fellman Theorem says that $R_{F,T} \geq 0$ for *any* income distribution F if, and only if, T is progressive. (But, of course, we may have $R_{F,T} \geq 0$ for *some* F even if T is not progressive.) Now the discussion above suggests to declare a tax function T^1 to be *more redistributive than* T^2 – due to the Jakobsson–Fellman theorem, one often says T^1 *is more progressive than* T^2 – relative to the income distribution F if$R_{F,T^1} \geq R_{F,T^2}$. This is, of course, a partial ordering, and when it does not apply one may wish to resort to a compatible index that sizes up the redistributive effects of T^1 and T^2. The most widely used index to this effect is the *Reynolds–Smolensky progressivity index* defined (as a function of a tax function T) by

$$I_F^{\mathrm{RS}}(T) := 2\int_0^1 R_{F,T}(p)\,dp,$$

which is the difference between the Gini coefficients of the distributions F and F^T. Other indices are proposed in the literature to compare the progressivity of tax functions (which are based, for instance, on the departure of a tax function from the equal-yield proportional tax). For an extensive discussion of such indices, and further results on the redistributional effects of progressive taxes, we refer the reader to the excellent survey by Lambert (1999).

Political Economy of Progressive Taxation

Now that we have examined a number of normative rationales for progressivity of income taxes, let us turn to the strand of literature that has attempted to explain the prevalence of such tax schemes from the viewpoint of behavioural political economy. This literature maintains that, given that her views about income tax policy is one of the most important traits of a political candidate, it is natural to expect this prevalence to reflect (however indirectly) the majority support in the population. In fact, this way of thinking seems to suggest a straightforward explanation of the empirically observed popularity of marginal-rate progressivity, provided that one subscribes to the 'one-man one-vote' rule. Since the income distribution of a country is always globally right-skewed (in the sense that the median income is strictly smaller than the mean income for any right truncation of the income distribution), the number of poorer voters always exceeds the number of richer voters, regardless of how one defines the cut-off that separates the poor from the rich. Since poorer voters are typically the supporters of progressive policies, so the argument goes, there would then be a natural tendency for the marginal-rate progressive tax policies to be favoured by the majority. Even though the actual political processes are far more complex than the scenario in which people vote directly over policies, this argument appears to suggest a convincing reason for why progressive tax policies are so widely adopted.

While there are a few direct democracy models in the literature that provide support for this argument (cf. Romer 1975; Roberts 1977; Cukierman and Meltzer 1991; Gouveia and Oliver 1996; Marhuenda and Ortuño-Ortín 1998; Roemer 1999), these models are either confined to rather specific settings (in which a tax function is characterized by means of at most two parameters) or are not couched in a political equilibrium framework. A natural direct democracy model of voting over income taxes would be a two-party voting game in which each party (whose objective is to win the elections) proposes a tax function from an exogenously given set of admissible tax functions (that raise a given amount of revenue), and voters vote selfishly for the tax function that taxes them less. To make transparent the difficulties that pertain to the political economic approach to progressive taxation, we now describe such a voting model in precise terms.

Let F be a strictly increasing income distribution (as modelled above), and assume that the median income is strictly less than the average income according to F, that is, $m_F := F^{-1}\left(\frac{1}{2}\right) < \mu_F$. (This assumption is but a straightforward formalization of the heuristic statement that 'the number of poor people in the society is strictly less than that of rich people'.) To focus on the issue of *redistribution*, it is assumed that tax policies are designed to collect an exogenously given amount of revenue $0 < \alpha < \mu_F$, or put differently, an *admissible tax function* T is defined in the model as one with the property $\int_0^1 TdF = \alpha$. We denote the class of all such tax functions by $\mathscr{T}_{F,\alpha}$.

Consider a two-party voting model in which each party advocates an income tax policy in $\mathscr{T}_{F,\alpha}$ which is to be put in effect in case this party obtains the support of the majority. Citizens evaluate proposals from a selfish point of view. Put precisely, an individual with income x regards the tax function

T^1 as more desirable than the tax function T^2 if $T^1(x) < T^2(x)$, that is, if this individual's tax liability is lower under T^1. It is assumed that indifferent voters abstain from voting. Thus, if party 1 proposes tax policy t_1 and party 2 proposes tax policy t_2, the share of votes obtained by the first party is determined as

$$\omega\left(T^1, T^2\right) := p_F\left\{x \in [0, 1] : T^1(x) < T^2(x)\right\},$$

where p_F is the probability measure induced by F on [0, 1]. Of course, in this case the share obtained by party 2 is ω (T^2, T^1). The formal model takes the form of a two-person strategic game in which the two players are the parties both of whose action spaces equal $\mathscr{T}._{F,\alpha}$ There is a multitude of ways of modelling the objectives of the parties here. We follow Carbonell-Nicolau and Ok (2007), and presume that the goal of party i is the maximization of the net plurality defined as the difference between the vote shares obtained by the candidates. (For instance, the payoff function of party 1 is the map $\left(T^1, T^2\right) \mapsto \omega\left(T^1, T^2\right) - \omega\left(T^2, T^1\right)$ on $\left(\mathscr{T}_{F,\alpha} \times \mathscr{T}_{F,\alpha}\right)$.

While this model is one of the simplest of its kind, it readily exhibits the familiar difficulty of (infinite-dimensional) voting games: it does *not* have a Nash equilibrium (for any given F and α). Intuitively speaking, this is because, given any admissible tax T in $\mathscr{T}_{F,\alpha}$, one can always find another tax function which is below T over an interval of p_F measure greater than one half. Not all hope is lost here, however, as it can be shown that there is at least one mixed strategy equilibrium of this game. The question then becomes whether or not the support of any such equilibrium consists only of progressive taxes. Curiously, Carbonell-Nicolau and Ok (2007) show that, if F and α satisfy a certain condition, then, generically, in at least one equilibrium the probability of parties proposing a non-progressive tax function is positive. All in all, after a lot of work, and absent a good economic reason for working with a particular way of restricting the set of admissible tax functions, one is left with the feeling that the prevalence of tax progressivity that we find in all industrial democracies cannot be attributed solely to the right-skewedness of income distributions.

In passing, we should note that, in the context of *representative* democracies (à la Osborne and Slivinski 1996; Besley and Coate 1997), one is sometimes able to escape from the equilibrium existence problem discussed above. Indeed some positive results on the majority support for progressive taxation are obtained in this setting (cf. Carbonell-Nicolau and Klor 2003). Unfortunately, it is not known whether or not these results would survive the inclusion of disincentive effects of taxation into the model. Furthermore, if we add to the picture dynamic considerations of voters, things would get even more complicated. Indeed, we know from Benabou and Ok (2001) that if the income mobility process has a particular property (called *concavity in expectation*) that is often met in reality, then individuals who are currently poor may oppose redistribution because they (rationally) expect to move up in the income ladder in the future. Indeed, it is possible that this *prospect of upward mobility* (*POUM*) *hypothesis* may be strong enough to overturn the majority support of progressivity (even at the steady state of the underlying mobility process).

To wit, it seems at present that we do not have a general political theory of income taxation that provides theoretical support for the observed prevalence of progressive taxation schemes. Nevertheless, this is an area of active research, and it is not unreasonable to expect that lasting contributions on this theme will be made in the near future.

Optimal Tax Structures

Any discussion of progressive taxation would be incomplete without putting on record the large amount of work conducted towards the end of 20th century on the optimal design of income (and commodity) tax schemes. Indeed, after the seminal contribution of Mirrlees (1971), there has been an immense amount of work in this area, which has, however, slowed down significantly in more recent times. Roughly speaking, the canonical model of optimal income taxation works with a population with a given distribution of income earning ability and with a utility function having disposable income and effort as arguments, pre-tax income being a function of ability and effort. Individuals then act to maximize their individual utility subject to an income tax schedule which is to be determined to raise a given revenue while resulting in a maximum of utility for the population which is obtained as an aggregation of the individual utilities. Unfortunately, despite the promise of the early work on this topic – see, for instance, Sadka (1976), Stern (1976) and Seade (1977) – this model is found not to produce robust qualitative results. (See Stiglitz 1982, for a careful discussion of this issue.) One exception to this is the infamous *end-point theorem* that states that, when the distribution of skills has a known upper limit, the marginal tax rate should vanish at the level of income of the highest-income earners. (Informally speaking, the argument here is that there is no point to deterring the highest-income earner from earning the last dollar of her income, since if she does not earn it there will be no revenue from it.) This has the unsettling implication that an 'optimal' income tax is perforce non-progressive.

There is reason not to take this conclusion too seriously, however. First, simulations show that the end-point theorem is very local (cf. Tuomala 1990; Saez 2001). Second, the assumption that the constituent individuals are identical in all aspects but ability is a rather stringent requirement (which is key for the validity of the end-point theorem). Third, if there is uncertainty in the model that results in the expected income distribution having unbounded support, then the result fails. (See Haveman 1994, for a variety of other critical comments on optimal income taxation theory.) All in all, while it has duly brought the incentive problems into the forefront of public finance, and has provided a new means of evaluating the notion of equity–efficiency trade-off, it appears that the theory of optimal income (and consumption) taxation has not realized its promise in shedding light on the nature of progressive taxation, either normatively or positively.

Perhaps it is best to conclude our discussion, as Haveman (1994) does as well, with the words of Joseph Pechman, taken from his (posthumous) 1990 presidential address to the American Economic Association: 'Most people support tax progressivity on the ground that taxes should be levied in accordance with ability to pay, which is assumed to rise more than proportionately with income. Economists have . . . had trouble with the "ability to pay" concept . . . I believe that the person on the street is right and that we should continue to rely on the income tax to raise revenue in an equitable manner.'

Project Evaluation

Partha Dasgupta

For a private commercial entrepreneur choice among alternative investment projects involves in principle a rather simple exercise. If he knows his own objectives, which would seem a reasonable assumption, all he has to do is to ascertain which projects satisfy his objectives best. For example, he may be interested solely in commercial profits; in which case commercial profitability – adjusted possibly for risk – is his criterion of choice.

The picture is a good deal more complex for a national planner. In choosing investment projects he has to ascertain which best satisfy the interests and objectives of the nation: his personal objectives are fairly unimportant. This is complex not merely because national objectives and interests are not easy to define, but also because the reading of these interests by different planners may well vary. If different planners pursue different national objectives the result may be unsatisfactory and conceivably disastrous.

There is another, equally important, reason why the problem is more complex for the national planner. To a private commercial entrepreneur market prices, when available, are hard bits of information. They enable him to estimate project profits. Not so for a national planner. To assess how an investment project affects national objectives the planner must have some understanding of how the economy will respond to the project; that is, what the project's impact is likely to be. For him market prices are often very soft data. He must have in addition some understanding of the technological and information constraints underlying the economy, in addition of course to the social and political constraints that impinge upon it.

The term 'project evaluation' refers to a branch of applied welfare economics concerned with just this class of issues: how should a national planner choose among alternative investment projects? It is part of a larger field of inquiry called) 'social cost-benefit analysis', which addresses the problem of evaluating all varieties of government activities, not just investment, with a view to providing a means of choosing among them. (See the pioneering work of Meade 1951, 1955; and also Arrow and Kurz 1970.) It should be emphasized though that the role of social cost-benefit analysis is not restricted to government use: the theory provides a conceptual framework with which any individual, as a citizen and social observer, can evaluate government action. Indeed, all concerned individuals perform social cost-benefit analysis continually.

Notional Prices

A particular approach to project evaluation consists of a systematic use of *notional prices* in valuing goods and services, estimating *notional profits* and then ranking investment projects in terms of such profits. These prices are notional because they are not necessarily equal to market prices. They are often called *accounting prices* (Tinbergen 1956; Little and Mirrlees 1969, 1974), and also *shadow prices* (Dasgupta et al. 1972). Mathematicians would call them *dual variables,* or *Lagrange multipliers.* They reflect the *social values* of goods and services measured in terms of national objectives. In a mixed economy the accounting price of a commodity or resource is the difference between its market price and the tax (or subsidy) that ought to be imposed on it. This last observation is useful to bear in mind because it reminds one that project evaluation cannot be thought about and conducted in a vacuum. Public investment choice must of necessity be integrated with the rest of government policy, in particular tax and trade policy (see Diamond and Mirrlees 1971, 1976; Mirrlees 1972; Dasgupta and Stiglitz 1972, 1974).

Selected History

The intellectual origins of the use of accounting prices lie in the brilliant work of Tjalling Koopmans on the possibilities of decentralizing the choice of optimal (or efficient) intertemporal production activities by the use of prices (see Koopmans 1951). In parallel was the establishment, due to Arrow (1951), of what is now called the Second Fundamental Theorem of Welfare Economics, which asserts that when preferences and production technologies are convex and closed, then under certain mild additional assumptions *any* Pareto-efficient preference allocation can be sustained in a decentralized environment if the government imposes appropriate lump-sump transfers among individuals and announces appropriate prices at which individuals and firms are instructed to trade. However, these contributions, and the immediate literature they inspired, were highly abstract and an attempt to make the entire approach operational was expounded by Tinbergen (1956).

There was in fact a parallel development. In market economies a *raison d'être* of government expenditure has been the supply of public goods, that is, commodities whose consumption among persons is non-rivalrous. In a seminal essay Samuelson (1954) revived Erik Lindahl's theory of public expenditure and established rules for the social cost-benefit analysis of government investment in the production of public goods. The key problem that was identified here lies in devising methods for estimating the social benefits from the consumption of public goods, for Samuelson noted that market data provide very soft information about these. (The theory of public goods was subsequently integrated with the economics of externalities by Arrow (1971). The recent literature on incentive compatibility and in particular preference revelation was much motivated by this problem. See e.g. Groves and Ledyard 1977; Green and Laffont 1977.)

A pioneering applied work on social cost-benefit analysis was a water-resource project studied by Robert Dorfman and his co-authors (see Dorfman et al. 1962). This did much to generate interest in the field. However, quite understandably the focus of attention shifted soon after to public investment in developing countries – where governments were busily engaged in producing ‘private goods’ like steel, cement, fertilizer and so forth. There was thus a need to integrate project evaluation within national plans and to ensure that national plans are influenced by the availability of desirable investment projects. This in turn meant that there was a need for a comprehensive analysis of accounting prices of various categories of goods and services in ‘second best economies’; that is, economies in which the government is forced to act in the presence not only of technological and resource constraints but also social, political and information constraints. This was presented in two treatises, Little and Mirrlees (1969) and Dasgupta et al. (1972), both aimed at developing countries, but differing sharply as regards government objectives and the extent to which project evaluators were seen to take constraints into account (see Dasgupta 1972). The decade of the 1970s saw an explosion of publications on theoretical and applied project evaluation based on the methods advocated by these treatises (e.g. Little and Mirrlees 1974; Little and Scott 1976; Squire and Van der Tak 1975; Hansen 1978; Helmers 1979). More recently both the theory and application of methods for estimating accounting prices have been extended to such categories of goods as environmental health benefits (Maler and Wyzga 1976; Freeman 1979), exhaustible resources (Dasgupta and Heal 1979) and renewable natural resources (Dasgupta 1982; Ahmad et al. 1984). We now present a formal model to illustrate the approach.

A Formal Model

Assume that there are $n + 1$ commodities labelled i or j, with $i, j = 0, 1, \ldots, n$. (Time can be introduced into the analysis by distinguishing goods by the date of their appearance and uncertainty by the states of nature contingent upon which they appear. See Debreu 1959.) Of these $n + 1$ goods $m + 1$ are non-traded ($i, j = 0, 1, \ldots, m$), the rest traded ($i, j = m + 1, \ldots, n$). For simplicity of exposition we take it that the country in question is small, so that we may as well normalize and set the border prices of traded goods equal to unity. We aggregate the government sector and denote by $\mathbf{z} = (z_0, z_1, \ldots, z_i, \ldots, z_n)$, the government net output vector and it will be understood that z_i is negative if i is a net input. Production possibilities in the government sector are represented by the set

$$G(\mathbf{z}) = G(z_0, z_1, \ldots, z_i, \ldots z_n) \leq 0.$$

It is best to aim at a general formulation of the problem and not be overly specific about the nature of the remaining sectors or indeed the extent of government control. As we are discussing project evaluation here we will certainly assume that the national planner chooses $\mathbf{z}$. However, we assume that the government can influence private consumption, private production and imports and exports only *indirectly.* Furthermore, we allow for the possibility that the private production, foreign trade and consumption sectors are non-competitive.

Let c_i be the aggregate consumption of commodity i. We assume that it is responsive to public production in a known way. This way we write as $c_i = c_i(\mathbf{z})$. (If there is uncertainty in this relationship the model can be extended in the obvious manner.) Now let y_i denote the net output of i in the private production sector. We suppose that it responds to public production $\mathbf{z}$ in a known way, $y_i(\mathbf{z})$. Private production is constrained by the relation, $y_0 = F(y_1, \ldots, y_n)$, where it should be emphasized that F is not necessarily a technological transformation curve but is, if the private sector is non-competitive, an amalgamation of technological possibilities and the industrial structure.

We denote by x_i ($i = m + 1, \ldots, n$) the net import of tradable i, and we let $x_i = x_i(\mathbf{z})$. Let R be the exogenously given endowment of foreign exchange, say aid. Finally we let social objectives be represented by the social welfare function W, defined directly on the aggregate consumption vector. Thus, $W = W(c_0(\mathbf{z}), c_1(\mathbf{z}), \ldots, c_i(\mathbf{z}), \ldots, c_n(\mathbf{z}))$. (Distributional issues can easily be incorporated into this, but at the expense of additional notation.)

The problem before the national planner is to:

Choose $\mathbf{z}$ so as to maximize $W(\mathbf{c}(\mathbf{z}))$ subject to

$$G(\mathbf{z}) \leq 0 \tag{1}$$

$$c_0(\mathbf{z}) \le F[y_1(\mathbf{z}), \ldots, y_n(\mathbf{z})] + z_0 \tag{2}$$

$$c_i(\mathbf{z}) \le y_i(\mathbf{z}) + z_i, \quad i = 1, \ldots, m \tag{3}$$

$$c_i(\mathbf{z}) \le y_i(\mathbf{z}) + z_i + x_i(\mathbf{z}), \quad i = m+1, \ldots, n \tag{4}$$

$$\sum_{i=m+1}^{n} x_i(\mathbf{z}) \le R. \tag{5}$$

Let non-negative numbers μ, λ_i $(i = 0, \ldots, n)$ and ρ be the Lagrange multipliers associated with the constraints (1), (2), (3), (4) and (5), respectively. It follows from the theory of non-linear programming that if there exist multiplier values μ^*, λ_i^* $(i = 0, \ldots, n)$ and ρ* such that they, in conjunction with the vector of public production, $\mathbf{z}^*$, constitute a saddle-point of the Lagrangean of the maximation problem, then **z*** is an optimal production vector: that is, a solution to the planning problem. It is now an easy matter to confirm that $\mathbf{z}^*$ must then satisfy the first-order conditions,

$$\begin{aligned} &\sum_{j=0}^{n}\left(\partial W/\partial c_j - \lambda_j^*\right)\partial c_j/\partial z_i \\ &+\sum_{j=1}^{n}\left(\lambda_0^*\partial F/\partial y_j + \lambda_j^*\right)\partial y_j/\partial z_i \\ &+\lambda_i^* + \sum_{j=m+1}^{n}\left(\lambda_j^* - \rho^*\right) \\ &\times\partial x_j/\partial z_i = \mu^*\partial G/\partial z_i, \quad \text{for}\, i = 0, \ldots, n. \end{aligned} \tag{6}$$

Equation (6) is fundamental to the theory and practice of project evaluation.

Let $i = 0$ be the numeraire good and define $p_i = \partial G/\partial z_i/\partial G/\partial z_0$ where the right-hand side is evaluated at $\mathbf{z}^*$. It follows that if G is a convex technology **z*** is a profit-maximizing production vector at prices $(1, p_1, \ldots, p_i, \ldots, p_n)$. These are the accounting prices to be used for project evaluation.

Certain special cases may now be mentioned. If the government has complete control over production, consumption and trade and if it wields these controls optimally and if the private production sector is competitive the economy attains a full-optimum allocation. (F in this case represents the private sector production possibility frontier.) According to the Second Fundamental Theorem of Welfare Economics this allocation satisfies the conditions,

$$\begin{aligned} \partial W/\partial c_j &= \lambda_j^* \qquad \text{for}\, j = 0, \ldots, n \\ \lambda_j^* &= -\lambda_0^*\partial F/\partial y_j \quad \text{for}\, j = 1, \ldots, n \end{aligned} \tag{7}$$

and

$$\lambda_j^* = \rho^* \quad \text{for}\, j = m+1, \ldots, n$$

From (6) and (7) we conclude that

$$p_i = \lambda_i^*/\lambda_0^* \quad \text{for}\, i = 0, \ldots, n \tag{8}$$

Conditions (7) and (8) tell us that accounting prices equal market prices and in particular that the shadow price of a tradable equals its border price. This is an undistorted economy.

A second important special case was studied by Diamond and Mirrlees (1971). They analysed optimal public policy in a world in which the private production and consumption sectors are competitive and in which, other than the production constraint G, the sole constraint facing the government is its inability to impose lump-sum transfers. (The rationale behind this inability could be incomplete information about private consumption needs.) Diamond and Mirrlees showed that at this particular ‘second-best’.

$$\sum_{j=0}^{n}\left(\partial W/\partial c_j - \lambda_j^*\right)\partial c_j/\partial z_i = 0, \quad \text{for}\, i = 0, \ldots, n$$

$$\lambda_j^* = -\lambda_0^*\partial F/\partial y_j, \quad \text{for}\, j = 1, \ldots, n$$

and

$$\lambda_j^* = \rho^*, \quad \text{for}\, j = m+1, \ldots, n. \tag{9}$$

It follows that $p_i = \lambda_i^*/\lambda_0^* \quad \text{for}\, i = 0, \ldots, n.$

The first condition in (9) circumscribes the set of optimal commodity taxes. The remaining conditions assert that, as in the Second Fundamental

Theorem, the government should seek economy-wide production efficiency (see also Dasgupta and Stiglitz (1972) and Little and Mirrlees (1974)).

In work parallel to this, Little and Mirrlees (1969, 1974), advocated the use of border prices of tradable commodites in project evaluation. This advocacy has been much debated (see e.g. the *Bulletin of the Oxford University Institute of Economics and Statistics,* February, 1972). It is a less stringent requirement than economy-wide production efficiency and thus might be expected to hold under a wider set of circumstances than envisaged in the Diamond–Mirrlees essay. This was precisely the point explored in Dasgupta and Stiglitz (1974), who located a wider class of circumstances in which

$$\sum_{j=0}^{n}\left(\partial W/\partial c_j-\lambda_j^*\right)\partial c_j/\partial z_i$$
$$+\sum_{j=1}^{n}\left(\lambda_0^*\partial F/\partial y_j+\lambda_j^*\right)\partial y_j/\partial z_i=0,\text{for}\, i=0,\ \ldots,n$$

and

$$\lambda_j^*=\rho^*\quad\text{for}\, j=m+1,\ \ldots,n$$

so that $p_i = 1$ for $i = m + 1, \ldots, n$: the Little–Mirrlees border-price rule.

Perturbation

In the above formulation accounting prices are obtained from an optimization exercise. A more restricted view of government capability sees it choosing investment projects sequentially on the basis of whether or not they *increase* social welfare (see Dasgupta et al. 1972). Let $\mathbf{z}'$ be the) 'current' state of public production. As it is feasible it must satisfy constraints (1), (2), (3), (4) and (5). An investment project is seen as a net addition to $\mathbf{z}'$ a perturbation, which we denote by Δz. For this to be feasible it must be that $\mathbf{z}'$ + Δz also satisfies constraints (1), (2), (3), (4) and (5). The criterion for choice is whether or not W increases as a consequence of accepting Δz. This, less ambitious, approach to project evaluation, originating in Meade (1951, 1955), is gaining much attention today, as it explicitly allows for limits on government rationality and will (see Hammond 1980; Blitzer et al. 1981).

Time and Social Discount Rates

It is not possible to discuss project evaluation without a mention of social rates of discount, unquestionably the most controversial matter in this field of discourse. We alter our notation somewhat and assume that there are k goods and services ($i = 1,\ldots, k$) at each date. Now let ($\mathbf{z}_1,\ldots, \mathbf{z}_t,\ldots$) be an intertemporal public production vector, where $\mathbf{z}_t$ is the k-vector of net outputs at date t. Now let $\mathbf{p}_t = (p_{1t},\ldots, p_{kt})$ be the accounting price k-vector at t ($t = 1, 2, \ldots$). It is a *present-value price vector.* Without loss of generality let $i = 1$ be the numeraire good at each date. Then the social rate of discount for the interval (t, $t + 1$) is defined as $(p_{1t}/p_{1t+1}) - 1$ (see Koopmans 1957).

Far too much has been written about social discount rates. (A comprehensive collection of essays is Lind 1982.) It is not that social discount rates are not important as an ingredient in project evaluation. They are. But then so are other accounting prices. Social rates of discount are the ratios of certain dated accounting prices. In general they are sensitive to the choice of social objectives and the economy-wide constraints, as is any other accounting price.

Increasing Returns

Convexity of the function G is a limiting assumption. Indeed, a *raison d'être* of the government engaging in the production of 'private' commodities is increasing-returns-to-scale. But this violates convexity. Clearly then project evaluation cannot be based exclusively on accounting prices. Even the classical marginal-cost pricing rule assumes that the government will provide a lump-sum subsidy to the public enterprise in order to cover its losses, and this argument is undertaken usually in a partial-equilibrium context. In a general case the matter is a great deal more complicated and no sure-fire rule for project evaluation would appear to be available. But the presence of scale-economies does not imply that accounting prices must be abandoned *in toto*. The contributions of Weitzman (1970) and Portes (1971) suggest that one ought to rely on accounting prices in the) 'convex' production sectors and quantity regulations in the) 'nonconvex' sectors. There is a great deal to be done in this field and we would expect it to be the area at which attention will now be directed.

Propensity Score

Jinyong Hahn

Abstract

Propensity score is an object often discussed in evaluation studies. It is defined as the conditional probability of treatment given covariates. It has attracted attention for its potential to control for the bias in the presence of high dimensional covariates.

Propensity score is an object often discussed in evaluation studies. It is defined as the conditional probability of treatment given covariates. It has attracted attention for its potential to control for the bias in the presence of high dimensional covariates.

Evaluation research typically begins by comparing the treated group with the control group. For example, estimates of the effect of training programmes on earnings compare the earnings of those who receive training with a candidate control sample of untrained people. Because typically trainees are not chosen randomly, a simple comparison of the two groups may not provide a very accurate picture of what would have happened to the trainees had they not been trained. Under some conditions, such problems can be avoided by comparing the treated and the control groups with identical covariate values.

For more formal discussion, denote the covariate vector for person i by X_i, treatment status by D_i such that $D_i = 1$ if the ith person is treated and $D_i = 0$ otherwise, and define the conditional probability of treatment, or propensity score, as $p(X_i) \equiv \Pr[D_i = 1|X_i]$. Let Y_{1i} denote the potential, or counter-factual, outcome if the ith person receives the treatment, and let Y_{oi} denote potential earnings if he or she does not receive the treatment. Note that Y_{1i} is observed only when $D_i = 1$. Likewise, Y_{oi} is observed only when $D_i = 0$. This implies that $Y_{1I} - Y_{0i}$ is not observed by the researcher, and therefore the average treatment effects, which are defined to be $\beta = E[Y_{1i} - Y_{0i}]$, cannot be estimated by the sample analog of $E[Y_{1i} - Y_{0i}]$. Because D_i is not usually assigned randomly, a simple comparison of the two groups, that is, the sample analog of $E[Y_{1i}|D_i = 1] - E[Y_{0i}|D_i = 0]$, does not provide a consistent estimate of β, either. On the other hand, if (Y_{0i}, Y_{1i}) is independent of D_i given X_i, that is,

$$Y_{0i}, Y_{1i} \perp\perp D_i | X_i, \tag{1}$$

then the sample analog of

$$E\{E[Y_{1i}|X_i, D_i = 1] - E[Y_{0i}|X_i, D_i = 0]\}$$

will provide a consistent estimator for β. In other words, β can be consistently estimated by ‘matching’ the treated and the control groups with identical covariate values.

A problem that often arises in studies of this type is the need to control for continuously distributed and/or high-dimensional covariates. In many evaluation studies, the sample sizes are small, there are many covariates, and some of the covariates are continuous. A number of variations on exact covariate-matching schemes have been developed to deal with such situations. These typically involve approximate matching, or nonparametric smoothing, of some sort.

An alternative strategy to control for covariates begins with Rosenbaum and Rubin’s (1983) observation that bias can be eliminated by controlling for a scalarvalued function of the covariates, namely, the propensity score. Rosenbaum and Rubin's propensity-score theorem states that, if Eq. (1) is true, then it must also be true that conditioning on $p(X_i)$ eliminates selection bias, that is,

$$Y_{0i}, Y_{1i} \perp\perp D_i | p(X_i). \tag{2}$$

This implies that the β can be consistently estimated by the sample analog of

$$E\{E[Y_{1i}|p(X_i), D_i = 1] - E[Y_{0i}|p(X_i), D_i = 0]\}.$$

It is easier to estimate $E\{E[Y_{1i}|p(X_i), D_i = 1]$ than $E[Y_{1i}|X_i, D_i = 1]$ because the former requires the nonparametric regression of $Y_{1\mathrm{i}}$ on a scalar object $p(X_i)$ whereas the latter requires the nonparametric regression on a multi-dimensional object X_i. (Such difficulty is often called the curse of dimensionality in the nonparametrics literature.) The value of propensity score matching is in the 'dimension reduction' generated by regions where $p(X_i)$ is constant while $E[Y_{1i}|X_i]$ or $E[Y_{0i}|X_i]$ are not constant. The value of the propensity score is not clear, though, when the applied researcher does not have any information about the treatment assignment. Without such information, the propensity score needs to be estimated, which requires a nonparametric regression of D_i on X_i. Because this estimation suffers from the curse of dimensionality, the propensity score theorem seems to have little practical value when the propensity score itself needs to be estimated nonparametrically. On the other hand, it can be quite useful when applied researchers may have more information or are willing to make stronger assumptions about treatment assignment than about the relationship between covariates and outcomes. A number of empirical examples using the propensity score suggest that this approach works reasonably well (see, for example, Rosenbaum and Rubin 1984, 1985; Dehejia and Wahba 1999; Imbens et al. 2001; Heckman et al. 1998).

This evidence of practical utility notwithstanding, from an asymptotic theory point of view propensity-score-based estimators present a puzzle. Hahn (1998) shows that the propensity score is ancillary for estimates of average treatment effects, in the sense that knowledge of the propensity score does not lower the semiparametric efficiency bound for this parameter. Moreover, covariate matching is asymptotically efficient, that is, it attains the semiparametric efficiency bound, while propensity score matching does not. These results based on conventional asymptotic arguments seem to offer no justification for anything other than full control for covariates in estimation of average treatment effects.

The propensity score may still be a useful device. First, the propensity score may enhance finite sample efficiency. Angrist and Hahn (2004) use a non-standard asymptotic argument to point out that the traditional first-order asymptotic theory misses some of the subtleties in finite sample property, and observe that an estimator based on propensity score matching may be superior to the one based on covariate matching. They note, though, that the finite sample efficiency gain becomes smaller as the sample size grows, which is in accordance with the prediction from the traditional asymptotic theory. Second, when the estimated propensity scores are used as a weight in a certain way but not as a basis of matching, the estimator of the average treatment effects based on estimated propensity score is as asymptotically efficient as the covariate matching (Hirano et al. 2003).

Propensity to Consume

John Eatwell

Keynes defined the propensity to consume as a functional relationship between the level of income and expenditure on consumption, and argued that ‘the amount that the community spends on consumption obviously depends (i) partly on the amount of its income, (ii) partly on the other objective attendant circumstances, and (iii) partly on the subjective needs and the psychological propensities and habits of the individuals composing it and the principles on which the income is divided between them’ (Keynes, 1936, pp. 90–91).

The determination of consumption by income, and, consequently, the determination of saving as a function of income, is the key proposition underpinning Keynes’s principle of effective demand. By means of this proposition he could transform Kahn’s multiplier (Kahn, 1931) into a theory of income and employment, in which the equality between investment and saving is ensured by appropriate adjustment in the level of income. Moreover, the fact that savings are a function of income whilst investment is an ‘autonomous’ expenditure (liberated from dependence on real saving by the revolving fund of finance) established the Keynesian proposition that in the aggregate investment *determines* saving.

An important characteristic of Keynes’s analysis of consumption is the absence of any behavioural role for the price mechanism. Relative prices might be assumed to have some impact on the composition of consumption, but the overall scale of consumption is a function only of the level, and perhaps the distribution, of income.

Keynes’s approach to the determination of consumption therefore stands in sharp contrast to the neoclassical analysis of consumption in which the composition *and* the scale of consumption is a function of relative prices, because income (or, more accurately, wealth) is determined by relative prices – i.e. by the valuation of individual endowments. If, in the neoclassical model, consumption is to be a function of income, then there must be some inhibition to the operation of the price mechanism which prevents the establishment of full Walrasian equilibrium. It was in this manner that Clower (1965) established the distinction between ‘effective’ and) ‘nominal’ demands, where the latter are associated with the Walrasian equilibrium, and the former are determined by income in a ‘rationed’ equilibrium (Benassy, 1975; Malinvaud, 1977).

The limited scope of Keynes’s critique of the neoclassical theory of employment, and his incorporation within his own analysis of some aspects of that theory in the form of the marginal efficiency of capital schedule, weakened his positive contribution, and resulted, ultimately, in the portrayal of the principle of effective demand as but another example of short-run market failure (see, for example, the papers in Harcourt, 1977). Yet, if an effective critique of the orthodox theory is deployed, then the principle of effective demand stands as the theory of the determination of output (Garegnani, 1964–65). At the core of that principle is Keynes’s) ‘fundamental psychological law’ – the propensity to consume.

Property

Alan Ryan

Property rights are as fundamental to economics as scarcity and rationality. Unless some human agency has the right to control the use of whatever resource is in question nobody can set prices, and there will be no incentive for anyone to calculate costs of production. In much of their work, economists can, and do, take it for granted that everything of value (both tangible goods and intangible objects such as skills) has an owner, and that the owner's powers of control will correspond to the motivational assumptions of orthodox economic theory. That the free market and 'the liberal conception of ownership' (Honoré 1961) imply one another is obvious enough, and rightly allows most economists to feel free to leave the nature of ownership to others, while they tackle the intricacies of market interactions. Although Mill and Marx accused their contemporaries of discussing economics as if all the world had the legal institutions of the North Atlantic seaboard, the accusation is not wholly just – and both of them willingly exempted Smith in any case. For many purposes, the economy an investigator is concerned with can be assumed to have the legal background of the countries of the North Atlantic littoral. Nor have economists been reluctant to broaden their interest in property. Speculation about the possibilities of socialism, the analysis of the economics of slavery, inquiries into the agriculture of developing countries and very much more besides have all provoked investigations into the effects of particular systems of property rights. Defences of the free market based on individual private property (Buchanan 1985), explorations of the outlook for workers' cooperatives (Vanek 1970), assessment of the efficiency of American slavery (Fogel and Engerman 1974) and the literature provoked by Coase's demonstration of the irrelevance to overall welfare of the distribution of property rights are only a fraction of what economists have done.

No definition of ownership is wholly satisfactory for all purposes; 'the right of property is the right of dealing with things in the most absolute fashion the law allows', declares the French civil code, and it is echoed in many other codes. That seizes on two crucial things. First, it is not an infringement of my *ownership* of this knife that I may not stick it in your chest. The law allows nobody to stick a knife in anybody's chest, but whatever anyone may lawfully do with any knife, I (and nobody else) may do with this one. Second, the owner must have *all* the rights anyone can have over the things in question. The suggestion sometimes encountered in textbooks that ownership can be reduced to a 'right to an income' is inadequate, because it mistakes one element in ownership for the whole. Ownership certainly grounds the right to an income, but many rights to an income are grounded on something other than ownership, and ownership embraces other rights than the right to an income. The *code civile* is right to emphasize this, but does not deal with our intuition that if the law circumscribed too closely what an owner might do with his 'property', we might hesitate to call it his property at all. If, for instance, nobody could leave land to their children, or sell a freehold in it, or raise a mortgage on it, we should be doubtful whether individuals could be said to) 'own' it at all. The crucial element in the *'ius utendi et abutendi'* is the ultimate power of disposal. It is, therefore, not only a question of having all the rights the law allows, but of the law conferring on some person or institution the right of disposal. The same observation casts doubt on theories of so-called 'new property rights'. As did theorists of the 'new class', writers who have claimed to identify 'new property rights' have observed, rightly, that in a socialist society where there is supposedly no private ownership of the means of production, individuals in favoured positions may exert the same power as did capitalist owners of businesses in the past or have the same security of occupation and income as did those owners; similarly, those protected by trade unions in mixed economies may have the same security as those who purchased military commissions or government offices in the eighteenth century. Where they have gone wrong is in thinking of these as property rights. For they have simply ignored the question of who has the right of disposal. They may well be right to think that these new powers are as important as ownership and even that they confer on people powers similar to those which ownership confers. They are wrong to think that they amount to ownership.

Until the eighteenth century, and perhaps later, property was a central concern of political theorists. Plato began a long tradition in demanding that the rulers of the ideal republic should have no property. They should possess in common the common property of the republic, to separate their private interests from the public interest. He was not concerned, as St Paul was, to condemn avarice and urge men to set their hearts on the goods of the next world; rather he was concerned to avoid class warfare and to secure uncorrupt leadership. The lower classes were welcome to engage in their usual occupations and hang on to whatever few possessions those occupations yielded. Aristotle began an equally long tradition by observing that common property would not be regarded as) 'belonging to us all' but as 'belonging to no one'. Unless owned as private property, land and other resources would be neglected. But although private property was essential if people were to live in moderate comfort, Aristotle did not approve of the market; he complained that profit making was a distraction from the proper use of goods – which existed to be consumed not traded – and that lending money at interest was doubly wicked, because it was setting barren metal to breed. Ownership, and especially land ownership, existed in order to give the better sort of people the leisure to cultivate their talents and govern wisely.

Neither the Greeks nor the Romans had much use for the conception of individual rights which provides the framework of modern discussions of property. None the less, it was the Roman Law conception of ownership that bred modern theories of natural right and of a natural right of property, just as it was Roman thinking about practical politics that bred a rival habit of thought. This is the tradition of 'statecraft' and is exemplified in the work of Machiavelli and Harrington, and to a lesser extent in Hume and Smith. A crucial question to be asked of any system of property rights is whether it favours political stability and political liberty. The question is one of political sociology – what kind of property encourages public spirit in the citizen, and what kind encourages 'corruption' in the ruling class? The exemplary figure of the Roman farmer who kept his weapons over his fireplace and would fight for republican institutions against enemies from without and would-be tyrants from within haunts this tradition. Adam Smith, who is rightly thought of as the apostle of the modern economy, was equally taken with the ancient conviction that military valour, public spirit and free institutions were inconsistent with a wholly commercial economy. Small, independent farmers were the source of republican virtue. Their independence was not the same thing as modern individualism; they must be independent of the wealthy but they would not think of their land as theirs so much as their family's. In Machiavelli, the argument is entirely nostalgic; by the time of Harrington, there is more understanding of the impossibility of simply recreating the Roman republic; Hume and Smith saw that the modern, fluid, commercial world in which money is the great solvent of other forms of property cannot be escaped and cannot be wholly regretted. It is then an open question what balance of social forces can preserve freedom. It goes without saying that this 'political' conception of liberty with its roots in stable, landed property is not congenial to critics of the welfare state and socialism, who identify freedom with what Smith termed 'the simple system of natural liberty' or freedom of contract.

The 'statecraft' tradition does not enquire into the origins of property rights, nor into the justice of present distributions of property, but only into their political results. The natural law tradition (and its successors) is concerned with justice, and with what Locke called the 'original' of property. By 'original' he did not mean its historical origins but its moral logic. The crucial questions which this tradition faces are not sociological but moral – what grounds a valid claim to ownership; is there a conflict between the goals of property as an institution and the distribution of property rights in practice? From Locke, through Hume, Rousseau, Kant, Hegel, Mill and their successors, a variety of answers was offered, some of which had a clear tendency to justify the status quo, some of which, as in Rousseau on the one hand and Mill on the other, led to its rejection. Natural rights theories like Locke's held that each individual had a right to appropriate and use the unowned bounty of nature; the exercise of his natural liberty was enough to give him the ownership of it. Did it follow that the propertyless labourer in contemporary society had been cheated? Locke thought not; so long as he can earn a livelihood by his labour, he can 'appropriate' what he needs. But it does follow that owners who fail to provide employment commit an injustice. Rousseau held the same view, but complained that in practice the owners reduced the propertyless to near slavery and that even where they did not they corrupted them in other ways.

Hume and Mill offered a utilitarian justification for property. Unless there are rules of 'meum et tuum', there will be no efficient employment of the world's resources; as to what rules should govern ownership, that is a matter of expediency. But where Hume thought that expediency favoured custom and prescription even at the price of considerable inefficiency, Mill argued for positive governmental pressure by way of the law on property to promote efficiency on the one hand and the creation of an economy of producer cooperatives on the other.

In a very different idiom, Kant and Hegel also explained property as the expression of human freedom. Human beings, who alone possessed free-will, conferred value on the merely material objects they took into ownership. Without ownership, the world of mere material objects is inert, useless and of no value. But if property in some form or other is essential, the particular form is a matter for different governments to decide for themselves. Kant and Hegel were fierce enemies of the feudal hangovers which disfigured the German states of their day. Neither advocated complete laissez-faire, but since property expresses human sovereignty over nature, it must be open to any individual to acquire property by his own work. This rather romantic justification of property rights was turned on its head by Marx, when he declared that the irrationality of capitalism and its evident moral failings showed that so long as there was property at all, things would be sovereign over men and men would continue to suffer alienation. On the whole this argument has appealed to Marxist philosophers rather than Marxist economists; the economist feels he can analyse the consequences of different systems of public ownership, but has little to say about what a world without the very concept of property would be like.

In the mixed economies of the West, some kind of utilitarian justification of property is the 'common sense' of politics, even if most writers now acknowledge that the defence of private property needs to take into account questions of justice as well as questions of overall efficiency. John Rawls's insistence on appraising economic institutions from the standpoint of the representative least-favoured person (Rawls 1972) has captured the imagination of writers of a broadly, but uneasily utilitarian persuasion. The least abashed intellectual heirs of eighteenth and nineteenth-century utilitarianism are the defenders of the so-called ‘economic theory of property rights’. In this account the property rights characteristic of developed capitalist economies came into existence by an evolutionary process which allowed production to proceed in ever more efficient ways. The capitalist firm, say, exists because a system of property rights developed which allowed entrepreneurs to act swiftly and decisively. One implication is that a government which forced some other ownership pattern on the economy would find that evolutionary pressures would gradually reintroduce de facto capitalism and that only political repression could preserve socialism. The value of property rights lies in the pattern of resource management (in the widest sense) that they promote; what Marx condemned as) ‘bourgeois’ forms of ownership create the most efficient management. Critics complain that this suffers from the same defects as other doctrines of ‘the survival of the fittest’ – it takes its standard of fitness from the behaviour of the institutions it explains. But this is certainly one place where the discussion of property rights most vividly engages the concerns of lawyers, economists and philosophers alike.

Property Law, Economics and

Dean Lueck

Abstract

This entry shows how the economics of property rights can be used to understand fundamental features of property law and related extra-legal institutions. It examines both the rationale for legal doctrine and the effects of legal doctrine regarding the exercise, enforcement, and transfer of rights. It also examines various property rights regimes including open access, private ownership, common property, and state property. Property law is understood as a system of societal rules designed to create incentives for people to maintain and invest in assets, which in turn leads to specialization and trade.

Property law is the body of court enforced rules that governs the establishment, use and transfer of rights to land and those assets attached to it such as air, minerals, water, and wildlife. In economic terms, property rights are defined as the (expected) ability of an economic agent to freely use an asset (Allen 1999; Barzel 1997; Lueck and Miceli 2007; Shavell 2004) and represent a social institution that creates incentives to use, to maintain, and to invest in assets. Property rights may or may not be enforced by courts; and because the actions of courts are costly legal rights are but a subset of economic property rights. In addition to law and regulations, property rights may be enforced by custom and norms (see, for example, Ellickson 1991) and by markets through repeated transactions.

Property Rights, Transaction Costs, and the Coase Theorem

Consider Coase's (1960) famous example of the rancher and farmer. The rancher's cattle stray onto the farmer's land causing crop damage. The rancher's profit, $\pi(h)$ and the amount of crop damage $d(h)$ are functions of the rancher's herd size h, so the first-best optimal herd size, h^* maximizes $\pi(h) - d(h)$ and h^* solves $\pi'(h) = d'(h)$. This is also the choice made by a single farmer-rancher, Coase's 'sole owner' case. If the rancher initially has the economic (and legal) right to impose crop damage without penalty, he would choose the herd size to maximize $\pi(h)$, adding cattle until $\pi'(h) = 0$, which implies $h^r > h^*$. The farmer would be willing to pay up to $d'(h)$, his marginal damage, for each steer that the farmer removes from the herd in order to avoid crop damage, while the rancher would accept any amount greater than his marginal profit, $\pi'(h)$.

If transaction costs are zero, the parties will instantly contract to reduce the herd to the efficient size. The farmer will purchase the rights to the straying cattle, and if the farmer had the initial rights the situation would be reversed: either way the outcome is first-best. This is the Coase Theorem: *When transaction costs are zero the allocation of resources will be efficient regardless of the initial assignment of property rights.* But transaction costs are not zero and thus property rights are not perfectly defined (Allen 1999; Barzel 1997; Lueck and Miceli 2007) so property law becomes important in defining rights and determining the allocation of assets. Indeed, Coase's (1960) discussion of nuisance law suggests an economic logic to the law in its assignment of property rights among various parties to these disputes.

Property Rights: Taxonomy and Models

Property law recognizes several fundamental property rights regimes: private property, open access, common property, and state property (Lueck and Miceli 2007). Property law also recognizes mixed regimes. Consider a fixed asset (such as a plot of land) used with a variable input (x) to produce a market output ($Y = f(x)$). If the input price is w, then the first-best use ($x^*(w)$) must maximize $R = f(x) - wx$ and satisfy $f'(x) = w$. The first-best value of the land is $V^* = \int_0^\infty R^*(x^*, t)e^{-rt}dt$, where r is the discount rate.

If there is 'open access' for n individuals, then output is $Y = f\left(\sum_{i=1}^n x_i\right)$ where x_i is the effort of the i^{th} individual, $f'(\cdot) > 0$ and $f'(\cdot) < 0$, and the opportunity cost of effort is w_i. Each person can only capture (and thus own) the output in proportion to his share of effort, so each solves:

$$\max_{x_i} R_i = f^i(x_i) - w_i x_i \ \text{ subject to } f^i = \left[x_i \Big/ \sum_{i=1}^n x_i\right] f\left(\sum_{i=1}^n x_i\right) \qquad (1)$$

On the assumption that users are homogeneous ($w_i = w_j.$ for all $i \neq j$), the Nash open access equilibrium is $x = x^{oa}(n,\ w_1,\ \ldots,\ w_n)$, which satisfies,

$$\begin{aligned}&(n-1/n)\left(f\left(\sum_{i=1}^{n} x_i\right)\Big/\sum_{i=1}^{n} x_i\right)\\&\quad-(1/n)f'\left(\sum_{i=1}^{n} x_i\right)\\&\quad=w_i,\quad i=1,\ldots n.\end{aligned}\tag{2}$$

In the limiting case as n → ∞, (2) becomes $f\left(\sum_{i=1}^{n} x_i\right)/\sum_{i=1}^{n} x_i = w$ which is the famous 'average product rule' (Gordon 1954; Cheung 1970; Brooks et al. 1999). The limiting case implies that rents are completely dissipated, or $\sum_{i=1}^{n} R_i = \sum_{i=1}^{n}\left[f^i(x^{oa}) - wx^{oa}\right] = 0$ and the present value of the asset is also zero, $V^{oa} = \int_0^\infty R(x^{oa}, t)e^{-rt}dt = 0$. With heterogeneous costs, the infra-marginal users earn rents and have incentives to maintain open access regime (Libecap 1989).

With private property the owner chooses $x^* < x^{oa}$ and generates $V^* > V^{oa} = 0$. Private ownership also creates incentives for optimal asset maintenance and investment (Bohn and Deacon 2000). Let future output be $Y_{t+1} = f(x_t)$, where x_t is current investment, available at a market wage of w. and the interest rate is r. The first-best use of the input $\left(x_t^*\right)$ must maximize $R = f(x_t)/(1+r) - w_t x_t$ and satisfy $f'(x_t)/(1+r) = w_t$. If $\pi \in [0,1]$ is the probability of expropriation (because of imperfect rights) of the future output, then an owner will maximize $R = f\ (x_t)[(1\ -\ \pi)/(1+r)] = w_t x_t$. The solution $\left(x_t^\pi < x_t^*\right)$ satisfies $f'(x_t)[(1-\pi)/(1+r)] = w_t$ and implies less than first-best investment. Pure open access means that no investor could claim future output ($\pi = 1$), so $x_t^{oa} = 0$, and the rent from investment also equals zero. This lack of incentive to invest is essentially the problem of the 'anti-commons' described by Heller (1998) and formalized by Buchanan and Yoon (2000).

Common property is exclusive ownership by a group and may arise out of explicit private contracting (for example, unitized oil reservoirs) or out of custom (for example, common pastures); it may have legal (for example, riparian water rights) or regulatory (for example, hunting regulations) bases that have implicit contractual origins. Common property is well documented for natural resource stocks in less developed economies (Bailey 1992; Ostrom 1990). It is also seen in modern 'common interest communities' (such as condominiums, homeowner's associations) where residents use quasi-governments to maintain common areas (such as pools, open space) and provide local public goods (Dwyer and Menell 1998). Contracting to form common property creates a group that can realize economies of enforcing exclusive rights. Equal sharing is a typical internal allocation rule; it avoids costs of measuring and enforcing individual use but still leads to overuse compared with first-best. With equal sharing rules a homogeneous membership maximizes the present value of a common property resource (Lueck 1994, 1995).

Governments own vast amounts of land, buildings, and capital equipment. State property rights are governed by administrative agencies, and the range of property rights regimes incorporates aspects of the three major types: private property, common property, and open access. State property rights commonly – and often severely – limit the transferability of rights, perhaps to limit the moral hazard incentives of agency bureaucrats. The relevant law for state property has its origins in common law (for example, mining on federal land is a first-possession rule) but is primarily governed by statutes and regulations, all shaped by bureaucrats, interest groups and politicians.

Real property regimes tend to mix the four fundamental types: open access, private property, common property and state property (Barzel 1982, 1997; Eggertsson 1990; Ellickson 1993; Kaplow and Shavell 1996; Merrill and Smith 2000; Rose 1998; Stake 1999), implicitly recognizing that assets are a collection of valuable attributes. A rancher's land is not typically completely private: the streams running through the property may be open access for fishing or recreation; the grass may be a lease from a federal agency with mineral rights held by yet another private party. Similar scenarios are found in residential and commercial real estate, and Bailey (1992) found a mixture of ownership regimes among aboriginal peoples. Smith's (2000) study of the common field system of medieval Europe is a rare study of the underlying economic logic of a mixed property regime.

Origin of Property Rights

In law and custom, first possession is the dominant method of establishing rights, be it to the *flow* of output from a *stock* or to the stock itself (Lueck 1995). Let $R(x(t))$ be the flow of benefits from an asset, where $x(t)$ is a variable input supplied at time t, r is the interest rate, and $g < r$ is the rate at which $R(t)$ grows over time. The first-best, full-information outcome is

$$V^{FB} = \int_{t=0}^{\infty} R(x^*(t))e^{-(r-g)t}dt, \qquad (3)$$

where $x^*(t)$ is the optimal input level and $t^* = 0$ since production begins immediately.

Under first possession the asset's first claimant obtains exclusive rights to the temporal flow of rents, $\int_0^\infty R^*(t)dt$. Since establishing a bona fide claim will be costly and because $g < r$. property rights to the asset will emerge as the value of the asset increases (Demsetz 1967). Along these lines an entire literature has developed to explain the 'evolution of property rights' or, more generally, the determinants – both temporal and cross section – of property rights regimes (Lueck and Miceli 2007; Rose 1998). This literature, mostly empirical, notes that property rights regimes can move in both directions (to and away from private property), that property rights regimes can move among mixed regimes, and that political and other institutions also shape the choice of property regimes.

Returning to first possession, a single claimant will choose the claiming time to maximize

$$V^S = \int_{t}^{\infty} \left[R(x^*(t))e^{-(r-g)t}dt\right] - Ce^{-rt}, \qquad (4)$$

where C is the cost of enforcing the claim and t is the time at which ownership of the stock (and the temporal flow of output) is established. The optimal time to establish ownership is when the present value of the asset's flow equals the present value of the opportunity cost of establishing rights at t^S, or $R^*e^{-(r-g)t^S} = rCe^{-rt^S}$. The asset value falls short of first-best, or $V^S < V^{FB}$, because the costs of establishing ownership delay ownership and production to t^S from $t = 0$.

First possession can dissipate value when there is unconstrained competition among homogenous claimants (Barzel 1968; Mortensen 1982). A competitive rush to claim rights causes ownership to be established at exactly the time t^R when the present value of the rental flow at t^R equals the present value of the entire costs of establishing ownership at t^R, or when $R^*e^{-(r-g)t^R}/(r-g) = Ce^{-rt^R}$. In this 'race equilibrium' rights are established at t^R, where $t^R < t^S$ since $t^R = (ln\,(r-g) + lnC - lnR)/g$ and $t^S = (lnr + lnC - lnR)/g$, and the rental stream is fully dissipated; or

$$V^R = \int_{t^R}^{\infty} \left[R(x^*(t))e^{-(r-g)t^R}dt\right] - Ce^{-rt^R} = 0. \qquad (5)$$

Heterogeneity among claimants can reduce, or eliminate, dissipation (Barzel 1994; Lueck 1995). If there are two competitors (i and j) with possession costs $C_i < C_j$, and neither party knows the other's costs, then i gains ownership just before j makes a claim, at $t^i = t^R - \varepsilon$, and earns rent equal to the present discounted value of his cost advantage. The key implication is that, as the differential between the two lowest cost claimants $(C_j - C_i)$ increases, the level of dissipation will decrease. With complete information there is no dissipation because only the low-cost claimant has a positive expected payoff in a race (Fudenberg et al. 1983; Harris and Vickers 1985).

If the costs of enforcing a claim to the asset are prohibitive, ownership may be established only by capturing or 'reducing to possession' a flow from the asset. The legal term 'rule of capture' describes this derivative of the rule of first possession. Wildlife and crude oil are the classic examples: ownership is established only when a hunter bags a pheasant or when a barrel of oil is brought to the surface. The stock itself (that is, the pheasant population or oil reservoir) remains unowned. The new 'race' is to claim the present flow $R(t)$ and leads to open access dissipation (Epstein 1986; Lueck 1995) since no one owns the asset's entire stream of flows, $\int_0^\infty R(t)dt$. The formal analysis is static rather than intertemporal as in the asset claim race, and is identical to the open access model developed above in eq. (1).

Property law implicitly recognizes the two potential paths of dissipation – racing and overexploitation – and is structured to limit such dissipation (Dharmapala and Pitchford 2002; Lueck 1995, 1998). Where first possession rules establish ownership in a resource stock, first possession tends to be defined so that valid claims are made at low cost and before dissipating races begin, thus exploiting claimant heterogeneity. Also, the transfer of rights to the resource is allowed, routinely reflecting security of ownership in the corpus. Where the rule of capture emerges (for example, oil and wildlife) access to the resource tends to be limited through legal, contractual or regulatory methods. As well, the transfer of rights to capturable flows tends to be restricted in order to limit overuse of the asset itself.

Externalities and Property Law: Nuisance, Trespass and Zoning

Externalities arise because property rights to at least some of the attributes of an asset will be imperfect and thus generate problems of open access or moral hazard. Land externalities are ubiquitous because any parcel (except an island) will have neighbouring owners and because related resources (for example, air, noise, minerals, water) do not tend to coincide with the surface ownership boundaries. Property law addresses externalities through doctrines of trespass, nuisance, servitudes, and through regulatory zoning.

Consider, à la Coase (1960), a railroad whose trains emit sparks that occasionally set fire to adjacent farmland. The number of trains is n_T and the number of farms is n_F, resulting in crop damage of $n_T n_F D(x, y)$, where D is the damage (reduced crop value per acre) each train causes, x is the cost of precaution per train, and y is the cost of precaution by each farmer. Assume $D_x < 0$, $D_y < 0$ $D_{xx} > 0$, and $D_{yy} > 0$. The marginal benefits are $b_T(n_T)$ and $b_F(n_F)$, where $b_j' < 0.j = T, F$. The total value of the two activities is

$$W = \int_0^{n_T} b_T(n_T)du + \int_0^{n_F} b_F(n_F)dz - [n_T n_F D(x, y) + n_T x + n_F y] \qquad (6)$$

If the numbers of trains and farms are fixed, as in tort models (Shavell 1980) that hold 'activity levels' fixed, the optimal precaution choices (x^*, y^*) that maximize (6) are $n_F D_x(x, y) + 1 = 0$ and $n_T D_y(x, y) + 1 = 0$. If the number of trains and farms (n_T, n_F) is endogenous, the resulting first-order conditions are $b_T(n_T) - [n_F D(x, y) + x] = 0$ and $b_F(n_F) - [n_T D(x, y) + y] = 0$.

Remedies for externalities can be viewed as a choice between 'property rules' and 'liability rules' (Calabresi and Melamed 1972; Polinsky 1980). Under property rules, rights holders can refuse any unwanted infringements of their rights, enforceable by injunctions (or criminal sanctions in the case of theft). Property rules thus form the legal basis for voluntary (market) exchange of rights. With liability rules, however, owners can only seek monetary compensation in the form of damages. Liability rules thus form the basis for court-ordered or non-consensual transactions. The choice between the two rules turns on transaction costs, particularly the costs of contracting, the costs of court adjudication, and legal administration. When contracting costs are relatively low, property rules are preferred because they ensure that all transactions are mutually beneficial. When contracting costs are high (for example, in public nuisance cases), property rules may prevent otherwise efficient transactions from occurring. Liability rules have an advantage because courts can force an efficient transfer. This advantage of liability rules must be weighed against the possibility of court error in setting damages, and, because liability rules require courts to establish the initial terms of a transaction by setting damages, the administrative costs of using this rule will likely be higher than under a property rule (Kaplow and Shavell 1996).

In the railroad–farmer case, if liability is strict the railroad must pay full compensation regardless of its level of precaution. Strict liability induces efficient precaution by the railroad, but farmers are fully compensated and thus have no incentive for precaution. Negligence, which holds the railroad liable for damages only if it takes less than the efficient level of abatement, will induce both parties to take efficient care. Neither rule, however, will achieve first-best railroad and farm activity levels. In general, liability rules cannot create first-best incentives because of the constraint that what one party pays the other must receive. This is an example of the *paradox of compensation* which is also found in tort law and contract law remedies (Cooter 1985). It can be avoided by 'decoupling' liability and compensation, or by using a contract or compensation mechanism that defines and enforces the optimal choices for both parties.

Trespass (for example, squatting, boundary encroachment) and nuisance (for example, air, water, noise pollution) doctrines are the primary common law responses to externalities. The primary remedy under trespass is an injunction, a property rule. The remedy under nuisance law is more complicated. A landowner can obtain relief only if the invasion is substantial, and even then he may have to be satisfied with money damages (a liability rule). If a landowner wishes the harm to be enjoined, he must meet the further legal standard of showing that the harm outweighs the benefit of the nuisance-creating activity. The trespass–nuisance distinction can be understood as a property–liability rule choice (Merrill 1998). Trespass ordinarily involves a small number of parties where the intruder is easily identifiable, so contracting costs tend to be low and property rules are likely optimal. Nuisance often involves large numbers or sources of harm that are difficult to identify, so liability rules are likely optimal.

Zoning is a common legal response to urban land externalities. The economic rationale for zoning is that 'similar land uses have no (or only small) external effects on each other whereas dissimilar land uses may have large effects' (White 1975), creating what the common law calls a 'public nuisance'. Ellickson (1973) argues that zoning may have administrative and enforcement costs that often exceed the saved 'nuisance costs'. A private alternative to zoning is the use of land use servitudes (for example, covenants, easements) that impose limits on what landowners can do with their property. Such restrictions are frequently observed in condominiums, homeowner associations, and other 'common interest communities' (Dwyer and Menell 1998; Hansmann 1991). The economic function of these restrictions is twofold: to overcome free rider problems in the provision of certain jointly consumed amenities; and to internalize neighbourhood and rental externalities.

Public Trust, Public Property and Public Use

The ancient doctrine of 'public trust' grants ownership of navigable rivers, shorelines, and the open sea to the public. It is judicially created common property, or sometimes open access. In its traditional application the public trust asset was a public good. When an asset is a public good, unrestricted access will not cause dissipation from overuse of the resource, but it could lead to underinvestment. When the resource has private good characteristics, unrestricted access can trigger the rule of capture and creates a classic open access problem, possibly causing resource degradation through overuse. Some courts have recently extended the doctrine into environmental assets, such as beaches, lakes, stream access and wildlife.

Large-scale projects like dams, railroads and highways often involve the assembly of a large contiguous parcel of land from relatively small and separately owned parcels. Developers face a potential holdout problem because, once assembly becomes public information, parcel owners might hold out for prices in excess of their true valuations, endangering completion of an otherwise efficient project. One solution is to force sales by replacing property rule protection of each owner's land with liability rule protection. This is the economic justification for the eminent domain power of the state (Posner 2003), which has common law origins. The ‘takings’ clause of the Fifth Amendment of the US Constitution explicitly grants such eminent domain power for ‘public use’ but requires ‘just compensation’, which courts have interpreted to mean ‘fair market value’. Since subjective value is part of the opportunity cost of a taking, failure to compensate for it potentially results in excessive acquisition of land by the government, though one study (Munch 1979) found that high-valued properties were overcompensated, while owners of low-valued properties were undercompensated.

A large literature has studied the link between compensation and investment decisions of landowners (Blume et al. 1984; Fischel and Shapiro 1988). Suppose there are many parcels, each worth $V(x)$ if the landowner makes an irreversible investment x, where $V' > 0$ and $V'' < 0$. The land also yields a public benefit of $B(y)$, where y is the number of parcels taken and $B' > 0$, $B'' < 0$. Compensation of $C(x)$ will be paid for each parcel taken, where $C(x) \geq 0$, $C' \geq 0$, and total compensation is $yC(x)$. Landowners choose x given the anticipated behaviour of the government and the compensation rule; then the government chooses y and pays $C(x)$. The first-best choices (x^*, y^*) maximize $B(y) + (1 - y)V(x) - x$, the sum of private and public benefits, and must satisfy $(1 - y)\,V'(x) - 1 = 0$ and $\mathrm{B}'(\mathrm{y}) - \mathrm{V}(\mathrm{x}) = 0$. If the taking is exogenous, y is fixed and the landowner will maximize $(1 - y)\,V(x) + yC(x) - x$, which must satisfy $(1 - y)\,V'(x) + yC'(x) - 1 = 0$ and also gives x^l as the solution. This means that compensation must be lump sum ($\mathrm{C}' = 0$) to ensure that $x^l = x^*$; a positive relationship between x and compensation creates over-investment moral hazard (another example of the paradox of compensation). Thus no compensation ($C(x) \equiv 0$ for all x) is actually efficient, although any lump sum rule is consistent with efficiency. The efficiency of zero compensation, however, depends on assumptions about government behaviour.

Government regulations often restrict land uses without depriving the owner of title (for example, zoning laws, environmental regulations). Historically, courts have granted broad powers to enact such regulations but, when a regulation becomes especially burdensome, the affected landowner may claim that a ‘regulatory taking’ has occurred and seek compensation. As above, the trade-off for regulatory takings concerns the efficiency of the land use decision on the one hand and the regulatory decision on the other. Miceli and Segerson (1994, 1996) propose the following compensation rule, where y is a landowner’s lost value from the regulation:

$$C = \begin{cases} 0 & \mathit{if} \quad y \leq y^* \\ V(x), & \mathit{if} \quad y > y^*. \end{cases} \tag{7}$$

Like a negligence rule in tort law, this rule requires full compensation if the government over-regulates ($y > y^*$) but requires no compensation otherwise ($y \leq y^*$). It also establishes a standard that is economically equivalent to the common law definition of a nuisance (an activity that is efficiently prohibited), and hence is consistent with the threshold for compensation implied by the nuisance exception.

Inalienability of Property Rights

Posner (2003, p. 75) notes, ‘the law should, in principle, make property rights freely transferable in order to allow resources to move to their most highly valued uses and to foster the optimal configuration of assets.’ Yet there are many legal restrictions that limit the alienability of property: body parts, children, voting, military service, cultural artifacts, endangered animal species, the right to freedom (laws against slavery), certain natural resources and state property.

The dominant economic reason for restrictions on alienability is that externalities can arise from transfers (Barzel 1997; Epstein 1985; Rose-Ackerman 1985; Posner 2003) if the rights to the assets are not well-defined with respect to the stock (and its stream of flows over time). This generates a rationale for limiting, even prohibiting, certain transfers of the claimed flows in order to protect the asset and its value. For example, the widespread prohibition on trade in wild game is likely to be such a case (Lueck 1989, 1998), though even here limits on markets can potentially deter the formation of property rights. Restrictions on the sale of children may have a similar rationale: a market for children (or game) would lead to 'poaching' of kids (or animals) for which property rights enforcement is extremely costly.

Another reason for restricting transfers is asymmetric information, particularly that leading to adverse selection (Rose-Ackerman 1998). Adverse selection can potentially dry up markets where product quality cannot be observed prior to purchase. Similar restrictions on the types of property servitudes allowed (such as limits on 'negative and in gross' easements) might be explained by reference to asymmetric information (Dnes and Lueck 2006). Legal scholars have argued that limitations on servitudes prevent 'clogging title' (Gray and Gray 2000). Consider the market for land of two types: fee simple (that is, unencumbered) and land encumbered with a servitude. Assume that only the seller knows whether the land is encumbered. Buyers do not have this information but know only that one-half of the land is encumbered. The value of an unencumbered plot is V^f, while the value of the encumbered plots is $V^s < V^f$. Given the information asymmetry, buyers will pay only the expected value of a plot, $EV = (V + V^f)/2 < V^f$. Following Akerlof (1970) and related literature, this means there will be no market equilibrium for the unencumbered plots; that is, only 'low-quality' encumbered plots will be present in the market. Institutions that provide information (such as title recording and registration systems) could eliminate asymmetry and even alter the law of property by allowing an expanded set of servitudes.

Summary

Economic analysis reveals a fundamental logic to the main doctrines and features of property law (Lueck and Miceli 2007). The observed structure of property rights and property law can be best understood as a system designed to create incentives for people to maintain and invest in assets, which in turn leads to specialization and trade. Among the most important remaining issues for study is a systematic analysis of how the law addresses the use and transfer of complex assets.

Private Property Rights

A property right is a socially enforced right to select uses of an economic good. A Private property right is one assigned to a specific person and is alienable in exchange for similar rights over other goods. Its strength is measured by its probability and costs of enforcement which depend on the government, informal social actions, and prevailing ethical and moral norms. In simpler terms, no one may legally use or affect the physical circumstances of goods to which you have Private property rights without your approval or compensation. Under hypothetically perfect Private property rights none of my actions with my resources may affect the physical attributes of any other person's private property. For example, your Private property rights to your computer restrict my and everyone else's permissible behaviour with respect to your computer, and my Private property rights restrict you and everyone else with respect to whatever I own. It is important to note that it is the physical use and condition of a good that are protected from the action of others, not its exchange value.

Private property rights are assignments of rights to choose among inescapably incompatible uses. They are not contrived or imposed restrictions on the feasible uses, but assignments of exclusive rights to choose among such uses. To restrict me from growing corn on my land would be an imposed, or contrived, restriction denying some rights without transferring them to others. To deny me the right to grow corn on my land would restrict my feasible uses without enlarging anyone else's feasible physical uses. Contrived or unnecessary restrictions are not the basis of Private property rights. Also, because those restrictions typically are imposed against only some people, those who are not so restrained obtain a 'legal monopoly' in the activity from which others are unnecessarily restricted.

Under Private property rights any mutually agreed contractual terms are permissible, though not all are necessarily supported by governmental enforcement. To the extent that some contractual agreements are prohibited, Private property rights are denied. For example, it may be considered illegal to agree to work for over ten hours a day, regardless of how high a salary may be offered. Or it may be illegal to sell at a price above some politically selected limit. These restrictions reduce the strength of private property, market exchange and contracts as means of coordinating production and consumption and resolving conflicts of interest.

Economic Theory and Private Property Rights

A successful analytic formulation of Private property rights has resulted in an explanation of the method of directing and coordinating uses of economic resources in a private property system (that is, a capitalistic or a 'free enterprise' system). That analysis relies on convex preferences and two constraints: a production possibility and a private property exchange constraint, expressible biblically as 'Thou Shalt Not Steal', or mathematically, as the conservation of the exchange values of one's good.

For the decentralized coordination of productive specialization to work well, according to the well known principles of comparative advantage, in a society with diffused knowledge, people must have secure, alienable Private property rights in productive resources and products tradable at mutually agreeable prices at low costs of negotiating reliable contractual transactions. That system's ability to coordinate diffused information results in increased availability of more highly valued goods as well as of those becoming less costly to produce. The amount of rights to goods one is willing to trade, and in which Private property rights are held, is the measure of value; and that is not equivalent to an equal quantity of goods not held as private property (for example, government property). It probably would not be disputed that stronger Private property rights are more valuable than weaker rights, that is, a seller of a good would insist on larger amounts of a good with weaker Private property rights than if Private property rights to the goods were stronger.

Firms, Firm-Specific Resources and the Structure of Property Rights

Though Private property rights are extremely important in enabling greater realization of the gains from specialization in production, the partitionability, separability and alienability of Private property rights enables the organization of cooperative joint productive activity in the modern corporate firm. This less formally recognized, but nevertheless important, process of cooperative production relies heavily on partitioning and specialization in the components of Private property rights. Yet this method is often misinterpreted as unduly restrictive and debilitating to the effectiveness and social acceptability of Private property rights. To see the error, an understanding of the nature of the firm is necessary, especially in its corporate form, which accounts for an enormous portion of economic production. The 'firm', usually treated as an output-generating 'black box', is a contractually related collection of resources of various cooperating owners. Its distinctive source of enhanced productivity is 'team' productivity, wherein the product is not a sum of separable outputs each of which is attributable to specific cooperating inputs, but instead is a non-decomposable, non-attributable value produced by the group. Thus, for something produced jointly by several separately owned resources, it is not possible to identify or define how much of the final output value each resource could be said to produce separately. Instead, a marginal product value for each input is definable and measurable.

Whereas specialized production under comparative advantage and trade is directed in a decentralized process by market price and spot exchanges, productivity in the team, called the firm, relies on long-term, constraining contracts among owners who have invested in resources specialized to the group of inputs in that firm. In particular, some of the inputs are specialized to the team in that once they enter the firm their alternative (salvage) values become much lower than in the firm. They are called 'firm-specific'. In the firm, firm-specific inputs tend to be owned in common or else contracts among separate owners of the various inter-specific resources restrict their future options to those beneficial to that group of owners as a whole rather than to any individual. These contractual restrictions are designed to restrain opportunism and 'moral hazard' by individual owners, each seeking a portion of each other's firm-specific, expropriable composite quasi-rent. Taking only extremes for expository brevity, the other 'general' resources would lose no value if shifted elsewhere. A firm, then, is a group of firm-specific and some general inputs bound by constraining contracts, producing a non-decomposable end-product value. As a result, the activities and operation of the team will be most intensively controlled and monitored by the firm-specific input owners, who gain or lose the most from the success or failure of the 'firm'. In fact, they are typically considered the 'owners' or 'employers' or 'bosses' of the firm, though in reality the firm is a cooperating collection of resources owned by different people.

Firm-specific resources can be non-human. Professional firms – in law, architecture, medicine – are comprised of teams of people who would be less valuable elsewhere in other groups. They hire non-human general capital, for complex example building and equipment. The contract, which defines 'hiring', depends on the specificity and generality, not on human or non-human attributes nor on who is richer. Incidentally, 'industrial democracy' arrangements are rare, because the owners of more general resources have less interest in the firm than those of specific resources.

The Corporation and Specialization in Private Property Rights

In a corporation the resources owned by the stockholders are those the values of which are specific to the firm. The complexities in specialization in exercise of the components of property rights and the associated contractual restraints have led some people to believe that the corporation tends to insulate (for example, 'separate') decisions of use from the bearing of the consequences (that is, control from ownership) and thereby has undermined the capacity of a private property system to allocate resources to higher market value uses. For example, it has been argued that diffused stock ownership has so separated management and control of resources from 'ownership' that managers are able to act without sufficient regard to market values and the interests of the diffused stockholders. Adam Smith was among the first to propound that belief. Whatever the empirical validity, the logical analysis underlying those charges rests on misperceptions of the structure of Private property rights in the corporation and the nature of the competitive markets for control and ownership which tend to restrain such managers. What individual managers seek, and what those who survive are able successfully to do in the presence of competition for control, are very different things.

An advantage of the corporation is its pooling of sufficient wealth in firm-specific resources for large-scale operations. Pooling is enabled if shares of ownership are alienable private property, thereby permitting individuals to eliminate dependence of their time path of consumption on the temporal pattern of return from firm-specific investments. Alienability is enabled if the shares have limited liability, which frees each stockholder from dependence on the amount of wealth of every other stockholder. The resultant ability to tolerate anonymity, that is, disinterest in exactly who are the other shareholders, enables better market alienability.

When voluntary separability of decision authority over firm-specific resources from their market value consequences is added to alienability, the ability to specialize in managerial decisions and talent (control) without also having to bear the risk of all the value consequences, enables achievement of beneficial specialization in production and coordination of cooperative productivity. Specialization is not necessarily something that is confined to the production of different end products; it applies equally to different productive inputs or talents. Voluntary partitionability and alienability of the component rights enable advantageous specialization (sometimes called 'separation') in (*a*) exercise of rights to make decisions about uses of resources and (*b*) bearing the consequent market or exchange values. The former is sometimes called 'control' and the latter, 'ownership'. Separability enables the achievement of the gains from specialization in selecting and monitoring uses, evaluating the results, and bearing the risk of consequent future usefulness and value. Because different uses have different prospective probability distributions of outcomes, and because outcomes are differentially sensitive to monitoring the prior decisions, separability and alienability of the component rights permit gains from specialization in holding and exercising the partitionable rights.

Thus, the modern corporation relies on limited liability to enhance alienability and on partitionability of components of Private property rights in order to achieve gains from large-scale specialization in directing productive team activity and talents. Rather than destroying or undermining the effectiveness of Private property rights, the alleged 'separation' enables effective, productive 'specialization' in exercising Private property rights as methods of control and coordination.

Government Property Rights

It might be presumed that Government property rights in a democracy are similar to corporate property with diffused stockholdings and should yield similar results. The analogy would be apt if each voting citizen had a share of votes equivalent to one's share of the wealth in the community, and if a person could shift wealth among governments, as one can among different corporations. If, for example, one could buy and sell land (as assets capturing essentially most of the value of whatever the government does in that particular state) in several different governments and could vote in each in proportion to the value of that 'land' then government property would be closer to private property in its effects. But it is difficult to take that possibility seriously. The nature of government, public or communal property rights surely depends on the kind of government. Because these are so vaguely and indefinitely defined, attempts to deduce formally the consequences of resource allocation and behaviour under each have been hampered.

Non-Existent Property Rights

Not all resources are satisfactorily controlled by Private property rights. Air, water, electromagnetic radiation, noises and views are some examples. Water under my land flows to yours. Sounds and light from my land impinge on yours. Other forms of control are then designed, for example, political or social group decisions and actions, though these other forms are sometimes employed for ideological or political purposes, even where Private property rights already exist.

If these other forms permit open, free entry with every user sharing equally and obtaining the average return, use will be excessive. Extra uses will be made with an increased realized total value that is less than the cost added, that is, the social product value is not maximized. This occurs because the marginal yield is less than the average to each user, to which each user responds. So, use occurs to the point where the average yield is brought down to marginal cost, with the consequence that the marginal yield is less than the marginal cost – often exampled as excessive congestion on a public road or public park, or overfishing of communal, free access fishing areas. The classic 'communal property' implication that apples on the public apple tree are never allowed to ripen is an extreme example of the proposition that property rights, other than private, reduce conformity of resource uses to market revealed values. Alternatively, if communal property rights mean that incumbent users can block more users, the resource will be underutilized as incumbents maximize their individual yield, which is the average, not the marginal. This results in fewer users. Though more users or uses would lower the average value to the incumbents and hence dissuade a higher rate of use, the addition to the total group value (of the extra use) exceeds the extra costs. Examples are public, low tuition colleges that restrict entry to maximize the 'quality' of those who are educated – that is, to maximize the average yield of those admitted. Some labour unions (that is, teamsters) are examples of similar situations.

A mistaken inference commonly suggested by the example of fishermen who overfish unowned lakes is that independent sellers with open access to customers will 'over-congest' in product variety and advertising to catch customers, with unheeded costs borne by other sellers. If, for example, Pall Mall cigarettes attract some customers from Camel, the loss to Camel is the reduced value of Camel-specific resources, not its lost sales revenue. General resources will be released from making Camels for use elsewhere with no social loss. But Camel-specific resources fall in value by the extent to which Pall Mall's product is better or cheaper. Camel's loss is more than offset by the sum of Pall Mall's increased net income plus the transfer gain to customers from lower prices or better quality. The loss to Camel is not from new entry itself, but from its incorrect forecasts of its earlier investment value. It is presumed here that mistaken forecasts should not be protected by prohibiting the unexpected future improvements. This differs from the over-fishing case in that consumers, in contrast to fish, have property rights in what they pay and what they buy. If every fish had a separate owner or owned itself, none would allow it to be caught unless paid enough, and over-fishing would not occur. One owner of all the fish is unnecessary; it suffices that each fish (or potential customer) be owned by someone who can refuse to buy. (Of course, unless the lake were owned, the lake surface might be over-congested with too many fishermen, each fishing to a lesser area, even if the fish were owned.)

Ownership of tradable rights by customers is the feature that is missing in the over-fishing, over-congestion case. Because rights to (or 'of') the fish or whales need not be bought, over-fishing does not imply over-customering where customers own rights to what the competing sellers are seeking. Otherwise, customers could be caught like fish, wherein sellers would be competing both to (1) establish property rights over the customers and to (2) possess those rights. Costly redundant competition for initial establishment of rights could be avoided simply by establishing customers' rights to themselves, as is in fact done. If the preceding seems fanciful, replace 'fish' with people and the lake surface with streets on which taxi-drivers cruise for customers. Excessive costs will be incurred in competition for use of unowned, valuable resources, in this case, the streets.

Mutual Property Rights

'Mutual' forms of organization are used apparently in order to sustain the maximum average per member, or to reserve for the incumbent members any greater group value from more members. Mutual private property, a form that has barely been analysed, does not permit anonymous alienability of interests in what are otherwise Private property rights. A 'mutual' member can transfer its interest to other people only upon permission of the other mutually owning members or their agents. Fraternal, social and country clubs are examples. These activities have not typically been viably organized and their services sold, as for example, in restaurants and health and exercise gymnasia. The intragroup-specific resources are themselves the members (erstwhile customers) who interact and create their social utility. More members affect each incumbent's realized utility in two ways: by social compatibility and by congestion. An outside, separate owner interested in the maximum value of the organization, but not the maximum average-per-member, could threaten to sell more memberships which, although enabling a larger total social value with more members, would reduce the average value to the existing members. This is an example of the earlier analysed difference between maximizing the average yield per input rather than the total yield by admitting more members, who while they would be made better off than if not admitted nevertheless reduce the average value to the incumbent members. In addition, the ability of newcomers to compensate incumbents for any loss in the individual (average) value to incumbent members is restrained if the membership fee were to go instead to an outside owner of the club. To the extent that a pecuniary compensation, via an initiation fee, were paid to an outside owner and exceeded the reduction in their average individual and total group utility, newcomers would be admitted, and the outside owner would gain, but incumbent members would lose their composite quasi-rent of their interpersonal sociability. (It is not yet well understood why, aside from tax reasons, the mutual form occurs in savings and loans and insurance firms.)

Torts, Conditional and Unassigned Property Rights

Private property rights may exist in principle, but, quite sensibly, not be blindly and uncompromisingly enforced against all possible 'usurpers'. For example, situations arise in which someone's presumed Private property rights do not exclude an 'invader's' use. Accidental or emergency use of some other person's private property without prior permission constitutes an example, sometimes called a 'tort'. Another possibility is that the property rights are so ill-defined that whether a right has been usurped or already belonged to the alleged 'usurper' is unclear. For example, my newly planted tree may block the view from your land. But did you have a right to look across my land? If the rights to views (or light rays) were clearly defined and assigned, we could negotiate a price for preserving the view or my putting up a tree, depending upon which was more valuable to the both of us and with payment going to whoever proved to have the rights. Or, while sailing on a lake, to escape a sudden storm and save my boat and life, I use your dock without your prior permission. Did I violate any of your rights, or did your rights not include the right to exclude users in my predicament? If such emergency action is deemed appropriate, then rights to use of the dock are not all yours, as you may have thought. Whereas in the tree and view case, where a prior negotiation might have avoided a 'tort' (except that initially we did not agree about who had what rights), in the emergency use of the dock, prior negotiation was unfeasible. If prior negotiation is uneconomic, rights to that emergency use 'should' and will exist if that use is the most valuable use of the resource under the postulated circumstances. And compensation may or may not be required to the erstwhile 'owner'. The principle underlying such a legal principle seems straightforward and consistent with principles of efficient economic behaviour. It suffices for present purposes merely to call attention to this aspect of economic efficiency underlying the law.

Property Taxation

George R. Zodrow

Abstract

Property taxation of both residential and nonresidential land and structures is the most common form of wealth taxation worldwide, and is often the revenue instrument of choice for local governments. Despite widespread use of the property tax and a voluminous academic literature examining the tax, its incidence and economic effects are still contentious issues, with the debate centring around whether the capital portion of the tax should be viewed as distorting the allocation of capital or as an efficient benefit tax or user charge for local public services.

Property taxation of both residential and nonresidential land and structures – or 'real property' – is the most common form of wealth taxation worldwide, and is often the revenue instrument of choice for local governments. For example, in the United States property taxes account for over 70 per cent of local own-source tax revenues. Property tax liability is calculated as the product of the statutory rate and the assessed tax base, subject to a variety of adjustments, such as partial exemptions for primary residences and 'circuit breakers' designed to reduce tax burdens for certain groups, especially relatively poor elderly homeowners. Although vagaries in the assessment process have long been a source of inequity in the administration of the tax, recent advances in computer-based assessment practices have mitigated this problem. More recently, rapid growth in residential home values and the concomitant increase in property tax burdens and the share of total local taxes paid by homeowners have led to increasing dissatisfaction with the tax in some regions, culminating in the passage of numerous property tax limitation measures. In addition, concerns about the equity implications of financing primary and secondary public education with the property tax when the tax base, including non-residential property, is unequally distributed across school jurisdictions have led to reduced reliance on the tax as well as equalization mechanisms that redistribute property tax revenues across school districts (Anderson 1994).

The Incidence Debate: The Three Views of the Property Tax

The academic literature on the property tax – as reviewed by Mieszkowski and Zodrow (1989), Ladd (1998), Ross and Yinger (2000) and Netzer (2001) – has focused on the incidence and effects on the allocation of resources of the residential property tax. There is general agreement that the land component of the property tax is capitalized into land values, is borne by landowners at the time of the imposition of the tax, and – since land is immobile – does not distort the allocation of resources. Indeed, the efficiency advantages of taxing land values, coupled with a belief that most increases in land values reflect the benefits of public services, have led some observers, most prominently Henry George (1879), to advocate replacing property taxes with taxes on land values.

By comparison, the incidence and economic effects of property taxation of the capital or structures component of real property are among the most contentious issues in state and local public finance. Three views dominate the debate. The 'traditional' view dates back to Simon (1943) and Netzer (1966), who focused on the partial equilibrium effects of increasing the tax in a local housing market. From this perspective, one can make the standard 'open economy' assumption that the national return to capital is fixed. This in turn implies that local capital bears none of the local property tax, as capital in the long run migrates from the jurisdiction until the local after-tax return to capital equals the national value. The burden of the tax is thus borne by local factors and/or consumers, with the traditional view holding that the entire burden is borne by local housing consumers. The traditional view thus implies that the property tax inefficiently reduces the size of the local housing stock and that its burden is borne in proportion to housing consumption – and is thus somewhat regressive with respect to annual income but, more importantly, roughly proportional with respect to lifetime income.

A second popular theory is the 'benefit tax' view, developed by Hamilton (1975, 1976); Fischel (2001a, b) provides a recent discussion. This view is an extension of the renowned Tiebout (1956) model, which argues that consumer mobility ('voting with the feet') and inter–jurisdictional competition in the provision of local public services can ensure efficiency of resource allocation in the local public sector. Although Tiebout assumed the existence of benefit/head taxes, Hamilton extended the analysis by deriving conditions under which the property tax can be converted into the head tax assumed by Tiebout.

Specifically, following Tiebout, Hamilton assumes that individuals sort into local jurisdictions according to their demands for local public services, and that there are enough local tax-expenditure packages to accommodate all tastes. In addition, Hamilton (1975) assumes that local jurisdictions are homogeneous with respect to house values, and that there are enough jurisdictions to accommodate all desired housing and government service/tax packages. Finally, Hamilton assumes the existence of binding zoning constraints that established a minimum house value for each community. Under these circumstances, individuals are precluded from purchasing homes with a value below the minimum, and would never elect to pay taxes in excess of benefits received by purchasing a home with a value greater than the minimum; all individuals in a given community thus pay exactly the same property tax, which becomes a benefit tax.

Hamilton (1976) extends this model to the more realistic case in which house values within a community are heterogeneous. In this case, Hamilton assumes all communities are fully developed, effectively precluding any tax-induced changes in the housing stock, and that alternative communities which are homogeneous with respect to both demands for public services and housing are available. Under these circumstances, Hamilton shows that 'perfect capitalization' converts the property tax into a benefit tax, as a relatively expensive home sells at a discount equal to its 'fiscal differential' or the present value of all future taxes in excess of benefits received, while a relatively inexpensive home sells at a premium reflecting its fiscal differential, the present value of all future benefits in excess of future taxes. The implications of the benefit tax view are striking, as it implies that the property tax is effectively a non-distortionary user charge that has no direct effects on income distribution.

Finally, the 'capital tax' view (or 'new' view) of the property tax, developed by Mieszkowski (1972), subsequently extended by Zodrow and Mieszkowski (1983, 1986b), and reviewed in Zodrow (2001a, b), argues that the property tax is a distortionary tax on the local use of capital that results in a misallocation of the national capital stock across local jurisdictions. Mieszkowski (1972) stresses that earlier partial equilibrium analyses ignored the fact that the property tax is used by virtually all local jurisdictions and applies to a large fraction of the capital stock, including most non-residential capital. Adapting the Harberger (1962) general equilibrium model of tax incidence, he models the economy as having a fixed national capital stock and two types of local jurisdictions, characterized by 'high' tax rates and 'low' tax rates. In this context, Mieszkowski shows that property tax rates that exceed the national average drive capital out of high-tax jurisdictions into low-tax jurisdictions, with opposing effects occurring in relatively low tax jurisdictions. Property tax differentials thus result in an inefficient allocation of capital across jurisdictions. In addition, concern about the extent to which use of the property tax may drive capital out of a jurisdiction creates a tendency for local governments to under-provide public services (Zodrow and Mieszkowski 1986b; Wilson 1986). In terms of incidence, the 'average burden' of all of the property taxes imposed across the nation – known as the 'profits tax' effect of the tax – is borne by capital owners generally, implying that the tax is relatively progressive (with respect to annual income). In addition, Mieszkowski stresses that property tax differentials about the national average result in 'excise tax effects' in the form of housing and commodity price increases and wage and land price declines in relatively high-tax jurisdictions, with offsetting effects in relatively low-tax jurisdictions.

Differentiating Among the Three Views

Much of the subsequent literature has focused on reconciling or differentiating among these three views, and the issue of which view most accurately describes the effects of the property tax is still contentious. Matters are simplified somewhat because the traditional view has been shown to be a special case of the capital tax view. Specifically, the traditional view can be interpreted as a partial equilibrium analysis that focuses exclusively on the excise tax effects of the capital tax view, while neglecting its general equilibrium profits tax effects. Moreover, the traditional view that these excise tax effects are fully reflected in higher housing prices is accurate only under special circumstances; more generally, excise tax effects are borne in some combination by housing consumers and the owners of labour and land in the taxing jurisdiction (Wildasin 1986). In addition, the profits tax effect still obtains when one takes a general equilibrium perspective of the use of the property tax by a single small jurisdiction facing a perfectly elastic supply of capital. Specifically, although the capital outflow caused by an increase in the property tax by a small local jurisdiction depresses the overall return to capital only very slightly, this reduction affects a large capital stock; under certain circumstances, the overall reduction in national capital income precisely equals the revenue raised by the taxing jurisdiction, yielding the profits tax result (Zodrow and Mieszkowski 1983; Brown 1924; Bradford 1978). At the same time, the burden of a property tax increase in a single jurisdiction is borne entirely by local residents as higher prices or lower factor returns (with offsetting effects in all other jurisdictions). A critical implication is that even under the capital tax view there is a close link between local public services and the burden of the property tax, as the cost of financing local expenditures largely falls on local factor owners and consumers; thus, this interpretation of the capital tax view clearly has a strong benefit view flavour as local residents 'pay for what they get' in public services.

Nevertheless, the debate between proponents of the benefit tax view and the capital tax view is still far from resolved. The original Mieszkowski (1972) derivation, based on a model of national tax incidence, has been criticized for ignoring many of the features of local government service provision stressed by Tiebout and Hamilton. However, Zodrow and Mieszkowski (1986a) present an expanded derivation of the capital tax view that includes most of these aspects, including interjurisdictional competition, varying tastes for local public services, individuals sorting into differing communities according to tastes for local public services, and a simple form of land use zoning. They conclude that these factors thus do not distinguish between the two views; instead, the key factor in determining the incidence of the property tax is whether housing consumption can vary in response to the imposition of the tax. Moreover, although zoning requirements are pervasive, take a wide variety of forms, and can have a significant impact on property values (Fischel 1992), these facts do not demonstrate that zoning ordinances are sufficiently binding on housing consumption choices to ensure the validity of the benefit view (Rubinfeld 1987; Ross and Yinger 2000). In addition, although empirical evidence suggests that intrajurisdictional and intrajurisdictional capitalization of differences in property taxes and local expenditures is widespread (Oates 1969; Yinger et al. 1988; and Fischel 2001a, b, who concludes that evidence of 'capitalization is everywhere'), capitalization is consistent with both the assumption of fixed housing stocks that underlies the benefit tax view and the tax-induced reallocations of capital that underlie the capital tax view (Zodrow 2006); moreover, some observers have argued that in the long run capitalization is inconsistent with the benefit view (Ross and Yinger 2000). Finally, although some recent empirical tests are consistent with the capital tax view (Carroll and Yinger 1994; Wassmer 1993), these results are quite tentative. The primary empirical issue remaining to be resolved is whether the zoning restrictions or other mechanisms stressed by proponents of the benefit tax view are sufficiently binding to preclude the long-run adjustments in housing capital predicted by the capital tax view. This question promises to be a fertile topic for future research, which hopefully will help clarify the answer to the long-standing and critical questions of the incidence and economic effects of the property tax.

Proportional Hazard Model

Jerry A. Hausman and Tiemen M. Woutersen

Abstract

This article reviews proportional hazard models and how the thinking about identification and estimation of these models has evolved since the mid-1970s.

Keywords

Baseline hazard; Convergence; Duration dependence; Duration measurements; Duration models; Gamma distribution; Heterogeneity; Mixed proportional hazard (MPH) model; Partial likelihood estimators; Proportional hazard models; Semiparametric estimation; Time-Varying regressors; Weibull model

The estimation of duration models has been the subject of significant research in econometrics since the late 1970s. Cox (1972) proposed the use of proportional hazard models in biostatistics and they were soon adopted for use in economics. Since Lancaster (1979), it has been recognized among economists that it is important to account for unobserved heterogeneity in models for duration data. Failure to account for unobserved heterogeneity causes the estimated hazard rate to decrease more with the duration than the hazard rate of a randomly selected member of the population. Moreover, the estimated proportional effect of explanatory variables on the population hazard rate is smaller in absolute value than that on the hazard rate of the average population member and decreases with the duration. To account for unobserved heterogeneity Lancaster proposed a parametric mixed proportional hazard (MPH) model, a partial generalization of Cox's proportional hazard model, that specifies the hazard rate as the product of a regression function that captures the effect of observed explanatory variables, a baseline hazard that captures variation in the hazard over the spell, and a random variable that accounts for the omitted heterogeneity. In particular, Lancaster (1979) introduced the mixed proportional hazard model in which the hazard is a function of a regressor X unobserved heterogeneity v, and a function of time $\lambda(t)$,

$$\theta(t|X, v) = ve^{X\beta_0}\,\lambda(t). \qquad (1)$$

The function $\lambda(t)$ is often referred to as the baseline hazard and $v|X$ has a gamma distribution. The popularity of the mixed proportional hazard model is partly due to the fact that it nests two alternative explanations for the hazard $\theta(t|X)$ to be decreasing with time. In particular, estimating the mixed proportional hazard model gives the relative importance of the heterogeneity, v, and genuine duration dependence, $\lambda(t)$ (see Lancaster 1990, and Van den Berg 2001, for overviews). Lancaster (1979) uses functional form assumptions on $\lambda(t)$, which were not required by the Cox model, and distributional assumptions on v to identify the model. Examples by Lancaster and Nickell (1980) and Heckman and Singer (1984), however, show the sensitivity to these functional form and distributional assumptions. Thus, Lancaster's MPH model is fully parametric and from the outset questions were raised about the role of functional form and parametric assumptions in the distinction between unobserved heterogeneity and duration dependence. (Heckman 1991, gives an overview of attempts to make this distinction in duration and dynamic panel data models.) This question was resolved by Elbers and Ridder (1982), who showed that the MPH model is semi-parametrically identified if there is minimal variation in the regression function. A single indicator variable in the regression function suffices to recover the regression function, the baseline hazard, and the distribution of the unobserved component, provided that this distribution does not depend on the explanatory variables. Semi-parametric identification means that semi-parametric estimation is feasible, and a number of semi-parametric estimators for the MPH model have been proposed that progressively relaxed the parametric restrictions.

Nielsen et al. (1992) showed that the partial likelihood estimator of Cox (1972) can be generalized to the MPH model with gamma-distributed unobserved heterogeneity. Their estimator is semi-parametric because it uses parametric specifications of the regression function and the distribution of the unobserved heterogeneity. The estimator requires numerical integration of the order of the sample size, as originally discussed by Han and Hausman (1990), which further limits its usefulness and makes it impractical for most situations in econometrics. Heckman and Singer (1984) considered the non-parametric maximum likelihood estimator of the MPH model with a parametric baseline hazard and regression function. Using results of Kiefer and Wolfowitz (1956), they approximate the unobserved heterogeneity with a discrete mixture. The rate of convergence and the asymptotic distribution of this estimator are not known. As a result, these estimators that use discrete mixture with an increasing number of support points cannot be used to test hypotheses. Another estimator that does not require the specification of the unobserved heterogeneity distribution was suggested by Honoré (1990). This estimator assumes a Weibull baseline hazard and uses only very short durations to estimate the Weibull parameter.

Han and Hausman (1990) and Meyer (1990) propose an estimator that assumes that the baseline hazard is piecewise-constant, to permit flexibility, and that the heterogeneity has a gamma distribution. Both papers find that the hazard rate, conditional on heterogeneity, is non-monotonic so that the Weibull model cannot hold. Hausman and Woutersen (2005) present simulations and a theoretical result that show that using a nonparametric estimator of the baseline hazard with gamma heterogeneity yields inconsistent estimates for all parameters and functions if the true mixing distribution is not a gamma, which limits the usefulness of the Han–Hausman–Meyer approach. Thus, Hausman and Woutersen (2005) find it important to specify a model that does not require a parametric specification of the unobserved heterogeneity.

Horowitz (1999) was the first to propose an estimator that estimates both the baseline hazard and the distribution of the unobserved heterogeneity nonparametrically. His estimator is an adaptation of the semi-parametric estimator for a transformation model that he introduced in Horowitz (1996). In particular, if the regressors are constant over the duration, then the MPH model has a transformation model representation with the logarithm of the integrated baseline hazard as the dependent variable and a random error that is equal to the logarithm of a log standard exponential minus the logarithm of a positive random variable. In the transformation model the regression coefficients are identified only up to scale. As shown by Ridder (1990), the scale parameter is identified in the MPH model if the unobserved heterogeneity has a finite mean. Horowitz (1999) suggests an estimator of the scale parameter that is similar to Honoré's (1990) estimator of the Weibull parameter and is consistent if the finite mean assumption holds so that his approach allows estimation of the regression coefficients (not just up to scale). However, the Horowitz approach permits estimation of the regression coefficients only at a slow rate of convergence and it is not $N^{-1/2}$ consistent, where N is the sample size. The reason for the slower than $N^{-1/2}$ convergence is that the information matrix of the MPH model is singular under Horowitz assumptions (see Hahn 1994; Ishwaran 1996a). In particular, Horowitz (1999) assumes that the first three moments of the heterogeneity distribution exist, and Ishwaran (1996b) shows that the fastest possible rate of convergence is $N^{-2/5}$ for that case and Horowitz's (1999) estimator converges arbitrarily close to that rate. In other words, the slow rate of convergence is implied by the assumptions and is not a peculiarity of the estimator.

Subsequent research has focused on strengthening the assumptions of the MPH model so that $N^{-1/2}$ convergence is possible. Ridder and Woutersen (2003) derive a $N^{-1/2}$ consistent estimator for the MPH model by assuming that the baseline hazard rate is constant over a small interval, $\lambda(t)= \lambda$ for $0 \leq t \leq \varepsilon$ for any $\varepsilon > 0$ while allowing for a nonparametric baseline hazard function for $t > \varepsilon$. For parametric baseline hazards, Ridder and Woutersen (2003) assume that $\lim_{t\downarrow 0} \lambda(t)= \lambda$ for $0 < \lambda < \infty$ and derive another $N^{-1/2}$ consistent estimator. Hausman and Woutersen (2005) derive an estimator for the mixed proportional hazard model (with heterogeneity) that allows for a nonparametric baseline hazard and uses time-varying regressors. No parametric specification of the heterogeneity distribution or nonparametric estimation of the heterogeneity distribution is necessary. Intuitively, Hausman and Woutersen (2005) condition out the heterogeneity distribution, which makes it unnecessary to estimate it. Thus, they eliminate the problems that arise with the Lancaster (1979) approach to MPH models. In this model the baseline hazard rate is nonparametric, and the estimator of the integrated baseline hazard rate converges at the regular rate, $N^{-1/2}$ where N is the sample size. This convergence rate is the same rate as for a duration model without heterogeneity. The regressor parameters also converge at the regular rate. A nice feature of the estimator is that it allows the durations to be measured on a finite set of points. Such discrete measurement of durations is important in economics; for example, unemployment is often measured in weeks. In the case of discrete duration measurements, the estimator of the integrated baseline hazard converges only at this set of points, as would be expected.

It may be argued that the bias in the estimates of the regression coefficients is small if the estimates of the MPH model indicate that there is no significant unobserved heterogeneity. The problem with this argument is that estimates of the heterogeneity distribution are usually not very accurate. Given the results in Horowitz (1999), this finding should not come as a surprise. The simulation results in Baker and Melino (2000) show that it is empirically difficult to find evidence of unobserved heterogeneity, in particular if one chooses a flexible parametric representation of the baseline hazard. However, Han and Hausman (1990) and applications of their approach have found significant heterogeneity using a flexible approach to the baseline hazard. Bijwaard and Ridder (2002) find that the bias in the regression parameters is largely independent of the specification of the baseline hazard. Hence, failure to find significant unobserved heterogeneity should not lead to the conclusion that the bias due to correlation of the regressors and the unobservables that affect the hazard is small.

Because it is empirically difficult to recover the distribution of the unobserved heterogeneity, estimators that rely on estimation of this distribution may be unreliable. Therefore, it may be advisable to avoid estimating the unobserved heterogeneity distribution and the remainder of the MPH model simultaneously. Nevertheless, after estimating the baseline hazard and regression function, one can usually identify the mixing distribution. In particular, Horowitz (1999) uses the following equation to estimate the mixing distribution,

$$\ln\{\Lambda(T)\} + X\beta - \ln(Z) = -\ln(v)$$

where $\Lambda(T)$ and β can be estimated and the unobserved Z has an exponential distribution with mean one. Thus, Horowitz (1999) solves a deconvolution problem and the speed of convergence depends on the assumptions on the distribution of v.

A hazard model is a natural framework for time-varying regressors if a flow or a transition probability depends on a regressor that changes with time since a hazard model avoids the curse of dimensionality that would arise from interacting the regressors at each point in time with one another. A non-constructive identification proof for the duration model with time-varying regressors can be produced using techniques similar to Honoré (1993b), and Honoré (1993a) gives such a proof. (A non-constructive identification proof is an identification proof that does not suggest an estimator.) In particular, Honoré (1993a) does not assume that the mean of the heterogeneity distribution is finite (nor does Honoré 1993a, assume a tail condition as in Heckman and Singer 1984). Ridder and Woutersen (2003) argue that it is precisely the finite mean assumption that makes the identification of Elbers and Ridder (1982) ‘weak’ in the sense that the model of Elbers and Ridder (1982) cannot be estimated at rate $N^{-1/2}$. As in Honoré (1993a), Hausman and Woutersen (2005) do not need the finite mean $N^{-1/2}$ assumption which gives an intuitive explanation of why Hausman and Woutersen (2005) can estimate the model at rate $N^{-1/2}$.

Prospect Theory

Graham Loomes

Abstract

Prospect theory sought to provide a descriptive model of risky choice which could accommodate a number of seemingly systematic violations of conventional ‘expected utility’ analysis. Although there are phenomena which the model cannot explain (even in its later ‘cumulative’ form), it constitutes a landmark in the development of alternative theories which have modified standard theory and/or have tried to incorporate psychological factors into decision theories.

Prospect theory (PT) was developed by psychologists Daniel Kahneman and Amos Tversky to try to account for a number of patterns of response to risky choices which departed systematically from the conventional wisdom about rational decision making in the form of von Neumann and Morgenstern’s (1944) expected utility (EU) hypothesis.

Kahneman and Tversky’s (1979) paper ‘Prospect Theory: An Analysis of Decision Under Risk’ has proved to be enormously influential. According to Kim, Morse and Zingales (2006), it is the second most frequently cited paper published in economics journals since 1970, with more than 4,000 citations in the 25 years since its publication. It provided a major stimulus to the development of a number of other ‘non-expected-utility’ theories in the 1980s and 1990s – see Starmer (2000) for a survey and review. It has also inspired much work in behavioural economics and in economic and psychological experiments exploring individual decision making under risk and uncertainty.

The following subsections consider what PT set out to do and how it did it. There then follows a discussion of the importance of the theory as well as its possible limitations.

Background

In the 1950s and 1960s, evidence had begun to accumulate which suggested that EU failed as a general *descriptive* model of risky choice. Two of the most influential 'paradoxes' had been identified by Maurice Allais in the early 1950s (see Allais 1953). These were renamed by Kahneman and Tversky (henceforth K&T) and are now widely known as the 'common ratio effect' and the 'common consequence effect'. Briefly, they are as follows, starting with the common ratio effect.

Consider the choice between two 'prospects' A and B where A offers a sum of money x with probability p (and 0 with probability $1 - p$) while B offers a smaller sum y with a larger probability q (and 0 with probability $1 - q$). An extreme form of this might involve setting $q = 1$, so that B offers the certainty of y: in an example used by K&T, B offered the certainty of 3,000 Israeli pounds while A offered a 0.8 chance of 4,000 (and a 0.2 chance of 0). EU does not predict which of A and B an individual will choose – that depends on the individual's personal tastes concerning risk – but what the independence axiom of EU *does* entail is that, if p and q are scaled down by the same factor so that the ratio of 'winning' probabilities is maintained, the preference between the scaled-down prospects will be consistent with the preference between A and B.

So – to continue the example used by K&T – suppose that both p and q are scaled down to a quarter of their original values, generating prospects C and D, where C offers a 0.2 chance of 4,000 and a 0.8 chance of 0, while D offers a 0.25 chance of 3,000 and a 0.75 chance of 0. Then EU entails that anyone who prefers A over B should also prefer C over D, and vice versa. However, the common ratio effect form of the Allais paradox is manifested when a substantial proportion of those who choose the safer option B in the first case switch to the riskier prospect C in the second case, while the combination of choosing A in the first case and D in the second case is relatively rare.

In the above case, the scaling down operated on the *magnitudes* of the winning probabilities, while *maintaining the ratio* between them. Another way of manipulating the prospects could work in terms of replacing some probability of a particular sum common to both prospects by the same probability of a different sum. Consider another example used by K&T. This time, E offers 2,500 with probability 0.33, 2,400 with probability 0.66 and 0 with probability 0.01, while F offers 2,400 with certainty. Now, for both prospects, replace the 0.66 probability of 2,400 by a 0.66 probability of 0: this transforms E into a prospect G which offers a 0.33 chance of 2,500 and a 0.67 chance of 0, and transforms F into a prospect H which offers a 0.34 chance of 2,400 and a 0.66 chance of 0. Once again, EU entails that individuals should either choose E in the first case and G in the second, or else they should choose F and H. However, the common consequence effect form of Allais paradox involves many more individuals switching from safer to riskier (that is, choosing F and G) than switch from riskier to safer (that is, choose E and H).

In addition to the common ratio and common consequence effects, two other 'effects' were influential in the formulation of PT. One of these is the 'isolation effect'. Consider again the 'scaled-down' pair of prospects from the common ratio example. In the way they were presented there, C offered a 0.2 chance of 4,000 together with a 0.8 chance of 0, while D offered a 0.25 chance of 3,000 alongside a 0.75 chance of 0. In this case, the implication is that the uncertainty is resolved in a single stage: perhaps a 20-sided die is rolled, and if a number from 1 to 4 comes up C pays 4,000 (and 0 otherwise), whereas D pays 3,000 if the number is anything in the range 1 to 5.

However, there is another way of presenting this choice which EU would regard as amounting to exactly the same thing, but which PT suggests people are likely to treat differently. Suppose that the uncertainty is resolved in two stages, as follows. In the first stage, there is a 0.75 chance of being 'knocked out' and getting 0, and there is a 0.25 chance of getting through to the second stage – at which point the choice is between, on the one hand, a 0.8 chance of 4,000 and, on the other hand, the certainty of 3,000. The logic of EU entails that the two stages can be 'reduced' to a single stage by multiplying through the probabilities: a 0.25 chance of getting through and facing a 0.8 chance of 4,000 can thus be reduced to a 0.2 chance of 4,000, as offered by prospect C; and a 0.25 chance of getting through to receive the certainty of 3,000 is regarded as just the same as a direct 0.25 chance of 3,000, as offered by prospect D.

Put another way, a 0.25 chance of what was prospect A in the common ratio example is equivalent to C, and a 0.25 chance of prospect B is regarded as the same as D. Yet the evidence of what K&T called the 'isolation effect' shows that people do not process the two-stage game in the way presumed by EU. When faced with such a two-stage problem and told that they have to make a commitment ahead of the first stage, most individuals appear to disregard (or isolate) the common first stage, focus on the alternatives that are contingent on getting through to the second stage, and then make much the same choices as they do when presented with the simple one-stage choice between A and B. In other words, when asked to commit ahead of this two-stage resolution of uncertainty, there is a much stronger tendency to pick the safer option than when presented with the one-stage choice between C and D where the calculus of probability 'reduction' has already been applied.

The fourth regularity that played a significant role in the formulation of PT was the 'reflection effect'. Essentially, this refers to the observations that changing payoffs from gains to losses (relative to the status quo) tended to reverse individuals' choices. Thus if A and B above were transformed into A′ and B′ such that A′ offered a 0.8 probability of *losing* 4,000 (and a 0.2 probability of losing nothing) while B′ entailed the certainty of a 3,000 loss, the modal preference for B over A would often be 'reflected' into a modal preference for A′ over B′. Thus, what appears as a predominant pattern of risk aversion in the choice between prospects such as A and B which involve gains seems to transform into a predominant pattern of risk seeking when the non-zero payoffs are losses.

Combining the reflection effect with the isolation effect can produce striking 'framing' effects. For example, consider first a scenario where an individual is given a lump sum of 1,000 and then asked to choose between a further 500 for sure or else a risky prospect offering a 50–50 chance of either 0 or an extra 1,000. If the individual isolates the initial 1,000 and displays risk aversion towards the 50–50 gamble involving gains, she will end up with a sure 1,500 rather than a portfolio consisting of a 0.5 chance of a net 1,000 and a 0.5 chance of a net 2,000. But now consider a scenario framed somewhat differently. The individual is given a lump sum of 2,000 and then asked to choose between the certainty of losing 500 or else a 50–50 chance of either losing 1,000 or losing 0. If the individual again isolates the lump-sum but now displays risk seeking towards the 50–50 gamble involving losses, she will end up with exactly the opposite portfolio preference: that is, she will choose the portfolio consisting of a 0.5 chance of a net 1,000 and a 0.5 chance of a net 2,000 rather than 1,500 for sure. K&T presented evidence which showed that this was indeed a strong tendency among those who answered their hypothetical questions framed in these various ways.

The Aims and Structure of Prospect Theory

PT can be seen as offering a descriptive (rather than a prescriptive/normative) model of a particular area of decision making. K&T were careful to specify the domain to which their model applied: it was a theory of *choice* over pairs of prospects each involving *no more than two non-zero payoffs* where the *objective probabilities were given* to decision makers. As formulated in the 1979 paper, the theory did *not* apply to valuation tasks (for example, tasks that asked people how much they would pay or accept in exchange for some risky prospect), nor to prospects involving larger numbers of possible payoffs, nor to cases where there was ambiguity about the likelihood of different events occurring (although in their concluding remarks K&T expressed some optimism that the model could be extended to accommodate the latter two features, while relevant valuations might be inferred via some iterative procedure involving a series of choices between a prospect and different sure sums). Most importantly, because it set out to provide an account of *actual* behaviour rather than a prescription for how decision makers *ought* 'rationally' to behave, PT allowed the possibility of patterns of behaviour that decision makers might wish to modify if they ever became aware of the 'inconsistencies' involved (although, in the absence of opportunities for such realization, the 'anomalies' implied by PT could be expected to occur and persist).

To *some* extent, the elimination of some potentially undesirable possible implications of PT was handled by dividing the modelling of people's decision processes into two phases: first, the editing phase, which involved simplifying prospects and screening out transparent transgressions of reasonable behaviour; and then the evaluation phase, in which the preferred alternative was identified.

The editing phase prepared the ground for the evaluation phase in various intuitively appealing ways. It involved the detection of *transparent* dominance and the discarding/rejection of dominated alternatives in such cases (while allowing the possibility that dominance might be violated if more complicated ways of presenting the prospects obscured the dominance relationship). There was also scope for some *simplification* of prospects (for example, *rounding* of payoffs and/or probabilities). In cases where there were transparently common and/or riskless components, these were liable to be *segregated* and/or *cancelled*. It was also supposed that, when a prospect offered the same payoff contingent on different events with separately expressed probabilities, those probabilities would be added together. For example, suppose a prospect offered a payoff of 100 if a card drawn at random from a standard pack of playing cards turned out to be a spade, and offered the same payoff if the card turned out to be a heart: then the probabilities of these two events – each 0.25 – would be *combined* to give an overall 0.5 chance of receiving 100. Finally, all payoffs were *coded* into gains or losses relative to some reference point – this latter normally being the status quo, although in some circumstances it might be otherwise (as discussed in the penultimate subsection of the 1979 paper).

The evaluation phase involved the interaction of two components: the *value* function, and the *decision weight* function.

A careful reading of the 1979 exposition makes it clear that the subjective value associated with a particular payoff should, strictly speaking, be expected to be a function of *two* factors: the asset position that constitutes the individual's reference point, and the positive or negative change from that point represented by the payoff in question. However, K&T argued that, over quite broad ranges of initial asset positions and for many practical purposes, it is sufficient to focus just on one argument, namely, the size of the gain or loss entailed by any particular payoff.

Drawing on existing evidence, including a substantial body of work from the realm of psychophysics, K&T argued that such a value function is characterized by two key characteristics.

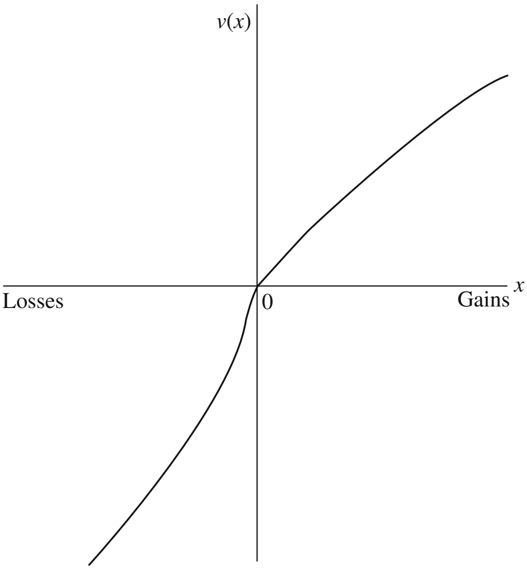
First, the marginal value of both gains and losses is presumed to diminish as the magnitudes increase. Thus the difference between a gain (or loss) of 100 and a gain (or loss) of 150 registers more strongly than the difference between a gain (loss) of 1,100 and a gain (loss) of 1,150. Such diminishing sensitivity means that the gradient of the value function becomes progressively less steep as payoffs are located further from the reference point. Denoting the value of any monetary payoff x by $v(x)$, diminishing sensitivity in the domain of gains can be more formally represented as

$$\begin{aligned} v(x+a)-v(x) > v(x+a+k) \\ - v(x+k) \text{ for all } x, a, k \\ > 0; \end{aligned}$$

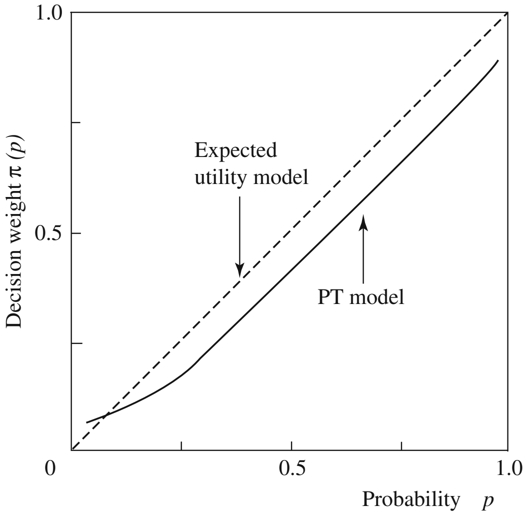
in the domain of losses, it entails

$$\begin{aligned} v(-x)-v(-x-a) > v(-x-k) \\ - v(-x-a-k). \end{aligned}$$

Second, the marginal value of losses is modelled as being greater than the marginal value of gains of the same magnitude: that is, for all x, the gradient of the function is steeper at $-x$ than at x. More formally, $v'(-x) > v'(x)$ wherever the derivative of x exists. In conjunction with the first characteristic, this implies a value function as



Prospect Theory, Fig. 1 Prospect theory's value function



Prospect Theory, Fig. 2 Prospect theory's decision weighting function

shown in Fig. 1: that is, concave in the domain of gains, convex and steeper in the domain of losses, and kinked at the (0) reference point.

Thus one part of the evaluation of any prospect involves converting money payoffs to their values via the $v(\cdot)$ function as specified above. The other part of the evaluation requires decision weights to be attached to the various values. These decision weights are not the objective probabilities, nor even degrees of belief of the kind that are conventionally supposed to constitute subjective probabilities. In the context of the 1979 exposition, they represent a psychological transformation, or modification, of the objectively given probabilities, with the weighting function being denoted by $\pi(\cdot)$.

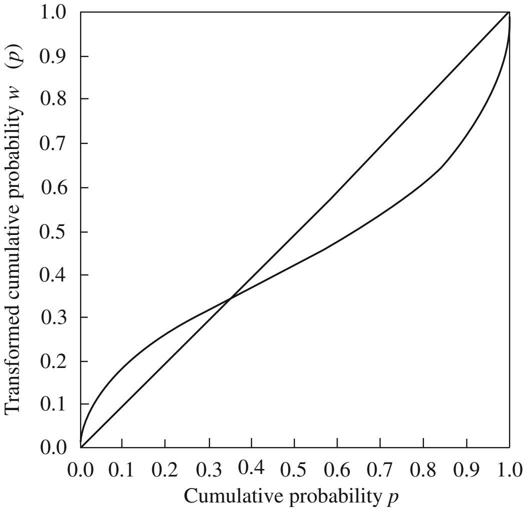
The key assumptions about $\pi(\cdot)$ are as follows. First, the weight attached to a zero probability event is 0, and the weight attached to a certainty is 1: that is, $\pi(0) = 0$ and $\pi(1) = 1$. Second, for low probability events, $\pi(p) > p$; but for higher probability events, $\pi(p) < p$; the 'crossover point', where $\pi(p) = p$, may vary from one individual to another, but is often depicted as being somewhere in the region of $p = 0.15$. Third, it is generally supposed that $\pi(p) + \pi(1 - p) < 1$: this property, labelled *subcertainty*, conveys the idea that complementary intermediate probabilities are jointly disadvantaged relative to certainty.

Taken together, the above assumptions are consistent with a decision weighting function of the kind depicted in Fig. 2. Over most of its range, the fact that $\pi(\cdot)$ is flatter than the 45 line suggests that the evaluation of a prospect is less sensitive to changes in the probability of its non-zero payoff (s) than would be the case under EU where the utilities of payoffs are weighted in exact proportion to their respective probabilities of occurring. It also has the implication that for any given ratio of probabilities, the ratio tends to get closer to 1 as the magnitudes of the probabilities fall: more formally, $\pi(pq)/\pi(p) \leq \pi(pqr)/\pi(pr)$ for all p , q , $r < 1$.

However, such a formulation also has the property that it entails abrupt changes/ jumps in the vicinities of $p = 0$ and $p = 1$. It might be said that the function is not 'well-behaved' – or indeed, not defined – in those regions, where there are 'quantal effects'. And this allows at least one pattern of behaviour that many decision theorists would find normatively undesirable/unacceptable, as follows. Consider a case where prospect C offers the certainty of some gain x, while A offers x with probability p and $x + a$ with probability $1 - p$, where a is some (small) positive amount. Evaluating each prospect separately,

$$\begin{aligned} v(\mathrm{C}) &= v(x)\,\text{and}\,v(\mathrm{A}) \\ &= \pi(p)v(x) + \pi(1-p)v(x+a). \end{aligned}$$

However, because $\pi(p) + \pi(1 - p)$ is liable to sum to less than 1, v(A) may be less than v(C), even though A dominates C. In a direct choice between the two, PT supposes that this dominance (if transparent) will be detected as part of the editing process, so that A will be chosen. But it should be possible to construct some other prospect B which neither dominates nor is dominated by either A or C but whose value lies between the two, so that $v(\mathrm{C}) > v(\mathrm{B}) > v(\mathrm{A})$. Hence in separate pairwise choices, C will be preferred to B and B will be preferred to A, while A will be chosen over C on the basis of transparent dominance, thereby giving a violation of transitivity.



Prospect Theory, Fig. 3 CPT's cumulative probability transformation function

More Recent Developments in Theory and Evidence

Because PT *does* allow such violations of principles that many decision theorists regard as normatively compelling, various modifications have been proposed to 'fix' this supposed defect: in particular, a method of deriving decision weights which ensured that they summed to 1 and disallowed any violations of stochastic dominance or transitivity was proposed by Quiggin (1982) and was subsequently incorporated into a revised and extended form of PT known as cumulative prospect theory (CPT) (see Tversky and Kahneman 1992).

The essence of Quiggin's proposal involved ranking the possible outcomes $x_1 \ldots x_n$ offered by a prospect according to their values and then assigning weights to each of the cumulative probabilities that the prospect pays at least xi, for all $i = 1 \ldots n$. (Hence this kind of model came to be labelled as 'rank-dependent'.) The function used to transform cumulative probabilities – call it $w(\cdot)$ to distinguish it from the $\pi(\cdot)$ discussed above – is fully defined in [0, 1] space, with $w(0) = 0$ and $w(1) = 1$. Like $\pi(\cdot)$, it is usually supposed to have an increasing inverse-S shape (although by contrast with $\pi(\cdot)$, the 'crossover point' in CPT is more often regarded as lying in the 0.3–0.4 region – see Fig. 3.

As a consequence of being steeper in the vicinities of 0 and 1, and less steep across the intermediate range, this form of $w(\cdot)$ gives greater weight to extreme than to intermediate outcomes. Although it may be psychologically implausible that most individuals transform probabilities *strictly* according to the rather cumbersome procedure specified by CPT and other rank-dependent models, the approach captures the general intuition that extreme outcomes may attract more attention and receive relatively more weight in decisions. And it appeals to those theorists who are inclined towards models that respect what are perceived to be 'fundamental' requirements of rationality such as transitivity, while also having the advantage of being applicable to prospects involving probability distributions over any number and range of outcomes.

However, the spirit of PT was to provide a *descriptive* model of risky choice, so that violations of transitivity of the kind outlined earlier were an implication of the model; and, to the extent that they occur in practice, PT can claim to be descriptively successful. And indeed there is evidence of such violations (see Starmer 1999).

On the other hand, as K&T acknowledge, there are limitations to the scope of PT. As discussed above, the domain of the theory was very specific and excluded a number of tasks that are of economic significance (such as the formulation of certainty equivalence values). Moreover, certain assumptions made in the model are open to question. For example, the phenomenon of 'event-splitting' (see Humphrey 1995) suggests that people may only imperfectly add the probabilities of the same payoff under different 'states of the world', contrary to the supposed process of combination in the editing phase. There may also be questions about just how transparent dominance needs to be before it is detected in the editing phase. And some researchers – see, for example, Birnbaum (2006) – have amassed evidence of patterns of choice which appear to run counter to the claims of prospect theories to provide a satisfactory description even of the behaviour which should lie within their domain.

All that having been said, there can be no doubt whatsoever of the success of PT in focusing the attention of decision theorists on patterns of behaviour that do not conform with the conventional (and still predominant) wisdom of EU, and in stimulating a very substantial body of experimental, empirical and theoretical work exploring behaviour outside of the strictures of standard economic 'rationality'.

Protoindustrialization

Sheilagh Ogilvie

Abstract

'Proto-industrialization' is the name given to the massive expansion of export-oriented handicrafts which took place in many parts of Europe between the 16th and the 19th centuries. An influential theory holds that these proto-industries generated the capital, labour, entrepreneurship, agricultural commercialization, and consumer demand needed for factory industrialization. Protoindustrialization, it is argued, also transformed traditional economic mentalities and institutions. However, deeper empirical study has cast doubt on most of these claims. Theories of protoindustrialization have stimulated much excellent research, but do not explain the significant economic growth, demographic change, and institutional transformation that occurred in Europe before the Industrial Revolution.

'Protoindustrialization' is the name given to the massive expansion of export-oriented handicrafts which took place in many parts of Europe between the 16th and the 19th centuries.

Often, although not always, such proto-industries arose in the countryside where they were practised alongside agriculture; usually, they expanded without adopting new techniques or centralizing production into factories. This growth of pre-factory industry in early modern Europe has long been a subject of specialized study. But in the 1970s it began to attract much wider interest, when several influential works christened it 'protoindustrialization' and argued that it was a major cause of industrialization and capitalism.

Protoindustrialization as the First Stage of Industrialization

The term 'protoindustrialization' was invented by Franklin Mendels, who first used it in his 1969 dissertation on the Flemish linen industry (published in 1981) and popularized it in a now famous article based on that research (Mendels 1972). Mendels claimed that protoindustrialization was the first phase of industrialization. In the 18th century, seasonally underemployed European country-dwellers moved massively into cottage crafts, exporting their wares beyond the immediate region. This, Mendels argued, broke down traditional urban institutions such as guilds that had previously limited industrial growth. Mendels contended that it also weakened rural institutions such as inheritance systems, communes, and manorial systems that had traditionally calibrated population growth to economic resources. Mendels claimed that this made nuptiality (and thus fertility) ratchet upwards: proto-industrial upswings saw more marriages, but downswings did not see fewer. High protoindustrial fertility fuelled rapid population growth, Mendels argued, in turn causing further industrial expansion. This self-sustaining proto-industrial spiral, according to Mendels, generated the capital, labour, entrepreneurship, agricultural commercialization, and consumer demand needed for factory industrialization.

Protoindustrialization and Proletarianization

Mendels's arguments were initially widely adopted, giving rise to several schools of protoindustrial theory. One emanated from David Levine, whose study of two villages in 19th-century Leicestershire appeared to confirm that proto-industry led to population growth (Levine 1977). For Levine, proto-industry was important mainly because he believed it broke down rural social structure and land ownership, creating a large group of landless people who had to work for wages. This broader process of 'proletarianization' was, Levine argued, crucial for capitalism and industrialization.

Protoindustrialization and Surplus Labour

A third view of protoindustrialization was put forward by Joel Mokyr (1976), who rejected almost all the arguments advanced by Mendels and Levine but argued that proto-industries provided the cheap 'surplus' labour to fuel a 'dualistic' growth of the European economy as modelled for modern less developed countries (LDCs) by Lewis (1954) and Fei and Ranis (1964). The key empirical problem for the Lewis–Fei–Ranis model was whether 'surplus' labour existed and where it came from. Mokyr argued that in pre-industrial Europe surplus labour came from protoindustry, creating a flat labour supply curve and hence very low wages for early factory industry. This 'dualistic labour surplus' view of protoindustrialization has hardly been pursued empirically, but is important because of its links with development economics and with Jan De Vries's influential theory of European urbanization (De Vries 1984).

Protoindustrialization and the Transition to Capitalism

The protoindustrialization debate was intensified by the publication of a massive book by Kriedte et al. (1977 (German original), 1981 (English translation)). Combining Mendels's and Levine's findings with the voluminous earlier literature on cottage industries, these scholars turned the theory of protoindustrialization into a general model of European economic transformation between the medieval and modern periods.

For them, protoindustrialization was the 'second phase' of this transformation process. The first phase, they claimed, was a loosening of feudalism caused by commutation of feudal burdens from labour or grain dues into money rents, polarizing the rural population into two classes: well-off peasants with enough land to live solely from farming, and land-poor or landless strata who had to seek work outside agriculture. The second phase, in their view, was the 16th-century growth in supra-regional and international trade, creating a growing demand for manufactures which the new rural proletariat could satisfy more cheaply than guild-regulated urban craftsmen. So protoindustries arose in the countryside.

These scholars proposed a stage theory according to which rural protoindustries then gradually transformed industrial organization. The first stage, they claimed, was the *Kaufsystem* (artisanal or workshop system), in which rural producers retained autonomy over production and selling. The second stage, the argument continues, was the *Verlagssystem* (putting-out system), in which merchants bought raw materials, 'put them out' to the rural producers who processed them in return for a wage, and then collected the output for transfer either to the finishing stages of production or to the final consumer market. This ultimately led to a third stage, it was claimed: the concentration and mechanization of production in centralized, mechanized factories.

Extensions to the Theories of Protoindustrialization

By 1977 at the latest, therefore, protoindustrialization had generated a family of different theories, based on differing definitions of protoindustry and differing explanations of economic development. Almost all they had in common was to emphasize the significance of European economic and demographic growth before factory industrialization, and to ascribe such growth to changes in a certain economic sector – export-oriented cottage industry. Over the following decades, these various branches of protoindustrialization theory stimulated a huge outpouring of research into pre-industrial manufacturing, not just in Europe but also in the non-European world, including modern LDCs.

By 1982 protoindustrialization had become such an influential concept that Franklin Mendels and Pierre Deyon were invited to convene one of the three main sessions of the Eighth International Economic History Congress in Budapest, with protoindustrialization as their theme. They pre-circulated a set of hypotheses, 48 researchers contributed papers (Deyon and Mendels 1982), and Mendels summarized the session with a report, a revised definition, and a set of hypotheses for subsequent debate (Mendels 1982).

This new 1982 definition of protoindustrialization stressed five key characteristics. First, protoindustrialization occurred not nationally or internationally, but *regionally*: 'within a small radius around a regional capital'. Second, protoindustries must be distinguished from traditional crafts: they produced not for local or regional consumption, but for sale to *export* markets outside the region. Third, protoindustry was mainly *rural* and *part-time* – only in its final or extreme phase did it involve full-time industrial employment. Fourth, protoindustrialization arose symbiotically with *agricultural commercialization*. Finally, protoindustrialization was 'dynamic': it was defined as a *growth* over time in the industrial employment of rural workers.

Deyon and Mendels also proposed four central hypotheses about the *effects* of protoindustrialization. First, protoindustry led to population growth and land fragmentation because it broke down traditional demographic regulation by communes, landlords and inheritance systems. Second, protoindustrial profits created the capital for factory industrialization. Third, protoindustry trained merchants and workers in the skills needed for factory industrialization. Finally, protoindustrialization caused agriculture to commercialize, thereby feeding urbanization and industrialization. Through these four mechanisms, proto-industry led to factory industry – although the authors admitted that sometimes it led to de-industrialization instead (Mendels 1982).

Criticisms of the Theories of Protoindustrialization

Somewhat more slowly than they attracted support, the theories of protoindustrialization also began to draw criticism.

For one thing, the precise size and structure of the unit that qualified as a protoindustrial *region* was unclear. Protoindustries could and often did extend beyond the radius around a single market town, or alternatively were sometimes found in only one or two communities in such a radius. One pragmatic solution was to define the region as simply the area within which a certain proto-industry was practised. But this seemed to leach the concept of the region of much of its analytical content. Second, there was no agreement about how large a proportion of the regional labour force must have been employed in protoindustry, or how fast or sustained the growth of this labour force must have been, in order to qualify as 'protoindustrialization' (Ogilvie and Cerman 1996).

There was also confusion about the precise importance of *export markets* for protoindustrialization. First, why were export markets uniquely important? Second, what proportion of production had to be exported in order for any given industry to qualify as a proto-industry instead of a craft? Third, how distant did final markets have to be to qualify as 'supra-regional' rather than 'local'? The demarcation between local crafts and export-oriented proto-industries was thus very unclear and its analytical importance remained obscure.

The *neglect of other forms of industry* was another weak point. The theories of protoindustrialization concentrated solely on one sort of pre-industrial manufacturing: cottage industry. But what justified this emphasis? Did manufacturing really develop just because of this single sort of industry, which was often technologically very primitive? What about highly skilled and technologically innovative crafts, export-oriented urban industries, or centralized manufactories? Mainstream historians of pre-industrial manufacturing argued that all these branches of the secondary sector should be included in any analysis of industrialization before the Industrial Revolution (Schremmer 1981; Coleman 1983; Mager 1993). Others argued that large *urban* export industries, and those involving centralized production units, should also be included under the rubric of protoindustrialization (Cerman 1993).

The *neglect of industrial technology and physical geography* was also criticized. Mendels referred in passing to industrial production functions and transportation costs, but neither he nor other proponents of the theory explored these factors further. Critics argued that any coherent view of protoindustry must consider the technical requirements of different branches of industry and the geographical and physical characteristics of the region (Mager 1993). Others urged that protoindustry, like any economic activity, be analysed in terms of 'opportunity costs', and pointed out that this would imply taking into account a whole array of technological, geographical, and institutional variables (Ogilvie 1993; 1997).

The theories adopted strong assumptions about the '*traditional societies*' transformed by proto-industry, and these assumptions began to be questioned (Coleman 1983; Houston and Snell 1984; Schremmer 1981; Ogilvie and Cerman 1996; Ogilvie 1997). Protoindustrialization theorists had uncritically accepted the theories of

Alexander Chayanov, who regarded peasants as unable and unwilling to calculate costs, seek profits, use money, or transact in markets (Chayanov 1966). But was this really true of the early modern European rural population? The subsistence-orientation assumed for rural domestic workers was not confirmed by empirical studies, and was inconsistent with the fact that proto-industrial producers often became traders, middlemen, putters-out and even manufactory-operators. The demographic decisions and productive choices of protoindustrial workers, rather than being governed by 'traditional mentalities', began to look highly rational (Ogilvie 1997).

The *demographic* predictions of the theories were widely falsified as empirical studies proliferated. It emerged that pre-industrial demographic behaviour was influenced by such a wide array of variables that proto-industry could have highly divergent effects on nuptiality, fertility, mortality and migration in different European societies. Case studies showed that not all protoindustrial regions had greater population density, faster demographic growth, lower ages of marriage, higher fertility rates, larger households, or a breakdown in the family and gender division of labour – all of which had been postulated in the original theories. Furthermore, many – even all – of these demographic changes could also be observed in some primarily agricultural regions (Schremmer 1981; Coleman 1983; Houston and Snell 1984; Ogilvie and Cerman 1996; Ogilvie 1997).

The relationship between *commercial agriculture* and protoindustry was also disputed. Protoindustries arose alongside many different kinds of agriculture, including subsistence cultivation, market farming, and even large feudal domains worked by serf labour. Protoindustries derived food and raw materials not just from commercial agriculture but from local cultivation by proto-industrial workers themselves. Simultaneous employment in proto-industry and agriculture was common but not universal in proto-industrial regions. While traditional agrarian institutions and rural social structure broke down in some protoindustrial regions, in others they survived unaltered for centuries (Houston and Snell 1984; Ogilvie and Cerman 1996; Ogilvie 1997).

The role of *social and political institutions* in theories of protoindustrialization has also been critically revised (Ogilvie 1993; Ogilvie and Cerman 1996; Ogilvie 1997; Ogilvie 2004). The original theorists assumed that protoindustrialization both required and furthered the replacement of 'traditional' social institutions with markets. But deeper research has shown that urban privileges, craft guilds, monopolistic merchant companies, village communities and manorial institutions remained important in many European protoindustries, and crucially influenced economic, demographic and social change in proto-industrial regions.

A final major criticism questioned the role of proto-industry in causing *factory industrialization*. Each of the mechanisms by which protoindustrialization is supposed to have led to industrialization has been subject to sceptical re-evaluation. Research shows that the demographic effects of protoindustrialization were extremely various, as was its impact on the fragmentation of landholdings. Protoindustry appears to have been only one of many sources of capital invested in the early factories, and in many cases proto-industrial profits flowed into agriculture, landholding or socio-political investments. Proto-industry was also only one of many sources of entrepreneurial skills for industrialization, and sometimes did not encourage entrepreneurship at all. There is little evidence that it was proto-industry that led to commercial agriculture rather than that agricultural surpluses made possible both proto-industrial regions and urbanization. It is now widely acknowledged by both the theorists and their critics that proto-industry often led not to factories but to de-industrialization and a return to agriculture. The critics argue that this finding denudes the theory of most of its empirical content (Coleman 1983; Houston and Snell 1984; Clarkson 1985; Ogilvie and Cerman 1996). Although, therefore, the theory of protoindustrialization has stimulated much excellent research, it does not explain the significant economic growth, demographic change, and socio-institutional transformation that indisputably occurred in Europe well before the industrial revolution.

Proudhon, Pierre Joseph (1809–1865)

H. Bartoli

Proudhon was born in Besançon, France, into a very humble family. Despite a scholarship, poverty forced him to interrupt his exceptionally brilliant studies. He became, in turn, a printer, print shop foreman, scholarship student at the Besançon Academy, owner of a small print shop, and managing clerk in a river transport company in Lyons. He then became a writer and journalist, following this profession through incessant material difficulties, political trials, election to parliament, prison and exile. On his death he left a vast body of work, in which he tackled at the same time problems of philosophy, ethics, sociology and economics. He can equally well be seen as one of the founders of sociology, the father of anarchism, one of the inspirational forces behind cooperativism and mutualism, one of the sources of syndicalist thinking, 'the boldest thinker of French socialism' (Marx), a pioneer of federalism and regionalism, or one of the apostles of mass education.

From his study of history and observation of the world, Proudhon derived a 'serial dialectic'. Everything in the world is 'serial' – i.e. is differentiated, divided, graduated and graded, but also coordinated, articulated, grouped; everything is multiple, everything is synthesis. The 'series' is a 'whole composed of elements arranged according to a certain reason or law'. 'Serial dialectic' is a 'law' of progression and organization, a general process of growth common to matter and spirit, to man and society. An antinomic dialectic, it unfolds as a chain of antinomic pairs whose opposition is the source of all movement and cannot be resolved into synthesis. Such a dialectic of tension, or of the 'balancing of opposites', is thus fundamentally opposed to the Marxian dialectic of synthesis.

To struggle to be, to unite to be, are the two poles of the vital dialectic of every person and every society. Work is the condition for survival, the constituent 'organic law', the) 'generative fact', the 'shaping force' of society. Antagonism and solidarity are no more than 'functional laws'.

All labour implies at the same time differentiation and association. In working society one does not find 'workers' but a single worker diversified to infinity. The 'fundamental' law of labour is the law of division. There is a further law connected with this – that of 'collective force' as expressed in the) 'collective surplus' generated by association, the collective product being the result not of the addition of individual efforts, but of their multiplication when they are brought together in association.

Labour, for Proudhon, is the 'field of observation' of political economy, which studies the division of labour and its series (organization, collective force), the distribution of the instruments of labour (right and mutuality), and the efficiency of labour and its results (value and economic accounting). To organize labour is to demarcate functions, and then to group them according to the laws of labour. The division of labour is the law of function; every individual worker is therefore necessarily an integral member of the enterprise, fulfilling an economic function. Starting from these individual functions, through a kind of integration, one can organize the entire society.

Labour is the real measure of exchange value, the only standard by which different products can be compared. The substance common to wages, investments, capital and profits is that they are either objectified labour or accumulated labour. Supply and demand are simply '*éléments traducteurs*', (translating factors) constantly disrupted by monopolies, fraud, speculation etc., and do not allow use value (utility) and exchange value (labour costs) to be objectively compared. For the 'law of proportionality of values' to be respected, a) 'constituted value', a synthesis of use value and exchange value, must be created; 'society's accounts' must also be drawn up, labour scientifically managed and the structure 'socialized'.

Proudhon regarded accounting as 'the whole of political economy'. An astonishing forerunner of many later theories, he drew a distinction between individual accounts and accounts relating to 'each type of value' ('chaque nature de valeurs') and combined them in a 'single account', a veritable set of national economic and social accounts. He hoped to establish a form of accounting by sector and by industry, prelude to a 'centralization of accounts', since 'all industries are bound together in one cluster by their mutual relations . . . all products act as ends and as means of each other'. He glimpsed the problem of variation in the 'proportion' of labour, and hence in input–output coefficients, and he connected this to technical progress. He believed that a kind of) 'higher mathematics' could help in developing 'social economics', but warned against any ill-considered use of mathematics in economics.

All the ills of mankind spring from 'mere accounting error'. The 'social balance' is inexact. The gratuitous appropriation of collective effort, the inequality of exchange, the law of escheat, all distort the economic accounts. Property is at the same time) 'right of exclusion and theft' and 'despotic power'. Competition, although a necessary stimulant, kills competition; it generates monopoly, which is necessary in that it consolidates the achievements of labour, but which corrupts economic life since it improperly appropriates to itself the profits of) 'collective force' and creates poverty.

Proudhon's historical labourism bears no relation to Marx's historical materialism. For Proudhon, social and economic facts are only the 'manifestations' and 'signs' of ideas. Economics is metaphysics in action, the implementation of the) 'eternal laws of reason'. Proudhon declared himself against capitalism, the exploitation of man by man; against statism, the government of man by man; against communism, 'the degradation of the personality in the name of society', and against Christianity, 'a system of personal degradation in the name of right'. All his works are a prodigious effort to lay bare the foundations, the elements and the method for a self-managed society free of all alienation. He foresaw and proposed the building of a 'scientific socialism'.

What makes society possible, for Proudhon, is the) 'opposition of powers', 'mutual counterbalance'. Society must be organized solely on the basis of contract. In industry, wage labour will be replaced by common, joint ownership by all those who play a part in production, while in agriculture individually owned farms will be integrated into communes or agricultural groups, and cooperatives will prevail in trade and commerce. Through the federation of 'business properties' (*propriétés d'entreprises*) and rural communes and the establishment of consumers' associations and a production/consumption union, a federative republic can be created, the government of which would be formed by successive delegations from 'natural', autonomous, self-managed groups. Within this industrial republic the equity of social relations will be assured by free credit and 'exchange vouchers' issued by an exchange bank and secured against products.

Proudhon had faith only in the 'proletarians' to bring into being this new social structure, but unlike Marx he saw the emancipation of the proletariat merely as a particular fact of world history 'which is in the process of taking place'.

Pseudo-distribution

Peter Groenewegen

A term devised by Edwin Cannan (1893) to distinguish the analysis of 'wages per head, profits per cent and rent per acre' (pseudo-distribution) from what he called) 'distribution proper' or analysis of 'division of the whole produce between aggregate wages, aggregate profits and aggregate rents' (Cannan 1893, p. 267). Cannan's argument in support of this distinction had both historical and analytical aspects while he also argued (1905) that it conformed to the meaning of 'division' ordinarily assigned to the word) 'distribution', in which 'a change in distribution', for instance, is taken to mean 'a change in the proportions in which the total is divided'.

His analytical reason for the distinction was as follows. 'In the equation, produce = wages + profits + rents,. . . the question should be to determine what settles the relative magnitude of the three terms on the other side of the equation' (Cannan 1893, p. 180). This problem only makes sense when aggregate wages, rents and profits are considered, and these are clearly not identical with changes in wages, profit and rent as rates of renumeration. When analysis concentrates exclusively on relative factor prices or 'pseudo-distribution', some analytical insights may be lost. In his last book, Cannan (1929, pp. 301–2) explained why in 1905 he had defended the role of) 'distribution proper' in economic analysis to combat what by then had become the traditional theory of distribution. Integrating the determination of wage, profit and rent rates with the supply and demand theory of value was insufficient to answer the distributional questions in which people and policy makers were interested, since by itself this could not explain variations in income shares over time.

Cannan implied that his distinction was particularly appropriate for historical investigation, presumably the reason why it surfaced in his history of production and distribution theories. However, although Quesnay's use of the term in the *Tableau économique* suggests shares as the essential feature of the distribution problem, Turgot's use of the term and that by Smith concentrates on rate of renumeration aspects. Even Ricardo (1817, p. 5), who defined distribution – 'the principal problem in Political Economy' – in terms of dividing total produce among landlords, labourers and capitalists, analytically emphasized the importance of determining the rate of profit as against the profit share. However, irrespective of the importance of treating distribution by means of analysing relative income shares accruing to social classes, by the end of the century major concern with such issues had disappeared and distribution was analysed exclusively in terms of rates of reward.

Few economists appear to have followed Cannan's terminology. Dalton (1920, pp. 136–9) approvingly referred to it; Robbins (1932, pp. 64–5) explicitly rejected it. By the end of the 1930s, Stigler (1941, p. 3) could refer to a classical 'failure to develop a theory of the prices of productive services' as confirmation of the fact that 'in 1870 there was no theory of distribution'. Only some catholic approaches to distribution theory since then (Bronfenbrenner 1971; Pen 1971) have recognized Cannan's complaint about confining distribution analysis to factor pricing. In Bronfenbrenner's case (1971, p. 121) this is combined with the apology that his treatment of the topic maintains stress on 'pseudo-distribution as modified aggregately since Cannan's day' by the type of distribution theory pioneered by Keynes and Kalecki, though it may also be noted that from the 1920s distributional consequences in terms of relative shares were being drawn from Cobb–Douglas production functions.

Psychological Games

Martin Dufwenberg

Abstract

Traditional game-theoretic models assume that utilities depend only on actions. This is not sufficient for describing the motivations and choices of decision makers who care about reciprocity, emotions, or social rewards. Psychological games allow utilities to depend directly on beliefs (about beliefs) in addition to which actions are chosen, and they can capture a wider range of motivations. This article contains several examples and it is indicated where research on psychological games is headed.

Traditional game-theoretic models presume that utilities depend on actions. While this framework is quite general (it can, for example, accommodate profit- maximization, altruism, inequity aversion and Rawlsian maximin preferences) it is not rich enough to adequately describe several psychological or social aspects of motivation which depend directly on beliefs (about beliefs) in addition to which actions are chosen. The following example illustrates.

Karen feels guilty if she lets others down. When paying her landscaper (Jim), this influences her tipping. The more she believes Jim believes he will receive as a tip, the more she gives. More precisely, she gives just as much as she believes Jim believes he will get, in order to avoid the feelings of guilt that will plague her if she gives less.

Beyond depicting something arguably realistic, the example illustrates in the simplest possible way how one may have to transcend traditional game theory to model a belief-dependent motivation. Consider a standard game form where Karen chooses a tip t such that $0 \leq t \leq w$, where w is the number of dollars in her wallet, and where the landscaper has no choice (his strategy set is modelled as a singleton $\{x\}$). Karen's choice of tip thus pins down a strategy profile (t,x). In traditional game theory, payoffs are defined on strategy profiles (or on endnodes induced by strategy profiles), so Karen's best choice (or choices) would be independent of her belief about Jim's belief about her choice of tip. This runs counter to the example.

Gilboa and Schmeidler (1988) and Geanakoplos, Pearce and Stacchetti (Geanakoplos et al. 1989) present several examples that illustrate the inadequacy of traditional methods of representing preferences that reflect various forms of belief-dependent motivation. Geanakoplos, Pearce and Stacchetti develop a new analytical framework, in which the centrepiece is the notion of a *psychological game,* which may be seen as a generalization of a traditional game and which can model some of the desired effects. A psychological game differs from a traditional game in that utilities are defined on beliefs (about actions and beliefs), as well as on which actions are chosen. (The term 'game with belief-dependent motivation' would be more descriptive than the term 'psychological game', but I stick with the latter, which has become established.)

Reciprocity

The best-known example of a psychological games-based application is Rabin's (1993) highly influential model of reciprocity, according to which players wish to act kindly (unkindly) in response to kind (unkind) actions. The key notion of kindness depends on beliefs in such a way that reciprocal motivation can be described only by using psychological games. To see why, suppose that I jump out in front of your car, blocking your way, so that you can't cross a bridge and therefore arrive late to an important meeting. Am I kind? Clearly one cannot say without knowing what my beliefs are. If I believe the bridge is as sturdy as bridges usually are and I am just goofing around, then I am unkind. However, if I believe the bridge is about to collapse, then I am kind. Arguably, I would be kind even if I mistook a sturdy bridge for a dangerous one. So should you be kind or unkind in return? The answer depends on your beliefs about my kindness, and hence on your beliefs about my beliefs. It takes a psychological game to model that. (The example given here is similar in spirit to another example given in Rabin 1998, p. 23. Rabin's model is normal-form based. See Dufwenberg and Kirchsteiger 2004, for an extension to extensive game forms. See Fehr and Gächter 2000, and Sobel 2005, for general discussions of why reciprocity has important economic consequences.)

Emotions

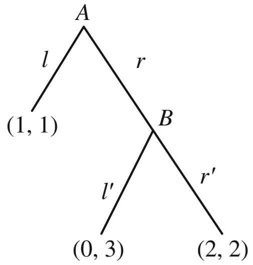
Reciprocity is but one form of motivation that can be modelled by means of psychological games. Many emotions are good candidates. In his article 'Emotions and Economic Theory', Elster (1998) argues that a variety of emotions have important economic consequences, and he laments how little attention economists have paid to this. He argues that a key characteristic of emotions is that 'they are triggered by beliefs' (Elster 1998, p. 49). He discusses anger, hatred, guilt, shame, pride, admiration, regret, rejoicing, disappointment, elation, fear, hope, joy, grief, envy, malice, indignation, jealousy, surprise, boredom, sexual desire, enjoyment, worry, and frustration. He asks (Elster 1998, p. 48): '[H]ow can emotions help us explain behavior for which good explanations seem to be lacking?' Psychological games may be useful for providing answers.

But little work has been done. One exception is Caplin and Leahy's (2004) health care model in which a physician is concerned with a patient's belief- dependent anxiety (compare also Caplin and Leahy 2001). Another exception is the emotion of guilt for which a string of results, both theoretical and experimental, have been established for the specific context of trust games (see Huang and Wu (1994), Dufwenberg (1995, 2002), Dufwenberg and Gneezy (2000), Bacharach, Guerra and Zizzo (Bacharach et al. 2007), and Charness and Dufwenberg (2006). I shall elaborate in some detail on these latter findings (borrowing eclectically from the cited works), since they may be suggestive of the importance of psychological games more generally in a variety of ways.

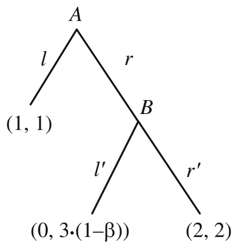
Consider the game in Fig. 1, where payoffs reflect money income (first for player *A*, then for player *B*) but not the players' preferences which may depend also on guilt as will be indicated.

Assume that the more strongly player *B* believes that player *A* believes that *B* will make choice r', the more guilt *B* would feel making choice l' and the more likely *B* is to make choice r'. Specifically, the players' utilities at the various end nodes in the game form of Fig. 1 coincide with the monetary payoffs, *except* following the choice sequence (r, l') where *B*'s utility is $3 \times (1 - \beta)$ rather than 3, and where β is a measure of B's belief (with range from 0 to 1) about A's belief that *B* will choose r'. (More specifically, *B* has a probability measure describing her beliefs about which probability *A* assigns to the choice r' conditional on *A* choosing r; β is the mean of that measure.) Say that *B* is *guilt averse.* This is all modelled in the psychological game in Fig. 2:

Psychological Games, Fig. 1



Psychological Games, Fig. 2



I wish to make several points. First, the guilt aversion modelled in Fig. 2 is similar to that involved in the above example featuring Karen and Jim. In fact, the idea that people feel guilty in proportion to the degree to which they do not live up to another's expectations can be extended to any game. (See Battigalli and Dufwenberg 2007, for a recent attempt at doing this.)

Second, one can test for guilt aversion experimentally, but this requires one to measure B's belief β. This can be done by inviting subjects to make guesses about one another's choices and guesses, rewarding accuracy in the guesswork. Such experimental tests have indicated that the prediction of guilt aversion is empirically supported in trust games. (The involved form of belief elicitation could conceivably be usefully complemented by two other forms of measurement: emotional selfreports and neurological methods such as functional magnetic resonance imaging.)

Third, guilt aversion may provide the seeds of a theory why communication can help foster trust and cooperation. To illustrate with reference to Fig. 2, suppose that, before play, *A* and *B* meet and talk. Player *B* looks player *A* in the eye and *promises* to choose *r*′. If *A* believes this, and if *B* believes that *A* believes this, then guilt aversion would make *B* live up to her promise. A promise by *B* can thus feed a self-fulfilling circle of beliefs about beliefs that *r*′ will be chosen. In combination with guilt aversion, words may be tools that create commitment power, which may in turn foster trust and cooperation.

Fourth, even without communication between *A* and *B*, one may argue that if *B* is guilt averse (as described above) then trust and cooperation will ensue. If *A* is rational and maximizes his expected monetary income (recall that we have assumed that *A* is selfish in this way) then by choosing *r* he *signals* a certain strength of belief in *B* choosing *r*′; if *A* did not assign a probability of at least 1/2 to *B* choosing *r*′ then he would rather chose *l*. If *B* figures this out, it puts a lower bound of 1/2 on β. So *B* is forced to hold a belief such that she would feel so guilty if she choose *l*′ that she prefers *r*′; in numbers, with $\beta \geq 1/2$ we get $3 \times (1 - \beta) < 2$. If *A* figures this out, he should of course choose *r*. The illustrated phenomenon has been labelled *psychological forward induction.*

To sum up: the idea of guilt aversion is intuitively plausible, experimentally testable, empirically supported, relevant for explaining why communication matters to economic behaviour, and suggestive of intriguing signalling issues that may shape emotions and behaviour. These insights concern a very special emotion and a very special psychological game, but seem profound given that limited scope. One may reasonably suspect that exciting conclusions are in store also for other emotions and other strategic settings, and that these conclusions may in part concern communication or belief signalling.

Social Rewards

The discussion so far may have been misleading with its rather heavy emphasis on reciprocity and emotions. Psychological game theory may be relevant also for describing certain social rewards (norms, respect and status), where decision makers somehow care about the opinions or views of others. Bernheim (1994) and Dufwenberg and Lundholm (2001) present models that bear this out. These authors do not make explicit mention of psychological games, but if one takes a close look at the mathematical details one can discover connections.

Developing the Theory

One might hope that Geanakoplos, Pearce and Stacchetti's framework is appropriate for tackling all the interesting problems to which psychological games may be relevant. However, this is not the case. A careful scrutiny reveals that their approach is too restrictive to handle many plausible forms of belief-dependent motivation (as they acknowledge themselves; see Geanakoplos et al. 1989, pp. 70, 78). There are several reasons, including the following:

(1) Geanakoplos, Pearce and Stacchetti only allow initial beliefs to enter the domain of a player's utility, while many forms of belief-dependent motivation require *updated* beliefs to play a role.
(2) Geanakoplos, Pearce and Stacchetti only allow a player's own beliefs to enter the domain of his utility, while there are conceptual and technical reasons to let *others'* beliefs matter.
(3) Geanakoplos, Pearce and Stacchetti follow the traditional extensive-games approach of letting strategies influence utilities only in so far as they influence which end node is reached, but many forms of belief-dependent motivation become compelling in conjunction with preferences that depend on strategies in ways not captured by end nodes.
(4) Geanakoplos, Pearce and Stacchetti restrict attention to equilibrium analysis, but in many strategic situations there is little compelling reason to expect players to coordinate on an equilibrium, and one may wish to explore alternative assumptions.

(1) is manifest, for example, in the above psychological forward induction argument which hinges crucially on B's motivation depending on an updated belief. (2) is relevant, for example, for modelling social rewards (compare the above comments on Bernheim's and Dufwenberg and Lundholm's models). As regards (3), one can show that the issue comes up if one wants to model, for example, regret, disappointment or guilt. (4) echoes considerations relevant also for traditional games; equilibrium play is not a self-evident proposition in many contexts, for example if one assumes (only) that there is common belief in rationality or in learning scenarios.

The list (1)–(4) is adapted from Battigalli and Dufwenberg (2005), who elaborate in more detail on each issue and take first steps towards developing psychological game theory in the indicated directions. Their approach draws crucially on Battigalli and Siniscalchi's (1999) work on how to represent hierarchies of conditional beliefs.

Decision-Theoretic Foundations

The decision-theoretic foundations of psychological game theory are not well understood. Classical decision theory (say, von Neumann and Morgenstern) does not apply straightforwardly. Too see this, take the emotion of disappointment as an example. It is plausible that disappointment is a belief-dependent emotion. To exemplify, I have I just failed to win a million dollars and I am not at all disappointed, which, however, I clearly would be if I were playing poker and knew I would win a million dollars unless my opponent got extremely lucky drawing to an inside straight, and then he hit his card. Another example could be based on the lotteries used in the so-called Allais paradox. In both cases the level of disappointment, which if anticipated might affect choice behaviour, may plausibly depend on the strength of the prior belief that a decision maker will win a lot of money. It follows that, unless consequences are described so as to include a specification of disappointment, the so-called 'independence axiom' will not make much sense for decision makers who are prone to disappointment.

Decision theorists have given related matters some attention, but not a lot. Machina (1981, pp. 172–3; 1989, p. 1662) presents examples in spirit related to the one million dollar example above. Bell (1985), Loomes and Sugden (1986), Karni (1992), and Karni and Schlee (1995) go on to develop models in which utility may depend directly on beliefs; the latter two references take axiomatic approaches. Robin Pope has written extensively, over many years, about how conventional decision theory excludes various forms of belief-dependent motivation; Pope (2004) expounds her programme and gives further references. Caplin and Leahy (2001) develop a model of 'psychological expected utility' that admits belief-dependent motivation. However, these contributions mainly develop perspectives for settings with single decision-makers, and more will be needed to address games more generally.

Conclusion

Research on psychological games is still in its infancy. This is true for all facets of investigation: the development of basic classes of games and solution concepts, the investigation of decision-theoretic underpinning, tests of empirical (most likely experimental) validity, and finally applied theoretical work which uses psychological game theory to analyse various economic models. In each of these domains some work has been done which is indicative of the viability of the line of research, and there is good reason to be thrilled about the prospects for future research.

Psychology and Economics

Charles R. Plott

Several developments have joined to stimulate economists to think about issues that have been on the forefront of psychological research. First, the information revolution in economics has focused economists on the subtle nature of individual information processing. Secondly, developments in game theory have so successfully identified new solution concepts that for almost any pattern of market behaviour there exists a reasonable theory consistent with that pattern. Introspection, a few principles of decision making, internal consistency, and a few stylized facts do not constrain possibilities enough to be sufficient guides to theory. Theorists are being forced to seek more systematic sources of data and additional principles to reduce the number of competing theories. Third, the rapid development of experimental methods applicable to economics has brought the testing of psychologically based economic theories within the realm of reality. Economists can accurately measure behaviour in economically relevant settings. As behavioural patterns become established that are difficult to reconcile with economic models alone, the profession has begun to look to psychology for answers. The data thus force the attention of economists to a broader class of models.

The interest of economists has also been stimulated directly by the work of psychologists whose own curiosity has brought their research closer to subjects that have been in the traditional domain of economics. Psychologists are deeply involved with risk/benefit analysis and normative decision analysis. Consequently, contact with traditional welfare economics and decision theory cannot be avoided. Psychologists have been actively studying commons dilemma problems. The literature has led them to an awareness of public goods, externalities, and notions of incentive compatibility. The trend is reversed in the study of non-human choices where economists interested in testing demand theory as applied to non-humans are being exposed to concepts of conditioning, shaping, reinforcement theory, etc., characteristic of the tools traditionally found useful to those who study animal behaviour in the laboratory.

A few exchanges between psychologists and economists have occurred recently. The focus of this section is on those exchanges. These are recent cases in which economists have become directly involved and have explored hypotheses that are of psychological origin. There is good reason to limit the material in this way. Almost any behaviour can have economic implications, and psychologists have not been particularly shy about making claims for the relevance of their research for economics. The whole field of psychology could be implicated. Consequently the focus will be on the work of economists that has been influenced by psychology as opposed to the work of psychologists that might have some economic import.

The Optimization Hypothesis

Economists tend to focus on choice and have had little to say about the process of choosing. The focus is natural. For the most part economics is about group phenomena and the behaviour of systems such as markets, whole economies, and political or other social units. The actions taken by each individual are the key contributions to the system behaviour and thus the individual actions are the important data. From this traditional perspective the particular cognitions that might have led to an act are of secondary importance to the action itself. The maintained hypothesis of goal seeking and purposeful actions as summarized by the optimization hypothesis provides a coherence and internal consistency to individual actions, but there has been no pressure to inquire deeper into the substance of the choosing process. The existence of attitudes is clearly acknowledged in the theory by the concepts of subjective probabilities and preferences, but the principles governing these attitudes have been maintained only at the most general level.

Choice is connected to the attitudinal parameters by a principle of optimization. The theory of rational choice claims only that observed choices will have that internal consistency necessary to be rationalized by a theory of optimization. Preferences will be revealed by choice.

There are many different types of rational choice. The choice can be influenced by random elements (McFadden 1974). The subjective probabilities and preferences can be related in ways not anticipated by the excessively strong expected utility hypothesis (Machina 1982; Chew 1983; Loomes and Sugden 1986). The preferences may not be transitive and instead only be devoid of cycles (Richter 1971). Only very recently has the literature seen generalizations of the concept of an optimum choice that does not require elements of maximization based on binary comparisons (Aizerman 1985). These principles are all of a most general nature and do not really address the issues of decision process because economic theory has evolved narrowly as demanded by the study of system behaviour.

By contrast, recent psychological research has been focused on the process of decisions as opposed to the choice or output of the process. The analysis reflects data generated by experimental methodology and is not constrained by systemic considerations. Perception, confusion, and the dynamics of preference and attitude formation are of central importance to psychologists.

Since the focus of psychological research is on decision processes, a natural tendency when confronted by the optimization hypothesis is to ask if people actually think in optimization terms. Do people consciously attempt to maximize something? The mathematics of optimization gives a rather clear outline of what a conscious process might be. Each option of a feasible set is compared in a series of binary comparisons of preference. The best is thereby identified and chosen. Do people do this? Do they *want* to do it?

Psychologists find little support for an optimization process as derived from the mathematical definitions. The lack of support for such a process is especially the case when uncertainty and information processing is involved. The natural response of the economics community when confronted by data that suggest that individuals do not consciously solve mathematical optimization problems has been to ask first, ‘so what?’. If the choices made by individuals naturally exhibit the internal consistency property of revealed preference then the cognitive processes are of minor consequence because the individuals would choose ‘as if’ optimizing and the substance of the theory of markets would be left intact. A second natural response of economists is to ask the psychologists if they have a theory that will ‘do better’ in explaining system behaviour. In the absence of an alternative theory, criticism of existing theory is not very compelling.

Psychologists have convincingly demonstrated that the ‘as if optimizing’ principle is not generally reliable. The easiest demonstration of the lack of generality of the principle involves the preference reversal phenomenon. The subject is given a choice between two lotteries. Lottery A is a .99 probability of winning \$4 and a .01 probability of winning nothing. Lottery B is a .33 probability of winning \$16 and a .67 probability of winning nothing. When asked to choose between the two, lottery A is the typical choice. When asked which lottery is valued the most, e.g., which of the lotteries has the highest reservation price or which has the highest selling price, then B is indicated. In other words the observed preference switches from A to B depending upon the way preference is measured. The phenomenon characterizes the behaviour of many people. It persists with monetary incentives and control for a variety of economic considerations (Grether and Plott 1979), training (Reilly 1982), and has been observed by a number of different researchers employing different techniques (Slovic and Lichtenstein 1983). The existence of the phenomenon is well documented.

The phenomenon is of interest to economists because it can be interpreted as an immediate intransitivity. Let $W =$ existing wealth, $\phi =$ the empty set, $\succsim$ indicate a preference relation, and $h(x)$ = the reservation price of lottery x. The pair (W, x) describes the possible states of an individual. The chain $(W + h(A), \phi) \sim (W,A) \succ (W,B) \sim (W + h(B), \phi)$ is observed from choice. Which do you prefer, A or B? Typically the subject chooses A as indicated. The minimum selling price when measured yields $h(A)$. Transitivity and the positive utility of money imply $h(A) > h(B)$, which contradicts the typical subject's expression of value; that B is valued more (has a higher reservation price) than A. The phenomenon is not only inconsistent with the expected utility hypothesis, it is inconsistent with all economic theories of preference. It demonstrates that choice is not universally consistent with an 'as if' optimization principle. Furthermore, since a single individual choosing among lotteries is a (degenerate) class of markets, the phenomenon bears directly on market choices.

Is there an alternative theory? The jury is still out on alternative explanations of preference reversals (Goldstein and Einhorn 1986; Loomes and Sugden 1982). However, the general approach to theories of decision processes taken by psychologists has been to retain the basic structure of optimization theory. People have transitive preferences but they might not be completely aware of them. Rather than ask what does a person want, the tendency of psychologists is to ask how a person *expects* to feel as a result of taking an act (March 1978). Perception, limited capacities for calculation, and perhaps the dependence of preferences on previous choices are integral aspects of the modified theory.

Choice is preceded by an editing phase of activities. Alternatives are first examined for attributes, which are coded as a gain or loss relative to some reference point. The reference point could be a status quo or it could be a level of aspiration. This editing phase is sometimes referenced as 'framing' (Tversky and Kahneman 1981).

The evaluation phase follows editing. Almost all psychological theories of the process of choice postulate that the individual compares options attribute by attribute. This is in contrast to a holistic assessment in which the individual evaluates all attributes of a single option and, having assessed the option, the process moves to another option which is wholly assessed. Studies that involve the tracing of eye movements during the process of choice support the psychologists' presumptions (Russo and Dosher 1983). Eye movement tends to fix on an attribute and move across options, remaining fixed on that attribute. After surveying objects, a new attribute is chosen. This process should be contrasted to one in which all attributes of an object are examined as if to gain a total assessment or utility of the object before moving to the next object.

Slovic and Lichtenstein (1983) think of evaluation in terms of anchoring and adjustment. This process begins with the identification and evaluation of a single attribute. The value of that attribute is attached to the option and then the valuation is adjusted upward or downward to compensate for other attributes. Inconsistencies such as those observed in preference reversals are the result of incomplete adjustments according to this model. Risk averse people tend to choose option A when the choices are offered. Then, when such people are asked to place a value on the options, they focus first on the monetary amount, attach that initial value to the object, and then adjust the amount downward to compensate for the probability. Incomplete adjustment for the probability and other attributes yields a higher value for B than for A, which began with a lower initial valuation because of the lower dollar figure from which base adjustments are made.

The result is the observed inconsistency with choice. Other evaluation models exist. Lexicographic rules involve an ordering of attributes. The chosen alternative has the highest level of the best attribute. Prospect theory (Tversky and Kahneman 1981) involves valuing attributes but the theory incorporates an asymmetry between losses and gains. When the options are lotteries, prospect theory holds that people are risk avoiders in gains and risk seekers in losses. Of course, since lexicographic rules and prospect theory are optimization theories, neither can account for the preference reversal phenomena.

Another class of models are suggestive of what Simon (1955, 1979) has called satisficing. The choosing agent is viewed as being involved in a costly search problem as objects are examined and attributes are compared. The theoretical problem becomes one of isolating the rules governing search and decision. Two important classes of such rules are conjunctive and disjunctive (Einhorn 1970). Conjunctive and disjunctive rules require cutoff levels be set on each attribute. A conjunctive rule requires that any option with an attribute below cutoff is rejected. Disjunction requires that options with attributes above cutoff be accepted.

Economists have pursued some aspects of this theory (Grether and Wilde 1984). Optimal risk-neutral conjunction decision rules were calculated by the researchers for an experimental economics setting involving sequential (search) decisions.In addition, a set of nonoptimal rules were calculated. The non-optimal rules were approximations of the optimal rules in which the cross derivative terms in the first-order conditions of an optimal sequential decision were ignored. Subjects were restricted to the use of conjunctive rules so the test was whether or not consumers used optimal rules or the postulated non-optimal rules given that a particular type of decision rule had to be used. Subjects tended to use the nonoptimal rules in which 'second-order' tradeoffs are ignored.

The Grether and Wilde study has two major dimensions of interest. First, their theoretical methods incorporate a way to identify 'rules of thumb' that have a systematic and theoretical departure from optimal. They have a way of using optimal rules to generate simplifications of the rule that can be interpreted as satisficing. Secondly, the experimental methods provide a way of testing such modified theories and getting good measurements on the nature of their inadequacies.

Bayes' Law

Economic models tend to treat individuals as if they were intuitive statisticians. Of course Bayes law is a central tenet. It is used in the theory without modification any time an economic agent is exposed to information.

By contrast, the psychological approach to subjective probability is similar to the psychological approach to decisions in general. People are viewed as using rules of thumb which may or may not reflect an appropriate statistical principle.

One of these rules called the representativeness heuristic has caught the attention of economists. According to this rule individuals will view samples as having come from the population that is most representative of the sample. The rule suggests a tendency to ignore prior probabilities or, in a sense, put too much weight on the sample while generating a posterior. The phenomenon has been studied extensively in the psychology literature. The following is an example of what is observed. Suppose urn A contains black balls and white balls with $Pr(black) = .75$ and $Pr(white) = .25$. Urn B has the opposite probabilities. A sample of four balls with replacement will be drawn from one of these urns. The subject must guess the urn that was used and is rewarded cash for correct choices. The urn to be used in the draw is decided from a draw from a third urn with $Pr(A) = .01$ and $Pr(B) = .99$.

Now suppose a sample of four balls is drawn. Three of the four are black. Which urn was used?

Bayes law gives $Pr\ (A) \approx 0.02$ Nevertheless, the representativeness hypothesis predicts that A will be chosen. The reason is the similarity between the sample and the distribution of balls in A. The prior probabilities will be underweighted according to this theory.

An experiment conducted by Grether (1980) was of the form used in the example. Rewards provide a financial incentive to choose the urn that the subject thinks is the most likely. That is, subjects are paid for guessing the correct urn. For a given sample, x, urn A is chosen when $Pr\ (A\,|\,x)/Pr\ (B\,|\,x) > 1$ and B is chosen otherwise.

The use of Bayes law gives the model

$$\frac{Pr(A|x)}{Pr(B|x)} = \left[\frac{Pr(x|A)}{Pr(x|B)}\right]^{\beta_1}\left[\frac{Pr(A)}{Pr(B)}\right]^{\beta_2}$$

where $\beta_1 = \beta_2 = 1$ and $Pr(A)$ and $Pr(B)$ are prior probabilities. Letting Y^*_{it} be the subjective log odds in favor of A for person i at time t so $e^{Y^*_{it}}$ is the posterior odds in favor of A. By taking the logarithm of

$$e^{Y^*_{it}} = e^{\alpha}\left[\frac{Pr(x|A)}{Pr(x|B)}\right]^{\beta_1}\left[\frac{Pr(A)}{Pr(B)}\right]^{\beta_2} et^{u_{it}},$$

where u_i is a random variable, a model suitable for estimation by logit is obtained. Of course Y^*_{it} is not observed but the observed choice provides a variable $Y_{it} =$ when $Y^*_{it} \geq 0$ and $Y_{it} = 0$ otherwise. Bayes law yields the hypothesis $\alpha = 0$, $\beta_1 = \beta_2 > 0$ and the representatives hypothesis, $\beta_1 > \beta_2 \geq 0$.

The qualitative predictions of the representativeness hypothesis have been supported by the experimental data. However, the coefficient β_2 tends to be strictly greater than zero so the prior probabilities are not ignored. Generally speaking the Bayes law model has very good predictive ability. Bayes law is not ‘bad’ as a model but its predictive power is increased by allowing for the possibility of a representativeness heuristic.

Conclusion

When examining psychologically motivated theories, economists have differed from psychologists in three methodological ways. First, economists have tended to use as the dependent variables an act or an observed choice. By contrast, psychologists have tended to elicit attitudes, such as a degree of preference, belief, or numerical probability. Secondly, economists have been more sensitive to the possibility that motivated choice might differ from unmotivated choice. The third difference is the context. Economists have tended to avoid the rich descriptive hypothetical contexts and scenarios used by psychologists. This no doubt reflects a fear that the verbal descriptions will influence behaviour.

For the most part, when testing directly, economists have observed for themselves what psychologists claimed they would observe. Incentives do matter but so far incentives have not been observed overriding the tendencies that psychologists have observed when incentives were absent. It is too early to speculate about what future research will uncover regarding this issue.

Whether or not the psychologically based theories will account for significant market behaviour remains to be established. The potential for such theories has been recognized (Thaler 1980) but so far the psychological theories, when applied to experimental markets, have not been sufficiently supported to suggest the need for a substantial overhaul in economic theory (Plott 1986). Nevertheless, the field has only just begun and, given the persistence and magnitude of effects uncovered at the individual level of analysis, it is reasonable to expect that the effects will soon be detected in experimental markets.

Psychology of Social Networks

Philippa Pattison, Garry Robins and
Yoshi Kashima

Abstract

We review the psychological processes underpinning network formation and network-based processes, focusing first on the nature of relationships and their formation, and then on the consequences of networks for individual outcomes and behavior. We argue that it is important to develop methodological approaches that allow us to regard these processes as hypotheses to be tested rather than as unquestioned assumptions. We suggest that different types of networks and processes are likely to lead to different conclusions about these hypotheses, and that the development of models for networks and network processes should therefore be grounded in careful empirical analysis.

The significance of social networks for an understanding of the structure and dynamics of our contemporary social world is now widely acknowledged. Different types of networks serve as channels through which, for example, knowledge is diffused, opportunities are recognized, cooperation is garnered and actions are coordinated. Networks have been invoked in many disciplines in order to explain the nature and consequences of these channelling effects, spawning interest in the capacity to model network structure. This capacity is important because of the potentially powerful interplay between network structures and the dynamics of the social transactions that they support.

Two broad strategies for network model building have been identified (Jackson 2005): a statistical approach, in which networks are seen as the outcome of locally interactive and self-organizing tie-formation processes; and a deterministic, game-theoretic approach, in which networks are seen as the outcome of self-interested behaviour of utility-maximizing actors. In association with the statistical approach, there has been a dramatic increase in our capacity to build theoretically defensible statistical models for social networks whose parameters can be estimated from empirical observations and that have the capacity to reproduce many important global characteristics of observed social networks (for example, Snijders et al. 2006a, b). The game-theoretic approach, on the other hand, is responsible for an impressive accumulation of theoretical results linking strategic activities of pairs of actors to the emergence of 'efficient' network structures.

These two modelling approaches differ in two important respects. The first is in the use of deterministic or stochastic models (but see Snijders 2001). The second distinction is a deeper one, contrasting a conceptualization of actors as self-interested rational decision makers, on the one hand, with more socialized and enculturated actors, on the other. The latter may sometimes be driven by personal utility, but may also engage in non- or extra-rational behaviours that are enabled and constrained by local social network configurations. Indeed, whereas the game-theoretic approach largely assumes that the actor's decision to form or discontinue a relationship is mediated by the actor's conscious computation of utility, the statistical approach treats this as a hypothesis, and empirically examines *whether* an actor's local network configuration appears to constrain or enable tie formation or maintenance. Thus, this second distinction encapsulates a fundamental empirical question: can network structures and processes be explained in terms of the rational activity of self-interested individuals, or are extra-rational affective, social and/or cultural processes systematically at work in the formation and impact of networks?

With this question in mind, we outline what is known about the social and psychological processes that underpin the formation of networks and the dynamics of network-based processes. We first discuss the nature of relationships and their development, and then examine their consequences for individual outcomes and behaviour. We finish by drawing some implications for model-building.

What is a Network Tie and Why Do Relationships Form?

A network relationship, or tie, is assumed to have some continuity in time, with a relevant past and a somewhat predictable future. This temporal continuity is facilitated by cognitive representation and the use of culturally laden relational descriptors, such as friend and friendship, or partner and partnership, features that also facilitate communication about the nature of ties. Relationships, in other words, entail complex socio-cultural schema that not only frame interpretations of past interactions but also shape expectations concerning future ones by the actors concerned as well as by third-party onlookers.

Although tie formation has sometimes been explained in terms of the utility that ties bring for tie partners (for example, Cook and Whitmeyer 1992), recent psychological research suggests that significant extra-rational psychological processes may also underlie tie formation. Anderson and Chen (2002) have invoked the concept of *relational self* to explain the pervasive impact of relationships with significant others on the way in which individuals interpret and respond to interpersonal encounters, and therefore form *future* interpersonal ties. This concept is founded on a demonstrable 'transference' effect, in which past experiences with significant others can be shown to influence new relationships, often outside of conscious awareness. Holmes (2000) has argued that the concept of relationship is best seen as grounded in the interaction between interdependent actors, and hence as an emergent property of dynamic interaction and influence processes. Generic cognitive representations about relationships called *relational schemas* are postulated to represent actors' developing knowledge of self, partner and expected sequences of interaction (for example, Baldwin 1992).

More generally, Fiske (2004) has proposed that four elementary and universal cognitive schemas frame *all* interpersonal relationships. These four schemas are proposed to structure potential interactions between two actors in terms of: collective belonging or solidarity, as in family membership (the *communal sharing* schema); asymmetrical difference, as in hierarchies based on skill, knowledge or social class (*authority ranking*); an egalitarian relationship, based on turn-taking and exchange, as in many friendship ties (*equality matching*); and a rational analysis of costs and benefits, as in a payment-for-service regime (*market pricing*). Fiske claims that any actual social relationship is constituted by some mixture of these forms, and that socially transmitted interpretive guidelines link these universal forms to specific relationship characteristics in a particular culture.

While relational schemas have advanced our understanding of the nature and variety of dyadic relationships, there is a recognized need to understand the specific ways in which they depend on social situations and give rise to interdependencies among relationships *across* a network. As Haslam (2004, p. 297) has observed, Fiske's relational models theory posits 'a universal grammar of social relations . . . out of whose rules and representations the myriad local forms of social life can be generated'. Haslam argues that the categorical nature of the relational models may underpin the complexity of human social organization by facilitating the required coordination of interpersonal obligations, rights and responsibilities. Social roles are important intermediate-level constructs in this account, and are seen as 'distinctively implemented admixtures' of relational models, a view that is supported by evidence that relational models mediate the effects of social roles on social cognition. More generally, social roles have been invoked by many theorists to explain interdependencies among multiple relationships across multiple actors (White et al. 1976).

It follows from these claims that tie formation processes should depend on the type of tie under consideration. While some ties may be consciously negotiated at a dyadic level, independently of other ties, others may be subject to subtle influences arising from the embedding of the potential tie in a local social setting that comprises ties to and among third-party actors with their own mix of potentially competing and potentially cooperative goals. As a result, Fiske's communal sharing relations, for example, should exhibit much stronger interdependencies across pairs of relation partners than relations of the market pricing kind. Such effects have been empirically demonstrated. For example, Granovetter's influential hypothesis concerning the 'strength' of weak ties was based on the distinction between the highly clustered structure of 'strong' tie networks and the less structured, more open, spreading character of 'weak' tie networks, an hypothesis that has received empirical support (Granovetter 1982). There is also evidence that different types of network tie can be mutually interdependent and subject to generalized forms of exchange and interlock through ties to third parties (for example, Lomi and Pattison 2006). Indeed, changes in patterns of cross-network interdependence have been invoked in explanations of social and economic innovation (for example, Padgett and McLean 2006).

In addition to the interdependencies just described, there is also compelling evidence for the impact of individual actors' characteristics on the formation of network ties. Tie partners are more likely to share socio-demographic characteristics such as gender, age, ethnicity and religion (for example, McPherson et al. 2001). The formation of relationships is also clearly a function of social settings that affect the probability of any two actors having an opportunity to interact (Feld 1981). The psychological literature on relationship formation emphasizes the importance of more psychological similarities among potential tie partners, a premise that has been extended by Robins and Boldero (2003) to include a comparison of potential tie partners' aspirations and obligations.

Taken together, these structuring influences on tie formation can be seen as operating at multiple levels, with broad socio-demographic factors at work on a larger scale, and more micro-social and psychological factors at work at more local scales. Whereas the broader factors can often be regarded as exogenous influences on tie formation, the more micro-level factors are usually best seen as endogenous, with the tie formation processes for one pair of actors having consequences for tie formation among their network partners, and their partners, and so on. While some of these interdependencies may operate outside the awareness of individual actors, there are also circumstances in which actors seek out institutional settings and particular relationships precisely for the strategic 'networking' opportunities that they provide. Moreover, expected interdependencies can themselves be countered: Padgett and Ansell (1993) coined the term 'robust action' to describe behaviour that is open to multiple interpretations, and therefore has the capacity to elide third-party influences on tie formation.

How Do Relationships Affect Individual Outcomes?

An actor's location in a social network is an important aspect of social context and hence potentially plays an important role in determining many types of future behaviour apart from the development of social ties. There are a number of related mechanisms by which such effects might occur (for example, Pattison 1994). First, network ties serve as a conduit for information, and hence specific network locations can have a dramatic impact on the information or other resources that any one actor possesses (for example, Burt 2004). This information can itself be subject to subtle filtering effects, such as the suppression of information perceived to be inconsistent with shared understanding at a community level (Lyons and Kashima 2003). Second, network ties can influence actors' understanding of relationships among others as well as expectations about the future behaviour of others. For example, they are likely to be more certain (and more accurate) in judging the relationships involving their network partners and, to a lesser extent, their network partners' partners (Kumbasar et al. 1994). Finally, social influence effects may be brought to bear as actors weigh up – consciously or unconsciously – the views of others in forming or modifying their own beliefs (for example, Friedkin 1998; Robins et al. 2001).

Implications for Model-Building

Models for network structure and network evolution almost certainly need to accommodate many of the exogenous and endogenous influences on tie formation just described. An appropriate model class is the exponential family of random graph models that was first introduced by Frank and Strauss (1986), building on the general formulation of statistical models for interacting systems of variables by Besag (1974). The use of principled approaches to specifying potential tie interdependencies (Pattison and Robins 2002) has led to models that yield impressive fits to even large observed network structures (for example, Goodreau 2007). Interestingly, these models combine a Markov dependence assumption (that potential network ties with an actor in common are dependent, conditional on the state of all other potential ties in a network) with a 'longer range' form of assumed dependence (Snijders et al. 2006a, b) in which, in some circumstances, ties involving discrete pairs of actors are also conditionally dependent. The necessity of these assumptions in many empirical contexts (Robins et al. 2006) suggests that interdependencies among ties within local social contexts are indeed an important influence on observed network forms.

Models for individual states and choices (including beliefs and actions) may likewise need to accommodate subtle network-based interdependencies among the states and choices of their tie partners. Robins et al. (2001) have developed a general social influence modelling framework for this purpose, akin to the network modelling framework just mentioned.

It is important in the context of the question posed earlier – whether network structures and processes can be explained in terms of the rational activity of self-interested individuals, or whether there are extra-rational processes at work in the formation and impact of networks – to develop observational designs and analytic methods that allow us to regard tie formation and network processes as hypotheses to be tested rather than unquestioned assumptions. We might speculate that different types of networks and different types of social processes are likely to lead to different conclusions about these guiding hypotheses, and that, as a consequence, models should continue to be developed from multiple perspectives and to be grounded in careful empirical analysis. Finally, it is worth noting that the development of methods for estimating models from longitudinal observations may prove particularly helpful in sifting among alternative approaches to model building, not just for models of network evolution and social influence dynamics but also for new approaches to modelling the co-evolution of networks and behaviour (Snijders et al. 2006a, b).

Public Capital

David A. Aschauer

Abstract

This article reviews recent research emphasizing the potential importance of public capital (or infrastructure) to aggregate economic performance, and provides a survey of empirical estimates of the productivity of public capital and of the impact of public capital investment on economic growth.

Keywords

Cobb–Douglas functions; Endogenous growth; Long-term economic growth; Neoclassical growth theory; Output elasticity of public capital; Productivity growth; Public capital; Public finance; Returns to public capital; Total factor productivity

Public capital (or often 'infrastructure') encompasses the publicly provided capital facilities which form the basis for private sector economic activity.

Empirically, public capital typically is defined as a net (of depreciation) stock of non-military structures and equipment and is often decomposed into *core* public capital (consisting of transportation facilities – such as streets and highways, mass transit, rail, and airports, water and sewer systems, and electrical and gas facilities), and *other* public capital (comprising educational structures, public hospitals, courthouses and the like).

The Productivity of Public Capital

Beginning at the end of the 1980s, a significant research effort has focused on estimating the contribution of public capital to macroeconomic performance. The research initiative seems to have been the result of the recognition of certain facts about public capital expenditures in the United States. First, infrastructure capital accumulation, when expressed as a fraction of output, began to decline toward the end of the 1960s and, as a result, was seen as a potential factor in explaining the productivity growth slowdown of the 1970s and 1980s. Second, during the same period, the United States devoted a smaller share of output to infrastructure than did other industrialized economies (such as those in the Group of Seven), which was taken as possible force in explaining the relatively low rate of productivity growth in the United States vis-à-vis other countries such as Japan and Germany.

The first stage of the research effort centred on estimating the contribution of infrastructure to private sector productivity, where infrastructure is taken as another factor of production, along with private capital and labour, in an aggregate production function of the form

$$Y = A \cdot F\left(l, K, K^G\right)$$

where Y denotes the aggregate level of economic output, A an index of total factor productivity, L, the labour force or employment, K private capital (usually restricted to business fixed capital), and K^G the stock of public capital. The basic goal of the research was to ascertain the value of the output elasticity of public capital

$$\varepsilon = \frac{K^G}{Y} \cdot \frac{\partial Y}{\partial K^G}$$

in order to determine the 'productivity of public capital'.

The early empirical results, typically employing level data in estimating a Cobb–Douglas production function, indicated (strikingly) high elasticity estimates, in the range of 0.25 to 0.50 for the United States and even higher for countries such as Canada and Sweden. These elasticity estimates, in turn, implied very high rates of return to public capital investments which some took as implausible. For example, Gramlich (1994) used Aschauer's (1989) elasticity estimate of 0.39 to generate an estimate of the marginal productivity of public capital in the range of 0.70 to 1.00, which, in his view, was implausible since it implied that investments in government capital generate enough extra output to pay for themselves in a year.

Later, a number of researchers estimated the production function using first-differenced data, arguing that the initial results were 'spurious' because (*a*) variables such as output and public capital were first-order integrated series and (*b*) the production function did not serve as a cointegrating relation between output and the various factors of production (including public capital). These studies (for example, Tatom 1991) often generated much lower, and less reliable, estimates of the output elasticity of public capital.

Recently, Kamps (2004) has developed new estimates of public capital stocks for 22 OECD countries over the period 1960–2001, and has estimated the output elasticity of public capital. The point estimates are positive in 20 of 22 cases and statistically significant in 12 of 22 cases. A panel regression employing first-differenced data leads to a reasonable elasticity estimate equal to 0.22 which leads the author to conclude that public capital is productive on average in the countries comprising the OECD.

Public Capital and Economic Growth

The finding that public capital is productive is not, in and of itself, evidence that increasing public capital investment will raise long-term economic growth. There are at least three considerations which must be addressed. First, there is the question of whether a permanent increase in public investment will induce a permanent or transitory increase in growth. The traditional neoclassical growth model predicts that an increase in national savings and investment rates will have only a transitory effect on growth; more recent endogenous growth models, on the other hand, would predict permanent effects. Second, given the level of national savings, the effect of public investment on economic growth depends not just on a positive output elasticity of public capital, but on the relative marginal productivities of private and public capital; an increase in public investment at the expense of public investment will raise or lower the economic growth rate depending on whether the marginal product of public capital exceeds, or is exceeded by, the marginal product of private capital. Third, the effect of public capital on economic growth will depend on the method of public finance – whether by current taxes, debt, or (potentially) money creation.

One approach which allows tentative answers to all three questions is that of Aschauer (2000), who extends the Barro (1990) model of productive government spending to explicitly include public investment. This model, which assumes (*a*) that public investment is debt-financed and (*b*) a production function which displays constant returns to scale across private and public capital stocks (per worker) generates endogenous growth in per worker output at the rate

$$\gamma_y = \frac{1}{\sigma} \cdot \left[(1-\tau) \cdot (1-\varepsilon) \cdot \left(\frac{K^G}{K} \right)^{\varepsilon} - \rho \right]$$

where y is the level of output per worker, $(1/\sigma)$ the intertemporal elasticity of substitution, τ the tax rate necessary to service the public debt associated with public capital, and ρ a rate of time preference. Evidently, increases in the tax rate lower economic growth, while increases in the ratio of public capital to private capital raise economic growth. It turns out that increases in public capital will raise or lower economic growth depending on whether the tax rate is lower or higher than the output elasticity of public capital – that is, there is a nonlinear relationship between public capital and growth and an 'optimal' level of public capital. Using US state level data, Aschauer finds robust evidence that the relationship between public capital and growth is, indeed, nonlinear and that public capital is underprovided – that is, the 'optimal' ratio of public capital to private capital is in the range of 0.60 while the actual average ratio equals 0.44. As a consequence, a ten per cent increase in the public capital ratio is estimated to raise economic growth by approximately one percentage point per year.

Public Choice

Gordon Tullock

Abstract

By assuming that voters, politicians and bureaucrats are mainly self-interested, public choice uses economic tools to deal with the traditional problems of political science. Its findings revolve around the effects of voter ignorance, agenda control and the incentives facing bureaucrats in sacrificing the public interest to special interests. The design of improved governmental methods based on the positive information about how governments actually function has been an important part of public choice. Constitutional reforms advocated variously by public choice thinkers include direct voting, proportional representation, bicameral legislatures, reinforced majorities, competition between government departments, and contracting out government activities.

In the 18th and 19th centuries a number of mathematicians (Condorcet, Borda, Laplace and Lewis Carroll) became interested in the mathematics of the voting process; their work was forgotten until Duncan Black rediscovered it (see, e.g., Black 1958). Black can be called the father of modern Public Choice, which is in essence the use of economic tools to deal with the traditional problems of political science. Historically, economics (political economy) dealt to a very large extent with the choice of government policies with respect to economic matters. Whether protective tariffs were or were not good things would be a characteristic topic of traditional economics and in examining the question, it was assumed, of course, that the government was attempting essentially to maximize some kind of welfare function for society.

We do not expect businessmen to devote a great deal of time and attention to maximizing the public interest. We assume that, although they will of course make some sacrifices to help the poor and advance the public welfare, basically they are concerned with benefiting themselves. Traditionally economists did not take the same attitude towards government officials, but public choice theory does. To simplify the matter, the voter is thought of as a customer and the politician as a businessman/entrepreneur. The bureaucracy of General Motors is thought to be attempting to design and sell reasonably good cars because that is how promotions and pay rises are secured. Similarly, we assume that the government bureaucracy will be attempting mainly to produce policies which in the views of their superiors are good because that is how their promotions and pay rises are secured.

In all these cases, of course, the individual probably has at least some willingness to sacrifice for the public good. Businessmen contribute both time and money to worthy causes and politicians on occasion vote for things that they think are right rather than things which will help them get re-elected. In both cases, however, this is a relatively minor activity compared to maximizing one's own wellbeing.

The only surprising thing about the above propositions is that they have not traditionally been orthodox either in economics or political science. Writers who did hold them, like Machiavelli in parts of *The Prince*, were regarded as morally suspect and tended to be held up as bad examples rather than as profound analysts.

Public Choice changes this, but even more important, by using a model in which voters, politicians and bureaucrats are assumed to be mainly self-interested, it became possible to employ tools of analysis that are derived from economic methodology.

As a result, fairly rigorous models have been developed which can be tested with the same kind of statistical procedures that are used in economics, although their data are drawn from the political sphere. The result is a new theory of politics which is more rigorous, more realistic, and better tested than the older orthodoxy.

While the basic thrust of the Public Choice work has been positive (directed towards understanding politics), from the very beginning it has also had a strong normative component. Students of Public Choice might modify Marx to read that 'the problem is to understand the world so that we can improve it'. Thus the design of improved governmental methods based on the positive information about how governments actually function has been an important part of Public Choice work, and is usually referred to as the theory of constitutions.

Before discussing this, it is necessary to outline briefly related discoveries in four general areas, viz: voters, politicians, the voting process which relates voters to politicians, and the theory of bureaucracy.

We begin with voters. One of the earliest discoveries of the new Public Choice (see Downs 1957, pp. 207–78) was that a rational voter would not bother to be very well informed about the votes that he cast. The reason is simply that the effect of his vote on his well-being is trivially small (see Tullock 1967a, pp. 100–14). Apparently voters have always known this, since empirical studies of voter knowledge show them extremely ignorant, but it was something of a revelation to traditional professors of Political Science. Further, this general ignorance of the voter is not symmetrical. The voter is likely to know a good deal about any special interest which he has. Further, organized special interest groups will put effort into propagandizing the voter in such areas. Thus the voter is not only badly informed, but what information he has tends to be biased very heavily in the direction of his own occupation or avocation. The farmer is much more likely to know the views of the candidates on farm programmes than their views on nuclear war. It could be said that even on the farm programme he is probably not very well informed, just better informed.

One should not exaggerate of course. The voter, simply by living and following current events in newspapers and on television, does acquire a certain amount of general information about politics. Not much of it seems to stick, however, and in any event it is very heavily affected by temporary fads. It should also be emphasized that some kinds of special interests of the voter are not in any real sense selfish. For example, in the USA many people are influenced in their vote by such institutions as Common Cause and Liberty Lobby and make voluntary cash contributions to them. Clearly, this is an expression by those people of their interest in good government, even though the two groups define this in a radically different way. There is no doubt, however, that a well organized special interest is apt to have more impact on any specific issue than either the general media or so-called public interest groups like Common Cause or Liberty Lobby, even though in the very long run, considering what one might call the 'general mystique' of government, the media are very important.

Consider next the politician. A politician is a person who makes a living by being elected by voters of the kind described above. Further, many politicians are themselves voters as, let us say, members of the House of Representatives. While in the latter capacity, although it is not true that politicians' information is as bad as that of the voter, a similar effect is still at work. An individual member of the House of Representatives or the House of Commons who switches one hour a week from general study of the issues on which he must vote to constituency service will normally reduce only trivially the quality of the legislation as it affects his constituency. On the other hand, by so re-allocating his time, he may materially improve his relations with his electors. Thus we would expect that politicians will be less well-informed on general matters than we would like.

This is simply one example of a large number of cases in which politicians' behaviour is not necessarily that which maximizes the public welfare: they vote in Congress and seek public positions in terms of what they think the voters *will* reward, not in terms of what they think the voters *should* reward. Since a politician knows that his constituents are badly informed, these two positions can be radically different. Nevertheless, if we are believers in democracy, which literally means popular rule, then the government should do what the people want and not what some wiser person feels that they should want. In any event, 'in order to be a great Senator, one must first of all be a Senator'.

Obviously the cost to the public of this kind of behaviour is quite considerable. It is particularly so when we think of the investment of resources and influence in the government which are, to a considerable extent, wasted. However, if we contrast functioning democracies with the other types of government which we observe, we are not likely to feel that democracies are markedly less efficient.

We now turn to the voting process, which connects the public to the politicians and the latter to the actual policy outcomes. Uninformed people think that this is basically a trivial problem, you simply count the votes. Unfortunately, this does not follow, even though the author of this essay is one of the few Public Choice theorists who regards the problems to be discussed next as being possibly illusory.

Condorcet, Borda, Laplace and Lewis Carroll and, in the 20th century, mathematical economists like Black and Kenneth Arrow discovered a set of mathematical problems sufficiently difficult to be taken as proof that democracy is either an illusion or a fraud. Basically, if we assume that all individuals can order various policy proposals, producing a personal ranking from top to bottom (indifference between alternatives being permitted) and that these orderings differ from person to person (and do not fall into a set of narrowly specified and rather unlikely patterns), then one of the following three phenomena can occur under any conceivable system of voting:

1. Endless cycling with A beating B and B beating C then C beating A.
2. An outcome which is dependent on the order in which the various proposals are voted on. (It should be pointed out in this connection that if this is so, and the people are well informed, voting on the order of voting reproduces the same problem.)
3. A situation in which the choice between alternative A and alternative B depends on whether alternative C (which in itself has no chance of winning) is or is not entered into the voting process. Most legislatures follow procedures which fall under the second of these possibilities.

If there is a possibility of arranging all of the alternatives in a single dimension with individuals having an optimal point and their preferences falling away monotonically as one moves away from that optimal point in either direction (single peakedness), then the problem is avoided. Unfortunately, most choices involve policies that differ from each other in more than one dimension and so cannot be arrayed in such a onedimensional continuum. Furthermore, voting on them one aspect at a time reintroduces the second of the problems above. Nevertheless, the assumption of single peaks (whose validity is probably due to voter ignorance) has been successfully used in much empirical work.

While there is no doubt about the mathematical accuracy of the proofs of the above propositions, the real problem is whether they are of great practical significance in voting. Unfortunately, this turns out to be an extremely difficult question whose solution is unlikely to be found in the near future. In essence there are two possibilities when we observe such voting bodies as the House of Representatives and look at the outcome. The first is that the outcome is essentially random, that is, matters are taken up in some order, that order determines the voting outcome and the members of the House do not realize that they could then change that outcome by changing the order in which the propositions are voted on. This possibility would imply that luck plays an immense role in democracy.

The alternative is to say that the outcome is manipulated by somebody who understands the situation and who has control over the agenda. The House majority leader, or the chairman of the Rules committee, is sometimes suggested as that person. This implies that we really have a dictatorship, one that is well concealed.

In my opinion, the indeterminacy thrown into the outcome by these propositions of social choice theory is actually quite small in practical terms. Thus the Chairman of the House Rules Committee may be able to change an appropriation bill by, say, one hundred thousand dollars, but not by an amount which (given the size of these appropriations) is particularly relevant (see Tullock 1967b). Among Public Choice theorists mine is a minority point of view. The majority, although it is deeply concerned about these problems, tends to ignore the implications of its point of view on the desirability of democracy as a form of government.

Empirical evidence has clearly demonstrated that agenda control can to some extent affect the outcome. This of course is going to surprise nobody. One does not need the complex mathematics of voting in order to realize that those members of any assembly who are in a position to control the order upon which things are voted have power. Similarly the control of what propositions are actually put before the voters can have considerable impact on the outcome. The demonstration of the empirical impact from agenda control, however, does not really support the theorems given above. Of course, we cannot say that the failure to find clearcut proofs that the outcome in a democracy is essentially either random or fraudulent (as would be implied by the mathematical work on voting) proves that it is not. The problem is difficult and subtle and in the present state of our knowledge must be left for further research. Meanwhile, we all go on with faith that the voting process produces an acceptable outcome even though mathematical investigation raises grave doubts.

Turning now to the theory of bureaucracy, once again Public Choice thought has worked a revolution. The traditional view was either that bureaucrats followed the orders of their political superiors or alternatively that they simply did what was right. Public Choice theorists, following the work of Tullock (1965), Downs (1967) and Niskanen (1971), believe that these are not proper statements about the bureaucrats' motives, although to some extent the bureaucrats do attempt to do what is right – including obedience to the views of their superiors. However, in modern societies where civil service legislation makes it all but impossible for the superiors either to dismiss them or even to reduce their salaries, the degree to which the bureaucrats are so compelled is moderate. Furthermore, in most civil service situations the power of a political appointee to reward his inferiors by promotion is very much restricted. Promotion decisions are to a considerable extent controlled by both legal and public-relations considerations which may compel a superior to promote someone whom he actually thinks has been sabotaging his policy.

While this is a characteristic of most modern civil service structures, there is no law of nature which says that government should be organized in this way. Traditionally, higher officials have been free to promote, demote or dismiss this subordinates. Even here, however, the fact that the higher official cannot possibly know everything that is going on at the lower ranks means that his control gradually diminishes as one moves away from his position down the pyramid of ranks.

For example, in the USA it was recently discovered that it is not possible for the Secretary of Defense to know the specifications which a civil servant, located at a vast distance down the pyramid, produced for a new coffee pot for military aircraft. In this case, the civil servant who specified a coffee pot capable of withstanding a crash that would kill the entire crew of the plane was neither dismissed nor even reprimanded. Indeed the newspapers that reported the story did not even mention his name, but instead concentrated on the Secretary of Defense. In 1870 a military procurement agent who make a mistake like this (and which got into the newspapers) would have found it necessary to hunt for a new job within an hour or so.

Basically the average employee in a bureaucracy is interested in retaining his job and gaining promotion and for this purpose wants to please his superiors. Under the old-fashioned system where he had little job security, and where promotion was determined strictly by his superiors, there was considerable pressure on him. In present circumstances, where to all intents and purposes he cannot be dismissed and where even his promotion is to some extent protected from political intervention by his superiors, this pressure is less important. However, even in a different case, in which he did indeed want to please his superiors, this would not necessarily lead to activity which is in the public interest. That would depend on the political situation of the party or individual who at that time was in control of his branch of the government.

This attenuation of control, in which much of what is done by lower-ranking officials is simply unknown to those of higher rank, is characteristic of all bureaucracies. There are however various ways by which the higher ranks can become, to some extent, aware of what is being done by the lower ranks. Undoubtedly the most efficient of these is simply an accounting system. In the case of a private company, whose motive is making money, the accounts do a reasonably good job (no more) of signalling what the various lower ranking officials are contributing to that goal. When we turn to government, however, we have the combination of a set of objectives that are either vague or not clearly specified, and a situation where there is no accurate way of measuring the contribution of each person to those objectives. Under such circumstances, control is much more severely attenuated.

When we have a civil service structure which separates the individual from much of the control power of his superiors, the problem is even more severe. Whether an individual bureaucrat works hard or not, prepares himself or herself well or not, is largely a matter of individual choice. As a rough rule of thumb, those people who do work hard and prepare themselves well are those people who have their own idea of what government should do in their particular division and work hard at that. In a way they are hobbyists. It should be said however, that their hobby is normally motivated by a desire on their part to maximize what they think is the public good. In other words, they are usually well-intentioned individuals who can be criticized only in that their idea of the public good may or may not coincide with that of their superiors. If it does not coincide, this does not prove that they are wrong and the superiors right, but it does mean that the government is not apt to follow a coordinated policy. In times past, it used to be normal to refer to the US Department of State as ‘a loose confederation of tribal chieftains’. The phrase is not used any more, but as far as I can see this is only because the confederation itself has broken down.

Bureaucrats normally have several private motives. One is, of course, simply not to work too hard – a motive which does not seriously affect the hobbyist described above. Another is to expand the size of one’s own department and in the process of so doing, being willing to go along with the expansion of all the rest. A third is to improve the ‘perks’ that accompany the particular position (see Migue and Balageur 1974).

Note that this is not intended as criticism of the bureaucrat. We would expect anyone who is given the kind of opportunities that are given to bureaucrats to do more or less what they do. However, the consequence is that large bureaucracies tend to grow larger, tend as they grow larger to follow less in the way of integrated policies and more in the way of policies that develop in the lower reaches of the pyramid, and tend in fact not to work terribly hard (see Bennett and Orzechowski 1983).

The problem is multiplied when bureaucracies become very large, because the members of the bureaucracy can vote. Furthermore, empirical evidence (see Bennett and Orzechowski 1983) shows they vote more frequently than non-bureaucrats. Thus their percentage in the voting population is somewhat larger than their percentage in the actual population (see Frey and Pommernhe 1982). Thus, the political superior must consider the people working for him as in part his employers rather than his employees. He may not be able to fire them, but in the mass they can fire him. Altogether, the system is not well designed and does not work very well.

So far we have been talking about Public Choice and what has been learned, but not of the lessons of a normative nature that have been drawn i.e. the theory of constitutions. It is to this that I now turn.

Not all students of Public Choice favour the same reforms in each area. Further, some have not specifically said what reforms they would prefer because they believe that not enough is yet known about the process to be able to suggest improvements. Nevertheless, there are several rather general propositions which most students would agree upon as ways of improving the functioning of government. In a discussion as brief as this, it is not possible to include all the differences of opinion and all the modifying clauses which would be appended to each suggestion for reform. Thus the reader should not assume that everyone studying Public Choice agrees with all the propositions which follow.

To begin with the voter, no student of the subject has any idea of how to improve the voters' information. With respect to voting itself there have been some proposals for improved voting methods, but no widespread support exists for any particular improvement. In spite of this, I think it can be said fairly that most students would like to see voters vote more than they do now, favouring more direct voting on issues, and legislatures with larger membership (so that the connection of an individual voter and his representative is closer).

The basic desire to give voters more control of the mechanism is not based on any false idea of how well the voters are informed. It is simply that the voters are the only people in the whole process who do not have an element of systematic bias in their decision process. They may be badly informed, but what they want is their own well-being. The well-being of its citizens should be the objective of the state. When we turn to other parts of the government invariably we find at least some conflict between the interests of the officials and the interests of the average man. Thus increasing the average man's control is not particularly likely to improve the efficiency of the government using some abstract definition of efficiency. But it is likely to make the government more in accord with the preferences of the common man; i.e. it brings us a little closer to the objective of popular rule which is supposed to be what democracy is about. Those who do not favour popular rule would not regard this as desirable, but there are few elitists among the students of Public Choice.

The actual decision-making procedures used in the legislatures have been widely discussed and some proposed improvements command wide acceptance. First, many would like to have at least one house of the legislature elected by proportional representation. Secondly, Buchanan and Tullock's arguments in *The Calculus of Consent* (1962) for bicameral legislatures have generally been accepted. The further suggestion there that more than a simple majority is desirable for most legislation is seldom directly criticized, but is not so widely approved. The argument that this higher-than-majority requirement would change the structure of the logrolling process in a favourable way has seldom been directly criticized, but the asymmetrical effect of such a rule (i.e., the status quo is retained unless a reinforced majority can be obtained to change it) offends some people.

Turning to the bureaucracy, there is much more agreement on reform. First, that a bureaucracy should be brought more firmly under the control of the political leaders is, I think, uniformly accepted. The dangers of this are recognized – but there are various ways in which the higher officials could be given the right to discipline civil servants while still reducing their power to fill the government with their cousins.

Apart from such straightforward proposals for changes in the personnel structure there are other ways of putting pressure on the government. The first is to work some competition into the system. Currently, not only do most government departments have a monopoly over whatever function they perform, but almost every proposal to increase the efficiency of government takes the form of eliminating what little competition has popped up. Competition between government departments should be encouraged rather than discouraged.

Finally, it may be possible to 'contract out' government activities or literally transfer them wholely to the market. The mere threat of this will frequently lower the cost of government activity. Having several private companies bidding for a government service, however, is better.

It can be seen that at the concrete level, those who study Public Choice have been able to provide more in the way of suggestions for reform within the bureaucratic structure than in the higher level parts of democracy where the voters control the legislature, and the legislature and executive then control the bureaucracy. This is unfortunate but not surprising. Nevertheless, there are suggestions for improving the whole structure of government and with time, it is hoped, there will be both more ways of making improvements and better scientific evidence that the 'improvements' are indeed improvements.

Public Choice is a new and radical approach to government, but its firm foundations in economic methodology mean that we have more confidence in its accuracy than with most new ideas. Further, it has by now been empirically tested very thoroughly. Government is the solution to some problems and the source of others. Public Choice shows strong promise of being able to reduce significantly the difficulties we now have with democratic government.

Public Debt

James M. Buchanan

Abstract

Classical principles of public debt limited debt financing to non-recurrent, extraordinary or temporary demands. Keynesian macroeconomics, viewing budget deficits as the only means of financing demand-increasing deficits during depressions, overlooked the exchange between government and lenders in debt-financed public expenditure. In the post-Keynesian 1970s and 1980s, governments explicitly used debt to finance ordinary public consumption, including transfers, which was equivalent to a destruction in national capital value and raised the prospect of default. Fiscal responsibility demands that the classical principles of public debt must eventually return to general acceptance.

Public debt (government debt) is a legal obligation on the part of a government to make interest and/or amortization payments to holders of designated claims in accordance with a defined temporal schedule. Public debt is created through government borrowing from individuals, corporations, institutions, and other governments. Borrowing is part of a bilateral exchange process in which lenders transfer funds to government and government, in turn, transfers to lenders designated instruments that represent claims on government revenues over a series of periods subsequent to that in which the borrowing occurs. In simple balance-sheet terms, public debt is a liability item on the government's account, and an asset on the combined accounts of the holders of the debt instruments.

In its essential respects, public debt is not different from the debt of individuals or non-governmental institutions. The positive analysis is equivalent over the several settings, and the normative principles for the use of debt are the same. These two propositions are not universally accepted by economists, whose understanding and analysis of established classical principles were eroded in the emergence of the macroeconomic mind-set of the postKeynesian era. Because of the continuing confusion and ambiguity in the basic economic theory of public debt, extended discussion is required on what should otherwise seem quite elementary analytics.

Taxes, Money and Public Debt

In order to finance spending programmes (including transfers) government must first secure revenues. Three means are available to governments with independent monetary systems: taxation, money issue, and public debt. Only two means are available to subordinate governments without money creation powers or to national governments that tie domestic currencies to external forces in the international economy: taxation and public debt.

It is useful to make two critical distinctions between taxation on the one hand, and public debt on the other. With taxation there is only one possible 'exchange' embodied in the combined fiscal process, that effectuated via government between individuals as taxpayers and individuals as beneficiaries of government spending programmes. This two-sided fiscal operation is 'exchange' only in the aggregative sense that persons in the community secure benefits from the taxes paid by persons, whether or not the taxpayer and beneficiary groups are overlapping. However, even if the fiscal process satisfies the aggregative and the individualistic efficiency standards such that all persons pay tax-prices, at the relevant margins, equivalent to public-goods benefits, coercion is required to implement the solution. The basic fiscal 'exchange' is not, and cannot be, voluntary.

With public debt issue, by comparison, *two* 'exchanges' are involved in the combined fiscal operation, one, the political 'exchange' analogous to that in taxation, and the other the whole set of privately negotiated and wholly voluntary exchanges between government and those who lend funds to government. Failure to recognize the double set of exchanges that public borrowing combined with spending of the proceeds embodies is the source of major confusion in determining the location of the burden of debt, to be discussed below.

A second critical distinction between taxation and debt issue lies in the temporal difference in the politically determined imputation of the liabilities that are made necessary by the fact of government spending. With taxation, these liabilities are imputed to those persons and institutions that make the funds available directly to government in the period of the spending operation. With public debt, by contrast, there is no current or initial-period imputation of fiscal liability. Revenues are secured from those who lend voluntarily, who do so in exchange for promises of future period interest and amortization payments, and not in 'political exchange' for the benefits of spending programmes, even indirectly. With government borrowing (debt issue) the ultimate fiscal liability made necessary by the spending programme in the initial period is postponed. This liability is placed, in the aggregate, on taxpayers in periods subsequent to that in which the debt is issued. The aggregate liability is not, however, imputed or assigned to individuals or to groups of individuals. The postponement of liability implies, therefore, postponement of payments for public programmes.

The Ricardian Theorem on the Equivalence Between Taxation and Government Borrowing

David Ricardo (1817, 1820) advanced a theorem to the effect that taxation and government borrowing are logically equivalent. This Ricardian theorem was rediscovered by macroeconomists in the 1970s, notably by Robert Barro, and it became an important element in the 'new classical macroeconomics' of that period.

On its face, the theorem seems to reject the critical distinctions between taxation and debt discussed above. In what respects are taxation and government borrowing alike rather than different? Both extract revenues from private citizens and transfer these to government for spending on public programmes. The basic Ricardian logic does not reject the difference in status between the taxpayer, who faces governmentally imposed coercive levies, and the bond purchaser, who voluntarily transfers funds to government in private exchange for future-period interest and amortization payments. The theorem does, however, reject the second distinction noted above, that which involves any postponement of the costs of public spending. In the Ricardian model, individuals recognize that any issue of debt by government embodies a commitment to meet payments in future periods. These payments can be converted into individualized shares in the aggregate liability, discounted, and capitalized into a present-value measure, which can then be reckoned as a liability item on individual initial-period balance sheets. If persons think that they will live forever, or if they have intergenerational bequest motives that cause them to act as if their lives are infinite, the liability items, summed over all persons, will just offset the value of the debt in the balance sheets of those who hold debt instruments.

If the equivalence theorem is valid, there are important macroeconomic consequences. If persons treat government debt equivalently with taxation in all respects other than the actual timing of the payments, they will make portfolio adjustments as required by this differential timing. When debt is issued, persons will, knowing that payments must be made in future periods rather than currently, put aside some funds to facilitate such payments. There will be no difference between tax and debt financing in their effect on consumption and investment spending. Individuals, as taxpayers-citizens, will when debt is issued, increase savings to allow a share of the future-period debt obligations to be met. However, this increase in saving will equal the full value of the debt only if the governmental outlays take the form of ideally efficient transfers. This *neutrality theorem,* which we may associate with

Barro, is more restrictive than the Ricardo theorem. If the governmental outlays are made for the provision of real goods and services, the neutrality theorem may not hold although debt financing and tax financing of these outlays may still exert equivalent effects (the Ricardo theorem).

The Ricardo equivalence theorem (along with the stronger neutrality theorem) is best evaluated as an extreme model of rational individual behaviour under idealized sets of circumstances. Ricardo himself recognized that persons did not, in fact, treat taxation and debt in the same way. All persons do not act as if they live forever; persons differ in age as well as interest in future-period tax obligations. Further, taxes are not lump sum, interpersonally or intertemporally. More importantly, there is no assignment of present-value liability among persons such as would allow portfolio adjustments to be made in the manner postulated in the equivalence theorem setting. Even if individuals do recognize that public debt does embody future-period tax liabilities, they cannot reduce this aggregate to individualized shares in any plausible reckoning.

The central flaw in the equivalence theorem stems from the logic of debt itself, which may be illustrated by analogy with private behaviour. Why does a person borrow? He does so in order to rearrange spending temporally. If borrowing and current payment (the private analogue to taxation) are equivalent, there is no point in the exercise. As an institution, borrowing has as its purpose the adjustment of spending flows through time. Governments, as agents are citizens, borrow for analogous reasons. There is no *raison d'être* for public debt if this instrument is behaviourally equivalent to taxation.

The empirical evidence gained from straightforward observation of modern politics points clearly toward rejection of the equivalence theorem. Taxation and debt are not treated as identical by voting constituents, as is suggested by the fact that politicians responsive to constituents are not indifferent as to the mix between these instruments. Within broad threshold limits, debt financed outlay arouses less political opposition than tax-financed outlay of comparable magnitude. The observed US Federal deficits of the 1980s could not have been eliminated by tax increases without generating significant political struggle.

Classical Principles of Public Debt

Both the positive analysis of and the normative precepts for public debt were broadly understood by the classical economists, and these principles were carefully articulated in the dominant theory of public debt developed in the 19th century. There is no essential difference between the government account and the account of an individual or private firm in the classical model. Borrowing is a means of raising revenues that allows the borrower to put off or to postpone payments. It is a means of adjusting spending needs to revenue flows over time; in effect, borrowing allows intertemporal trades to be made.

For the government, as for the individual or firm, there would be no basis for borrowing unless the burden of payment could be delayed in time. By the very meaning of debt, therefore, there must be a shifting forward of burden intertemporally. The ultimate payments for the enhanced spending programme during the initial period when debt is issued must be borne exclusively in later periods.

From this straightforward and indeed simple analysis, normative principles for public debt creation emerge. Resort to debt financing is indicated only with nonrecurrent or extraordinary demands, or requirements for public spending that are expected to be temporary. Traditionally, such demands were associated with war emergencies, and the principles of fiscal prudence dictated that debts accumulated during was periods would be retired when the emergency spending demands were past. In addition to these extraordinary spending justifications for resort to borrowing, government is also within bounds under classical norms when debt is issued to finance genuinely productive capital projects, analogously with private firms making capital investments.

When capital spending is debt financed by government, the principles suggested that a scheme for debt retirement be put in place to insure that the pay-off period corresponds to the income-yielding period from the investment asset.

Public Debt in Keynesian Macroeconomics

The classical principles of public debt were not understood by the pre-classical mercantilists and these principles were also questioned by a few fiscal and monetary expansionists in the pre-Keynesian period. Only with the 'Keynesian revolution' in economic thinking in the middle of the 20th century, however, did a rejection of these classical principles become a 'new orthodoxy'. An analysis of public debt, along with relevant normative implications, came to be dominant during the 1940s and 1950s that sought to contradict basic elements of the classical model.

As noted earlier, the classical principles are starkly simple, and are based on the essential similarity between the government and the individual account. The Keynesian logic rejected this analogy. Specifically, the argument denied that public debt embodies any shift of burden onto taxpayers in periods of time subsequent to debt issue, a temporal shift that was acknowledged to occur in both private debt and external public debt.

The conclusion that public debt could involve no intertemporal shift of burden emerged from an undue concentration on the macroeconomic aggregates and an overlooking of individual adjustments to macroeconomic instruments. Again, the logic is seemingly quite straightforward. Resources are used up only in periods when spending programmes take place; if government borrows to finance spending on guns, the resources that go into producing these guns must be given up by some persons during the period and not later. With internal public debt, therefore, the burden of war spending could not, by definition, be transferred forward.

The basic flaw in the argument is clear from the discussion in section I. The two-part exchange that debt-financed public spending embodies is overlooked. The argument fails to recognize that those who actually give up claims over resources during the period of the spending do so because they voluntarily exchange funds for promises of interest in future periods. These purchasers of bonds do not, in any sense, 'pay for' the benefits of the public spending programme. The fact that these persons may also be members of the community of citizens-taxpayers is irrelevant for the temporal location of burden. Taxpayers in later periods are faced with claims against their incomes that must be met, and which exist only because of the initial-period debt issue. If, indeed, the Keynesian orthodoxy of public debt were valid, economists and finance ministers would have discovered the fiscal equivalent of the perpetual motion machine. No non-voluntary transfers of revenues are required to finance spending in the initial period, and, if there is no burden on future-period taxpayers, the spending that is carried out would have required no burden on anyone.

The Keynesian argument was driven by a stance on policy that viewed public debt as the only means of financing demand-increasing deficits during periods of depression. The primary policy instrument of Keynesian economic policy was the budget deficit, and there was an elementary failure on the part of pro-Keynesian economists to recognize that demand-enhancing deficits could be financed with noninterest bearing money creation. If this macroeconomic objective is the only justification for the creation of budgetary deficits, it becomes totally unnecessary to impose the future-period taxes that debt interest reflects. Money creation in such settings carries with it no future-period burden.

Public Debt and Deficits in PostKeynesian Politics

The Keynesian replacement of classical principles of public debt was never total, and in the late 1950s and early 1960s there was a reemergence of economists' support for the earlier analysis, along with its normative implications. There was not, however, a 'paradigm shift' at all comparable to the earlier overthrow of the classical analysis.

Somewhat begrudgingly perhaps, economists of the 1960s came to recognize the deficiency in the simplistic Keynesian logic, but there was no general reaffirmation of classical principle. The discussion of public debt that characterized the 1960s, 1970s and 1980s remained confused by an admixture of the two contradictory models of analysis. Economists seemed to concentrate attention on the secondary and tertiary macroeconomic consequences of debt-financed deficits; their considerable formal skills were directed toward attempts to extend the ancient Ricardian theorem.

While confusion and ambiguity described economists' discussion of public debt, the politicians had learned the Keynesian policy lessons with roughly a two-decade lag. By the early 1960s, the 'old-time fiscal religion', based on adherence to the normative precepts of the classical analysis, had lost its constraining influence. The political leaders of the 1960s and beyond had learned that demand-enhancing deficits may be justified in some economic settings. Their natural proclivities to spend without the levy of taxes on constituents caused them to look on economic settings in a biased or one-sided fashion. The idealized Keynesian policy set – deficits in depression, surpluses in booms – proved to be unworkable in democratic politics.

The regime of apparently permanent debt-financed deficit spending was born. During the 1970s and 1980s, for the first time in modern fiscal history, governments explicitly used debt to finance ordinary public consumption outlay, including transfers. This fiscal operation, considered in isolation, is equivalent to a destruction in national capital value. When persons, privately or publicly, abstain from consuming current income, capital value is created. When persons, privately or publicly, consume more than current-period income, capital value (defined as the discounted present value of anticipated future incomes) is destroyed. For both individuals and governments, resort to borrowing allows a 'using up' of future-period income as a means of increasing current consumption, just as resort to saving allows a 'using up' of current income (in an opportunity cost sense) to increase future-period consumption. Only if borrowing is used to finance genuine capital investment, private or public, will the net effects be intertemporally neutral; only in this case will the capital value of anticipated income be unchanged. With debt-financed public consumption, the present value of anticipated future incomes of persons in the polity is reduced relative to that which might have been maintained in the absence of the combined fiscal operation. The fact that some or all of the debt is held by foreigners rather than citizens does not modify this conclusion.

Consider the case where debt instruments are purchased exclusively by domestic citizens, who may also be future period taxpayers. Securities are purchased voluntarily; hence, there is no change on the asset side of purchasers' balance sheets at the time of debt issue. Purchasers could, alternatively, hold or buy privately issued securities with equivalent yields. On the other hand, the fiscal operation does place debt-interest claims against the anticipated private income flows of citizens as taxpayers. There is a net increase in the present value of liabilities on properly calculated individual balance sheets. This increase in the value of liabilities is, of course, equivalent to the value of the debt instruments. But these two items are *not* offsetting since there are two fully offsetting items on the asset side of the accounts, leaving no net change from this side. The combined fiscal operation necessarily reduces net worth, or capital value, in the economy, so long as the government outlay does not generate anticipated income flows from public assets, a result that is ruled out with pure public consumption.

Return to Classical Principles?

Public debt is a topic in political economy in which the level of understanding experienced serious retrogression over the course of the middle decades of the 20th century. Policy-motivated macroeconomic confusion generated political spillovers that remained in the 1980s. Economists seemed unable to contribute to clarification in analysis, in part because they were reluctant to drop either suprarational models of individual behaviour or erratic manipulation of data. The classical analysis, out of which emerged precepts that offered simple guidelines for governmental fiscal authorities, no longer commanded widespread support, either among political economists or among politicians and, indirectly, their constituencies. Governments in the 1980s were observed to be financing sizeable shares of their public consumption outlays by interest-bearing debt. Interest outlays made up ever-increasing proportions of total government budgets.

The simple logic of compound interest guaranteed that the budgetary regimes observed in the 1980s were not sustainable. Default on government's debt obligations becomes increasingly attractive to politicians as interest charges mount and as borrowing rates for new issues of debt simultaneously increase. Default on public debt has occurred often in history, both through explicit destruction of real value obligations and by means of inflation.

The ultimate prospects for default may be generally recognized, but the political difficulties in restoring some adherence to classical norms cannot be overlooked. Once debt-financed deficit spending for public consumption came to be an element in the quasi-permanent *status quo,* attempts to restore budgetary balance faced enormous political opposition, as indeed the events of the 1980s demonstrated. To reduce the deficits, and hence merely to reduce the rate of increase in public debt issue, governments must resort to tax increases or to spending cuts, both of which arouse political opposition. Those taxpayers who must bear the burden of continuing debt are, at best, only partially and indirectly represented in the decision structure of democratic politics.

Restoration of the classical principles of public debt seemed unlikely from the temporal perspective of the 1980s. The old-time or pre-Keynesian 'fiscal religion' did exert an influence on the behaviour of politicians, and through them, on governments. Public debt, as a revenue-raising instrument, has an appropriate and well-defined use as a means of allowing governments to alter the time stream of payments for extraordinary outlays. There was nothing comparable to a 'fiscal religion' in postKeynesian politics. Public debt, as it was actually used in the years after the 1960s, became a mere balancing element between proclivities of politicians to tax on the one hand and spend on the other. The absence of immediate fiscal breakdown was explained by some residual carry over of classical norms, some introduction of a Ricardian-like consciousness of future tax liabilities, and some fear of default risk on the part of prospective lenders. But the situation observed over the decades of the 1970s and 1980s could not have represented temporal stability.

The classical principles of public debt, whether they be labelled as such, must eventually return to general acceptance if the fiscal responsibility of governments is to be maintained. Whether or not this acceptance comes before or after a sequence of default-engendered fiscal crises could not be predicted from the temporal perspective of the middle 1980s.

Public Economics

Serge-Christophe Kolm

The Modern Economic Theory of Public Actions: Aim and Scope

Public Economics is the study of the public economy, i.e., of economic questions which are not purely market, intra-household or intra-firm, with emphasis on logic-intensive (scientific) analysis and on ethical–normative questions.

'What must the government do?' is therefore a large part of the problem to which Public Economics sets out to provide answers, with the widest understanding of the 'government', and no real limitation in scope as to which acts it applies – this is because the term 'economic' is so extensive and in studies of this kind often defines more an approach, a point of view, than a domain in the substantive sense. Public expenditures, taxes, regulations of many kinds, public production and prices, public debt and money, exchange rate policies, etc., are the variables to be chosen. With a public sector using 30 to 70% of GNP in 'Western' developed countries – and much more in 'Eastern' socialist ones – with multifarious regulations, a vast array of bodies in between the purely public and the purely private, plus the global macroeconomic regulation of the market sector, the scope for Public Economics is a priori vast. But where the public sector must, or must not, lay its hands is the first question of Public Economics (not to intervence is a possible solution to the problem of what to do or how to do it). The discipline aims to provide specific and scientific answers to this question, rather than leaving it to ideologies. In fact, most Public Economics has been concerned with the interface between the private and the public sectors, seeking to analyse its place and structure and advise about it.

Institutionally, Public Economics is concerned with the behaviour and existence of public bodies in the largest sense – governments at all levels, quasi-public organizations such as public social insurance or health and education services in many countries, public firms and 'utilities', etc. It has a deep interest in the border or common domain between the public economy and the market, that is the voluntary associations of various kinds and aims. And, of course, the factual working of the private economy (markets and intra-agent), and normative judgements about it, are crucial for Public Economics, since it undertakes to advise on how to correct its defects.

Public economics, in its final aim, is thus largely an applied normative intellectual endeavour, which finds both means and aims in man and society and their environment, and for which constraints and possibilities contain capabilities and motivations both of private agents and of persons or groups constituting the public sector (civil servants, politicians in government or in parliaments, etc.). However, at some point social ethics must intervene in the reasons for public sector activities in a way in which it does not for those of the private sector – be it through an ethic of the Public Service, a constitution, the higher aims of politicians or the social objectives of the voting electorate – if only because the State has the monopoly of dominant force.

In societies where the economy is based primarily on a market system supported by an ethos praising its virtues, Public Economics naturally began with analyses of what came to be called 'failures' of the market, i.e., aspects where some intervention or another kind of organization and decision-making might improve performance. Phenomena such as public goods, externalities, non-discriminating monopolies, absence of futures markets, barriers to entry, poverty and distributive justice, widespread unemployment, inflation, destabilizing speculations, process preferences on the type of economic relations, effects of exchange and market relations on man and on culture and society, norm and status roles of prices and wages, many kinds of ignorance, etc., were in turn analysed with a view to helping, supporting, supplementing, correcting or straightening the market, or eventually replacing some of its elements by other defined decision-making processes or critieria. Public Economics was then supplemented by the analysis of the possibilities and limitations of non-market decision-making, in particular of political and public administrative choices – a research programme referred to as 'Public Choice'.

Born in the early 19th century and enriched by a small but steady flow of studies, Public Economics – apart from important but ill-found macroeconomics – experienced a burst of activities after the mid-1960s (when it was named), a time of rapid government growth in the West. This development was the Old Public Economics, which was superseded in the 1980s by the New Public Economics. Both engage in refined analysis of economic relationships. But the ethical part of the former was either primitive or incomplete (Pareto-optimality) or unacceptable (Social Welfare Function); in fact it was not even explicitly thought to be ethics, and this seriously impaired the practical acceptance, application and usefulness of its ideas. By contrast, the New Public Economics takes into account the relevant properties of the ethical question (a development that was influenced by the simultaneous upsurge in the analysis of social ethics in political philosophy, which itself borrowed much from economics).

[The term Public Economics, like its original ideas, seems to have been coined in France, a market economy endowed by history with a large public sector, important public firms, a civil service ethic and institutions, an ideology for some economic role for the State (from Colbert to the Plan), and bodies of both public-minded and mathematically oriented State engineers. The present author's *Fondements de l'Economie Publique, introdùction à la théorie du role économique de l'Etat* (1964) probably first used the term in print, and Leif Johansen's *Public Economics* (1965) soon followed. But, of course, Richard Musgrave's previous *Theory of Public Finance* (1959) was Public Economics, and a crucial landmark in the field. From 1966 on there came, under this name, regular meetings, an association and a journal founded by A. B. Atkinson.]

The Ethical Foundation

For Public Economics to reach its results, the problems it meets must be evaluated by ethical criteria, which are thus as important as technical and behavioural structures. Society reveals these criteria in the form of desires and rights. The traditional ideas supplied by) 'Welfare Economics' are of little help. The maximization of a Social Welfare Function depending upon individuals' preferences is in fact an ethic rejected by everybody in society because the resulting allocation concerning one person would depend upon structures of preferences of other persons in ways which are considered unacceptable. Pareto-optimality (the impossibility of improving the situation for one person without hurting some other) does not provide the unique solution and distribution which is required for practical application, and the corresponding 'efficiency' alone is of no avail – that is why so many proposals by economists are rejected by the practical men who would have to apply them. Various 'compensation schemes' have the same defects. Furthermore, anything the public sector does is bound to displease someone, so that with respect to these relevant variables the existing situation is always Pareto-optimal, and the practical problem is to choose between various solutions all having this property. Yet Pareto-optimality is a useful subordinate and partial criterion as will be seen below.

De facto, the most pervasive form of social judgement is that such specific action is 'legitimate' because it respects legitimately held or acquired rights ('legitimate', an ethical notion, is distinct from the juridical concept of 'legal'). Then, deducing from individual freedom both the legitimate ownership of oneself and thus of one's own labour, and the right to give or give up services or rights (the property of an object is a bundle of rights concerning its use) – hence the right to freely (unanimously) exchange or agree between two persons or more – there results, if previous relevant acts were legitimate, the basic legitimacy of the free market, of voluntary associations, and of the resulting allocations of rights and ownerships.

But legitimate, free and unanimous exchanges or agreements between any number of persons may fail to be directly and explicitly achieved because of a series of phenomena which are difficulties, costs or impossibilities in the realization of transactions, in the informational requirements of exchange, of bargaining, of transmitting demands and propositions (and to begin with of knowing the other parties), in the writing of contracts and in guaranteeing their implementation (through checking facts and acts and enforcement), in exclusion from the benefits of a public good or of receiving a positive externality or of creating a negative one, in relations between persons who do not exist at the same time, etc.

To implement by public means what these 'impeded' legitimate agreements *would* have decided if they had spontaneously emerged is the unavoidable ethical basis of modern Public Economics: it is unanimously desired at levels of both specific decisions and of general freedombased principles. This precludes neither a primary concern for welfare and redistribution, nor the necessity of the use of force in the implementation. On the contrary, Public Economics is concerned with welfare and redistribution because people are, and one of its main tasks is to find out what transfers direct general agreements would have produced. Secondly, private contracts are made of two parts: the voluntary unanimous agreement between the parties, and the implementation which is obligatory under the threat of public force. In the implicit contracts which establish this public ethic, the first part does not show explicitly, and there remains only the second one, compulsory implementation: hence the apparent pure obligation in public actions such as taxation or regulation.

In order to find out (or to make the public sector achieve) the content of these implicit, putative and tacit contracts, modern Public Economics draws upon theories of choice, exchange and bargaining, statistics, polls and observation of political processes, and it offers advice about those political structures or processes which would help to reveal the necessary information or achieve the right outcome (aspects of constitutions, referenda on public issues and their financing, optimal decentralization of public choices and 'levels of government', etc.). Each of these implicit contracts (called) 'liberal social contracts') determines a set of public actions and expenditures, and of taxes, which is desired by a group of citizens and violates no legitimate right of any citizen. It is such that no sub-group of the concerned persons could quit this cooperative agreement while securing to each of its members a situation he prefers, given that this person is in general influenced by what all others find their best interest to do (this last proviso differentiates this concept from the traditional one called 'the core') and if this sub-group is not itself impeded in a similar manner, etc. This condition implies Pareto-optimality with respect to the constraints which have not been abstracted from in defining the putative free agreement (the omitted constraints bear upon information, transaction, possibilities to constrain or exclude people, etc.).

We shall consider now the various elements that constitute Public Economics.

Collective Concerns and Consumption, Public Goods

The existence and analysis of collective concerns and consumption, and 'public goods', is central in Public Economics.

A 'collective concern' is something which concerns several persons or agents. Something which pleases several persons together came to be called a 'public good' for them. If it displeases them it is a 'public bad', the decrease of which is a public good for them. In particular this good can be a genuine good or service in the sense of economics, and then there is a collective consumption (either final or intermediary or both together). 'Non-rivalry' in consumption is the term sometimes used (Musgrave) to characterize the difference with 'private goods'.

A private profit-making agent can produce a public good if he can exclude the would-be beneficiaries from its benefit, so as to grant them access only in exchange for payment of a fee or price or toll. These receipts may cover the costs of producing the good and allow a profit. The producer's problem is to obtain information about the willingness to pay, since if he asks too little he may not be able to cover costs, and if he asks too much for some access he may prevent it, whereas the user would be ready to pay more than the individual specific costs he causes (which may be zero). In addition, the producer may not be able to discriminate his price sufficiently between the beneficiaries, not only because of difficulties in discerning differences (which is an information problem), but also because he may not be able to prevent them from reselling between themselves the rights to access or private goods produced thanks to the public good, or for reasons of practicability or fairness. These problems of course interfere with the quantity of the good the producer decides to create. The lack of unanimous collective agreement between the beneficiaries, in addition to exchanges between them and the producer, may prevent the latter from knowing that he can extract extra prices which would cover the extra cost of producing more, or from achieving this extraction (the extra contribution that each beneficiary is ready to give usually does not by itself cover the cost); this is a cause of underproduction of the public good. But overproduction is also possible, because the producer may attribute some of the beneficiaries' global willingness to pay which he extracts to their willingness to pay for the last units.

In addition, exclusion from the benefit of the public good may not be possible. More generally, it has costs, difficulties or inconveniences which at some point deter the producer from excluding or the consumer from demanding access to the benefit of the good. These are of the following kinds: (1) Costs to the excluder such as doors, walls, fences, screens, guards, scrambling devices for herzian waves, hiding information, suing 'trespassers', etc. (2) Costs to users by inconvenience in consumption, use or benefit, as would for instance be the case of tolls on urban streets. (3) Costs to users by co-exclusion from other services, a case to be found notably when exclusion would be achieved by excluding from a complementary consumption, an important example being exclusion from a location (on private or public space) where the collective benefit can be received. (4) In the latter cases, the producer of the public good may not have the right to exclude from these other services (without problems 3 and 4 exclusion could always be made, for instance by banishment or even killing). (5) Logical impossibility such as when the desire for the consumption requires experiencing the consumption so that exclusion destroys demand, or the related situation described below in the very important case of 'collective gifts'.

If exclusion is not possible, or is too difficult or costly, production through individual initiative does not occur. Whatever the situation of excludability, the solution is a unanimous collective agreement between the beneficiaries and the producer(s), as to the good to produce and to each beneficiary's contribution to its financing. It is right and legitimate if the concerned persons use only legitimate rights to reach and achieve the agreement. But two things may prevent its spontaneous emergence. Firstly, if exclusion from the benefit of this public good is impossible or too difficult, a beneficiary is induced not to take part in the collective agreement, so as to benefit from the good produced thanks to others without contributing (he would be a 'free rider'); the result is inefficient, and if each beneficiary does that, relies on the others and is relatively small, no quantity of the good is produced at the limit. Secondly, whatever the situation as to exclusion, the transaction and information costs necessary to reach the agreement may prevent its achievement – all the more so when the number concerned is large. In these cases, there arises an ethical duty for a public service to achieve as far as possible what these free agreements would have done. This implies both the production of the public good and paying for it in the form of taxes.

This principle indicates both what quantity of the good must be produced and what the taxes must be.

This implicit exchange implies that the good must be produced up to the point where what the beneficiaries are ready to pay for an extra unit ceases to cover the cost of the latter (Dupuit's condition). It also implies that each beneficiary must not contribute to the payment more than the monetary equivalent of its value to him, whereas their total contribution must not fall short of total cost. This is ‘benefit taxation’, but for implementation this tax can either be levied specifically in relation to this advantage (and eventually be ear-marked for the provision of this good), or be aggregated to other notional taxes paid by the person for other specific reasons, i.e., into a more general tax scheme. Furthermore, this principle is not sufficient since it only gives an upper limit for each of the taxes and a lower limit for their sum – and it does not say how the) ‘surplus’ due to the provision of this public good is allocated. The implicit agreement principle however implies that the surplus is allocated between the putatively contracting parties, the beneficiaries and the producer(s) of the good (for its primary allocation, since general economic interdependence induces further effects). Not infrequently the sole information that taxes must not exceed willingnesses to pay and must not in total amount to less than cost defines them relatively precisely, in particular when beneficiaries have alternatives to the consumption of this public good. For the general case, the levels of these taxes, or the distribution of the surplus, are determined thanks to the bargaining theory which is relevant to the situation. This theory relies on the fact that the pre-agreement allocation and distribution is a legitimate starting point from the very definition of the general ethical theory. It deduces, in general, that the surplus must be allocated in relation to the agents’ legitimate bargaining power. The latter is itself determined by the fact that the solution must not be such that a group of persons can prefer to leave the general agreement and eventually build and finance a public good for themselves. The members of this group are influenced by the choices of the others (in opposition to the usual assumption in the concept of the) ‘core’), and in particular by what the others decide to produce of the public good if these ‘dissidents’ can still benefit from it. The result thus depends very much on this structure and on the possibility of ‘exclusion’ from the benefits of the good, but the general ethical theory leads to the adoption of a solution which assumes the possibility of exclusion (i.e., which disregards its difficulties) as a principle of what the taxes and the surplus allocation must be.

The practical application of the theory to determine the right amounts of public goods and the corresponding taxes requires the estimation of agents’ willingness to pay and potential bargaining power. A whole array of various methods is available, and more or less used, to gather information about these variables (Kolm 1972–74, 1973a, 1974b). For the monetary values, knowledge of technology and production functions provide the answer when agents are firms or when the public good benefits consumers through the technical production of some more final good. These values can also be inferred from the observation of market values of consumptions which are substitute or complementary to the public good (for example private material protection for public police protection, land values or rents for environmental quality differences, wage as value of time to estimate the worth of improved transportation infrastructure, etc.). Furthermore, in a poll asking people about the value of the public good to them (or of a variation of its quantity), they have no incentive to lie if they perceive that the public good produced and what they will pay are unrelated to their answer. If the beneficiaries are numerous, the relatively small ones know that their own answer will practically not influence the quantity chosen and, therefore, their payment through this way (except, perhaps, if it is considered as representative in a small sample). This allows us to gather easily the information necessary to produce the good, but not the one to set individual taxes (we would for instance gather the answers in an anonymous way). However, empirical experiences show that, de facto, people’s answers do not differ much according to whether their payment is tied or not to their answers (Bohm 1972). The political process is also often a notable source of information on the variables under consideration. And quasi-political processes can also be set in order to help solve the problem; for instance, the right quantity of public good and corresponding taxes, compared to nothing, gain unanimity in a referendum.

Several types of social situations and psychosocial phenomena help to secure the spontaneous collective realization of public goods or, at least, the relatively truthful revelation of preferences for them. Simultaneous contributions with each contributor watching the others contribute are possible in small groups, and, even in somewhat larger ones, the recurrence of similar situations allows retaliatory threats against free riding. But the most important are social norms and ethical behaviours (which are similarly necessary for private goods through the respect for property which establishes free exchange rather than widespread theft). These norms and behavioural patterns are acquired through socialization or, eventually, selection, and they tend to act better when the individual costs are either relatively small (voting, non-polluting) or dramatic (individual or collective danger). They include truth-telling, Kantian categorical imperative, altruism, communitarian feeling, internalized or approved good citizenship, imitation, the 'helping behaviour'studied by social psychology, gratitude and return gifts, general reciprocity, etc. Economists have also devised a series of 'revelation mechanisms' where a public centre receives information from the consumers of the public good and imposes on them incentives so as to induce them to 'reveal' the information about their tastes or needs which is necessary for the efficient production of the good; such devices have been proposed by Vickrey – in a different context – Kolm, Drèze and de la Vallée Poussin, Malinvaud, Groves, Ledyard, Clarke, Tideman and Tullock, Green and Laffont, and a number of others; although some of these mechanisms might eventually find some applicability, their general efficiency still requires that the agents have some motivation of the mentioned categories, beyond exclusive restricted self-interest.

The economics of public goods is as old as that for private goods (aside from literary remarks such as those of David Hume about public goods). In Paris in 1838, when Cournot was drawing a demand curve for a private good to theorize monopoly exploitation, Jules Dupuit drew one for a public good in order to choose the socially best quantity and financing of public works. Dupuit's 'demand curve' for a public good gives the number of users for each level of a putative toll (if they could be excluded) – i.e., the number of beneficiaries who value the good at more than this level. Equivalently, it is the distribution curve of the willingnesses to pay for this benefit classified in decreasing order. Dupuit's) 'surplus', the area under this curve, is thus the sum of all these willingnesses to pay. Dupuit's rule was to implement a variation in the specifications of the good as long as the surplus for this variation exceeded the cost of implementing it. Dupuit then set out to discuss how to discover willingnesses to pay, noting in particular its correlation with capacity to pay as revealed (in part) by the evident belonging of the user to a social class.

The history of ideas then leads us through the very perceptive Italian school of public finance (Mazzola, Pantaleoni, etc.) and to Wicksell's and Lindahl's 'just taxation' propositions, both of which based, on a clear conception of joint consumption and quantity optimality, illjustified fiscal schemes. (Wicksell's global public budget chosen at unanimity – 'quasi' for practicality – violates the right of a group of citizens to receive a public good and pay the corresponding taxes even if its effects displease other citizens, as long as it does not violate their legitimate rights. As for Lindahl, his pricing at marginal willingness to pay multiplied by quantity has no more justification than many others and its formal mimic of private good optimality formula is irrelevant. See these authors' articles in Musgrave and Peacock 1958.) Later, Bowen (1943) tried to achieve the optimum through a uniform given charge plus majority voting on the amount of the good, and Samuelson derived the quantity optimality condition from a welfarist, utilitarian, ethic with free lump-sum income redistribution.

The observation that the world exhibits few 'pure' public goods, whereas collective concern is widespread, led to the analysis of the various mixtures of privateness and publicness, and of their consequences for public finance and action. A 'good' may have to be defined by several parameters, some of which are privately divided whereas others are collective concerns. In fact, a uniform quality of a private good is technically a 'public good'. Increasing returns to scale in production is due to inputs which collectively serve several units of output, and this takes us to the classical public good case when this output is divided between several users (or even measured by the number of users served). A good can be privately divided between collectivities each of which consumes it collectively (this is usual for the intermediary private commodities entering into the production of several different public goods, and an example is the case of 'local public goods' the benefit of which is limited in space). Conversely, a good can be consumed collectively by groups each of which divides it between its members (an example is that of a given space which is fully occupied successively in time by different groups of persons). Different agents can benefit more or less from a public good according to some characteristic (location is an example). Or an extra consumption may neither crowd out another one as for private goods, nor leave other consumers indifferent as is the case with pure public goods, but just decrease some quality of the situation (as does for instance congestion and relative crowding). Or, also, uniform prices are collective concerns, with the corresponding optimality formula. (A systematic analysis of these pervasive intermediary situations with optimality conditions can be found in Kolm 1969a, b.)

Collective Gifts and Public Redistribution and Transfers

A liberty-based social ethic implies that legitimately held rights and property can be legitimately transferred by gift. The most common character of benevolence is that a single person is ready to pay something in order for someone in need to receive one dollar more, but far less than one dollar. However, it is commonly the case that several persons, often many, have a disposition of this type towards the needy individual. If the sum of what people are ready to pay for this specific person to receive one dollar more exceeds one dollar, a set of such transfers will be made by free agreement. The welfare of the person helped is a public good for the givers, and this situation is a special case of the public good questions. However, this category of public good is bound to be in a particularly unfavourable situation for spontaneous realization. Firstly, it is a case where exclusion is impossible for a purely logical reason since consuming the public good is knowing the needy person's situation, so that exclusion is hiding it or keeping another in ignorance of it, and then the potential giver is no longer ready to give (he does not give to know but to improve, if he does not know he does not give to improve, but if he knows he is not excluded). Secondly, the number and dispersion of co-givers and potential receivers creates information and transaction difficulties which impair direct agreements (this aspect, though, contrary to the 'free rider' aspect, could partially be met by private charitable institutions, which would however tend to be in undersupply because they cannot be profit-seeking). These transfers are thus an essential task of the public sector. As in the general public good case, each payer must be forced to pay the corresponding optimal taxes although he prefers the whole system of these redistributive transfers to its absence.

The determination of these transfers uses the whole gamut of means described in the general public good case. In addition, an important source of global information about them consists of analysing the reasons which motivate the co-givers, since these are often cultural and held in common. Beyond the basic relief of wretchedness, some of these reasons are more subtle, yet very important and widespread.

One of them is 'fundamental insurance'. Social insurance against basic life contingencies (disease, old age, cost of children, unemployment, etc.) presently often use as much or more money than public budgets not counting them. They are mutual insurance schemes which a priori can be private and frequently are. The basic reason why they are often public involves the idea of 'fundamental insurance'. This is a putative mutual insurance against causes of hardship which happened before an effective insurance could be taken out by the person, such as proneness to disease, genetic disposition, or poor education or motivation resulting in low income in the labour market, etc. The idea is that people who happen to have such 'bad luck' or 'misfortunes' must be helped by the more ‘lucky’ or ‘fortunate’ ones – in addition to the insurance consequences of occurrences which happen later. Since insurance against these previous events (allocation of natural abilities, genes or education) cannot be effectively taken out by the existing adults, this market is missing and the public sector must supplement it.

A number of insurance markets for future contingencies are also missing for the more standard difficulties of envisioning and defining the risk (this often happens, for instance, for economic downturns and unemployment or for major natural catastrophies). This provides a reason for a second category of ‘implicit insurances’ achieved by public transfers to people incurring the specific misfortune.

More generally, transfers to people in need, for reasons of helping, solidarity or fairness, also imply some equalization of situations, and egalitarian feelings are very common in opinions about public policy actions. These must however be carefully defined, scrutinized and sorted out. Freedom is equality of basic rights. But it so happens that transfers from rich to poor, when no mention is made of the cause of the disparity, and when no disincentive indirect effect makes everybody finally worse off, has an appeal wider than it may seem, as various people approve of diverse redistribution schemes which are equivalent to it although that is not apparent (Kolm 1966, in Margolis and Guitton 1968–9). But this has an applicability limited to the distribution of income without previous legitimacy either from pure chance or from some natural resources. On the other hand, feelings of envy or jealousy are not commonly regarded as ethically defensible reasons for transfers (but equality of opportunities, a principle of wide acceptance, leads to general no-envy and no-jealousy since each person had the opportunity to choose what each other has chosen and he has preferred his own choice).

Finally, a recurrent and practical issue about public transfers and assistance is whether they should be in cash or in kind. The decision here rests with the givers who initially own the funds. The arguments are for them to consider, and if cash has the advantage of leaving the receiver free to choose what he prefers, they must be convinced of it.

Externalities

If a person’s action or situation importantly concerns another person without there being an exchange (or a chain of exchanges) between them so as to adjust their interlocking desires, there results (inefficient) ‘externality’ and a duty for the public sector to implement what this exchange would have been (from legitimate rights), were it not for the information or transaction difficulties or costs, or uncertainties about rights, which prevent its spontaneous existence. The corresponding compulsory money transfers can be either way between the creator and the receiver of the externality: for an external diseconomy it is a tax on the creator and a compensation to the receiver, or a subsidy to the creator who abstains somewhat, paid by the receiver, and for an external economy it is a payment to the creator from the receiver, or a tax on the creator, who does not create as much as he can be required to, and a payment to the receiver. (The result is Pareto-optimal but, in opposition to the Old Public Economics, ‘welfarist’, utilitarian or ‘efficiency’ view, firstly just to impose the level of the action will not do – there must be compensation; secondly, the tax on or subsidy to the producer of the externality alone will not do – it must be paid to or from the victim or beneficiary, and this even is the aim of the operation, Pareto-optimality being a secondary consequence of it; and thirdly, the reference situation defining the base of the tax or subsidy is a definite right and not any indifferently arbitrary point.)

Quite often, an external effect concerns several, or many, persons together, thus mixing externality and public good problems. Conversely, joint production of an effect exists when one cannot identify the specific producer of it (as in car pollution). These collective aspects bring in ‘free rider’ and transaction costs problems which often prevent direct agreement, thus creating the situation of externality rather than exchange. Such phenomena, along with the question of the allocation of new environmental rights emerging from scarcities created by economic growth, are the core of the problems and theories of the economics of public environment, an outgrowth of Public Economics, buoyant since the early 1970s.

Extensive studies have been devoted to a special but important case, which is also an essential social phenomenon. This is the situation where a creator of an externality puts himself by the same act in the situation of being receiver of an externality of the same kind. These are called *congestion externalities* (since this happens particularly in situations of congestion). The problem is that if someone is compensated for the external diseconomies he incurs (or pays for the external economies he creates), this may erase his having to pay for the diseconomies he produces (or what he receives for his external economies), so that the relevant transfers are not possible or are only imperfect, and in particular they cannot induce efficiency. The solution is to devote the product of the tax to improve global quality (for instance more room in the case of congestion) which is a public good the correct amount of which does not depend upon the decision of any single individual if he is relatively small enough (the financial result depends upon the basic structure of 'qualitative return to scale': Kolm 1969b, 1974a).

Rectifications

A consequence of the public sector's duty to protect rights is its duty to rectify past violations of legitimate rights. Such judgements are commonly considered by the courts, but one may have to rectify, at least in a global way, the effects of more ancient and deeper violations (given a statute of limitations provision). The resulting actions are compulsory transfers and, eventually, some specific measures like education.

The Theory of the Public Debt

The public debt is the means of making *retro-payments*, that is, payments when the payer exists later in time than the receiver: the receiver receives from the public sector which pays out of public borrowing, and the payer pays by later taxes used to redeem the public debt and meet its interest. Time introduces two kinds of constraints on the relations between persons at different dates, hence two causes of 'market failures'. Nothing can be received before it is handed out, and the individuals involved in the exchange cannot make an explicit mutual agreement; the only possible relation is forward transfer (through asset accumulation) decided by the transferer, that is, a forward gift. From its general principle, the public sector must abolish these constraints on free relations if it can. Indeed, it can make retro-payments through public debt, and it can attempt to evaluate the desires of future generations. This opens up the possibility of publicly implemented retro-buying intertemporal exchange and retro-gift. Public debt enables one to buy the earlier production of a durable commodity which yields benefits he desires (to him or to others), and it enables one to make at some date a gift which helps satisfy previously existing needs of other people. For instance one can in this manner buy durable improvements (or protection) of the environment, and also give to victims of a previous bad specific or general situation. Of course, even if this buyer or giver desires this, his payment must be compulsory – i.e., it is a tax, since when it occurs the first payment has already been made. This reason for public intervention and for public debt often intervenes with the other reasons for public intervention: the benefit taxation to finance a durable public good implies public borrowing later redeemed thanks to contributions of beneficiaries which actualize their implicit basic agreement with the beneficiaries at other dates; a global reflation through deficit finance, when it works, is paid for by the future beneficiaries of higher employment, demand and capital formation, through taxes which will redeem the debt; there are also collective retro-gifts, inter-temporal implicit – and in particular fundamental – insurances, and intertemporal allocation of the values of natural resources.

Macroeconomic Policy

Another category of market failure has such pervasive effects and implications that a collective rights-preserving unanimous agreement as to corrective action would involve a prohibitively large number of persons, so that the public sector has to intervene. Such phenomena are those which result in mass unemployment and inflation, with possible effects as to large indebtedness to foreigners or slow productivity growth. (Inflation and insufficient global demand are public 'bads'. In the case of inflation, the primary reasons are psychosocial effects which disrupt social predictability, general confidence, and the implicit social contract, due to uncertainty and volatility of relative prices; see Kolm 1984a.) The 'market failures' which cause them involve a whole array of informational limitations, the non-existence of pure market equilibria (at least of those in which no one starves), the lack of a spontaneous tendency to equilibrium of a multimarket system, the income effects of wage decreases which diminish income and employment, the general absence of futures markets which would have guided investment decisions, downward price inflexibilities due to status and norm effects of wages and prices and to average asymmetries in the optimal allocation of selling and buying efforts, monopolistic situations and collusions (in labour markets for instance), etc. Apart from some direct microeconomic income-price or employment or other policies, the corresponding corrective tools are those of macroeconomic policy; that is, arrangements between public expenditures, taxes, public debt, money supply, foreign money, through decisions about quantities or rates (rates of interest, rates of foreign exchange, and taxes).

The Right Taxation

What the public sector must do is the whole of all the specific actions described above. In particular, ethical consistency in general requires taxes to be justified by expenditures. Institutionally and practically, however, taxes can be pooled and levied more or less as a single tax or as a relatively small number of taxes. The corresponding economy of administration must be balanced against the advantages of decentralized and specialized public services financed by the logically ear-marked right taxes, regarding the budget allocated to this service, the closeness of the public management to the users and its better knowledge and awareness of their needs; the better understanding by the taxpayers of the use of their money and of the benefit they derive from it and, therefore, their greater possibility of checking the use of public funds and of controlling the public service by political means.

However, the above reasons for specific constitutive taxes imply some general structures of the global taxation faced by the individuals. A large number of specific taxes (in the sense of justified tax elements), taken as function of income, have the form of an increasing tax (often a relatively proportional one) above some exemption level. This tends to be the case for public goods which yield benefits according to some ownership or activity, for redistributive transfers due to collective gifts and in particular to fundamental insurance, for rectification compensations. The summing up of all these taxes therefore yields a progressive tax schedule, and even approximately a succession of tax 'brackets' with flat tax rates increasing from one to the next. Furthermore, collective gifts, fundamental insurance and rectification for past infringements of rights, globally conduce to a negative taxation scheme at low income levels (i.e., people whose incomes fall below a certain level receive an assistance which increases with this gap).

Public Prices, Taxes and Production

Taxes must be based on observable facts, which practically will often mean quantities or values of commodities of many possible kinds, including incomes – whether these are the right base or only proxies adopted to confront informational or management difficulties. To choose these taxes is thus equivalent to choosing the corresponding prices. Now, to choose prices is also a problem the government faces in the case of public firms or regulated industries. In addition, a standard reason why firms are public or controlled is the existence of strong increasing returns to scale, so that competitive prices would bring them into deficit, and a private monopoly with limited discriminatory power would produce inefficiencies; yet these are financially autonomous firms which must not have a permanent deficit. Therefore, the problems of choosing the socially best taxes in order to provide a public income, and that of choosing the socially best prices respecting a budget constraint, are de facto identical. This problem was extended in a general 'theory of value constraints', which are constraints on elements of budget (global or partial or ratios) and on prices. In addition, the choice of a non-linear public tariff applicable to several users is isomorphic to that of an income tax structure. Determinations of optimality conditions and structures in all these cases involved the successive works of Colson (1901–5), Divisia (1927), Ramsey (1927), Boiteux (1956), Kolm (1969), Mirrlees (1971), Diamond (1975), Atkinson and Stiglitz (1980), Guesnerie (1980) and others.

Situation of Public Economics

Public Economics is probably for many reasons the most paradoxical field of economics. It specializes in what has always been the central problem of the discipline – whether it was attacked frontally or treated in a devious, consequential and somewhat hypocritical way: what must be market, what public, and how? Yet it often works at the borderline of the profession, flirting more and more with moral philosophy, political science, organizational studies (public choice and the economics of institutions), with breakthroughs to come with psychology ('multidimensional man') and sociology. It specializes in the public sector, yet it must for this reason involve the finest analysis of the market and of its problems. It has a well-defined, specific style and flavour, yet it is hard to circumscribe rationally: for instance does it contain Macroeconomics – which comes more and more to the core of Public Economics as it relies more and more on microeconomic analyses of market failures? What is its relation to International Economics which studies markets but owes its existence to that of States? It probably contains Public Finance in scope, yet the latter's tradition has a quite different, less analytical, style; and we could go on with Public Choice, Social Choice, the theory of constitutions, 'Political Economics', the theory of bureaucracy, Welfare Economics whether theoretical or applied, the essential benefit-cost analysis, the economics of socialisms, comparative economic systems, etc. Public Economics is founded on positive views of the public economy and of the market, yet its final aim is almost always normative. It is one of the oldest fields in economics, yet it also is one of its newborns.

These distinctions, however, are interesting but not essential. The thing is to take an important problem and to find powerful tools to crack it. Public Economics' central question – to know what the public sector must do, when the markets work better, or if a hopeful 'third sector' and reciprocity relationships would be a still better possible solution – can hardly see its import challenged. As for the tools, it started with sharp economic analysis, but saw its utility impaired by ethical naiveté it is now incurring a new boom in useful results thanks to an equivalent input of social ethics; as for the future, the next threshold will probably be to work out the consequences of a much richer and more truthful account of man's motives and capacities, along with an understanding and a consideration of institutions, both meaning psychology since it is how institutions enter into an individualistic social theory: through people's heads and hearts.

Public Finance

Richard A. Musgrave

Abstract

Public finance may well be the oldest branch of economics. It concerns not only the effects of fiscal operations on the market but also principles of public sector economics, which address a distinct set of issues and are linked closely to the perspectives of political and social science. This article covers (a) expenditure on public goods and transfers, including its macroeconomic effects as analysed by the classical and the Keynesian schools, and (b) taxation, including issues of tax equity and tax efficiency, definitions of income, consumption and expenditure, and tax shifting and incidence.

Concern with public finances may well be the oldest branch of economics. Statesmen have needed advice, and writing on fiscal affairs dates back to antiquity. It concerned the scholastics of the 16th century and occupied the mercantilists of the 17th. Systematic study of the public household by the Cameralists followed, and the ‘L’impôt unique’ was a central part of Physiocrat doctrine. In England, the writings of Petty, Locke, and Hume preceded Book V of Adam Smith’s *Wealth of Nations,* the first ‘modern’ statement of the field. Thereafter, fiscal analysis followed (and in some cases led) the advances of economic science. Ricardo, Mill, the marginalists, Marshall, Pareto, and Pigou all left their stamp on the economics of public finance, not to mention the impact of Keynes and the emergence of stabilization as a goal of budget policy. But fiscal economics also added to the general body of economic analysis. Its concern is not limited to the effects of fiscal operations on the market, and market responses thereto. There remains the more basic question of why a public sector is needed and what rules should be applied to its conduct. Principles of public sector economics are required to provide the answer. These principles, to be sure, are coordinated with those of the market by the broader frame of economic welfare, but they address a distinct set of issues and, by their very nature, are linked more closely to the perspectives of political and social science.

Public Expenditures

We begin with the expenditure side of the picture, and public goods in particular. Thereafter, transfers are examined.

Public Goods

Here the basic issue is why certain goods and services have to be provided for through the budget, i.e., paid for by taxes and made available free of direct charge. Such goods and services may be produced under public or private management, e.g., government may install traffic lights itself or engage a private firm. Which is done does not matter here. The crucial point is that traffic signals are provided free of direct charge to the individual consumer when passing the intersection. Given a general presumption that consumer preferences should be met by the *quid pro quo* of the market, why should budgetary provision be chosen in the case of public goods?

A modern answer was anticipated by Hume’s early insight. Two neighbours, so he argued, might agree to drain a meadow, but no such agreement can be reached by a thousand persons, as each will try to place the burden on others (Hume 1739, p. 539). Adam Smith also examined why certain services must be provided by the Prince (Smith 1776, Book V). These included the upkeep of the court, defence, police, and minimal education for the poor. More generally, the Prince was to provide for 'those institutions and public works which, though they may be highly advantageous to a great society, are, however, of such a nature that the profit could never repay the expense to any individual' (Smith 1776, vol. 2, p. 539). The issue was joined but Hume's earlier insight had been lost. The reason why private provision will not work remained unanswered. John Stuart Mill subsequently came a bit closer. He noted that individual preferences, under certain conditions, cannot be met without common concert and legal sanction. The lighthouse illustration appeared (Mill 1848, p. 976), and the difficulty of collecting tolls for the use of its services was stressed. Market failure due to inapplicability of exclusion was thus noted, but not as yet the more basic proposition that exclusion would be inefficient (absent crowding) even if it could be applied.

The discussion took a new turn in the 1880s, when utility analysis grounded value theory on the demand side. Public no less than private services are provided to meet the preferences of individual consumers, so it was argued, and this provision through the budget may be viewed in analogy to the exchange mechanism of the market. Taxes may be viewed as price payments, offered by the consumer. Thus a voluntary exchange model of the tax-expenditure process emerged (Sax 1887; Mazzola 1890). This vision of the fiscal process was rejected at once by Wicksell (1896). While public provision should be in line with individual preferences, it could not be implemented by voluntary exchange. As Hume had recognized a century and a half before, exchange will not work in the large number case. The level of public services available to A will not be affected significantly by his own contribution. Hence A will not reveal his preference for public services. Unlike the case of private goods, where the individual must bid to obtain his share in the auctioning process of the market, the consumer will now act as a free rider. A political process of budget determination by voting, combined with a legal sanction of its enforcement, is needed so that preferences are revealed. Thus the basis was laid for the modern discussion of public choice and the voting rules by which an efficient solution may be approximated. Though the simplistic hypothesis of voluntary exchange was rejected, the exchange formulation as developed by Lindahl (1919) nevertheless had an important role to play. With any given supply of the public service available to both A and B, A's demand curve may be viewed by B as a supply curve.

Equilibrium is then reached where the vertically aggregated demand curves of A and B intersect the supply schedule for the product, i.e., where the tax prices paid by the two consumers add up to the social cost of the service. Lindahl's formulation, with its vertical addition of demands, thus anticipated a significant feature of Samuelson's later formulation.

The next phase of the development of public goods theory emerged with Pigou's analysis of externalities (1920). External costs and benefits remain unaccounted for by the market and thus call for correction by public policy. Pigou did not develop this theme in his treatise on public finance (1928), where the proper sphere of public services is defined only in general terms, calling for extension to the point where marginal social costs and benefits will be equal. However, the concept of external benefits might be extended readily to that of public goods, where externalities appear not as a by-product of internal gains but all benefits are external. Introduction of the Scandinavian model into the English-language literature followed (Musgrave 1939), but the crucial implication of public goods for efficient resource use was not drawn clearly until Samuelson's statement (1954). Whereas efficient use of resources in the provision of private goods calls for an equating of the marginal rates of substitution in production and consumption (with the latter equal for all consumers), that of public goods calls for equality of the marginal rate of substitution in production with the *sum* of the marginal rates of substitution (differing among consumers) in consumption. Lindahl's earlier exchange solution, arrived at by the vertical addition of demand curves, was compatible with this outcome; but, as shown in Samuelson's model, an efficient solution did not require the Lindahl-type determination of tax shares.

The basic difference in the two formulations should be noted. Lindahl, following Wicksell, began with a distribution of money income and then proceeded to assign efficient tax prices. This is accomplished by charging each consumer in line with his marginal evaluation and setting total supply so as to equate the sum of these charges with cost. Moreover, by postulating a just state of distribution to prevail to begin with, a requirement also advanced by Wicksell, the resulting burden distribution of tax shares would also be just. Samuelson, like Wicksell, rejected Lindahl's 'pseudo demand curves' as unrealistic. But where Wicksell proceeded to examine the process of preference revelation, Samuelson provided a more general definition of the efficient solution. Preference revelation is disregarded as the model visualizes an omniscient referee to whom preferences are known. He then establishes a utility frontier, showing various mixes of public and private goods, as well as private good distributions among individual consumers. The optimum optimorum (bliss point) on the utility frontier is then chosen on the basis of a social welfare function. The Lindahl solution becomes a special case only; but given the assumption of known preferences, there is no particular reason why it should be selected.

This more general formulation resolves the allocation and distribution aspects of the problem simultaneously, and deals with distribution in its basic welfare rather than income terms. The Lindahl model by comparison separates allocation and distribution issues. Since welfare is a function of real, not money income, it is open to the objection that the just distribution of money income cannot be determined without also setting tax prices, thus suggesting circular reasoning. However, this critique may be met by adding the determination of the voting rule (designed so as to best secure preference revelation) as a further equation to the model. Moreover, the Lindahl formulation provides a closer linkage to the real world. While tax prices cannot be seen as voluntary offers, there exists no omniscient referee to whom preferences are known. Preferences, as Wicksell noted, must be revealed through a voting process and this presumes a distribution of money income to begin with. The Lindahl price thus remains as a benchmark against which the quality of the voting process can be measured. Separation of the allocation and distribution phase of budget policy was extended subsequently to include the stabilization function as a third branch (Musgrave 1959).

Subsequent developments in the theory of public goods recognized the fact that particular goods and services may not meet the polar conditions of purely private or public goods, but fall in between. A's consumption of X may provide benefits internal to A and hence be undertaken by him. But it may also generate external benefits or costs for B, C, and D. Thus, partial provision through the budget, that is, a subsidy solution, may be called for. Or, the number of consumers may be sufficiently small to permit a bargaining solution without voting; yet there is no assurance that an efficient outcome will emerge. Moreover, it may be possible to satisfy certain needs via the provision of public or of private goods, thus permitting a choice between the two modes.

A special problem arises also from the fact that the benefits of public services may be subject to spatial limitation. The resulting distinction between 'local' and 'national' public goods provided the basis for a theory of fiscal location (*see* "▶ Local Public Finance") according to which the provision of public services should be arranged so that each jurisdiction will provide and pay for the public services the benefits of which accrue within its borders. Moreover, the spatial limitation of benefits led to the proposal (Tiebout 1956) that preference revelation may occur through 'voting by feet'. Individuals with similar public goods preferences would find it advantageous to congregate. At the same time, individuals with lower incomes will find it advantageous to congregate with higher income individuals, so as to generate an unstable distribution across jurisdictions.

The general theory of public goods has thus been extended and qualified to deal with particular situations. It should be noted, however, that all these variants assume public goods to be provided in line with the preferences of individual consumers. The theory of public goods is thus similar in its psychological underpinnings to that of private goods. The concept of communal needs or goods which the community considers meritorious offers an alternative perspective not included in the mainstream view of expenditure theory (*see* "▶ Merit Goods").

Cost-Benefit Analysis

Moving from general theory to practical application, the development of cost–benefit analysis has attempted to design an operational framework by which the appropriateness of particular expenditure projects may be evaluated and ranked. In the process, the present value of the expected benefit stream is balanced against that of its opportunity cost. For this purpose, a social discount rate has to be determined, a rate which may or may not be taken to equal that of the market. Moreover, opportunity cost is found to depend upon whether the resource withdrawal is from consumption or from capital formation. Since the income tax enters as a wedge between gross and net return, capital formation in the private sector falls short of the optimal level so that resource withdrawal from private investment carries a higher social cost than does resource withdrawal from consumption. Shadow prices are applied to measure the social cost of labour and other inputs, thus correcting for further distortions in market prices. Finally, distributional weights, based on a social welfare function, may be applied to the resulting costs and benefits. Thus, a framework is provided by which the value of alternative expenditure projects may be assessed and ranked. However, the analysis assumes that the value of the benefit stream can be determined. This involves no difficulty where the output of the public project is sold at the market, but approximations have to be used where the services are in the nature of public goods. Thus, the value of a park may be measured by the opportunity cost reflected in the visitor's travel time or by similar proxies.

Transfers

While economic analysis has focused on the provision of public goods and services, transfers have come to claim an increasing share of total spending. Aimed at correcting the distribution of income, they may be viewed as negative taxes. While resource use for the provision of public goods may be fitted into the Paretian mould of allocation efficiency, transfers pose a more difficult problem. To be sure, a theory of giving, or Pareto optimal redistribution, may be developed in the context of interpersonal utility interdependence. If the donor's satisfaction is derived from the pleasure of individual giving, giving remains a private good. But if it is derived from the welfare of others, giving assumes a social-good quality and calls for budgetary provision. Yet the outcome reflects the initial distribution of income and thus does not resolve the more basic problem of primary distribution. This transcends considerations of Pareto efficiency, and broader grounding in a theory of justice is required, be it a Lockean rule of entitlement, a utilitarian concept of maximum welfare, or a Rawlsian sense of justice as fairness. But notwithstanding this inherent link to a theory of justice, economic analysis retains a decisive role. The size of the pie is linked to its distribution, and redistribution involves an efficiency cost. The one, therefore, cannot be determined without the other.

Turning to the form in which transfers should be given, economists have traditionally argued in favour of a general income subsidy, rather than selective subsidies designed to support particular uses of income. The general subsidy will be more valuable to the recipient as it does not interfere with his choice among income uses. But various exceptions may be noted. Transferors, consenting to a transfer, may do so on condition that the income is put to specified uses. Giving may take a paternalistic form. Moreover, distributive justice may be viewed in categorical terms, applying different standards of equality to basic items than to other income uses (*see* "▶ Merit Goods"). Beyond this, the logic of optimal commodity taxation, calling for differential rates of tax on various goods and services, may also be shown to call for differential subsidy rates to be applied to various commodities.

Macroeconomic Aspects

The preceding discussion has dealt with the role of public expenditures in providing for public goods and for adjustments in distribution. In the process, the fiscal system may add to capital formation via public investment and detract therefrom via reduced capital formation in the private sector. Public finances thus have an important bearing on the rate of economic growth, a fact which has been dealt with throughout the literature, and which was central to Ricardo's critique of the public sector. Moreover, the choice between tax and loan finance becomes an instrument of intertemporal burden distribution. Since loan finance falls more heavily on capital formation, it leaves future generations with a smaller capital stock. Considerations of intergenerational equity thus permit public investment, the benefits from which accrue to future generations, to be loan financed, while calling for current services to be tax financed. This establishes the rationale for a dual budget system, with balance in the current and loan finance in the capital budget. This reasoning, in turn, calls for the inclusion of depreciation in the current budget, with corresponding debt retirement over the useful life of the asset. It should be added that inclusion of outlays in the capital budget does not require public acquisition of real assets (with its fictitious analogy to a balance sheet) but simply the creation of future benefits, including these of investment in human capital through outlays on health and education.

A quite different macro-perspective on public expenditures emerged with the Keynesian model. While the classical framework had left the budget aggregate-demand neutral, deficit and surplus finance now became a source of demand expansion and restriction. With initial emphasis on fiscal expansion (restriction) directed at increase (decrease) in public spending, tax reduction (increase) subsequently entered as an alternative way of achieving similar results. The early Keynesian model, which left money impotent and viewed fiscal policy as allpowerful, was modified in the neoclassical synthesis of the 1950s and 1960s, and attention moved to the correct mix of fiscal and monetary constraint. Moreover, the supremacy of aggregate demand controls become questionable as attention shifted from full employment to inflation. Nevertheless, aggregate demand effects of fiscal operations have remained of major concern, joining the earlier issues of allocation and distribution as a third dimension of fiscal economics.

Fiscal Politics

The preceding discussion, in line with the tradition of fiscal economics, has dealt with normative issues of expenditure policy, that is, why such expenditures are needed and how they should be designed to obtain efficient results. More recently, a new perspective has been added. Not resting on the assumption that prescription of correct policy will be followed once laid down by economic analysis, attention has turned to how public policy does in fact behave and how its behaviour is determined. In the process, emphasis has shifted from concern with market failure to focus on failure in public policy (Buchanan and Tullock 1962). Early efforts to develop a theory of public-sector behaviour had been made in a Marxist framework, viewing the state as an instrument of exploitation by the ruling class. Recent analysis proceeds in analogy to microeconomics, involving the self-interested behaviour of voters, bureaucrats and politicians. An important focus in this analysis has been the growth of the public sector, the extent to which it reflects the inherent needs of modern society as expounded in Wagner's Law (1883), or a malfunctioning of the fiscal system based on an inherent bias towards over-expansion (*see* "▶ Public Choice").

Taxation

We now turn to the tax side of the fiscal picture, beginning with the normative requirements for a good tax system.

Criteria for Equity

From Adam Smith on, students of taxation have been concerned with the qualities of a good tax system. One such requirement, traditionally ranked first, is that the tax burden should be distributed in an equitable fashion. This requirement has taken two forms, one calling for taxation in line with benefits received, and the other for taxation in line with ability to pay. Both approaches were reflected in Smith's maxim that 'the subject of every state ought to contribute towards the support of the government, as nearly as possible in proportion to their respective abilities, that is, in proportion to the revenue which they respectively enjoy under the protection of the state' (Smith 1776, vol. II, p. 310). The benefit principle has the advantage that it links the tax and expenditure side of the budget and thus relates to the theory of public goods. The Lindahl price, after all, was the benefit tax par excellence. But benefits are not readily assigned, thus leaving the benefit rule inoperative in most cases. Moreover, as noted before, fee finance, related to the level of individual consumption of public goods, interferes with their efficient provision; nor does the benefit principle admit redistributional uses of the fiscal process.

The ability to pay approach in turn has the disadvantage that it views the distribution of the tax burden (or the resulting change in the distribution of the tax income) as independent of the expenditure side of the budget. Nevertheless, this approach has received primary attention. Beginning with J.S. Mill (1848, p. 804), taxation was viewed as imposing a sacrifice and the problem was how to distribute this sacrifice in an equitable fashion. Justice requires that people in equal positions be taxed equally so as to undergo an equal sacrifice, people in unequal positions, however, are to pay unequal amounts of tax, differentiated so as to involve an equal sacrifice. Underlying this formulation was the assumption of declining, similar, and comparable marginal utility of income schedules. Subsequent refinement by Edgeworth (1897) and Pigou (1928) differentiated between equal absolute, equal proportional, and equal marginal (least total) sacrifice. Equal marginal sacrifice calls for maximum progression provided only that the utility schedule is declining. Equal absolute sacrifice calls for progressive proportional or regressive taxation, depending upon whether the elasticity of the marginal utility of income schedule falls short of, equals, or exceeds unity. No simple rule, finally, can be given for the case of proportional sacrifice. Authors such as Edgeworth and Pigou, as had Bentham (1802), opted for the equal marginal sacrifice rule, given the utilitarian premise that least total sacrifice (or a maximum level of remaining welfare) should be the goal of rational conduct. Given the further assumption of equal utility schedules, the formulation calls for a move towards equal distribution. But having drawn this basic conclusion, it is then qualified to allow for incentive effects and the resulting shrinkage in the overall level of income which is available for distribution.

The sacrifice theory of tax equity nicely fitted the framework of the 'old welfare economics', which was willing to assume inter-personal utility comparison. As this assumption was discarded in the 1930s, equal sacrifice rules became inoperative but subsequently were replaced by the hypothesis of a social welfare function, assigning marginal social utilities to various levels of income. People with equal income should still pay the same tax (the principle of horizontal equity), while differential taxation at different levels of income would be determined in line with society's view of declining social utility as income rises. Notwithstanding Arrow's demonstration that a social welfare function cannot be derived in an unambiguous fashion, such a concept is now widely used in policy evaluation, including cost-benefit analysis and the setting of optimal tax rates.

Definition of Income

Dating back to Adam Smith, the analysis of tax equity has focused on income as the index of ability to pay. While expenditures or consumption have entered as alternatives, income has received the major attention. But the definition of income for purposes of taxation is not obvious, especially not in the context of a highly complex financial and industrial economy where income may be received and used in a variety of forms. A large part of tax analysis has thus been concerned with the definition of income and its application in this complex setting.

The analysis has proceeded from the basic concept of net income (Schanz 1896; Simons 1938) as accretion to wealth or, which is the same, increase in net worth plus consumption.

On this basis, a host of specific issues are dealt with, including the treatment of unrealized gains, depreciation, interest paid, income in kind, imputed income, as well as many other items. While economists have argued for a broad and comprehensive income base which would permit the needed revenue to be obtained at lower rates, they have had only limited success. The tax base has been diluted by an expanding net of tax preferences and it remains to be seen whether a political consensus for base-broadening can be reached. The problem is complicated by the fact that not all omissions from the tax base reflect gross efforts at tax avoidance. Others may be viewed as providing incentives to secure policy objectives which may be valid on their own terms. Economists have opposed such use of 'tax expenditures', noting that the underlying policies, if valid, may be pursued more efficiently through the expenditure side of the budget, including subsidies to solicit private sector responses. More recently, the problem of tax base definition has been complicated further by the impact of inflation. With ability to pay relating to real rather than nominal income, inflation adjustments are appropriate, both with regard to the indexing of rate brackets and the measurement of capital gains and interest income.

A further central issue relates to the tax treatment of the corporation. The purist position has been that equity in taxation refers to the tax treatment of individuals, and that all income ultimately belongs to them, be it directly or via their ownership of legal persons such as corporations. From this it is concluded that corporate source income should be taxed to its owners, and not be subjected to an additional or absolute tax at the corporate level. Dividend and interest disbursement by the corporation should be taxed to the shareholder, as should undistributed earnings. For purposes of administration, shareholders' taxes on corporate source income may be withheld at the corporate level, but they would then be credited under the individual income tax. This approach, however, is rarely followed. Instead, a separate corporate tax is imposed and corporate source income if retained is allowed for but imperfectly at the individual shareholder level.

Finally, and of increasing importance, the structural problems of the income tax are complicated by international capital flows and multiple jurisdictions. Techniques have been devised to protect capital income against multiple taxation, and the question of which jurisdiction (e.g. origin or destination) is entitled to a particular tax base has been debated.

Consumption Base

While primary focus has been on the nature of income as the tax base, consumption has been considered as an alternative thereto. Hobbes (1651) argued at an early point that a person should be taxed on what he takes out of the pot (i.e. consumes) and not on what he adds (i.e. saves). Also, economists from Mill to Marshall, Pigou and Fisher, have held that the income tax involves a 'double taxation' of saving. By taxing income when saved and then taxing interest thereon, the tax differentiates unfairly against savers and in favour of consumers, and an excess burden or efficiency cost results from such tax discrimination against saving. The case for a consumption base was impeded, however, by the assumption that it would have to be applied in the form of 'in rem' taxation, i.e., through excises or general growth income taxes such as the retail sales or value added tax (*see* Kay 1987). Because of their impersonal nature, such taxes would not be acceptable on equity grounds. This objection no longer applies, as the case for the consumption base has been reformulated in the context of a personal expenditure tax (Kaldor 1955), with personal exemptions and progressive rates applicable as under the income tax.

Much recent attention has been given to the way in which a comprehensive expenditure base would be computed. Determined as cash income plus net borrowing minus net investment, consumption would be arrived at as a residual, rather than by attempting the aggregation of outlays. Determination of the expenditure base would bypass certain central difficulties of income determination (especially the treatment of postponed income, unrealized gains, and depreciation), but new problems would arise as well, and pressures for base preferences would not disappear.

Difficulties would have to be met, especially in relation to the transition from income to expenditure taxation.

There is also the question whether consumption is indeed the correct base. The expenditure tax avoids disincentive to saving and gives equal treatment to individuals who consume early and late in their lives. But preference is given to those who make gifts and leave bequests. Thus critics hold that the index of equality should be defined as equal present value of potential (not only actual) consumption. It then follows that bequests and gifts should be included in the testator's expenditure base. Also, it may be argued that the gain from saving not only consists in increased future consumption but that the holding of wealth itself carries utility, allowance for which may call for a supplementary wealth tax. Viewed as the equivalent of a wage income tax, the expenditure tax stands in uneasy contrast to the traditional view that if anything income from capital should be taxed more heavily than income from wages.

The preceding discussion of the tax base has focused on income and expenditures as the primary options. In a fuller treatment, other forms of taxation, in particular the property tax and payroll tax, would have to be considered as well. Indeed, the growth of tax structures has reflected the changing patterns of economic institutions and availability of 'tax handles'. What are good taxes for a highly developed financial economy such as the US of today were not feasible when selective property taxes provided the main revenue source under colonial conditions. Nor can the same tax rules be applied to developing countries of today. Moreover, the choice of appropriate taxes differs at the central and local levels of government, all of which renders the problem of tax structure design richer and more complex than can be accounted for here.

Efficiency Rules

An equitable distribution of the tax burden is one important attribute of a good tax structure. But it is not the only one. We now turn to the further and related issue of efficiency in taxation. As Adam Smith noted (1776, p. 310), taxes ought to be designed so 'as to take out of the pockets of the people as little as possible over and above what it brings into the public treasury of the state'. Compliance and collection costs should be minimized, but this is not all. At a more subtle level, as later discussion has shown, a given revenue should be drawn from any one taxpayer so as to impose the least welfare loss. Taxes other than lump sum taxes impose an efficiency cost, i.e., leave the taxpayer with a loss which exceeds the value of revenue which government obtains. In the extreme case, a taxpayer may be burdened while there is no revenue gain: for example, a person may cease to consume a taxed product, leaving the treasury without gain and forcing the taxpayer into a less satisfactory consumption mix. Or, imposition of an income tax may induce the taxpayer to substitute leisure for income, thereby reducing the tax base while burdening him with a less satisfactory work–leisure choice.

The measurement of deadweight loss or loss of consumer surplus as a triangle under the demand curve was anticipated by Dupuit (1844) and Jenkin (1871), and was subsequently developed by Marshall (1890, Book III, Chapter 6). Modern discussion of deadweight loss begins with Pigou's treatment of announcement effects (1928). Assuming leisure to be fixed, the optimal solution (which minimizes deadweight loss) calls for all products to be taxed at a uniform ad valorem rate, but the problem is more difficult if leisure is allowed to vary. Since leisure as such cannot be taxed, the taxation of products complementary to leisure must take its place. As first shown by Ramsey (1927), deadweight loss is minimized by imposing a set of differential ad valorem rates, such as to reduce the production of all commodities in equal proportion. After an interval of nearly fifty years, this rule then laid the basis for the theory of optimal taxation (Diamond and Mirrlees 1971). Discussed elsewhere (*see* "▶ Optimal Taxation"), it will not be expanded on here.

Further problems arise in moving from the optimal treatment of a particular taxpayer to that of the group. If the utility function of all taxpayers is assumed to be the same, no difficulty arises. But if it is allowed to differ, the ideal pattern of optimal taxation would call for the tailoring of differential rates of tax to the particular preferences of each taxpayer. Since this is impossible, a general tax formula has to be used, based on representative behaviour. This bypasses issues of horizontal equity, issues which arise precisely because behaviour patterns differ.

Shifting and Incidence

Economists have for long been aware that there exists a difference between the point at which a tax is imposed (its statutory incidence) and that at which its final incidence comes to rest. The in-between process or shifting has filled the largest chapter in the history of public finance, and by its nature as market economics has developed in close linkage to the general body of economic theory.

In the context of the Physiocratic model, only a tax on land could be productive as only land was a true source of income. The classics continued to focus on the division of output among factor shares, but the addition of capital to land and labour provided a three-factor model. This expanded model not only fitted the analytical scheme but also reflected the social structure of the times. Ricardo in particular devoted a large part of his treatise to this aspect of taxation. He agreed with the Physiocrats that a tax on rent cannot be shifted, but replaced the view of land as the basic source of income by recognition of rent as an intra-marginal return which does not affect price. A tax on wages must in the short run be borne by profits, so he held, since wages are at subsistence and cannot be reduced. But accumulation declines in the longer run, forcing a reduction in population. The same holds for a tax on necessities. Taxes on luxury products are absorbed by the payee as are taxes on profits. But the latter once more reduce accumulation, and hence the demand for labour. In the end only luxury consumption remains as a solid tax base.

This simple solution crumbled with the subsistence hypothesis. Replaced by a generalized theory of factor pricing, based on marginal products, no factor share remained immune to taxation, and tax incidence had to be viewed in the context of a general equilibrium system of competitive factor and product pricing (Walras 1874). With factor and product pricing interacting in a general equilibrium setting, a product tax might come to affect the position of households from the sources as well as from the uses side of their account, just as a tax on factor income might come to be felt from the uses as well as from the source side. Advancing in many directions, the theory of incidence came to distinguish between partial and general taxes, short and long run results, as well as outcomes in competitive and imperfect markets.

Moreover, while the classics had been concerned primarily with the distribution of the burden among factor shares, subsequent concern turned to the more complex issue of burden allocation among income groups.

Analysis of partial product taxes in terms of supply and demand curves and their elasticities were first undertaken by Jenkin (1871), developed by Marshall (1890), and extended in detail by Edgeworth (1897). As concluded later (Hicks 1947), a tax would be divided between buyers and sellers in inverse relation to the elasticity of substitution in supply and demand. As first suggested by Barone (1899) and later developed by J.R. Hicks (1939), a distinction was drawn between the income and substitution effects of a tax. As the two effects contradict each other, the net effect of an income tax on factor supply was no longer evident. Moreover, it no longer followed that a progressive tax schedule must depress work effort more than would a proportional one. The former, to be sure, involves higher marginal rates at high levels of income, and hence imposes a more severe substitution effect on such taxpayers; but the latter requires higher rates further down, so that the net effect is not evident.

While most incidence analysis has been conducted in competitive markets, attention has also been given to non-competitive conditions. Cournot (1838) early on showed that a tax on monopoly profits cannot be shifted, but later analysis dealing with other forms of market imperfection showed that profits taxes may indeed be passed on. Returning to the competitive case, analysis has focused on the incidence of profits taxes imposed on selected industries only. As Marshall (1890) had pointed out, such profits in the short run are quasi-rents so that the tax stays put; but given sufficient factor mobility, such is not the case in the longer run. A reduction in the return to capital in any particular industry eventually comes to be shared by capital at large. As capital moves from the taxed to tax-free industries, net returns are equalized. In the process, consumers and other factors may come to share part of the burden (Harberger 1974).

The emergence of neoclassical growth models (Solow 1956) soon invited a reformulation of long run incidence in the classical tradition (Krzyzaniak 1967; Feldstein 1974). Incidence under steady growth is shown to depend on savings propensities as well as the elasticities of factor supplies. Thus substitution of a tax on capital income for an equal tax on labour income will leave part of the burden on labour, even if factor supplies are inelastic, provided that the propensity to save out of capital income is higher; and capital income will bear the entire burden, even if labour supply is elastic, provided that the propensities to save are the same.

As is not infrequently the case, theory advanced more rapidly than its empirical verification. Econometric testing of incidence outcomes has been undertaken but rarely (Musgrave and Krzyzaniak 1963) and has led to controversial results. Instead, two more hypothetical approaches have been undertaken towards quantitative estimation of tax-burden distribution. One approach has relied on what seem reasonable assumptions regarding the shifting of particular taxes, which assumptions are then implemented on the basis of available income and expenditure data (Colm and Tarasov 1940; Pechman and Okner 1974). The other involves simulation of a general equilibrium model, reflecting the observed structure of the economy. This model is then made to respond to the introduction of particular taxes (Shoven and Whalley 1984), and the resulting changes in household positions are observed. The former approach has the advantage that the implications of various shifting hypotheses can be tested, but it fails to allow for second round effects. The latter has the advantage of accounting for a full sequence of adjustments and includes deadweight losses in the burden estimation, but it has the disadvantage that the result are drawn from the premise of perfectly competitive markets. In comparing the two, much depends on the weight of first round effects.

Public Goods

Agnar Sandmo

Abstract

This article provides a mathematical and diagrammatic exposition of the theory of public goods as originally formulated by Paul Samuelson. It describes the extension of the model to take account of the costs of distortionary taxation, and discusses the concept of the marginal cost of public funds. Different types of public goods (such as mixed goods and local and global public goods) are discussed before a survey of the incentive problems related to preference revelation.

The development by Paul Samuelson (1954, 1955) of the modern theory of public goods must be counted as one of the major breakthroughs in the theory of public finance. In two very short papers Samuelson posed and partly solved the central problems in the normative theory of public expenditure:

(a) How can one define analytically goods that are consumed collectively, that is, for which there is no meaningful distinction between individual and collective consumption?
(b) How can one characterize an optimal allocation of resources to the production of such goods?
(c) What can be said about the design of an efficient and just tax system which will finance the expenditures of the public sector?

None of these questions was entirely new to the literature of public finance. Indeed, more than 250 years ago David Hume (1739) noted that there were tasks which, although unprofitable to perform for any single individual, would yet be profitable for society as a whole, and which could therefore only be performed through collective action. The theme was later taken up by Hume's friend Adam Smith, who maintained that one of the duties of the state consisted in

> erecting and maintaining certain publick works and certain publick institutions, which it can never be for the interest of any individual or small number of individuals, to erect and maintain; because the profit would never repay the expense to any individual or small number of individuals, though it may frequently do much more than repay it to a great society. (Smith 1776, pp. 687–8)

Apart from this insight, however, the progress made over the next centuries, certainly with regard to problems (a) and (*b*), was rather modest. From the point of view of the history of ideas, this is hardly surprising. What is required is a satisfactory theory of market failure. But this presupposes a clear understanding of the optimality properties of the market allocation of resources, which was not established until the modern development of Paretian welfare economics in the late 1930s. More was undoubtedly achieved with respect to problem (*c*), reflecting the fact that problems of tax incidence had been a central area of theoretical analysis ever since the time of the classical economists, and that criteria of just taxation had developed independently of any analysis of the expenditure side of the public budget. Still, Samuelson's formulation was in every respect a great leap forward, presenting an integrated solution to all three problems, and determining the research agenda for the years to come. It is therefore natural to begin by setting out the basic elements of his model.

In a short article it is of course impossible to do justice to the large literature in this field. For more comprehensive surveys the reader is referred to the textbooks by Atkinson and Stiglitz (1980, lectures 16–17) and Myles (1995, ch. 9), and the article by Oakland (1987).

The Samuelson Model

The aim of the model is to derive conditions for optimal resource allocation in an economy in which there are two types of goods, private and public. It is worth emphasizing that these terms do not prejudge the respective tasks of the private and public sectors; the analysis at this stage is institution-free and can best be considered as representing the problems of a planner who knows the production possibilities of the economy, the preferences of the consumers and his or her own ethical values. The definition of the two types of goods is technological, not institutional.

The nature of the two types of goods is defined by the equations which give the relationship between individual and aggregate consumption. For private goods the total quantity consumed is equal to the sum of the quantities consumed by the individuals, so that

$$x_j = \sum_{i=1}^{I} x_j^i, (j = 0, \ldots, J) \qquad (1)$$

where the superscript refers to individuals and the subscript to commodities. For public goods the corresponding relationship is one of *equality* between individual and total consumption, namely

$$x_k = x^i_k, (i = 1, \ldots, I; k = J + 1, \ldots, J + K). \tag{2}$$

Individual preferences, represented by utility functions, are then defined over the quantities consumed of private and public goods, so that we can write the utility of individual *i* as

$$\begin{aligned} U^i &= U^i\left(x^i_0, \ldots, x^i_J, x^i_{J+1}, \ldots, x^i_{J+K}\right) \\ &= U^i\left(x^i_0, \ldots, x^i_J, x_{J+1}, \ldots, x_{J+K}\right), (i = 1, \ldots, I). \end{aligned} \tag{3}$$

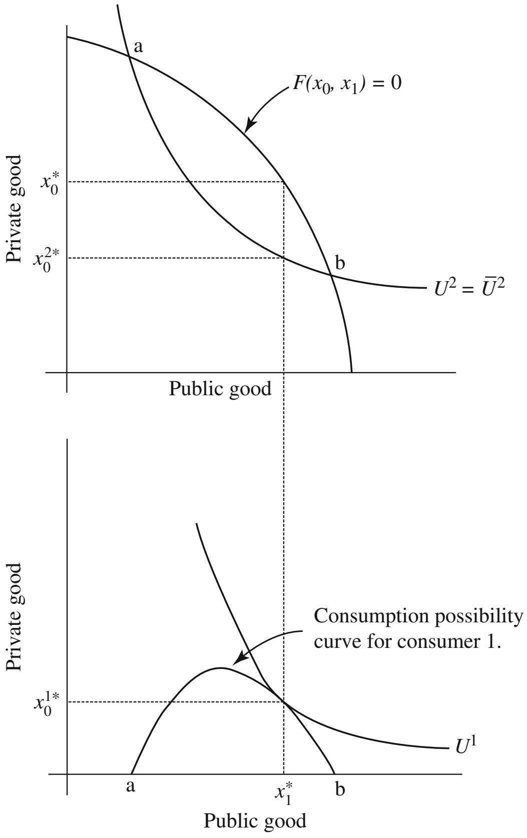
The definition (2) has given rise to some confusion and controversy. Are there actually any goods which can be described by this definition? The usual answer is that there are some cases of 'pure' public goods, like national defence, which can indeed be so described; in such cases consumer benefits are directly related to the total availability of the good in question, and the consumption benefits of any one individual do not depend on the benefits enjoyed by others. This property of public goods is usually referred to as non-rivalry in consumption; given the supply of the good in question, the consumption possibilities of one individual do not depend on the quantities consumed by others as they do in the case of private goods. However, many goods that one naturally thinks of as public turn out on closer inspection to have elements of rivalry. A road may satisfy the definition of a public good as long as volume of traffic is low, but with higher density and consequent congestion this will no longer be the case. Accordingly, several studies have been devoted to the analysis of 'impure' public goods, combining in some way the properties of private and public goods in the original Samuelson definition; we shall return to this below.

It should be observed, however, that the Samuelson formulation does not assume that the *benefits* derived from the supply of the public good are the same for all, even though a*vailabilities* are the same. Neither does it assume that the benefits from public goods are independent of the quantities consumed of private goods. And the elements of rivalry in the road congestion example may be captured by introducing externalities in the consumption of a private good – car use – whose benefits depend on the supply of a public good – the road. Thus, the original Samuelson formulation offers great flexibility of interpretation, and we have been provided with an answer to the first of the main problems noted above.

We now turn to the problem of optimality of resource allocation and begin by characterizing a Pareto optimum for this kind of economy. Since the interesting special features of the model are on the consumption side only, we assume that the conditions for efficient production are satisfied, so that the production possibilities for the economy can be summarized in the transformation or production possibility equation

$$F(x_0, \ldots, x_J, x_{J+1}, \ldots, x_{J+K}) = 0. \tag{4}$$

The problems of Pareto optimality may now be formulated as follows: of all allocations satisfying Eq. 4, find the allocation which maximizes utility for consumer 1, given arbitrary but feasible utility levels for all other consumers. As shown by Samuelson (1955), the solution can be given an instructive graphical solution in the two-dimensional case. We therefore begin with the case where there are two consumers and one private and one public good. In the upper panel of Fig. 1 we have drawn the production possibility curve as well as an indifference curve corresponding to the fixed level of utility for consumer 2; since the two curves intersect, there are obviously a number of allocations which satisfy these two constraints. In the lower panel the curve as shows the consumption possibilities for consumer 1, the points a and b corresponding to the points of intersection in the upper panel. For any point on U^2 between a and b, it must be the case that the two individuals consume the same amount of the public good, while consumer 1's private good consumption is equal to the vertical difference between the production possibility curve and consumer 2's indifference curve. The best allocation from 1's point of view is then given by the



Public Goods, Fig. 1 Pareto optimality with one private and one public good

tangency between his indifference curve and the consumption possibility curve in the lower panel. This determines the optimum supply of the public good $\left(x_1^*\right)$ and consumer 1's consumption of the private good $\left(x_0^{1*}\right)$ as well as the consumption of consumer 2 $\left(x_0^{2*}\right)$.

The slope of the consumption possibility curve must of course be equal to the difference of the slopes of the two curves from which it is derived. The tangency point can therefore be characterized in terms of marginal rates of substitution and transformation as

$$\mathrm{MRS}^1 = \mathrm{MRT} - \mathrm{MRS}^2, \text{or } \mathrm{MRS}^1 + \mathrm{MRS}^2 = \mathrm{MRT}.$$

In more precise mathematical terms this condition can be rewritten (if we let subscripts denote partial derivatives) as

$$\frac{U_1^1}{U_0^1} + \frac{U_1^2}{U_0^2} = \frac{F_1}{F_0}. \qquad (5)$$

In words: the sum of the marginal rates of substitution should be equal to the marginal rate of transformation between the public and the private good. Or, since the private good may be taken as a numeraire commodity, the sum of the marginal willingness to pay for the public good should be equal to the marginal cost of production. The intuition should be clear: an extra unit of supply benefits both consumers simultaneously; to find the total marginal benefit we have to take the sum of the marginal benefits accruing to all consumers. Problem (2) has been solved.

The mathematical derivation of the corresponding condition in the general case need not occupy us here. To extend the analysis to more than two consumers, we have only to add more terms on the left-hand side of (5). An increase in the number of public goods simply requires us to introduce similar conditions for every such good. To generalize to an arbitrary number of private goods, we note that for any given allocation of public goods, the allocation of private goods should be a Pareto optimum relative to this, so that the usual marginal conditions must hold. This gives us two sets of first order conditions for Pareto optimality, namely:

$$\frac{U_j^i}{U_0^i} = \frac{F_j}{F_0}, \ (i = 1, \ldots, I, J = 1, \ldots, J) \qquad (6)$$

$$\sum_{i=1}^{I} \frac{U_k^i}{U_0^i} = \frac{F_k}{F_0}, \ (k = J+1, \ldots, J+K). \qquad (7)$$

In the two-dimensional case the first order conditions could be taken to describe a true maximum because the diagrams introduced the required convexity–concavity conditions. In the more general case one has to assume quasi-concavity of the utility functions as well as convexity of the transformation surface for the second order conditions to be satisfied.

There is of course an element of arbitrariness in the concept of Pareto optimality, corresponding to the arbitrary location of consumer 2's indifference curve in Fig. 1. The model can be closed by assuming the existence of a social welfare function, and the usual assumption is that this is of the Bergson-Samuelson type, where the arguments of the function are the individual utility levels. Maximizing the welfare function $W(U^1, \ldots, U^I)$ gives as the optimality conditions first (6) and (7) – since a welfare optimum must be a Pareto optimum – and then a set of conditions for optimal distribution of consumption between individuals. These can be written as

$$W_i U_0^i = W_h U_0^h, \; (i, h = 1, \ldots, I). \qquad (8)$$

The marginal social utility of consumption should be the same for all. (Note that although the conditions as stated here refer to the consumption of private good 0, they can be converted, by using conditions (6), to express the equality of the marginal social utility of consumption in terms of any private good.)

Suppose now that private goods are allocated through a system of perfectly competitive markets, and that the allocation of resources to public goods also satisfies the efficiency conditions (7) as the result of some decision procedure which is yet to be specified. Imagine further that at least part of the provision of public goods is undertaken by the public sector, and that taxes are needed to finance this. What is the ideal tax system for this purpose? We wish the tax system to satisfy conditions (8), but these are conditional on the remaining first-order conditions being satisfied. Under competitive conditions the marginal rates of substitution will be equal to consumer prices, if we take commodity 0 to be the numeraire good, while marginal rates of transformation will correspond to producer prices. Thus, conditions (6) will be satisfied in a competitive economy provided that consumer prices are equal to producer prices. But this means that there must be no distortionary taxation; the only taxes that are consistent with a fully optimal solution are lump-sum taxes in amounts independent of all components of demand and supply for consumers and firms. This insight is of course well known from the standard competitive model with private goods only, but it is worth restating in the present context as the answer to problem (*c*).

This exposition of the basic elements of the Samuelson model can be used to put his contribution into historical perspective. Earlier writers on public finance, for example Mazzola (1890), Sax (1924) and Pigou (1928), did in fact apply marginal utility theory to the problem of the optimal supply of public goods, emphasizing the optimality rule that marginal benefit at the optimum should be equal to marginal cost. They failed, however, to develop a definition of public goods that could be used to characterize the difference between such goods and private goods. For the same reason they were also vague about the nature of the marginal benefit and how to measure it in the absence of market prices. Finally, although there is much interesting discussion by the older writers of the ability to pay and benefit theories of taxation, the efficiency aspect of taxation played a very minor part in their writings, and so they were unable to face the basic problem of how to reconcile the objectives of a just distribution and economic efficiency. With the Samuelson formulation all these issues had been clarified, and the foundation had been laid for further progress.

Distortionary Taxation

The above optimality rules hold for the case where taxation is non-distortionary, that is, where taxes are imposed to raise revenue and to redistribute incomes without disturbing the efficiency properties of the price mechanism. For a variety of reasons such taxes are hardly feasible, and it is interesting to consider the modifications that will have to be made if taxes are distortionary. Pigou (1928) argued that the cost of tax distortions should be taken into account in balancing the costs and benefits of public goods supply:

> Where there is indirect damage, it ought to be added to the direct loss of satisfaction involved in the withdrawal of the marginal unit of resources by taxation, before this is balanced against the satisfaction yielded by the marginal expenditure. (Pigou 1928, p. 34)

As pointed out by Atkinson and Stem (1974), however, this argument is not necessarily correct. Their analysis is an interesting exercise in the theory of the second best.

To abstract from problems of redistribution, consider the case where all individuals are identical. There are two private goods, numbered 0 and 1, and one public good, identified as commodity 2. The representative consumer maximizes his or her utility function $U(x_0, x_1, x_2)$ subject to the budget constraint

$$x_0 + P_1 x_1 = 0. \tag{9}$$

Thus, there is no lump-sum income, and commodity 0 serves as the numeraire.

Given the optimum of the consumer, the government maximizes the sum of the utility functions (a special case of the welfare function in the previous section) subject to the constraint that the resource cost of public goods supply equals the tax revenue. Thus, the government maximizes $IU(x_0, x_{1;}\, x_2)$ subject to

$$It_1 x_1 = p_2 x_2. \tag{10}$$

Here I is as before the number of consumers, t_1 is the tax per unit of commodity 1 such that $P_1 = p_1 + t_1$. The small *p's* denote producer prices, which for convenience are taken to be constant, corresponding to constant unit costs of production in terms of the numeraire. The government determines t_1 and x_2 simultaneously.

The analytical details of the model need not concern us here. To understand the result, one should note that from the formulation of the consumer's problem it follows that demand for the taxed good depends on the supply of the public good, so that the demand function can be written as $x_1 = x_1\,(P_1, x_2)$. Thus, when the supply of the public good is increased, there will be two effects on the demand for private goods. One is the effect via increased availability of the public good, another is the price effect via increased taxation. It can be shown that the condition corresponding to the Samuelson Eq. 7 in this case becomes

$$\sum_i \mathrm{MRS}^i = \frac{p_2 - t_1 I(\partial x1/\partial x_2)}{1 + (t_1/x_1)(\partial x_1/\partial t_1)}. \tag{11}$$

If there is no distortionary taxation, the right-hand side becomes simply p_2, which is the marginal rate of transformation, and we are back to the original Samuelson case. An increase in the tax rate lowers the demand for the taxed good, and the corresponding term in the denominator shows that this 'blows up' the cost of the public good; this is the effect alluded to by Pigou. On the other hand, the additional term in the numerator can in principle be of either sign and may therefore reverse Pigou's conclusions. Suppose that $\partial x_1/\partial x_2$ is positive, meaning that increased supply of the public good increases the demand for the taxed good. Then the relevant social marginal cost of the public good may in fact be lower than the pure resource cost. The point is that in this case the effect of the public good on the demand for the private good serves to counteract the tax effect. The commodity tax is distortionary because it lowers consumption and production of the taxed good. If an increase of the amount of the public good serves to push the quantity of the taxed good back towards its first best optimal level, this could lower the economic cost of production.

This analysis has inspired a considerable literature about the concept of the *marginal cost of public funds* (MCF). To start from the insight provided by the formula (11), it has been suggested that practical calculations of the optimal amount of public expenditure should be based on the formula

$$\sum \mathrm{MRS}^i = \mathrm{MCF} \cdot \mathrm{MC},$$

where MC corresponds to p_2 and the presumption is that MCF >1. The use of the MCF for practical cost-benefit analysis of public goods provision – one of the more important applications of the pure theory of public goods – would therefore tend to depress the provision of public goods below the level indicated by the Samuelson rule.

This conclusion may be disputed, however. First, it is not clear that Eq. 11 supports the hypothesis that the marginal cost of public funds exceeds 1. Even if we assume, which seems reasonable, that the tax elasticity is negative, complementarity between private and public goods ($\partial x_1 / \partial x_2 > 0$) might lead the right-hand side of (11) to become less than p_2. However, since the sign and magnitude of the complementarity term must be expected to differ between different types of public sector projects, there is a good case for considering this term to be project specific and therefore not to include it in a general measure of the cost of distortionary tax finance. In this view, it is the tax elasticity of demand that is important for the MCF.

Second, there is one feature of the Atkinson-Stern analysis which calls for particular caution in practical application. This is the assumption that the government optimizes with respect to both public goods supply and the tax rate. In principle, therefore, their results are valid only for an optimal tax system, although it can be shown that the formal expression for the MCF is the same also for a non-optimal tax system (see, for example, Sandmo 1998). More importantly, however, in the more realistic case where there are many tax rates which have not been chosen optimally, there is no reason to expect that the MCF will be the same for all sources of tax finance. It will therefore be misleading to speak about the marginal cost of public funds, as if it were a general characteristic of the whole complex system of direct and indirect tax rates.

Third, in order to focus on the efficiency aspects of the problem, Atkinson and Stern made the assumption that all consumers are identical. But one of the reasons why we have distortionary taxation is that they are not, and that governments try to achieve some measure of redistribution through the design of the tax system. As shown by Sandmo (1998), an explicit modelling that takes account of the redistributive objective leads to a measure of the marginal cost of public funds where the efficiency loss from taxation may, depending on the distributional preferences embedded in the government's policies, be partly or wholly offset by distributive gains.

Types of Public Good

In line with the original Samuelson formulation we have so far limited the discussion to pure public consumption goods. Various alternative formulations have been discussed in the literature, and we shall briefly discuss some of these.

We have already observed that many consumption goods that may be classified as public turn out also to have important elements of 'privateness'. This has two aspects. In the first case it may be argued that a public good like a national park cannot really be enjoyed by the individual without expenditure on private goods such as hiking equipment, and that even such an apparently clear case of a public good should be analysed as a mixed case of a private and a public good. To some extent this argument is based on a misunderstanding of the theory. There is no presumption that the benefit that an individual derives from the availability of a public good be independent of his or her consumption of private goods. Still, it may sometimes be useful to model the interaction between private and public goods consumption in a more explicit manner than is done in the standard formulation. One way this can be done is to take as the point of departure the consumption technology approach and assume that there are some final goods such as road trips and nature hikes that are intrinsically private but that are produced by the individual consumer by means of private and public goods inputs. The second aspect of mixed goods is that the benefits enjoyed by any one individual may depend on the consumption of others, as in the cases of a crowded road or a congested national park. This aspect, too, may be handled by the consumption technology approach by letting other people's consumption of complementary private goods enter every individual's production function for the final good in question. This would be a special case of the Samuelson formulation when in addition it is assumed that some private goods create externalities in consumption. Thus, the advantage of the consumption technology approach to the theory of public goods lies not in greater generality, but in a formulation that captures in a more intuitive fashion a natural way of thinking about public goods. An additional advantage is that the theory becomes more closely related to the practice of cost-benefit analysis, where willingness to pay is typically computed not by observing preferences directly, but by calculating the private cost reductions that would follow from an increase in the provision of a public good. The theory is further elaborated in Sandmo (1973); for an alternative formulation of similar ideas see Bradford and Hildebrandt (1977).

Not all public goods are naturally analysed as consumption goods. One of the classical examples, the lighthouse, is more easily interpreted as a producer good or a factor of production. Public factors of production were first introduced into the theoretical literature by Kaizuka (1965), who derives the efficiency conditions analogous to Samuelson's for the production case. Sandmo (1972) shows how the formulation can be used to derive shadow prices for such goods when the private sector is competitive.

The Samuelson formulation implies that the availability of any public good is the same for all individuals and independent of their decisions about private goods consumption – although, as we have noted, the benefit is not. This ignores the fact that many public goods are available only to individuals residing in a particular location, and that an individual may therefore select the amount available of the public good by changing his or her place of residence. This was first pointed out by Tiebout (1956) in a paper which has since given rise to a rich literature on the important topic of local public goods and, more generally, local public finance. We shall return below to the demand-revealing aspects of mobility between communities. But it is worth noting here that, although the original application of the basic idea was to individual choice among residential communities, there are possibilities of application to other interesting areas as well. In the labour market, workers' choice among firms might be affected by public good aspects of the working environment which are specific to the individual firm. Following Buchanan (1965), 'clubs' has become the generic term for voluntary associations of individuals whose purpose is to provide the members with a public good. Internationally, country-specific public goods might influence the pattern of international migration; in this perspective, almost all public goods would be local, and the original formulation becomes a special case characterized by geographical immobility of the population. For surveys of the theory of clubs and local public goods the reader is referred to Rubinfeld (1987) and Scotchmer (2002).

At the other end of the scale from local public goods are global public goods, goods that provide benefits to the whole of the world's population. Examples of such goods are international security, global environmental quality and scientific knowledge. One might perhaps think that in this case the theory is directly applicable, since the complications associated with geographical mobility are ruled out by assumption. On the other hand, additional problems arise because the world is not one jurisdiction but composed of a number of independent nation-states. In the original Samuelson formulation, the economy is at its production possibility frontier; this is evidently a strong assumption even for a national economy, and it becomes even more unrealistic when applied to the world as a whole. Moreover, Samuelson assumed redistribution in the form of individualized lump-sum taxes and transfers; this also is an assumption which is much farther from reality when considered in a global context. Even the assumption of redistribution via progressive taxation, which is a more realistic description of national redistribution policy, is far from the economic realities of the international community of countries.

It can be shown that the problems of global production efficiency and redistribution are in fact interrelated, as one would in fact expect on the basis of the theory of the second best; see Sandmo (2003). If one takes the viewpoint of global welfare maximization and assumes that there are perfect lump-sum transfers both within and between countries, the Samuelson optimality conditions must hold for the world as a whole. In particular, there will be global production efficiency, and the social marginal utility of income must be the same for all individuals. However, if for some reason the international transfers are not made, then production efficiency is in general not desirable. If one assumes that the global welfare function displays inequality aversion, poor countries should not be required to contribute as much to the production of global public goods as their comparative advantage would otherwise call for. But the model also points to a serious problem of incentives, because each country, in deciding how much to contribute to the production of global public goods, finds itself in a strategic situation similar to that of the single individual in the nation state, who has an incentive to be a free rider on the contributions of others (see below). At least if one assumes that national governments are motivated by a fairly narrow concept of national self-interest, there is likely to be an under-supply of global public goods.

Equilibria with Public Goods

We have concentrated on the theory of public goods as an extension of welfare economics; the central question has been how to characterize optimal or efficient allocations in economies with public goods. But just as in the case of private goods it is interesting to go on from there to consider the equilibrium allocations that would follow from particular institutional arrangements in the economy and to compare these with the optimality conditions. Thus, the theory of public goods ought to be positive as well as normative, a view emphasized strongly in the influential contributions by Buchanan (for example, 1968).

The first clear formulation of a theory of public expenditure which can be given a positive interpretation was presented by Erik Lindahl (1919), who in turn was inspired by Wicksell (1896); an important modem exposition is that of Johansen (1963). In this formulation, individuals bargain over the level of public goods supply simultaneously with the distribution of the cost between them. The bargaining equilibrium is Pareto optimal, implying that the efficiency conditions (7) are satisfied. In addition, each individual pays a price in terms of private goods which is equal to his or her marginal willingness to pay. Formally, let π^i_{J+k} be the price which individual i pays for public good k, and let p_{J+k} be the producer price or marginal cost. Then the Lindahl equilibrium will be characterized by the condition

$$\sum_i \pi^i_{J+k} = p_{J+k}, (k = 1, \ldots, K). \tag{12}$$

Thus, at first glance the concept of a Lindahl equilibrium seems to establish an analogue to competitive markets for private goods with the interesting difference that prices should differ from one individual to another, depending on their marginal willingness to pay. This also ties in with older notions of the benefit theory of taxation, according to which taxes were seen as payments for public goods, to be levied in accordance with the benefits which each individual derived from them.

At the technical level it may be noted that there is an interesting ‘duality’ between the definitions of private and public goods on the one hand and the properties of equilibrium prices on the other. In terms of quantities, for private goods the sum of individual quantities consumed a*dds up* to the quantity produced, while for public goods individual consumption *equals* aggregate production. In terms of prices, on the other hand, for private goods each consumer price *equals* the producer price, while for public goods individualized consumer prices a*dd up* to the producer price.

There is, however, one crucial difference between a Lindahl equilibrium and a competitive equilibrium for private goods. With private goods, individuals facing given prices have clear incentives to reveal their true preferences by equating their marginal rates of substitution to relative prices. Without paying, the individual is excluded from enjoying the benefits of consumption. With public goods this no longer holds. Because individuals have the same quantity of public goods available to them whether they pay or not, they have an incentive to misrepresent their preferences and be free-riders on the supply paid for by others. Moreover, this problem is likely to be particularly severe when the number of individuals is large, since an individual contribution will then make little difference to the total supply. The connection between Lindahl equilibria and the game theoretic concept of the core was discussed by Foley (1970); see also the survey by Milleron (1972).

The equilibrium of the Lindahl model is not compatible with individual incentives to reveal preferences truthfully; for this reason Samuelson (1969) has referred to the individual Lindahl prices as pseudo-prices and to the equilibrium as a pseudo-equilibrium. In this case one would conjecture that, because all individuals have the same incentives to understate their true marginal willingness to pay, the Lindahl mechanism would result in equilibrium levels of public goods supply which would be too low relative to the optimum. But there is really no need to associate the problem of preference revelation with this procedure alone; as another extreme, one might think of the case where individuals are asked to state their preferences on the assumption that the cost to them is completely independent of their stated willingness to pay, but there is a positive association between this and the quantity supplied. Then there will be incentives to exaggerate the willingness to pay and a consequent tendency towards oversupply. Thus, the general problem which arises is how to design a mechanism that will allow the decision-maker to implement the efficiency condition.

Various solutions to this problem have been discussed in the literature. The most practically oriented solution is that of cost-benefit analysis, which takes as its point of departure that people's preferences for public goods are revealed in the market through their demands for complementary private goods (see above). But in theoretical terms it has been shown that this will be true only on certain rather restrictive assumptions about technology and preferences. Another solution is represented in the literature on local public goods, where it has been suggested that people reveal their preferences for public goods by moving to the community offering them their most preferred combination of taxes and public goods. But whether this process will result in an optimum satisfying the efficiency conditions must clearly depend first on how the supply of public goods is determined within each community and second on whether there are enough communities to satisfy the variations of preferences in the population as a whole. Thus, in general, observation neither of the consumption of private goods nor of individuals' mobility between local communities provides reliable information on preferences.

Presumably as a response to the problem of market failure, decisions on public goods supply are largely made by political processes. In a democracy, the natural decision-making process to study is that of voting, and there is by now a substantial literature on this. Most of this is concerned with the stylized situation where public goods supply is determined by majority voting with the consumers themselves being the voters; thus, 'direct democracy' is assumed. The first paper in this area was that of Bowen (1943), who also considered the question of when a voting equilibrium would be Pareto optimal. Later contributions have emphasized that very restrictive assumptions on preferences are sometimes required for a voting equilibrium to exist, and these – like the so-called single-peakedness assumption – are not always attractive in the public goods context. Nevertheless, voting models have become quite popular in descriptive analyses of public goods decisions, particularly at the local government level.

There has also been a great deal of interest in studying planning procedures whereby individuals find it in their own interest to reveal truthfully their preferences for public goods. The first discussion of such a procedure – although in a somewhat different context – was that of Vickrey (1961), but the more recent developments are based on the work of Clarke (1971) and Groves (1973). It is shown there that truthful preference revelation will result if individuals pay a tax on the marginal unit demanded of the public good which is equal to the difference between the marginal cost and the sum of the marginal benefits received by all other individuals. These procedures are of great theoretical interest, perhaps mainly because they clarify the nature of the free-rider problem. However, at present they seem rather far from the state where they could be implemented in practical situations; they would probably be administratively costly to operate, and they also make heavy demands on individual consumers' ability to understand and participate in the process. For surveys of this area see Tulkens (1978) and Laffont (1987).

Doubts have occasionally been voiced on whether the free-rider problem has been given too much prominence in the theoretical literature. Johansen (1977) has argued that there is no clear evidence that this is seen as a major problem in practical public sector decision-making, and suggests that individuals are much more likely to reveal their true willingness to pay than the literature indicates. This is so, he argues, both because truthfulness is a strong social norm and because it is a simple strategy that does not rely on complicated strategic considerations. There is also some empirical evidence from experimental situations to suggest that the revealed willingness to pay is not very sensitive to the associated method of cost distribution; see Bohm (1972).

The point of view taken in most of the literature considered here is that the incentive revelation problem requires decisions on public goods supply to be taken by some governmental body. However, starting with Olson (1965), there has emerged a literature on the voluntary provision of public goods. This literature is perhaps most naturally interpreted as concerned with relatively small groups, in which the incentive to free ride is limited, and not with public goods provision on a national scale. In the framework of this theory, as formulated for example by Bergstrom et al. (1986), the decision to contribute to a public good is formulated in the standard framework of consumer demand theory. Consumers allocate their incomes between private goods and contributions to public goods, which are made under assumption that the contributions of all other consumers are taken as given, and one can then study the properties of the resulting Nash equilibrium. Particular attention has been given to the effect on contributions of a redistribution of income; as first shown by Warr (1983), under some assumptions this will change individual contributions in such a way that the aggregate supply of the public good is unaffected.

Perspectives

The Samuelson theory of public goods has been of decisive influence for the theory of public expenditure, which was developed in a number of directions during the second half of the 20th century. The extensions and reinterpretations of the original theory to the cases of public factors of production, mixed (public-private) goods and local and global public goods have significantly increased the applicability of the theory. Much has also been achieved to enrich our understanding of the incentive problems that arise in actual allocation mechanisms for public goods supply; however, it is probably fair to say that the normative theory of public goods has become much more satisfactory from a theoretical point of view than the positive theory. This state of affairs may in fact be unavoidable. The normative theory has little need to model institutional details and can thus be given a more unified appearance. A positive theory, on the other hand, must to a greater extent model economic and political institutions, and there is no single institution corresponding to the competitive market in the private goods case which can serve as a unifying benchmark for the analysis. Moreover, development of the positive theory of public goods must necessarily be closely tied to the progress of the positive theory of public sector behaviour in general; it will be interesting to see whether this theory can be developed to provide descriptive models of public goods provision that are both realistic and reasonably simple.

Public Goods Experiments

Rachel T. A. Croson

Abstract

Economic theory often cites the existence of goods with externalities as justification for government intervention, either as taxation to fund goods with positive externalities which would otherwise be underprovided, or as regulation on goods with negative externalities which would otherwise be overprovided. A series of experiments tests these predictions of under- or over-provision. This article describes the landscape of public goods experiments, identifying similarities and differences between them and summarizing the broad findings.

Since the vivid description of the Prisoner's Dilemma game and the accompanying tension between self-interest and efficiency, economists, political scientists, psychologists, sociologists and others have wondered about how individuals resolve these conflicting motivations. Many have investigated this question by experimentally examining behaviour when individual interest and group interest conflict. This research goes under different names – for e7xample, social dilemmas in psychology, commons dilemmas in political science and public goods problems in economics.

This article does not provide a comprehensive review of this research; other excellent reviews aimed at economists (Ledyard 1995), psychologists (Dawes 1980) or sociologists (Kollock 1998) exist. Instead, I highlight the different categories of public goods problems and introduce their commonalities.

The rest of this article is organized as follows. First, I offer some definitions of characteristics that public goods problems share. Next I discuss some dimensions on which they differ, and how these dimensions translate into different equilibrium and efficient outcomes. Then I describe three specific public goods problem types that have been extensively studied in the economics literature: the voluntary contribution mechanism, the provision point mechanism and the common pool resource. I conclude with a description of other games that have been studied, but where more work could be done.

Similarities

The common feature in public goods settings is the existence of externalities. In public GOODS problems, individuals can use private resources to provide goods that have positive externalities for others. Since some social benefits are not captured by the individual making the decision, this results in under-provision relative to the socially optimum level. Self-interested economic theory, then, argues that these goods will be under-provided, justifying taxation as a role for government.

Parallel to the public goods situation is the case of public BADS. Here, individuals receive private resources by producing goods that have a negative externality for others. Since some social costs are not captured by the individual making the decision, this results in overprovision of public bads relative to the socially optimum level. Self-interested economic theory, then, argues that these goods will be over-provided, again justifying a role for government, here in regulation. (A number of models have extended the existing theory to internalize the externalities. In models of altruism – for example, Becker 1974; Andreoni 1989 – the utility function of one party includes the consumption of others. Thus, when an action creates positive externalities, the value from it is increased over the self-interested model. Charness and Rabin 2002, posit that individuals care not only about their own consumption but also about social welfare directly. These other- regarding preferences can internalize some of the externalities in public goods problems, but typically the over- or under-provision problems are not eliminated.)

The defining characteristic of the public goods problems described here, however, is the existence of positive externalities. My actions affect others, and I do not take this effect (sufficiently) into account in my own maximization problem. Often these problems are symmetric; each individual faces the identical conflict, but this is not necessary for there to be a public goods problem. For a problem to exist, it must only be that the individual's welfare and the group's (social) welfare conflict.

Differences

The largest, most important and least-recognized difference in public goods situations is the production function. How does an individual's action create positive or negative externalities for others? Different production functions have different implications for equilibrium predictions as well as socially optimal outcomes.

A second important dimension on which these situations differ is the decision space. Public goods problems can involve acting to provide goods with positive externalities at a private cost, refraining from acting so as to avoid imposing negative externalities on others at a personal cost, or acting to capture what would otherwise be public benefits for private consumption. Unlike the first dimension, these differences in the decision space have only a superficial impact on the equilibria; that is, one can easily describe 'not polluting' as 'producing a public good'. However, they may affect how individuals think about (and act in) these problems.

To clarify these differences, let's examine the three classic games discussed below in terms of the production function and decision space. In the voluntary contribution mechanism (VCM), the decision space involves *GIVING.* Individuals are given an endowment, which they can use for their private consumption or to produce the public good. Their allocations toward the public good provide value for others in the experiment (positive externalities). The production function of the VCM game most extensively studied is *LINEAR* (thus it is sometimes also called a linear public goods game). The more that is allocated toward the public good, the greater are the social benefits in a linear fashion. This linearity means that (with appropriate parameters as discussed below) this game has a unique Nash equilibrium in which no participant allocates any resources towards producing the public good. Deviations from the equilibrium are both welfare-enhancing and represent deviations from pure self-interest maximization. They are thus referred to as 'cooperation', and concepts like altruism, warm glow and reciprocity are offered as their explanation.

In contrast, consider the provision point mechanism (PPM). Again, this game typically has a *GIVING* decision space. Individuals are given an endowment which can be allocated to private consumption or towards providing the public good. But, in contrast with the VCM, in the PPM the production function involves a *THRESHOLD.* If enough resources are collected, then the public good is provided and all receive its benefits. If too few resources are collected, then the public good is not provided and no positive externalities are enjoyed. The threshold nature of this production function has critical implications for the equilibria of this game. With appropriate parameters (discussed below), the full free-riding equilibrium still exists. But there also exist a set of efficient equilibria, in which the public good is exactly provided with each individual contributing a share of its cost. In each of these equilibria, the share contributed by each individual varies. (For example, there may be one equilibrium in which I contribute 80 per cent and you contribute 20 per cent of the cost of providing the public good, and another where I contribute 20 per cent and you contribute 80 per cent.) The problem then becomes one not of cooperation but primarily one of coordination; how do we select among these efficient equilibria? Formally, this game can be thought of as a large battle-of-the-sexes game (a game of impure coordination), with multiple equilibria each of which is somebody's favourite.

Finally, consider the common pool resource (CPR) game. Here the decision space involves *TAKING*; for example, individuals can harvest grass from the commons for personal gain. Surprisingly, these experiments are often described as *GIVING* games, with negative externalities rather than positive, as in the VCM or PPM. So the decision is made on 'how many hours to spend grazing' with the resulting negative externalities as cattle eat more grass. The production function used in CPR games is typically *NONLINEAR.* A small amount of harvesting creates more benefit for the individual than harm to the society (and is thus socially efficient). However, as the individual harvests more, the personal benefits decrease and the social costs increase until societal costs outweigh private benefits (the socially optimal point). With appropriate parameters (described below), however, private benefit is still above private costs, leading individuals to continue harvesting past the socially efficient point. Eventually, private benefits equal private costs, leading individuals to stop harvesting. These equilibria are thus internal (individuals typically harvest more than zero but less than the full amount) but still suboptimal (total harvesting is larger than the socially optimum level).

There are many additional dimensions on which these games can vary. For example, experimenters have varied the number of players from two (the classic Prisoner's Dilemma game) to as many as 100 (Isaac et al. 1994). The particular parameters can vary, subject to constraints that preserve the public goods nature of the problem. The institutional rules can vary, participants can decide simultaneously or sequentially, they can discuss the game in advance or not, and so on. The games can be (finitely) repeated or one-shot. I discuss some of these variations in the sections below, but their impacts on the equilibria of the games are straightforward.

In summary, the set of public goods games is broad. When one looks at a game, however, it is critical to understand the production function that is being used to translate decisions into outcomes (positive/negative, linear/threshold/nonlinear), and the decision space that participants face (giving/taking/refraining from action). These dimensions have important impacts on the equilibrium predictions, the observed behaviour and the attributions that one can make about the causes of differences between the two.

The Voluntary Contribution Mechanism (VCM)

The work of Marwell and Ames (1979, 1980, 1981) is often cited as the earliest VCM experiments. Unfortunately these early experiments did not involve a linear production function. Instead the return from the public account was discrete (chunky) although some of the experiments involved a linear approximation (for example, 1981, study I). Furthermore, the experiments were relatively uncontrolled; subjects had instructions mailed to them at home, were individually called and had the instructions explained to them, and then called back one week later and made their (one-shot) decision by phone.

The first paper using a linear VCM in a controlled lab setting was Isaac et al. (1984). This paper set a number of precedents for how such experiments are run. In this experiment, participants were brought into the lab and arranged into fixed groups of four. In each period, each group member was given tokens, which he could allocate between a private account and a group account. Tokens allocated to the private account earned 1¢ per token. Tokens allocated to the group account earned 0.3¢ per token for each member of the group, whether or not he had contributed to the group account. As the production function is linear, these parameters remain constant regardless of how much is contributed.

More generally, for there to be a public goods problem in these linear games, a few conditions must be satisfied. First, the return from the public good to the individual must be lower than the return from the private good ($0.3 < 1$). This ensures that individuals do not have an individual incentive to contribute, and that the dominant strategy equilibrium in the stage game is thus to contribute zero tokens. Furthermore, the social benefit from contributing toward the public good must be greater than the social cost ($0.3*4 = 1.2 > 1$). This ensures that contributing toward the public good is socially efficient.

The game is finitely repeated for ten periods, to allow for convergence to (and learning of) the equilibrium. In the finitely repeated game, backward induction results in the unique Nash equilibrium of zero contributions. Deviations from that equilibrium are attributed to cooperation, altruism, reciprocity or various other- regarding preferences.

A number of precedents set in this original article have been used in subsequent research.

Many papers use a group size of four, although some have gone as low as two and others as high as 100. Most experiments have participants 'allocate' tokens between multiple funds rather than 'contribute' towards a public good, as this experiment did. Participants typically have multiple tokens to allocate rather than simply one. Most papers use repetition with fixed groups, and many choose ten periods.

The results from this wide variety of experiments are quite robust. First, on average, contributions to the public good begin at about half the endowment of tokens. Second, there is considerable variation in the decisions of individuals. Third, those contributions reduce over time until the contributions in the final round are 10–20 per cent of the endowment. An example of this pattern of contributions is depicted in Fig. 1. A number of interesting papers have hypothesized and tested for the source of these regularities. Some explanations include errors (Palfrey and Prisbrey 1997), confusion (Andreoni 1995b), strategies and learning (Andreoni and Croson 2008), and reciprocity or conditional cooperation (Croson 2007), among others.

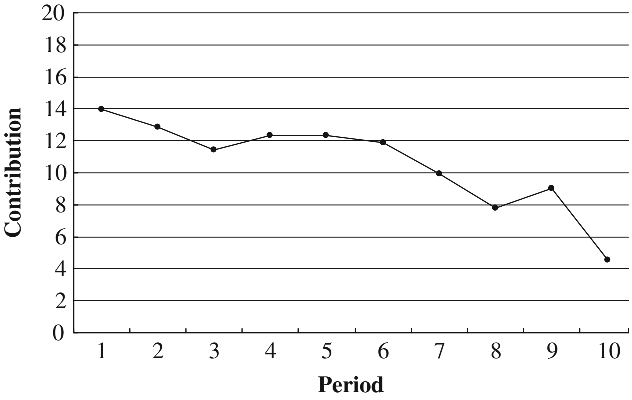
Variations in the parameters have been explored as well; individual papers manipulate group size (Isaac and Walker 1988b), the ratio of the return from the public good to the return from the private good (Isaac and Walker 1988b), the existence of communication (Isaac and Walker 1988a), fixed groups (Andreoni and Croson 2008), anonymity (Laury et al. 1995) and framing (Andreoni 1995a). Recent work in this area extends the paradigm to incorporate more realistic assumptions, including heterogeneity of players (Buckley and Croson 2006), endogenous group formation (Croson et al. 2005), and punishment/reward (Fehr and Gächter 2000). Data has been collected from various subject pools, including children (Krause and Harbaugh 2000) and residents of Asian slums (Carpenter et al. 2004). (For a fascinating look into underappreciated but related psychology literature, see research on *SOCIAL LOAFING*, reviewed in Karau and Williams 1993.)

In summary, the VCM captures the pure tension between individual gains and social efficiency. It is thus used in many settings and by many researchers to investigate the causes (and consequences) of this tension, as well as to describe behaviour in the world.

The Provision Point Mechanism (PPM)

One concern with the VCM is that in equilibrium the public good is not provided at the socially efficient level. Bagnoli and Lipman (1989) discuss a logical response to this problem: add a threshold (or provision point) to the production process. The threshold needed to provide the public good is announced. If at least that much is allocated to the group account, then the public good is produced; if not, no public good is produced.

It is straightforward to see that a VCM can be 'discretized' to the PPM by adding a threshold.



Public Goods Experiments, Fig. 1 Average contributions to public account in VCM. *Source:* Croson (2007)

With the appropriate parameters (discussed below) this game now has a set of efficient Nash equilibria in which the public good is exactly provided. There are also inefficient equilibria of this game, in which the public good is not provided, but this mechanism nonetheless represents a theoretical improvement over the VCM.

There are some parameter values necessary for the existence of these efficient equilibria. In particular, imagine the threshold is T, the value from private consumption is 1 and individual endowments are $E_{\rm i}$. Define V_I as an individual's value from the public good. For an efficient equilibrium there must exist a set of contributions $\{\sigma_i\}$ such that $\Sigma\sigma_i \geq T$. Furthermore, the individual rationality constraints must be satisfied $(\forall_I)$ $\sigma_i \leq \min\{E_i,v_i\}$ and providing the public good must be efficient $T \leq \Sigma v_i$.

Additional assumptions are needed before this mechanism is completely described. When the threshold is not reached, the resources contributed to it can be returned or can be lost. This feature has been called the 'money back guarantee' in psychology, and in economics is the *refund* (Isaac et al. 1989; Bagnoli and McKee 1991). The existence of a refund does not affect the set of efficient equilibria, but does change the set of inefficient equilibria. With no refund, there is one (unique) inefficient equilibrium of zero contribution. With a refund, there are many (weak) inefficient equilibria in which some is contributed towards the public good, but not so much that any player can supplement to reach the threshold. Those contributions are then refunded, making the contributors indifferent between these strategies and contributing zero.

The second dimension is the disposition of resources above the threshold. This is referred to as the *rebate* (Marks and Croson 1998). Experiments have been run including no rebate (excess contributions are lost), proportional rebates (excess contributions are returned proportionally based on contributions), and utilization rebates (excess contributions are used to provide the public good in a VCM fashion). None of these changes the set of equilibria.

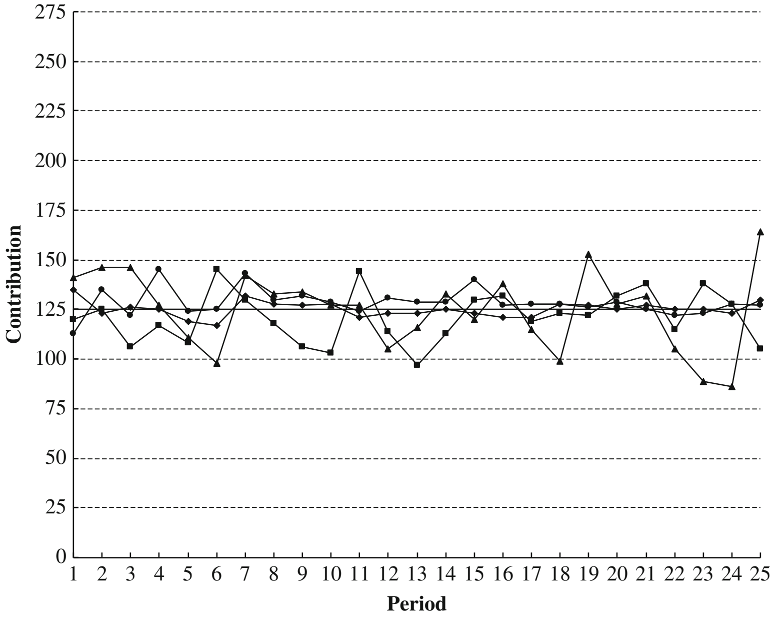
While the PPM has the advantage of the existence of efficient equilibria, it has the disadvantage of too many equilibria. For example, in a typical parameterization used by Croson and Marks (1998), five players each had 55 tokens to allocate. Tokens allocated to the private account earned 1¢ each. If there were at least 125 tokens allocated to the public account, each participant in the group received 50¢. These parameters satisfy the conditions above; the collective benefit from the public good (5 people × 50¢ = \$2.50) is greater than the social cost of provision (\$1.25). There exists a set of allocations such that the public good is provided; one is the unique symmetric equilibrium in which each player allocates 25 tokens, the threshold is exactly met, and each participant receives their value of 50¢, strictly greater than their costs of 25¢.

Unfortunately, this is not the only efficient equilibrium. In particular, the set of allocations {25, 25, 25, 24, 26} is also an equilibrium, as is {25, 25, 25, 26, 24}, although player 4 prefers the former and player 5 the latter. All told, there are 4,052,751 efficient equilibria using these parameters. Thus the main problem in the PPM is not one of *cooperation;* avoiding the inefficient outcome as in the VCM. It's a problem of *coordination*, of choosing which of the many efficient equilibria the group will play.

The coordination problem is difficult enough in the stage game. However, in the lab this game is typically finitely repeated. In the repeated game, the number of potential equilibria grows exponentially, as any sequence of stage-game equilibria are themselves an equilibrium of the repeated game.

In practice, almost no instances of the inefficient equilibria are observed. Group contributions tend to cycle around the efficient equilibrium level, although they are almost equally likely to be above the threshold as below. Examples of group contributions in the PPM can be seen in Fig. 2.

Further research has investigated other dimensions of the PPM. These include the effect of subject pool (Cadsby and Maynes 1998), binary versus continuous giving (Cadsby and Maynes 1999), heterogeneous valuations (Croson and Marks 1999), identifiability of contributions (Croson and Marks 1998), incomplete



Public Goods Experiments, Fig. 2 Group contributions to public account in PPM, four groups. *Source:* Croson and Marks (2000)

information (Marks and Croson 1999), and framing (Sonnemans et al. 1998).

The PPM has a number of important and interesting properties. It allows for efficient equilibria, thus to some extent 'solving' the public goods problem. However, this solution brings costs: too many equilibria and the need to coordinate among them. This distinction, between the cooperation motive of the VCM and the coordination motive of the PPM is a critical and often-overlooked one.

The Common Pool Resource Game

The structure of the CPR game is based on work by Gordon (1954) and Hardin (1968) on the tragedy of the commons. In the typical tragedy, ranchers graze their herds either on their private land or on the commonly owned land in each village. Since grazing on the commons is free, individuals prefer it to using their own land, which can be used to grow cash crops. However, grazing imposes a negative externality on others; if my cows eat the grass, there is less left for your herd. The CPR game, thus, is a *CONTINUOUS TAKING* game; each unit of grass that I take exerts a negative externality on the rest of the village.

Unlike the VCM, the externalities imposed are typically nonlinear, with public costs initially being lower than private benefit, but rising until the two cross. Thus the game has internal equilibria, in which more grazing than is optimal is predicted. (These games are similar to a class of *RENT-SEEKING* games, which have recently been experimentally explored. Rent-seeking games are beyond the scope of this article; but see Önçüler and Croson 2005, for some recent work.)

In the first CPR economics experiment, Walker et al. (1990) arranged subjects into groups of eight. Each participant was given a homogeneous endowment and was told he could allocate this endowment between two markets. Like the VCM, the private market paid a fixed amount, 5b per token. The public market (the common pool) had externalities for other group members' consumption. Unlike the VCM this externality was negative rather than positive. Also unlike the VCM, the externality was nonlinear, with increasing social cost. Conceptually, allocating resources to the public market captures the idea of grazing the herd on public land.

When x_i is the amount player *I* allocates to the public market, the earnings from the public market for player *I* are:

$$x_i / \sum x_i \left(23 \sum x_i - 0.25 \left(\sum x_i \right)^2 \right).$$

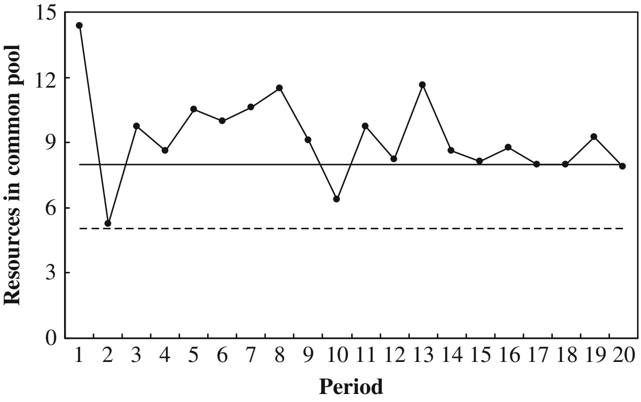
The negative squared term creates the nonlinearity. If no one is allocating resources to the public market, an individual earns more from that market than the private one (the first token allocated there earns 22.5¢ versus 5¢ in the private market). However, this return quickly diminishes, so the value from investing in the public market falls below the value from investing in the private market as the number of tokens increases. This captures the negative externalities. For each token that player *i* invests in the public market, the marginal value of player's *j's* investment in that market is lowered.

The self-interested, symmetric Nash equilibrium in this game is for each player to invest eight tokens in the public market (for a total investment of 64 tokens). (When each participant invests nine tokens in the public market, the return for that marginal token is exactly 5¢. The authors assume that, when indifferent participants choose not to impose negative externalities on others, thus the equilibrium of eight tokens is used.) This equilibrium prediction is parallel to the prediction of full free-riding in the VCM. In contrast, the symmetric, socially efficient solution is for each participant to invest five tokens in the public market. This is not an equilibrium, however, since each individual privately captures more by investing further in the public market. This capturing is at the expense of the other players, who suffer the negative externality imposed. So five tokens is the socially optimal level, and is parallel to the prediction of full contributing in the VCM.

If behaviour in the CPR were parallel to that in the VCM, we should see allocations to the common market of between eight tokens (the equilibrium) and five tokens (the social optimum). As in the VCM, the stage game described above is repeated finitely many times, either 20 or 30 rounds, depending on the particular parameters. (A parallel literature in CPR games examines *dynamic* versions of the game, in which the resource replenishes itself round to round, with the replenishment rate being dependent on the harvesting rate observed. These are sometimes referred to as *renewable* CPR games. Equilibria in these dynamic games are more complicated, and Herr et al. 1997, experimentally compare the different games.)

The results from the experiment can be seen in Fig. 3. The solid line represents the equilibrium prediction, while the dotted line represents the social welfare maximizing outcome. Unlike the VCM, where contributions lay between these two, here contributions lie on the opposite side of the equilibrium. This indicates excessive allocation to the public market, and excessive negative externalities, over and above the equilibrium prediction.

This result of less-than-Nash levels of cooperation is replicated in other experiments, reviewed in Ostrom et al. (1994). Other work also reviewed there examines other questions in CPR games, including probabilistic destruction, communication, monitoring and sanctions, voting and heterogeneity.



Public Goods Experiments, Fig. 3 Average resources allocated to the common pool (CPR). *Source:* Ostrom et al. (1994)

One lingering puzzle remains: why are subjects more generous/cooperative than the equilibrium in the VCM and less generous/cooperative than the equilibrium in the CPR game? A number of studies have investigated this question by adding complexity to the VCM to make it resemble the CPR (for example, the stream of research on nonlinear VCM games below). Others investigate framing, suggesting it is the difference between providing a positive externality in the VCM and a negative externality in the CPR game. Unfortunately no study has offered either a definitive experiment or compelling data to explain why the outcomes from these games differ.

Other Public Goods Settings

In addition to the games described above, a small literature explores different types of public goods games. A number of papers examine nonlinear VCMs, with internal equilibria (see Laury and Holt 2008, for a review). Here the production of public good is nonlinearly related to the amount allocated to the public account. This yields an internal social optimum and Nash equilibrium level of contributions. As before, parameters are set so that the public good is under-provided in equilibrium.

Others have explored markets with externalities rather than public goods per se (for example, Plott 1983). Still other researchers combine these games in creative ways, for example a PPM with a VCM for excess contributions (as in the utilization rebate of Marks and Croson 1998), or a PPM with a VCM for under-contributions (as in Vesterlund et al. 2005).

Finally, a number of papers have experimentally tested other proposed mechanisms for solving the public goods problem. For example, Chen and Plott (1996) provide a test of the Groves–Ledyard mechanism (a mechanism designed to elicit individuals values for public goods). Reviews of experiments using incentive-compatible mechanisms can be found in Chen (2008). These literatures are less developed than the previous three games, a disadvantage when trying to summarize a stream of research but an advantage when seeking a new contribution.

Commonalities and Puzzles

The underlying similarity between all public goods experiments is the existence of externalities. These externalities can be positive or negative, and they can be linear, nonlinear or involve thresholds. The decisions participants make can be described as giving or taking. These varying situations affect the equilibrium predictions of the games.

Individuals are ‘cooperative’ in the VCM; they contribute more towards the public good than equilibrium behaviour would predict. There are many explanations for why this may be the case, including altruism, reciprocity (conditional altruism), warm-glow and errors, but no one causal factor has emerged as dominant.

In the PPM, the issue is not one of cooperation but coordination. On average the efficient equilibrium outcomes describe the data. However, there is also ‘gaming’, with groups sometimes failing to provide the public good as one individual attempts to move towards a more attractive equilibrium. Thus, while outcomes from these mechanisms are more efficient than those from the VCM, the coordination problem is severe and unsolved.

Finally, individuals harvest *MORE* than the Nash equilibrium predictions in CPR games. This result contrasts with the VCM; here individuals are more competitive than the equilibrium prediction. The source of these differences is still unexplored and represents an excellent direction for future research.

Summary

The tension between self-interest and social efficiency is one we experience every day. Experiments like those discussed in this article have been developed to explore how humans resolve this tension. Results from these experiments highlight the impact of different public goods structures, institutional arrangements and repeated interactions on human behaviour. Ultimately they help us to design mechanisms to better provide public goods, and allow for a deeper understanding of human motivations in the wide set of activities involving externalities for others.

Public Health

Alan Williams

It is widely believed that prevention is better than cure, and there is an obvious sense in which it is. But there has been a chastening tendency for the dismal science to indicate that measures enthusiastically advocated as ways of stopping people from becoming ill are often rather poor investments compared with 'curative' activities.

What Is 'Public Health'?

Before getting to grips with that particular issue, however, we need to give some attention to what constitutes 'public health' as a distinctive activity. Several characteristics seem relevant. Public health could be concerned with the health of whole populations rather than with that of individuals, in which case 'public' is being contrasted with 'individual'. Or it could be concerned with measures that *have* to be applied to whole communities (e.g. fluoridation of water supplies) rather than to individuals (e.g. immunization) hence 'public' is being contrasted with 'personal'. Or it could be concerned with all *preventative* activity, as opposed to *curative* activity, so that the contrast is rather between a positive emhasis on promoting public *health* in contrast with alleviating public *illness*. Some 'public health' activities (e.g. ensuring that water supplies are wholesome and sewage disposal facilities are functioning effectively) clearly embody all three attributes, but what about anti-smoking campaigns? For the purpose of this particular discussion, public health will be held to embrace *any* governmental activity designed to keep healthy people healthy. This would include counselling people about their lifestyle (smoking, alcohol, diet, exercise, etc.), plus all safety legislation, and much consumer protection, as well as such 'traditional' areas as protection from environmental pollution, immunization and vaccination programmes, and the control of epidemics. They are rather disparate activities, and many of them do not lie within the field of responsibility of those providing personal health services, nor indeed of Ministries of Health, so that organizationally they manifest a rather complex picture of overlapping responsibilities in some fields, and rather yawning gaps in others, so their organizational aspects may be of as much interest as the analytical problems they pose.

What Is Wrong with the Market?

Since it is impossible to cover this whole complex territory in any depth in a short essay such as this, a few representative problems will be selected to give the flavour of the *economic* issues involved. These economic issues can most conveniently be organized around the notion of 'market failure', though this in turn leads inexorably to notions of 'government failure' too, if we are to pick up the organizational difficulties.

Generally we economists have a bias in favour of market solutions, once we are satisfied that consumers are fairly knowledgeable (and the consequences of ignorance are not likely to be fatal), that they are properly regarded as the best judges of their own interests, that when acting in their own interests they are not likely to affect other people's interests in unacceptable ways, that consumers are not subject to exploitation by suppliers (or vice versa) through disproportionate market power, and that the distribution of power (and the distribution of welfare which flows from it) is equitable. These are quite stringent conditions, and should not be taken for granted (i.e. there should be no unscrutinized *presumption* that market solutions are best).

Consumer Ignorance

Consumer ignorance is thus a possible basis for public health activity directed at changing people's diet, promoting physical exercise, and launching anti-smoking campaigns. It also lies behind much consumer protection activity, such as that concerned to prevent adulteration of food and drink, and with safety of other products from the viewpoint of fire-risk, the use of toxic materials, electrical safety, etc. Although there are *private* consumer protection associations offering such advisory services, they suffer from the weakness that only those who are already aware of such risks in a general way will be prepared to pay for such advice, and once products have been shown to be health hazards the ethos of such private organizations makes them wish to disseminate such information as widely as possible, so there is an obvious 'free-rider' problem. Moreover, powerful producer interests may unscrupulously protect themselves by blocking adverse publicity in the media by using the market power of advertising revenues. Moreover, through superficial product differentation, rapid product 'development' may enable may adverse effects of bad reports to be sloughed off, and it therefore requires continuous, prompt, and expensive reappraisal of products to keep consumers well informed. It is, therefore, not surprising that the coercive power of the government is sought to prevent these dangers from presenting themselves in the first place, by banning certain food additives, setting minimum safety standards for products, and enforcing these by law. Problems of inspection and testing then fall in the public domain, and their rigour and effectiveness depends on the resources devoted to them and the attitudes of the inspectorate and of the courts on which they ultimately depend. There is no guarantee that such regulations will be 'optimal' in the sense that the social costs and benefits at the margin will be roughly equal. For instance, it appears that fire and construction safety regulations for buildings imply much higher values being placed on human life than do road safety measures, so there is a further field for economic analysis here to rationalize piecemeal and often quite impulsive legislation (often sparked off by some disaster or scandal).

Externalities

The next feature which often seems to underlie public health activity is the 'externality' argument, i.e. that individuals, behaving rationally in their own interests, will ignore the interests of others, and it may be in the interests of all to coerce each and every one to behave in a different manner. On the external cost side this has been the classic rationale for the isolation of suffers from infectious and contagious diseases. But it has some more subtle and pervasive applications, e.g. to drunken driving, or to smoking in enclosed public places or to failure to maintain motor vehicles in a roadworthy condition, where individuals may rationally choose to accept risks themselves, but in so doing put others at risk involuntarily and without offering proper compensation for accepting such risks. This then raises the issue of how far we are able to go in using *coercive* measures to control people's behaviour for the sake of other people's health. Should people be compelled to wash thoroughly everyday, or not wear dirty clothing on public transport, since one person's low standard of cleanliness may endanger someone else's health? Extending the point still further, have I the right to insist that an ill person seeks treatment for an illness which I cannot catch, simply because it causes me distress to see that person ill when I know he or she could be made well? The externality argument, if pushed hard, is extremely intrusive, and finding an acceptable balance between protecting ourselves from other people's irresponsibility and protecting our own private area of responsibility from outside interference is consequently a much debated issue in this as in other fields of human activity.

The externality argument applies equally strongly in principle on the benefit side, of course, and the classic case is the draining of the malarial swamp. Most such instances are closer to 'local' public goods (i.e. ones that have a strong spatial dimension) than to 'pure' public goods, but they do have the key characteristic that the benefit is equally available to all (within some designated geographical area) and exclusion from benefit (conditional upon paying for it) is impossible. External benefits may also flow from personal health-promoting activities, such as inoculation and vaccination, suggesting that people should perhaps be paid to undergo such prophylactic treatments so as to reflect the benefits they confer on others. It has, however, been more common to resort to compulsion, since it takes only a few 'non-co-operators' to undermine the benefits to the co-operators (such procedures seldom give 100% protection), and it must be acknowledged that the elimination of smallpox is a major triumph for that approach, making it now unnecessary for anyone to be vaccinated.

Distributional Judgements

Smallpox eradication was essentially a case where costs were imposed on some, in order that others might benefit, and in this respect it seems similar to the vexed case of fluoridation of water supplies, where the beneficial effects on young people seem beyond doubt, but the most efficient way of getting the fluoride into their teeth is by increasing the levels of fluoride in most public water supplies. But this means that the fluoride has to be consumed also by people who will get no benefit, and there may even be a few who may be harmed (as with vaccination). A distributional judgement has then to be made, and it cannot be escaped by *actual* compensation of objectors, because for some of them it seems to be an ethical issue of fanatical proportions, and they are never going to be 'bought off'.

Who Is the Best Judge of My Welfare?

For economists generally the toughest line of justification for public health measures of a coercive kind is the argument that consumers are not the best judges of their own welfare. Our strong upbringing in notions of consumer soverignty, and in the individualist calculus of the market, makes it very hard for us to accept that there are such things as ‘merit goods’ or ‘demerit goods’, i.e. goods where we think that someone other than the consumer is the best judge of whether that good is good or bad *for the consumer himself* (i.e. this has nothing to do with externalities, though they may also be present). We may be able to accept it for children, the mentally handicapped, or the mentally ill, but why should anyone (except by dependents) insist that I wear a seat belt when a passenger in a car, since only my own health is at stake? It may be argued that the costs of treating me (or burying me) will fall on others, in which case perhaps I should be forced to pay higher insurance premia if I wish to behave in that way. Is the argument then that there are some risks which we are not going to *permit* people to take, because we are confident that they will subsequently regret it. This line of reasoning seems strong in the case of the wearing of crash helmets by motorcyclists, who are mostly young people who seem to place ‘too low’ a value on their own lives and health.

Consumer Sovereignty?

Which brings us to the major contemporary public health issue, smoking. Assuming that smokers are compos mentis, well-informed and that the taxes they pay on tobacco fully cover any additional costs they impose on public services, and that they never smoke in any circumstances which place other people at risk (including the fire risks). There is presumably pleasure to be obtained from smoking, as there is from drinking, gambling, going to the opera, or playing bridge. Why then should we pressurize people to stop smoking, or never to start? The only reason would appear to be its addictive characteristics, i.e. there is a kind of ‘ratchet’ effect on the demand function for smoking, making it much more responsive upwards when prices fall or incomes rise, than it is downwards when prices rise of incomes fall. Moreover, smokers themselves seem to acknowledge the difficulty of ‘giving up’ on a scale that exceeds that of drinkers or gamblers or opera-goers or bridge players. Addictive behaviour sits awkwardly alongside consumer sovereignity, and especially when the producers of addictive substances are devoting large sums of money to persuading consumers to experiment with their products. It is an area of public policy where the ‘market failure’ and ‘public choice’ literatures fuse into a most excruciating scenario of conflicting ideologies and interest groups, with the economics of public health caught up in the difficulty of not knowing quite how much weight to give to the pleasure of smoking in such a tangled situation.

Public Health as an Investment

So let us come back to prevention being better than curve. We have rehearsed various phenomena (consumer ignorance, externalities, free-rider problems, economies of scale, and consumer incompetence) which have been adduced as reasons why there is a role for ‘public health’ measures of a preventative kind for people who are still well, alongside personal or state measures of a curative kind for people who are already ill. This leaves only one other consideration to be stressed, namely that many such preventative actions involve interventions at time t, which will not generate benefits until $t + n$, where n may be measured in decades rather than days or months. Thus a justification in *principle* for public health interventions may not translate into a justification *in practice*, because it needs to be subjected to empirical investigation to see whether the rate of return is worth it. Here the ‘rate of return’ will be measured as an improvement in the present value of people’s future health per unit of present value of the resources used, which has to be better than that obtainable from any alternative use of the resources. It is here that preventative programmes frequently show up badly. It seems persuasive to argue that a particular screening test costs only the equivalent of a packet of cigarettes, and it will save a hundred lives a year. But it frequently turns out that the costs of the tests are severely understated (e.g. ignoring the costs borne by patients in getting to and from where the test is given), that the costs of follow-up tests for ‘positives’ are excluded, as are treatment costs, both of which may be incurred (ineffectively) for many more people than the 100 people whose lives are ‘saved’ (i.e. whose death is ‘deferred’ . . . for how long? and with what quality of life?). And what if it takes a million tests to detect one successfully treatable case? And what discount rate do we use to reduce both costs and benefits to ‘present values’? Even a rate as low as 2% can have a devastating effect on benefits that are not going to show up for 40 years, as might well be the case with any public health intervention which would stop teenagers from smoking.

Public Health and the Economy

Thus it is that economists working in this field (as with many other areas of public policy) have not won enthusiastic acclaim from the professionals, or indeed from the public, who suspect that we are obsessed with income issues, such as maximizing conventionally measured GNP by making sick workers better as soon as possible, that we have lost sight of the broader issues, and especially of the fact much illness and injury is in fact *caused* by the unthinking pursuit of short term profit in activities that are good for GNP (as conventionally measured) but bad for human welfare on any commonsense interpretation. I have much sympathy with this broad viewpoint, and we need to do a lot more work on the extent to which economic activity produces ill health as well as goods and services for people to buy. But nothing in what I have written here is in any way affected by that important observation. Perhaps in the next issue of Palgrave there will have been enough work done on *this* issue for there to be a place for an entry on ‘The Economy as a Producer of Ill Health’, as well as on the Economics of Health, the Economics of Public Health, the Economics of State Provision of Medical Care, and so on.

Public Infrastructure

Teresa Garcia-Milà and Therese J. McGuire

Abstract

Numerous empirical studies have investigated the contribution of public infrastructure (the stock of publicly provided physical capital) to private economic productivity and growth. Using aggregate time-series data to estimate a production function with private capital, labour and public capital as inputs, the authors found substantial elasticities of private output with respect to public infrastructure. The result did not withstand scrutiny. Studies using disaggregated data (by region and industry), employing econometric diagnostics testing for nonstationarity, fixed effects and endogeneity, and using natural-experiment techniques found public infrastructure’s contribution to economic growth to be minor.

Keywords

Aggregate production functions; Cobb–Douglas functions; Cost functions; Output elasticity of capital; Productivity growth; Public infrastructure

Public infrastructure (the stock of publicly provided physical capital comprising highways, sewage and sanitation systems, water systems, school buildings, hospitals and so forth) comprises an important component of the US economy. In 2004, there were just under seven trillion dollars of public capital in the United States, including 1.7 trillion dollars of highways and streets. By comparison, the stock of private capital stood at 27 trillion dollars.

Public infrastructure has figured in several related economic enquiries. What are the causes of private-sector productivity growth and decline? What causes lesser developed regions or countries to grow? Do country growth rates tend to converge over time? Research into each of these questions has examined the role of public infrastructure.

The contribution of public infrastructure to economic productivity and growth has been the focus of many empirical studies in recent years. The idea that public infrastructure should be considered an input in the aggregate production function, together with labour and private capital, was introduced in early theoretical models, but it was not taken into account in empirical work until the late 1980s. The increased attention to empirical analysis was linked to concerns about the decrease in productivity observed in the United States after 1970. In Europe much of the infrastructure literature has examined the role of public investment in boosting the growth of less developed regions.

The Theoretical Framework

The most widely used framework for studying the impact of public infrastructure on productivity and growth has been estimation of aggregate production functions where public capital is considered a production input along with the standard inputs, labour and private capital.

The general form of the aggregate production function can be written as follows:

$$Y_{rt} = A_{rt}F(L_{rt}, Kp_{rt}, Kg_{rt})$$

where Y is a measure of output, L represents labour, Kp is the stock of private capital, Kg is the stock of public capital, A is total factor productivity and the subscripts allow for regional and time variation.

Although the production function can take many functional forms, most empirical studies have estimated a Cobb–Douglas production function. Under that specification, and taking a logarithmic transformation, the estimating equation can be written as follows:

$$y_{rt} = a_{rt} + \alpha kp_{rt} + \beta kg_{rt} + \gamma l_{rt} + \varepsilon_{rt}$$

where the variables are measured in natural logarithms, and ε is an error term.

The aim of an important part of the public infrastructure literature is to estimate the output elasticity of public capital β, so as to measure its contribution to private productivity. An alternative approach to obtaining similar parameters, based on the duality of production and cost functions, is to estimate a cost function.

The Empirical Evidence

The first widely known results were those obtained by Aschauer (1989), who estimated a production function using aggregate post-war time series data for the United States. He estimated an output elasticity of public capital of 0.39, larger than the corresponding value for private capital (0.35). These estimates imply large returns for public investment (above 60 per cent, double of those for private capital), and were challenged by many authors, who considered them implausibly high.

Some authors attributed the high output elasticity of public capital found by Aschauer (and by Munnell 1990a) to a spurious correlation between output and public capital due to a common time trend. Aaron (1990) and Tatom (1991) corrected for the common time trend by first-differencing the data and obtained small and statistically insignificant coefficients.

The incorporation of state or metropolitan level data adding cross-section information to the time-series data opened up new possibilities for handling the spurious correlation and getting more accurate estimates of the contribution of public capital. Eberts (1986) focused on the manufacturing sector for 38 metropolitan areas and obtained a significant but much smaller estimate of the output elasticity of public capital, with a value of 0.03. Munnell (1990b) and Garcia-Milà and McGuire (1992) pooled state and time variation and obtained public capital elasticity estimates that range between 0.04 to 0.15. These estimates struck researchers as being more reasonable; however, they were subject to criticism because of endogeneity problems related mainly to omission of state-specific characteristics and to reverse causality.

Holtz-Eakin (1994), Evans and Karras (1994), and Garcia-Milà et al. (1996) used panel-data techniques not only to take into account state-specific productivity differences in the estimation, but also to explore non-stationarity of the data and possible endogeneity of the production factors. In all cases the estimates of the output elasticity of public infrastructure dropped dramatically compared with the time-series and pooled-data estimates, with values close to zero (and sometimes even negative) and not statistically significant.

By disaggregating by industry, Fernald (1999) avoided the endogeneity problem: if road infrastructure grew as a result of overall economic growth, and therefore the causality were reversed, one would not expect to find a relationship between increases in road infrastructure and the productivity of some industries but not others. He found that an increase in road infrastructure enhances productivity growth of vehicle-intensive industries much more than other industries. Fernald concluded that the US interstate building of the late 1950s and 1960s was one important factor in explaining the productivity increases up to the early 1970s, but the impact of road-building after the main network was built was small. A productivity burst because of road-building is a one-time effect and cannot be historically repeated. This is also the view of Hulten and Schwab (1993), who argue that, once the basic network is constructed, which has a major impact on the economy of the country, additional road construction has little, if any, effect on private productivity.

The results of Mas et al. (1996) support the idea that the impact of infrastructure investment is greater at earlier stages of development of the infrastructure network. They examine regions in Spain over the period 1964–91 and find that the output elasticity of productive infrastructure is 0.14 in the first ten years of the sample, but falls as more recent years are added to the sample, with a value of 0.08 when the whole period is considered. As the highway network in Spain was not yet completed in 1991, their results for Spain are compatible with those obtained for the United States, where the highway network was virtually complete, which showed that highway construction produced little or no effect.

Another possible response to the endogeneity problem is to estimate aggregate cost functions. The estimation of aggregate cost functions avoids the endogeneity bias if one can assume that prices of inputs are exogenous. Although it is reasonable to assume that individual firms are input price takers, it may not be plausible to assume that input prices are exogenous when considering aggregate (state or national level) cost functions. In spite of this shortcoming, there are several interesting papers that estimate aggregate cost functions and obtain, through the duality between cost and production functions, estimates of the output elasticity of private and public inputs. Berndt and Hansson (1992), Lynde and Richmond (1992), Nadiri and Mamuneas (1994), and Morrison and Schwartz (1996) are good examples of cost function estimations. They differ in the functional specification, the geographical and industrial scope, and the scope of public infrastructure, but in all cases they find that public capital reduces costs and therefore improves productivity. The size of the effect tends to be quite small, along the lines of the production-function estimates obtained by Eberts (1986), Munnell (1990b) and Garcia-Milà and McGuire (1992).

A very different way to avoid endogeneity bias is to look for a natural experiment related to infrastructure investment. The idea is to compare the economic performance of two otherwise similar areas except that in one area, the control group, there has not been any highway construction whereas the other area, the treated group, has experienced highway construction. Rephann and Isserman (1994) apply matching techniques to analyse the effectiveness of US interstate highways as an economic development tool. Results vary significantly depending on the characteristics of the counties considered. Counties close to a large city or containing small cities (more than 25,000 residents) benefit from new investments in interstate highways, while rural counties without these characteristics do not experience economic growth when interstate highways are built within them. Chandra and Thompson (2000) exploit the fact that in the United States much interstate highway construction was designed to link major metropolitan areas. Thus, the rural counties in between the metropolitan areas through which the interstates run can be considered the treatment group, while the counties adjacent to the treatment group, which in essence just missed having an interstate highway run through them, can be considered as a suitable control group. The authors find that counties that have a new interstate highway running through them experience an increase in overall earnings, while earnings fall in the adjacent counties. The authors conclude that interstate highway construction affects the spatial allocation of economic activity, but has no net effect on the economic development of non-metropolitan areas as a whole.

The question of whether investment in public capital yields a net positive social return has also been addressed. Morrison and Schwartz (1996) calculate a measure of the net social return to public infrastructure investment as the difference between the cost savings to manufacturing firms minus the cost to society of the public capital investment. Their results range from small positive values to negative estimates of the net social return depending on how the price of public capital is adjusted for taxation and for the marginal cost of public funds. Haughwout (2002) examines the impact of public infrastructure on both productivity and consumer utility in a sample of large US cities. He finds that the local benefits of public capital are largely realized by households rather than firms and that the aggregate benefits of large investments in public infrastructure are not likely to be sufficient to offset the costs.

Concluding Remarks

Based on the aggregate analysis, we can conclude very little. The most credible aggregate production–function estimates of the impact of public infrastructure on private output hover around zero, as do estimates of the net social benefit of public infrastructure investment. However, when the focus is on sub-aggregates such as particular industries or certain areas or incomplete networks, researchers tend to find that public capital investment boosts private output and productivity for some industries, some areas, and some networks. What is clear from the accumulated evidence is that public infrastructure is not a panacea for all that ails economies, but rather a tool that when properly targeted can be effective at enhancing growth.

Public Sector Borrowing

Terry Ward

Public sector borrowing is the difference between the total receipts of central government, local authorities and public enterprises, considered in aggregate, and their total expenditure. As such it is somewhat broader in coverage than the public sector financial balance or the Federal deficit in the US which largely, though not entirely, exclude financing items. It thus encompasses the issue of short and long-dated securities not only to finance government expenditure of the conventional kind on goods and services and transfers, but also to fund investment projects carried out by public enterprises, which might yield attractive commercial rates of return. It also includes purely financial transactions such as lending to the private sector or purchases of assets, typically treated as 'below-the-line' items and as part of the Credit Budget in the US.

Each of these types of activity has very different implications for aggregate demand, real output and monetary conditions in the economy. Purely financial transactions in particular may have very little macroeconomic relevance at all. This together with the fact that borrowing relates to the net cash flow position of the public sector rather than to the gap between income and outlays measured on an accruals basis, means that the magnitude is liable to give a misleading impression of its financing implications as well as of its wider influence on the economy. Moreover it does not even give a reliable indication of the total value of securities which the government needs to sell over any particular period to fund its activities, since this will be affected by the amount of existing debt which has to be rolled over as well as by the monetary policy being followed (sales of government debt may be used as a means of controlling credit or the level of interest rates). Accordingly it ought to be magnitude of relatively little interest to economists and much less relevant than the public sector financial deficit or budget deficit which is largely confined to 'above-the-line' items and excludes financing transactions.

These shortcomings have, however, not prevented public sector borrowing becoming a focal point of government policy in number of countries, including the UK. A major reason for this is the rise of monetarism and the central role assumed by monetary targets in the conduct of macroeconomic policy since the mid-1970s throughout the industrialized world. Since public sector borrowing is an important component of money supply growth and the part ostensibly under the most direct control of government, it has come to be regarded as the key to keeping monetary growth within the limits thought to be necessary for containing inflation, without putting undue upward pressure on interest rates.

In practice, things are not quite so simple. Attempts to control public sector borrowing by raising tax rates or cutting public expenditure programmes are liable to have depressing effects on economic activity and real incomes. This in turn can accordingly give rise to a greater need for private sector borrowing to maintain expenditure and, in the case of companies, to avoid liquidation. A reduction in one major component of monetary growth can therefore induce a compensating rise in the other major component. This helps to explain why, empirically, there appears to be no close correlation between public borrowing and money supply growth in many countries.

Nevertheless, imposing limits on public sector borrowing or on the budget deficit represents an ultimately effective and readily verifiable, if crude means of reducing financial instability and containing national debts, even though it may well be at the cost of real output growth and employment. On the other hand, the fact that public borrowing, and to a less extent the budget deficit, include some transactions which have relatively little effect on economic activity gives some scope for governments to manipulate its scale and thereby appease financial markets without markedly depressing output or real income. Such so-called ‘window-dressing’ was a feature of the interwar years and has re-emerged in the UK, for example, in the 1980s. Ironically, however, the scope for such manipulation tends to be greatest for right-wing market-oriented Governments which are relatively well disposed towards selling of State assets but which are usually least favourably inclined towards fiscal expansion.

Public Sector Investment Efficiency in Developing Countries

Alvar Kangur and Chris Papageorgiou
International Monetary Fund, Washington,
DC, USA

Abstract

There are numerous examples where public investment has been grossly mismanaged and where corruption has overwhelmed the entire process (unfinished roads, highways leading to nowhere, incomplete or unusable bridges and power generation projects). This entry aims at reviewing the existing literature on the potential impact of such public investment inefficiencies on productivity and output, in theoretical models and empirical exercises. We conclude that despite recent progress in assessing and incorporating such inefficiencies in economic analysis, the composition of public capital and its interlinkages with other factors of production and with structural economic conditions should remain a key area of future research.

Unlike with private investors, there is no plausible behavioral model in which every dollar that the public sector spends as “investment” creates economically valuable “capital”. While this simple analytic point is obvious, it has so far been uniformly ignored in the empirical literature on economic growth. Lant Pritchett (2000)

The views expressed in this project are the sole responsibility of the authors and should not be attributed to the International Monetary Fund, its Executive Board, or its management.

Introduction

There is a broad consensus that a scaling-up of investment in developing countries, particularly in infrastructure, is critical to achieve sustained growth. Particularly in many low-income countries, deficiencies in infrastructure may sometimes reduce productivity by at least as much as structural factors, such as bureaucracy, corruption and lack of financing. Recent studies by the World Bank and the IMF suggest that the growth impact of higher infrastructure spending in low-income countries is potentially substantial – if low-income countries halved their infrastructure gaps, reaching the level of middle-income countries, annual growth rates would increase by about 2% points.

In many developing and low-income countries, however, the link between public capital spending and capital stock accumulation, and hence growth, is weakened by evidence of low efficiency of public investment. The notion that public investment spending leads to equivalent capital accumulation rests on the assumption that public investment is inherently productive. This assumption is particularly problematic in many developing countries, as a high degree of inefficiency, waste, or corruption often distorts the impact of public spending on capital accumulation, leaving a trail of poorly executed and ineffective projects.

While the literature suggests that a scaling-up of investment in developing countries is vital, the link with outcomes depends critically on the quality and efficiency of public investment. This highlights the importance of going beyond discussions of spending levels and addressing issues of the broad institutional framework underpinning the provision of investment. As accurately described by Caselli (2005) "less-accountable poor-country governments are likely to be disproportionately less efficient (relative to the private sector) than rich country ones. Hence, there are good reasons to expect the government to play an especially detrimental role in the productivity of investment in poor countries". This translates into variability in the market value of the capital stock.

In terms of theory, this would imply adjusting our standard models of economic growth. A clear way to achieve this would require incorporating in the capital accumulation process, a parameter to capture public investment inefficiency, and consequently modifying the stock of public capital in the aggregate production function. Recognizing that both the investment and the stock of public capital are compromised by government inefficiencies is likely to alter predictions of standard models. In terms of empirics, being able to estimate the difference between investment cost and capital value is of first-order empirical importance especially for developing countries for whom public investment is the primary source of investment. In practical terms, assessing the quality of project selection, appraisal, implementation and evaluation in a country can help identify the specific weaknesses that contribute to poor outcomes and guide appropriate institutional and technical remedies that could correct such failures.

This entry is structured as follows: In section "Two Generations of Research on Public Capital" we provide a selected literature review focusing on two distinct generations of analytical work on the productivity of public capital. In section "Recent Work Sheds More Light on the Way that Public Investment", we turn our attention to estimation issues, particularly related to efficiency of public capital, by challenging some of the main assumptions made in the basic growth models. Subsequently, we consider and discuss in some detail different measures of inefficiencies found in the literature, and conclude the section with some examples of empirical applications using such measures. In section "Towards the Third Generation of Research" we present recent work that focuses on general equilibrium models that incorporate public investment inefficiencies and analyse in detail their effects not only on aggregate output but also several sectors of the economy. Finally, section "Conclusions" concludes with discussion on future research.

Two Generations of Research on Public Capital

Substantial research has been devoted to measuring the productivity of public capital. In response to the massive public sector investment booms in many developing countries in the 1970s, Little and Mirrlees (1974) provided a systematic and practical cost-benefit methodology to assess public investment decisions. In a follow-up article, Little and Mirrlees (1990) expanded on their methodology and demonstrated some of the benefits of their approach which inspired an extensive literature that lasted for decades and is the starting point of most project evaluation work today. Partly using some of the work by Little and Mirrlees, the first generation of research that started in the late 1990s typically found that public capital can offer very large productivity gains, notwithstanding the wide range of theoretical and empirical frameworks employed. Aschauer (1989, 1998) in a series of papers estimated the output elasticity of public capital in the range of 0.3–0.4 and was the first to assign public capital an important role in explaining the fall in US productivity growth observed in the 1970s and 1980s. The literature that followed largely confirmed Aschauer's findings. Munnell (1990a, 1992) estimated the impact of public capital on growth at 0.31–0.39 at the national level though in Munnell (1990b) found a lower impact of 0.15 at the state level. In a similar setting, Lynde and Richmond (1993) found that the services of public capital are an important part of the production process and that about 40% of the slowdown in the growth rate of labour productivity is explained by a fall in the public capital-labour ratio. Several other papers reached similar conclusions; see Sturm et al. (1998), for a comprehensive review of this generation of studies.

Over time these first-generation estimates were questioned on the grounds of numerous methodological and econometric limitations (Gramlich 1994). Issues ranking high on the list of potential problems included reverse causation from productivity to public capital (public capital affects productivity, and in turn is affected by productivity) and spurious correlation due to non-stationarity (time-varying properties of the public capital series). This controversy sparked a new generation of research, which compared to the results surveyed by Sturm et al. (1998) estimated substantially lower effects of public capital on growth; see Romp and de Haan (2007) for an extensive review. Moreover, while attempting to address the aforementioned estimation problems, the research unveiled substantial heterogeneity among countries, regions and sectors. This is not surprising, as the effects of new investment spending depend on the quantity and quality of the capital stock in place. In general, the larger the stock and the better its quality, the lower will be the impact of every additional unit of capital added to this stock (the marginal productivity of capital). The network character of public capital, notably of infrastructure, also results in non-linearities in the impact of public capital on growth. It is these non-linearities which explain some of the above heterogeneity. Thus, the effect of new capital will crucially depend on the extent to which investment spending is targeted to alleviate bottlenecks in the existing network. Further studies suggest that the effect of public investment spending on growth may also depend on institutional and policy factors (Tanzi and Davoodi 2000; Sawyer 2010).

Bom and Ligthart (2010) summarized the estimates of the output elasticity of public capital available from the literature by means of a meta-regression analysis. They find that the unconditional average output elasticity of public capital centres around 0.15 but suggest substantial heterogeneity across countries. They also show that studies that impose constant returns to scale restrictions across private labour and capital (Mas et al. 1993; Otto and Voss 1994; Kavanagh 1997), control for the business cycle (Aschauer 1989; Hulten and Schwab 1991; Sturm and De Haan 1995), and incorporate some measure of education (Garcia-Milà and McGuire 1992) find larger output elasticities of public capital, whereas studies that include energy prices (Tatom 1991) tend to find lower estimates.[1] The conditional output elasticity of public capital in

[1] Imposing constant returns to scale across private inputs implies increasing returns to scale across all inputs if the factor share of public capital is positive. This could produce upward bias in the estimates if the true model is characterized by decreasing returns to scale across private inputs.

the regression equation which captures typical study characteristics is estimated at 0.17, which is not that far from its unconditional (without capturing the study characteristics) value of 0.15. These values imply a marginal productivity of public capital for the United States in the range of 29–33% in 2001.

Given data limitations and the difficulty in constructing public capital stock series for developing countries, the early empirical literature on these countries often looked directly at the impact of public investment on economic growth (Devarajan et al. 1996). Arslanalp et al. (2010) was among the first to estimate a production function using the public capital stock as an explanatory variable, for a sample of 48 developed and developing countries. The effect of public capital on growth is estimated to be stronger for developed countries in the short term (0.13), while it is stronger for developing countries in the long term (0.26). In some countries, they find that the positive impact of public capital on output is partially or wholly offset if the initial ratio of the capital stock to GDP is high. Their results also show that in developing countries certain types of constraints (financing or the ability to absorb) can limit the growth benefits of higher capital stock and, unlike in advanced countries, the benefits of new investment tend to accrue more gradually.

Recent Work Sheds More Light on the Way that Public Investment

Efficiency might decline during investment booms. Warner (2014) looks at big long-lasting drives in public capital spending in developing economies, and concludes that only a weak positive association exists between investment spending and growth, and that too only in the same year. According to the author public investment drives have tended to be financed by borrowing and have been plagued by incentive problems and interest-group-infested investment choices at the time investment projects were chosen. In addition to the inefficiency issues public investment booms are also faced by severe absorptive capacity issues. Presbitero (2016) reports evidence in a panel of a large number of developing economies that investment and infrastructure projects are less likely to be successful when they are undertaken during periods of higher than average public investment. This evidence is consistent with the presence of supply bottlenecks and poor project selection and with the importance of sound policies and institutions for the selection and management of public investment projects.

One of the most basic dynamic equations in macroeconomics is that of the accumulation of capital which (under some conditions) is given by:

$$G'_{it} = G'_{it-1} - \delta_{it}{}^{*}G'_{it-1} + q_i{}^{*}I_{it-1} \tag{1}$$

where for each country i, G'_t is the stock of public capital at time t, and I_{t-1} is public investment spending at time $t-1$. δ_{it} is country i's time-varying rate of depreciation of the capital stock. Equation 1 indicates that the stock of physical capital in any period is equal to the fraction of total investment converted into capital in addition to the existing undepreciated capital stock.

As most prominently noted by Pritchett (2000) – a criticism that goes to the heart of this topic – the behavioural model embedded in this universally used equation and hence in all of the existing empirical literature as summarized previously assumes full public-sector efficiency (i.e. $q_i = 1$) even when there are no empirical or theoretical grounds for making such an extreme assumption. To the contrary, it is widely believed that in many countries only a fraction of the actual accounting cost of investment passes into the value of capital. Yet this obvious point is routinely ignored and cross-national estimates of physical capital still continue to be based on the assumption of full efficiency of public investment. As such, the assumption of full public capital efficiency cannot be the last act in drawing meaningful conclusions on the impact of public capital or investment on growth.

One does not have to look far to see the difference the public investment efficiency can make. The quality of infrastructure component of *The Global Competitiveness Index* taken from *World Economic Forum* (2016) shows that for

Public Sector Investment Efficiency in Developing Countries, Table 1 Public Investment Management Index (PIMI) by income group

	PIMI	Appraisal	Selection implementation		Evaluation
Low income (40)	0.47	0.21	0.28	0.30	0.20
	(0.26)	*(0.13)*	*(0.11)*	*(0.10)*	*(0.10)*
Middle income (31)	0.57	0.21	0.30	0.28	0.22
	(0.25)	*(0.09)*	*(0.11)*	*(0.07)*	*(0.07)*
All countries (71)	0.51	0.21	0.29	0.29	0.21
	(0.26)	*(0.11)*	*(0.11)*	*(0.09)*	*(0.09)*

Sources: Dabla-Norris et al. (2012) and authors' calculations. Standard deviations are in parentheses.

advanced countries the quality of infrastructure measured on the 1–7 scale is clustered at the high end with very low variation, suggesting that efficiency differences might not play a pivotal role among these countries. However, for low- and middle-income countries the median scores are almost two points lower than advanced countries with much larger variation in the scores. Thus, to truly understand the impact of investment or capital efficiency on economic outcomes, it is most useful to explore this issue for the developing world.

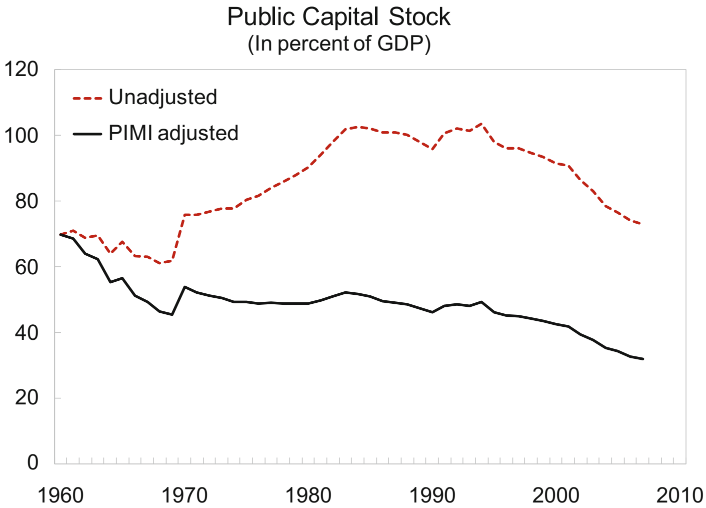
While the WEF index captures *the quality of capital*, for a researcher it is more informative to understand *the quality of the process* that turns investment into public capital. To our knowledge the first such more comprehensive Public Investment Management Index or PIMI is provided by Dabla-Norris et al. (2012) for the four stages of public investment management – appraisal, selection, implementation, and evaluation – covering 71 developing countries (40 low-income and 31 middle-income countries).[2] Table 1 suggests that, on average in the PIMI sample, only about half of public investment efforts translate into actual productive public capital. Even when accounting for possible biases that may exaggerate this finding, inefficiencies in public investment remain massive and are well recognized by both academics and policymakers alike.

This masks significant heterogeneity between countries and, even more notably, between each of the sub-indices. Further, the pair-wise rank correlations between PIMI and other similar indices such as the Budget Institution index constructed by Dabla-Norris et al. (2010), Kaufmann and Kraay (2008) governance indicators (including Government Effectiveness, the average of the Governance Indicators, and the Control of Corruption index) and the World Bank's (2009) Country Policy and Institutional Assessment (CPIA) index are positive though not overly high, ranging from 0.3 to 0.6. This indicates that the PIMI can carry information on the quality of public investment not fully captured by other more general institutional and governance indices and can thus be considered as a complement to, and not a substitute for, these more general indices.

Gupta et al. (2014) are the first to directly adjust public investment for efficiency. Their methodology to accumulate the capital stock series by Eq. 1 is similar to that used by Collier et al. (2001), Kamps (2006) and Arslanalp et al. (2010). For the crucial efficiency parameter q_i they use normalized PIMI as well as its four subcomponents. The Fig. 1 showing the general results of capital accumulation exercise indicates a significant gap between the traditional and efficiency-adjusted public capital stock in the order of 40% of GDP in the recent years available. It is also remarkable that throughout the sample period, and contrary to the unadjusted stock, efficiency-adjusted capital has substantially declined – a trend led mostly by low-income

[2] To construct PIMI data were compiled from a large number of sources including from World Bank Public Investment Management case studies, Public Expenditure and Financial Accountability assessment reports, the Budget Institutions database, World Bank Public Expenditure Reviews, World Bank Country Procurement Assessment Reviews, World Bank Country Financial Accountability Assessments and country websites.

Public Sector Investment Efficiency in Developing Countries, Fig. 1 Public Capital Stock (In percent of GDP)



countries – indicating that high-quality public investment would be associated with a high marginal product.

Armed with the new efficiency-adjusted capital stocks Gupta et al. (2014) proceed to estimate an otherwise standard unconstrained Cobb-Douglas production function:[3]

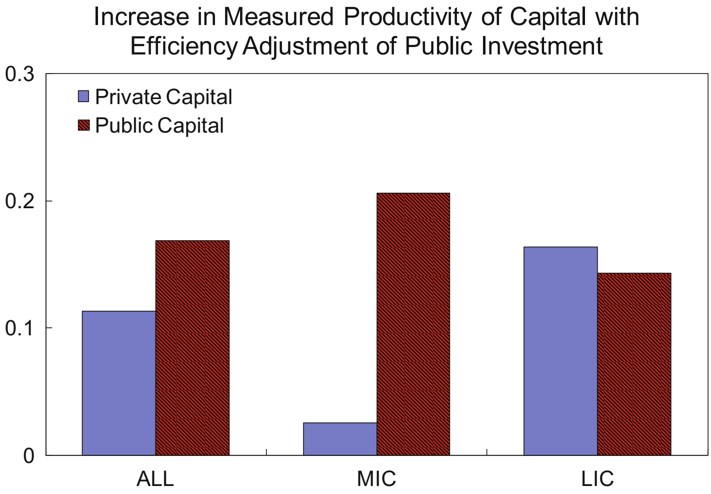
$$Y_{it} = A_0 S_{it}^{\alpha} K_{it}^{\beta} G_{it}^{\gamma} e^{\lambda_t + \varepsilon_{it}} \qquad (2)$$

where skill-adjusted labour S_t is computed according to $S_{it} = L_{it}{}^{*} e^{\varphi(h)}$, where L_{it} is raw labour and h is the average years of schooling in the population aged 15 years and older. $\varphi(h)$ is a stepwise linear function adjusting the average years of schooling by estimates for returns on education. The econometric results indicate that adjusting public capital for public investment efficiency better explains the evolution of relationship between public capital and growth. The efficiency adjustment reduces the estimated share of public capital in the production function to around 0.15 that is statistically significant for both low- and middle-income countries. More importantly, it leads to a corresponding increase in the shares of private capital, especially for LICs. As a result of efficiency-adjustment and corresponding changes in estimated production function coefficients, the marginal productivity of both private and public capital increases (see Fig. 2). The increase in private capital productivity is higher in low-income countries (LIC), whereas the increase in public capital productivity is higher in middle-income countries (MIC).

PIMI components can be omitted one-by-one, from the accumulated stock of public capital. This exercise indicates that the importance of investment stages for productivity of public capital varies with income levels. Project implementation (which comprises competitive and open bidding and internal audit) is the most critical component of the investment process. This result, which holds on aggregate, is driven mostly by low-income countries in the sample, for whom project selection (that is related to medium-term framework) assumes secondary importance. For the middle-income countries, project appraisal (which comprises transparency of appraisal standards) and projection evaluation (which comprises external audits) are relatively more important. While for all countries for which PIMI is available, implementation stands out as the stage with higher relative productivity, the results for sub-samples are mixed. This indicates that new public investment must be accompanied

[3] Aggregate data on output, investment and raw labour are taken from PWT version 6.2, public investment shares to accumulate capital stocks are taken from WEO databases, and the average years of schooling come from the Barro and Lee (2013) database on educational attainment.

Public Sector Investment Efficiency in Developing Countries, Fig. 2 Increase in Measured Productivity of Capital with Efficiency Adjustment of Public Investment



by strengthening of specific bottlenecks in investment processes to enhance the productivity of public capital.

Towards the Third Generation of Research

A number of theoretical applications have directly modelled public sector investment efficiency as in Eq. 1 in the DSGE framework to allow for a richer set of interactions, including the presence of a zero lower bound on nominal interest rates. Berg et al. (2013) are among the first to model declining investment efficiency in the stock of public capital capturing capacity constraints. Especially for resource rich countries, this can support a more gradual public investment strategy for windfall savings that could initially be saved in an external fund.

More importantly, Berg et al. (2015) identify and clearly explain a key steady-state result characterized by the invariance of growth with respect to investment efficiency: the impact of additional investment on the growth rate of output does not depend on the level of the time-invariant efficiency parameter q. This is easy to see in a two-equation system consisting of capital accumulation Eq. 1 and a Cobb-Douglas production function such as Eq. 2 with only public capital as an input:

$$Y_t = A_t G_t^{\gamma}. \tag{3}$$

Equation 1 implies that, in a steady state:

$$K = \frac{qI}{\delta}. \tag{4}$$

The rate of return of a marginal unit of investment can then be expressed as follows:

$$\frac{dY}{dI} = \frac{dY}{dK} * \frac{dK}{dI} = \gamma \frac{Y}{I} \tag{5}$$

Equation 5 implies that the impact of a marginal change in investment on the growth rate of output (which is a product of the marginal productivity of capital and the capital stock per unit of investment) is simply equal to the public capital share γ in the production function and does not depend on the level of investment efficiency q. The general intuition to this invariance lies in the law of diminishing marginal productivity: since the time-invariant efficiency q permanently scales down the capital stock, diminishing returns imply higher marginal productivity. These two effects work in the opposite direction and with Cobb-Douglas exactly offset each other. This implies that inefficiency, per se, would not lead to lower growth and should not be considered as a reason to not invest.

However, it must be noted that the impact of public investment and its efficiency on output and growth can be more complex than implied by the aforementioned two-equation system. At least four key reasons can be brought out that can support growth effects of investment efficiency. First, the Berg et al. (2015) is a long-run *steady-state result* that does not preclude that changes in investment efficiency affect *transitional growth* towards the steady state, in a manner similar to the saving rate in exogenous growth models. Second, as is also acknowledged by the authors, patterns of complementarities between the production factors matter: if public and private capital are complements, public investment in low-efficiency countries could still have an impact on the growth rate of output through higher marginal productivity of private capital. Third, intuitively investment inefficiency can have an impact on growth (even at steady state) through scale effects, if the level of effective capital determines the level of technology at the aggregate level, creating positive externalities similar to the pioneer endogenous growth models of Romer (1986) and Lucas (1988). Fourth, the impact of investment and efficiency on growth can depend on the *structural conditions* of the economy, including cost of financing, the fiscal space, and the level of debt.

For example, Buffie et al. (2012) show that *productive* public and private capital are complements. However, if structural conditions are weak, including low public investment efficiency and collection rates, instead of crowding-in a surge in public investment can crowd-out private investment and could lead to unsustainable public debt. Model simulations by IMF (2014) show similar results for developing economies characterized by *structural conditions* that usually exhibit less slack, less accommodative monetary policies, and importantly lower public investment efficiency. In these economies, a public investment shock leads to substantially lower long-term output effects compared to advanced countries, and a higher public debt to GDP ratio that in turn can impinge on growth.

Finally, interactions between public and private capital pose an important policy question on the use of public-private partnerships (PPPs): if accounting for high public sector investment inefficiencies also leads to higher marginal productivity of private capital, can more widespread use of PPPs be associated with higher growth, especially in LICs? While research here is still scarce, it can prove to be a promising field. Buffie et al. (2016) document that, even if costlier, PPPs produce higher quality capital at shorter times compared to public sector own investment. Their general equilibrium simulations suggest that PPPs can have a social return 5–8 points higher than own public investment.

The work on the efficiency of public investment has highlighted several limitations and would benefit from research across the following dimensions. First, the PIMI is available only for one period 2007–2010 and is thus time-invariant. While it encompasses cross-sectional variation, it is not able to capture changes that have incurred to investment processes over time. Second, the determination of depreciation rates of public capital stock that vary across time and countries as well as the level of the initial public capital stock deserves further investigation to reduce measurement errors. Third, the empirical literature is yet rather silent on whether public capital is complementary to, or a substitute for, other production factors, including wealth of natural resources that is highlighted by Caselli (2005) as one of the factors that could bring the estimated marginal productivities of capital across countries closer together. Fourth, in an open-economy growth model with perfect capital mobility convergence would happen instantly as a fully integrated global economy ensures that differences in rates of return on capital are eliminated across countries. To explain why we do not observe this requires consideration of the possible frictions in international capital markets that slow down or eliminate convergence altogether. Obstfeld and Rogoff (1996) present an open-economy growth model that demonstrates in a very tenable and intuitive way the ability of market imperfections to yield convergence dynamics in an integrated global economy. Whether lack of efficient public capital can provide an explanation of why capital does not flow to less developed countries is a promising research avenue (see, e.g. Lowe, Papageorgiou and Perez Sebastian). Finally, investigation into the productivity of public capital would benefit from a wider exposure to different methodologies.

Direct estimation of the investment efficiency parameters in a DSGE model as done by Berg et al. (2013, 2015) is a useful alternative if reliable information is otherwise lacking.

Conclusions

Public investment in bridges, roads and ports is truly essential in low-income countries which suffer from massive infrastructure gaps. It is considered one of the most important drivers of growth and a primary component of the development strategies of governments in the developing world. Significantly boosting investment in physical infrastructure to achieve sustained growth rests on the high returns to investment in capital-scarce environments, and the pressing deficiencies in these areas. However, inefficiencies in project appraisal, selection, implementation and evaluation lead to devastating losses in public capital accumulation and output. The history of public investment booms is filled with disheartening stories about "roads to nowhere" and "white elephants" especially in poor countries where public goods are in dire need.

This entry suggests that considerable progress has been made by economists in better measuring, and more appropriately, incorporating public investment inefficiencies in economic models. In addition, our understanding of the drivers of these inefficiencies, such as poor incentive systems, inadequate capacity to appraise and implement projects, and absorptive capacity, has improved. Nonetheless, more needs to be done in this important area of economics. As better data become available, including at the firm and sectoral level, economists should improve existing indices of public investment inefficiencies. This is resource-intensive work that requires careful collaboration with governments and researchers. But without the necessary and high-quality data, assessment of inefficiency will not be possible. At the same time, country authorities must pay particular attention in improving their processes of project selection, appraisal, implementation and evaluation. This is a very attainable goal that encouragingly has started to become a priority in most economies of the developing world.

Public Utility Pricing

Pierre B. Massé

Public utility goods and services are, for any given state of the economy and of technology, those to which the members of a society are regarded as entitled at reasonable charge, and which could not be satisfactorily distributed through the usual market channels.

The organizations responsible for distributing such goods and services, referred to here as public utilities, are characterized by the legal system which governs them, but not by the nature of the capital employed (whether public, private, or mixed).

The legal system governing public utilities is as a rule laid down under a grant of license and terms of reference. The granting authority is the central government, the local authority or some intermediate territorial entity. The grantee is bound by certain obligations, of which the main ones are the duty to ensure continuity of service and equality of treatment among users. It enjoys prerogatives of expropriation and easement which are especially valuable when setting up a *network* (whether railway, electricity, telephone, or drinking-water supply etc).

The ethical consideration that governs public utilities and is discussed in this entry is that of *benefit to the community.*

I. Pricing is a procedure involving the following preliminary stages: (a) a reasoned expectation of future demand, future technology and future costs of factors of production; (b) an optimal choice of technology and production factors so as to minimize the discounted total cost of the output that is in keeping at any time with demand, together with whatever prudent margin is considered necessary.

Pricing as such consists of calculating prices which maximize the benefit to the community, taking into account any economic, financial or social constraints. If there is neither rationing of the product, nor any unduly high margin of production potential, then the whole process is validated. Otherwise, it has to be adjusted in detail so as to remove any deficiencies or reduce any excess margin.

Historically, the problem of public utility pricing was first discussed with a modern outlook by Harold Hotelling in 1938. In France, after the work by Maurice Allais in 1943, an early reference text is the address by Gabriel Dessus of Electricité de France, 1949. This text uses the argument of the woodcutters' and miners' cases to illustrate the greater advantage – in terms of benefit to the community – of marginal-cost pricing compared with average-cost pricing. If it were possible to optimize continuously at every moment, then marginal cost would be defined without ambiguity. But because of the indivisibilities, as the same author showed using the paradox of the passenger for Calais, it is preferable to keep to long-run marginal cost (LRMC) and to smooth the irregularities of short-run marginal cost (SRMC).

The theory of LRMC which results from these analyses is developed in two monographs, Nelson (1964) and Morlat and Bessière (1971). Among these texts is an article by Marcel Boiteux (1956) on managing public monopolies which are under a duty to balance their budgets. This is a special constraint, but the method used is a general one and gives that paper value as a reference.

In striving to secure price-variations in keeping with economic efficiency, the public utilities were encouraged by contemporary advances in theoretical economics, initiated in the early 1950s by K.J. Arrow and G. Debreu (e.g. Debreu 1959). The worth of that approach is, in the first place, that it defines a commodity not just by its physical nature but also by the date and place of its supply, so justifying the varying of public utility prices. Next, it is valuable because it provides a modern and rigorous demonstration of the existence of a price equilibrium – combined with a Pareto optimum – based on the assumption under which economic transactors are compelled to optimize at *fixed prices* their behaviour as producers and consumers. A public utility that prices at LRMC is thus behaving 'appropriately' in its own field.

The dissemination and implementation of these principles encountered a number of difficulties. First, the theory led to price differences according to time of day and seasons, but the desired degree of variation could not be taken too far without making metering appliances complex and hence costly, as well as making for subtle differences in charging that might be ill-perceived by users.

More basic obstacles were the heritage from the past, the attachment to budgetary balance, a strong tendency to assign to a physically defined commodity or service (a cubic meter of water, a passenger-kilometre, a ton-kilometre or a kWh) a price that took no account of the time and place of its supply. The desire for equality made for a standardization of charges across the board. This is not to mention the political determination to redistribute incomes, which all too often took the convenient line of manipulating public utility prices. The economy may be 'imperfect' upstream of public utilities' inputs and downstream of their outputs. The Government's economic advisers must have a say regarding the impairments occasioned to economic efficiency in the name of social justice, in order to make the search for a compromise a consciously thought-out process.

II. The quarter-century after World War II was marked by a high level of employment and rapid growth. It was generally accepted in France that a moderate dose of inflation was 'the socially-acceptable price to pay' (Malinvaud 1983, p. 17). Optimizations at nominal fixed prices then had to be replaced by optimizations at *real* fixed prices.

International monetary instability, competition from Asia, and the oil shock in late 1973 resulted in an abrupt change in 1974 (see Dubois 1980). The world economy entered a zone of turbulence, and the West was struck by the scourge of unemployment, even though the social diffusion of almost thirty years of expansion staved off a recurrence of the tragedies of the Great Depression.

This situation led to the view in certain quarters that public utilities, quite apart from their duty to serve the public, should be required to fulfil an instrumental function of helping to restore the major equilibria of the economy (Courbis 1972). This concept gained further momentum from the post-war wave of nationalizations in Great Britain, France and Italy, followed by further nationalizations in France in 1981. The State, as the licensing authority, became the sole shareholder of a great many public utilities and hence, attempted to harness them to its general economic policy.

Experience has shown that the immediate response of many Western economies to a major and unexpected shock is equilibrium at fixed prices with under-employment (or other forms of rationing). What happens next depends upon the degree of flexibility of the economy. If sensitivity is shown to market indications, adjustment through prices can begin to take place. If, on the other hand, rigidity has its way, the managers of the economy are compelled to abandon the idea of a first-best optimum which would involve unacceptable real wages. They can then resort to macroeconomic models, either to compute shadow prices by second-best optimization (under pressure to reduce rationing), or to simulate the effects of changes in the behaviour of economic agents induced by the use of shadow prices supplied exogenously.

III. Long-run marginal cost is a conceptually desirable guide that is used empirically, and at times unconsciously, to an increasing extent; for example, the World Bank has endorsed its use for water and electricity supplies in developing countries (Munasinghe and Warford 1982). Even so, its application comes up against the heritage from the past, the temptation to unify prices for reasons of simplicity and/or egalitarianism, the concern to work towards greater social justice through non-apparent transfers of benefits, or again, the public utilities' own commercial considerations.

For these reasons, public utilities are at times compelled to compromise between practical or policy constraints and the purity of the theory. Knowledge of the theory nevertheless remains valuable to public utilities in democratic countries, since they can use it to gauge the extent of demands for transfers which sidestep parliamentary sovereignty.

Three Applications in France

The Railways

The railways, in France around the third decade of the nineteenth century, were very soon brought under the control of six private licensee companies with a tendency towards monopolistic practices. These companies were tied to the State by agreements, principally those of 1859 and 1921, under which a mutual financial support scheme was instituted, which took the practical form of a financial pool.

The Popular Front government of 1936, although it stopped short of outright nationalization, merged the networks in 1937 under a single company in which the State held a 51 per cent capital interest, the Société Nationale des Chemins de Fer Français (SNCF). After World War II, developments in the network were marked by two strategic changes: electrification using industrial current, with the backing of Louis Armand, and from 1980 onwards, the development of the new 'TGV' high-speed-train network which, from the passengers' point of view improved competitiveness on high-traffic trunk routes.

At the end of 1982, when the 1937 agreement expired, the assets of the SNCF reverted to the state under the terms of the agreement. Thereupon, a new outline act on domestic transport defined a 'new' SNCF with the status of an industrial and commercial public body, without resorting to the earlier principle of licensing.

Throughout this long process of change, passenger pricing is seen to have been a compromise between two tendencies: (a) the heritage from the past, which accounts in particular for nationwide standardization, a habit of thought deeply rooted in French mental attitudes; and (b) the pressures of economic efficiency in a climate of lively competition with the motor car, and then with airline flights.

As matters stand, the basic price per kilometre is the same everywhere, except on the new Paris–Southeast line, where the distances used in pricing are still based on the old routes, which are appreciably longer. A policy of variation according to time, gradually developed over the last 15 years, is based on supplements for certain trains, side by side with reductions in keeping with social as well as commercial considerations. A red, white and blue timetable, devised for the purpose, distinguishes off-peak days, normal weekends and some 30 or so major holiday departure dates. This policy is being pursued under new legislation and regulations which reserve to the State powers for approving pricing levels and structure.

For goods, railways were subject in the early days to two opposite influences. One was political and anti-monopolistic, and favoured standardizing charges; the other was economic, and motivated in particular by competition from road transport which 'creamed off' the more lucrative traffic. This led the railways to look for an efficient pricing structure (Hutter 1950). That took shape in particular through de-standardization adopted in 1961, on the basis of the Rueff–Armand report, and confirmed in 1967 after the Nora report: the terms of reference were relaxed, with greater flexibility for pricecompetitiveness. The legal provisions of 1982–3 seek to go still further by giving SNCF complete freedom in principle to set its own prices, while making it liable to observe 'the rules of fair competition'.

In practice, SNCF refrains from reducing its prices below LRMC – an important guide to its commercial policy. The intensity of competition with other modes of transport was considered sufficient to protect users against the possible 'abuse of a dominant position'.

Electricity

The licensed electricity distributing companies, which were formed in the late nineteenth century and grew up in the twentieth, were private-capital utilities. Their numbers tended to fall with takeovers, but even so in 1945 there were still over a thousand of them. Most were nationalized by an Act of 8 April 1946, under which Electricité de France (EDF) was formed as an industrial and commercial public body.

For EDF, forecasting demand, the choice of equipment and pricing are three links in the same chain. To begin with, demand was predicted according to the empirical rule, seductive in its simplicity, of a doubling in ten years. Very soon, however, less rudimentary models had to be developed, to take into account the general expansion of the economy and the prospects for the different types of use.

As a first stage, the optimum capital stock was sought by comparing, at the margin of the grid, the performance of the projected hydroelectric power stations with that of a reference fuel-burning power station. In the mid-1950s, EDF, with the help of computers which had just appeared on the market, conducted first linear, then non-linear programming for the entire grid, with the optimum solution generating dual prices that are associated with the easing of physical constraints.

All pricing policies are two-part (a fixed premium and proportional charges). The fixed-premium amount relates to demand-ratings subscribed by users in advance, and any excess demand drawn because too little demand was subscribed is billed separately. The charging scales comprise eight different periods of the year for major customers, and taking transactions' costs into account, the charging scheme becomes gradually simpler going down towards smaller-scale supply.

On account of the considerable impact of random events, control is necessary to balance supply and demand. Supply control (using hydraulic reservoirs and pumping stations) is supported by demand control, particularly through pricing. The requirements to subscribe to an amount of demand meets that objective by involving users in the coverage of risks. In addition, the rapid expansion of heating uses, which accentuates sensitivity to climatic hazards, has led the electricity suppliers to consider optional charging scales in which posted prices relate to periods of which customers know the duration (roughly 400 hours at the shortest and dearest), without knowing exactly when they will occur; this is currently specified by the supplier at the last moment.

There are few departures in France from the principle of LRMC pricing. The most notable was the practice of applying the same standard for charge to low-voltage sales in both urban and rural areas, when costs 40 years ago were appreciably lower in the former. However, the choices against efficiency that might have resulted from this practice remained limited, since low-voltage prices have virtually no impact on private individuals' choice of geographical location. What is more, cost differentials have narrowed appreciably with the expansion of consumption and increase in density of networks.

Concerning industry, public utilities in many countries are subject to – at times considerable – pressure to offer prices at less than cost to very large users, particularly in electrometallurgy and electrochemistry. As a rule, any really serious departures from the principles of pricing have been avoided. In the main, however, pricing remains a valuable guide for both customers – particularly industrialists – and producers in making their choices, including commercial policy choices.

Telecommunications

Ease of access to a telecommunications network at any point within national boundaries is a public utility for which pricing changes as the network expands and services develop (Hazlewood 1950; Squire 1973).

In the early stages, traffic was mainly local. A fixed charge reflecting the cost of average usage was the price of access to the service. Then the local networks spread, with small users alongside large. In pricing, transmission and switching costs were separated from access and rental charges, which are the responsibility of connection and management services.

In the stage which followed, trunk traffic services developed and, on account of their high value of usage, they subsidized for a time a portion of local traffic costs. A reduced rental charge was designed to draw in lower-income users. A further attraction to new subscribers was the consumption externality which is a particular feature of the telephone network: the utility of being connected to the network increases with its size, so that the increase in number of connections to the network stimulates demand and causes the service to spread by a snowball effect. This was observed in France in the 1970s, when the allocation of capital-investment priorities to telephone capital-equipment projects caused an explosion in demand which until then had been rationed by supply.

The network then entered its mature phase, with a slowing of growth in the size of the stock of mainstations and in traffic. The concern for economic efficiency led to a search for reductions in the cross-subsidizations induced by differentials between the prices charged and LRMC (Brunetière and Curien 1985), since trunk-call traffic was in fact subsidizing local traffic and connection costs, and calls were not charged at a fair rate taking account of time of day (Littlechild 1970) and duration. Recent measures taken in

France (Curien and Pautrat 1973) to make charges uniform according to distance when it exceeds 100 km (in 1969), to introduce a four-tier time-of-day variation (1984), and to charge local calls according to duration (1985) are tending to reduce cross-subsidizations internal to traffic. On the other hand, the high cost of the unit pulse and the lowering of access and rental charges are maintaining a high level of cross-subsidization of households by business. These cross-subsidies are in keeping with social concern for the more deprived groups. Existing subscribers also benefit from the external benefit of new subscribers coming onto the network, although the marginal investment costs of connection must remain profitable at the social rate of discount.

Changes in pricing are also made necessary by the diversification of uses. After access to the basic network, the routing of telephone traffic, the commodity supplied by the telecommunications service has become the bandwidth, a non-dedicated carrier that the user can use to transmit vocal information (telephone) or non-vocal information (data, text, pictures etc). Strict principles of economic rationality, that is, pricing the carrier regardless of content, will have to be relaxed in order not to deter people from using devices for which the potential market is promising. Finally, with the change in the regulatory environment and the emergence of deregulation, competition is appearing in the most profitable segments of the telecommunications market, prompting network managers to remove cross-subsidies.

Public Utility Pricing and Finance

Frank A Wolak

Abstract

The theory of public utility pricing provides clear recommendations when the regulator and utility have same information about the underlying economic environment – the structure of demand and the production process. In reality, the utility has private information about the underlying economic environment, and the

incentives created by the regulatory process can cause it to exploit this information by producing in an inefficient manner. This insight complicates virtually all aspects of the theory of public utility pricing, and has led to theoretical characterizations of the public utility price-setting process as the solution to a mechanism design problem.

Public utilities typically provide goods and services using a physical or virtual network infrastructure under a legal monopoly status. Public utilities can be privately owned, government-owned and customer-owned. Products provided by public utilities include electricity, natural gas, water, sewage treatment, waste disposal, public transport, telecommunications, cable television and postal delivery services. In the United States, all the different ownership forms can exist within the same industry. For example, in the electricity supply industry, there are privately owned, investor-owned and municipally owned utilities, and cooperative utilities owned by their customers.

Many explanations have been offered for the public utility industry structure. The standard economic efficiency argument is that the industry is natural monopoly, meaning that a single cost-minimizing firm is the least-cost way to serve the current level of demand. However, this logic relies on the implicit assumption that the single firm will produce in a cost-minimizing manner, which is unlikely to occur under government ownership or government regulation, for the reasons discussed below. In addition, although the current level of demand may be served at least cost by one cost-minimizing firm, this is unlikely to be that case for all future levels of demand as the number of customers or their purchasing power grows. Recognizing that public safety and health concerns argue for universal access to many of these services and the fact that the demand is very inelastic with respect to its own price leads to political economy explanations for this public utility industry structure. As Waterson (1988) notes, a government-owned or -regulated monopoly may better ensure that all customers have access to these services at reasonable prices.

Over the 100 years or more of state and federal regulation of public utilities in the United States there has been debate over what constitutes a reasonable price for goods and services of public utilities. A price that recovers the firm’s operating costs including return on its capital stock is generally considered to meet the legal standard of a reasonable price. This form of price regulation in the United States is often referred to as ‘cost-of-service’ regulation. However, as Joskow (1974) has persuasively demonstrated, the price-setting process for privately owned utilities in the United States does not guarantee the firm a fixed rate of return on its capital stock or full operating cost recovery. In that sense, to call this regulatory price-setting process ‘cost-of-service’ regulation is a misnomer. Joskow (1974, p. 325) states:

‘The rate of return aspect of regulation is merely a method by which a regulatory commission justifies its approval of price increases or major changes in rate structures. Without such triggering mechanisms the rate of return constraint is essentially inoperative.’ When the cost-of-service regulatory process operates it sets a price that allows the public utility an opportunity to recover its operating costs and the regulated rate of return on its capital stock through prudent operation.

If the firm earns a higher rate of return at this price because of superior management, then it is allowed to keep the revenue. If the firm earns a lower rate of return because of poor management, then shareholders must accept a lower rate of return. Only when the regulatory commission has overwhelming evidence that the higher or lower rate of return is due to extraordinary events beyond the control of the firm and not anticipated at the time the regulatory commission set the price will it make *ex post* adjustments to alter the public utility's regulated rate of return. A well-known example of an extraordinary event is a price change for fossil fuels used to produce electricity. The extreme volatility in oil, natural gas and coal prices since 1977 has led many regulatory commissions in the United States to implement fuel price adjustment clauses that automatically pass through in any input fuel price changes in the price of electricity. Baron and De Bondt (1979) discuss the impact of these fuel adjustment mechanisms on the investment and operating decisions of regulated electricity and natural gas utilities.

The terms and conditions surrounding this promise of full cost recovery through prudent operation is often referred to as the 'regulatory contract' between the regulatory commission and the public utility. This implicit contract requires the utility to serve all demand at the price set by the commission in exchange for a price that allows the utility the opportunity to recover its operating costs and a reasonable return to its capital stock. A major challenge to this regulatory contract is determining when imprudent operation is the cause of a failure to achieve full cost recovery.

For a number of reasons, unexpected events outside the control of the regulatory commission or utility and *ex post* opportunism by the regulator are often very difficult to distinguish from valid reasons for the regulatory commission to disallow price increases. Utilities typically require substantial investments in a network infrastructure that has limited alternative uses. The future demand for the public utility's services is uncertain, so there is a substantial risk that investments in network infrastructure will not be needed to serve the demand that exists when the investment is completed.

Several aspects of the regulatory process in the United States are designed to address the problem of the regulator setting a price that is insufficient to provide a reasonable return on past investments. The concept of a ratebase and the requirement that the regulatory commission sets a price that recovers operating costs and a reasonable return on the entire ratebase limits opportunistic behaviour on the part of the regulatory commission. To a first approximation, the ratebase is the sum of all past investments judged as prudent and therefore worthy of cost recovery by the regulatory commission. Phillips (1993, ch. 8) provides a detailed discussion of this concept. The requirement that the entire ratebase earns the regulated rate of return ensures that the current regulatory commission compensates the utility for investments that previous commissions have deemed prudent.

Gilbert and Newbery (1994) construct a dynamic model of the regulatory price-setting process where the commitment to allow the firm to earn a reasonable rate of return on a ratebase composed of past prudent investments results in a socially efficient level of investment by the regulated firm. Lyon and Mayo (2005) investigate the empirical relevance of regulators' opportunistic behaviour by examining the investment behaviour of regulated electric utilities and the propensity of the relevant state regulatory commissions to disallow investments by these utilities from entering the ratebase. Lyon and Mayo (2005) find little evidence that these cost allowances by the state regulatory commissions were due to opportunistic behaviour, and instead argue they were motivated by a desire to punish poorly managed firms.

Optimal Pricing of Public Utility Services with Full Information

Prices that adhere to the implicit regulatory contract of allowing full cost recovery only impose one restriction on the set of possible prices. For the case of a single-product utility that must set the same price for all customers, this restriction implies that the regulated price is equal to average total cost. However, virtually no public utilities sell a single product or are required to set a single price for all customers, so that regulatory commissions are free to pursue additional goals, besides the promise of cost recovery, in setting regulated prices.

This section discusses methods for setting economically efficient prices – those that maximize some social welfare function – under the simplifying assumption that the utility and the regulatory commission have the same amount of information about the utility's production process and demand. The remainder of this section assumes symmetric information between the regulated utility and the regulatory commission, so the commission can credibly set a price that only recovers the firm's minimum cost of serving its demand. Although the assumption of symmetric information about the production process and nature of demand between the utility and regulatory commission is unrealistic, the literature on optimal pricing for public utilities described in this section relies on this assumption.

Two-part tariffs relax the assumption that a single uniform price is charged to all customers for each unit of output. If the production of the good or service is subject to increasing returns to scale, setting price equal to the marginal cost of the last unit sold violates the legal requirement that the firm has an opportunity to recover total production costs. Coase (1946) addresses this problem by considering a regulated public utility producing a homogenous product with a monthly fixed cost of production, *F*, and a constant marginal cost, *c*. Coase (1946) argues that the total surplus maximizing two-part tariff sets the price of each unit consumed, *p*, equal to *c* and the fixed charge for each customer equal to *F*/*N*, where *N* is the number of customers served by the public utility.

If consumers differ in their willingness to pay for the product, then the surplus accruing to some consumers can be increased by the commission setting multi-part tariffs that charge different marginal prices for different ranges of monthly consumption. If the level of the monthly fixed charge necessary to recover total monthly fixed costs causes some consumers not to purchase the product, then a multi-part tariff can increase total consumer surplus. Assuming the marginal cost of a minute of telephone service is two cents per minute, setting a low monthly fixed charge and charging two cents per minute for the first 200 minutes of phone calls in the month and four cents per minute for all minutes above 200 minutes per month can allow the phone company to increase the number of consumers that benefit from having a telephone service without violating the promise of cost recovery. In this way, those consumers with the highest willingness will select through their consumption choice the higher marginal price, while those with the lowest willingness will select the lower marginal price, and virtually all consumers will pay a monthly fixed charge that does not cause them to disconnect from the telephone network. Brown and Sibley (1986, ch. 4) discuss consumer and producer welfare properties of multi-part tariffs.

The nature of the goods and services sold by public utilities often allows them to segment customers and to charge different prices for the same product. In addition, virtually all public utilities are multi-product firms, which implies that the regulatory process involves setting prices for all goods sold by the firm. Both of these circumstances provide opportunities for regulatory commissions to pursue objectives beyond the promise of cost recovery.

Consider the case of a homogenous product with increasing returns to scale in production that is sold to M different sets of consumers and a regulatory commission that can set a single price for each set of customers. Deriving the total surplus maximizing prices for all customer types subject to the constraint on cost recovery fits into the framework considered by Ramsey (1927). Let $CS_i(p_i)$ equal the consumer surplus accruing to consumers of type *i* and when they face price p_i, and $PS_i(p_i)$ equal the producer surplus from serving consumers of type *i*. Ramsey prices maximize the objective function $TS = \sum_{i=1}^{M} [CS_i(p_i) + PS_i(p_i)]$ subject to the cost recovery constraint, $F \leq \sum_{i=1}^{M} PS_i(p_i)$, where *F* is the firm's fixed cost. Let *c* equal the marginal cost of production and $\varepsilon_i(p_i)$ the own-price elasticity of the demand by customers of type *i* at price p_i. The solution to this constrained optimization problem yields the inverse elasticity pricing rule:

$$\frac{(p_i^* - c)}{p_i^*} = -\frac{k}{\varepsilon_i(p_i^*)}, i = 1, 2, \ldots, M$$

where k is some positive constant and the p_i^*, $i = 1, 2, \ldots, M$, are called Ramsey prices. These prices raise the revenue necessary to achieve full cost recovery with the smallest total surplus loss. Those consumer types with relatively more inelastic demands for the goods pay higher markups above marginal cost than other consumer types.

This same Ramsey-pricing logic can be applied to the case of multi-product public utilities. However, the simplicity of inverse elasticity pricing rule is complicated by the fact that customers can substitute across the products that the public utility offers. For example, in the pricing of postal delivery services, a business mailer has the option to use different US postal service products to communicate with its customers. To set Ramsey prices, the regulatory commission must know the multi-product cost function for postal products and the consumers' surplus associated with each postal product, which depends on the price charged for other postal products that the consumer can use as a substitute. As shown in Brown and Sibley (1986, ch. 3), both own-price and cross-price elasticities of demand now determine the total surplus maximizing markups that solve the Ramsey-pricing problem.

The properties of the regulatory pricing mechanisms described in this section rely on the assumption that the public utility's cost function is the minimum cost way to produce each vector of outputs. Specifically, let T equal the public utility's technology set, the pairs of vectors of input quantities, x, and output quantities, q, such that q can be produced using x. If w is the vector of input prices, then the minimum cost function is equal to

$$C(q) = \min_{x \geq 0} w'x \quad \text{subject to} \quad (x, q) \in T.$$

Although a price-taking profit-maximizing firm would like to produce along its minimum cost function, the structure of the regulatory process could cause a privately owned profit-maximizing regulated utility not to produce along its minimum cost function. Averch and Johnson (1962) present an example of a regulatory mechanism that causes a profit-maximizing firm not to produce in a least-cost manner. This work led to a massive theoretical and empirical literature exploring the distortions from minimum cost behaviour caused by regulatory price-setting processes.

State-owned utilities are likely to have even less incentive to produce in a least-cost manner. Besides the incentives provided by the regulatory price-setting process, earning revenues in excess of operating costs is just one of the many objectives that managers of state-owned companies must balance. As Waterson (1988, ch. 4) notes, state-owned utilities are often asked to pursue political or social goals that conflict with maximizing profits and therefore minimizing production costs.

Economists have begun to recognize the distinction between a public utility's observed cost function and its minimum cost function. The observed cost function, $CO(q)$, gives the firm's actual cost of producing output vector q given the incentives provided by the regulatory process. For example, in the case of a state-owned utility, political constraints could require a firm's management to hire a certain number of workers for each level of output despite the fact that it is technologically feasible to produce using fewer workers at each output level. In general, the value of the firm's observed cost function is greater than the value of its minimum cost function for the same level of output, and this difference can be substantial.

There is a vast empirical literature documenting violations of the assumption of cost-minimizing behaviour by public utilities. Christensen and Greene (1976) is a well-known example in the electricity supply industry and Evans and Heckman (1984) is one for the telecommunications industry. There are few empirical studies of regulated utility behaviour where the assumption of cost-minimizing behaviour is not rejected.

Optimal Pricing of Public Utility Services with Asymmetric Information

Public utility regulation has long been recognized as an example of agency relationship where the regulator (the principal) attempts to provide incentives for the public utility (the agent) to serve its demand in a least-cost manner at a price that only recovers observed costs. This link between the utility's production costs and the price it is allowed to charge creates the opportunity for the public utility to exploit its superior information about the production process and the demand it faces. This recognition has led researchers and regulatory policymakers to consider ways to either break this link between the price charged and the firm's observed cost or to design incentive mechanisms that exploit the link between the regulated price and the firm's observed cost.

Price-cap regulation attempts to break this link by committing to change the price the utility is allowed to charge according to a formula that cannot be altered for a sustained period of time. For a profit-maximizing firm, the price-cap mechanism creates the same incentive to minimize cost as the assumption of price-taking behaviour. In the United Kingdom (UK) this form of regulation is also called RPI minus X price-cap regulation because the rate at which prices are allowed to change on an annual basis is equal to rate of change in the retail price index (RPI) minus an X-factor chosen by the regulatory commission. Armstrong et al. (1994, ch. 3) describe the details of choosing an X-factor for a specific firm and extensions of this basic regulatory framework.

The major challenge associated with price-cap regulation is balancing the desire to commit to a pre-specified pattern for the X-factors for as long as possible against the fact that the longer duration of the commitment to this pattern of X-factors the greater the likelihood that the commitment will run afoul of the regulatory contract or political concerns. The experience of many public utilities in the UK privatized during the 1990s provides an instructive example of this phenomenon. According to Armstrong et al. (1994), the regulator for the water industry and the regulator for the electricity distribution sector initially committed to a five-year initial duration for values of the X-factors. However, in both these industries the regulator was forced to abandon these commitments before the end of the five-year period because of what was argued to by the water utilities to be inadequate revenues and what was argued by many consumers as excessive revenues in the case of the electricity distribution sector. Wolak (1998) discusses practical problems associated with implementing price-cap mechanisms and why they often evolve into an extremely ineffective form of cost-of-service regulation.

The development of game theoretical models of private information environments has led economists to derive optimal prices in this 'second-best' world. Baron and Myerson (1982) derive the total surplus maximizing prices when the public utility has private information about its production process not observable by the regulatory commission. The Baron–Myerson model assumes that the commission offers the firm a menu of prices and fixed fees that depend on the public utility's report of its private information. This report determines what price and fixed fee the firm is able to charge to its customers and therefore the revenues it is allowed to earn.

Recognition that informational asymmetries between the regulatory commission and utility can lead to significant distortions from minimum cost production and regulated prices that recover revenues substantially higher than these minimum costs has led to an explosion of theoretical work on the design of optimal regulated prices in this private information environment. Laffont and Tirole (1993) provide a comprehensive presentation of this literature.

Wolak (1994) attempts to quantify the cost of this private information in the regulatory process. Using a sample of California water distribution utilities, he estimates a full or symmetric information solution to the utility and regulatory commission interaction and a private or asymmetric information model of this interaction based on the Baron–Myerson (1982) model. Wolak (1994) finds that the asymmetric information model of the regulatory process provides a superior fit to observed data relative to the symmetric information model in addition to computing various estimates of the cost of the informational asymmetry between the firm and regulatory commission.

Concluding Comments

The explicit recognition of the impact of the private information possessed by the firm on the price set by the regulatory commission has increased the realism of the assumptions underlying models of the public utility price-setting process. Unfortunately, the form of the optimal price-setting mechanism derived from these models depends crucially on the source of informational asymmetries between the firm and the regulatory commission, as well as many other details of the economic environment. This implies that much more empirical work on actual regulatory price-setting processes is needed to implement these theoretical advances in actual regulatory practice.

Public works to relieve unemployment is an idea as old as the pyramids. From the cathedrals of the

Middle Ages to the dams of the Tennessee Valley Authority, recent centuries abound with examples of such government-supported schemes. However, it is only fairly late in the history of economic theory that economists started devoting some analytical thought to this problem. In fact, it was around the turn of the 20th century, with the appearance on the Continent of the first systematic work on business cycles, that economists stopped looking at unemployment as a 'pathological' problem to be tackled primarily as one of charity and relief. Even down to the British 1909 *Report of the Poor Law Commission* a majority still considered unemployment as no challenge to economic theory: if properly applied, in the long run, the normal laws of value and distribution would see to a solution to this problem.

A notable exception to this general neglect is, of course, the heated discussions that took place between early 19th-century classical economists during the so-called 'general glut controversy'. In the course of that well-known debate on the self-adjusting capacities of the economic system, public works as a means to combat unemployment came many times to the forefront of the argument. Ricardo, James Mill and Say fairly easily won the day against public works. However, though dissenters like Malthus, Lauderdale, Bentham and Sismondi rejected Ricardo's doctrine on the stability of the economic system and Say's rigmarole about the equality of supply and demand, they involved themselves in a logically very damaging acceptance of the dominant Turgot–Smith saving-is-investment doctrine, together with the aggravating assumption that hoarding cannot take place. Trapped in such contradictory statements, these dissenting authors never managed to put their case convincingly either against Ricardo's self-adjustment doctrine or, of course, in favour of contra-cyclical public works. Showing very little interest in 'immediate and temporary effects [and fixing his] whole attention on the permanent state of things' (1952, vol. 7, p. 120), Ricardo was left in a very strong theoretical position to dismiss arguments in favour of credit expansion and/or public works to reduce unemployment. Furthermore, his lack of a theory of output (that is, his full-capacity utilization assumption) allowed Ricardo to close in an even tighter way a line of argument that was to dominate economic theory for nearly a century, and economic policy for an even longer period. Anticipating nearly word for word Churchill's 1929 Budget Speech and what was to be known in the 1920s and 1930s as the 'Treasury View', in 1821 Ricardo already observed in the Commons:

> When [I] heard the honourable members talk of employing capital in the formation of roads and canals, they appeared to overlook the fact that the capital thus employed must be withdrawn from some other quarter. (1952, vol. 5, p. 32)

This 'Ricardian view' on public investment was to be perpetuated down the 19th century; after having been defended and illustrated by most classical economists, and notably by Mill, it even survived the marginalist revolution: Marshall never advanced much beyond it and Böhm-Bawerk subscribed substantially to its conclusions.

However, during the 1880s, Foxwell and Hobson were among the first to take up the challenge again. More preoccupied with the social effects of the 'irregularity of employment' linked with price fluctuations, than with strictly theoretical questions, they both called for abandoning the charity and relief approach and for turning the fight against unemployment into a major objective of economic policy. Foxwell concludes his analysis by favouring (unlike most leading economists) a slightly rising price level 'for more regular employment'. Hobson, for his part, suggests solutions to prevent under-consumption crises at the root of unemployment by a redistribution of income to encourage 'high consumption'. Despite a few attempts by local authorities to provide relief work to the unemployed, nothing systematic surfaced in Britain in the realm of economic policy despite growing concern about unemployment.

In the history of public works doctrine, the *Minority Report of the Poor Law Commission* (*R*oyal Commission on the Poor Law and the Unemployed 1909) clearly marks a watershed: for the first time ever the minority commissioners advocated a systematic counter-cyclical policy of public works and investment to smooth out cyclical fluctuations and to stabilize employment and the level of economic activity. However, this fundamental turnabout was not confined to Sidney and Beatrice Webb, largely responsible (with A.L. Bowley for the statistical material) for drafting the *Minority Report*. In the same year as the *Report*, Beveridge in *Unemployment, a Problem of Industry* broadly supported its main conclusion, and a few years later the Webbs in their volume *The Prevention of Destitution* (1911) offered a more elaborate version of their original argument.

However, the first modern refutation of the 'Ricardian view' by a professional economist is due to Pigou in his 1908 inaugural lecture as Marshall's successor at Cambridge. Worked out again in his *Wealth and Welfare* (1912) and *Unemployment* (1913), Pigou's argument became the standard pre-Keynesian case for public works: without having to resort to the notion of budget deficit, Pigou is able to demonstrate that public spending can increase aggregate employment and does not simply divert it from the private to the public sector:

> . . . it is probable that only part of the extra taxes people pay would be taken from funds they would otherwise have devoted at that time directly or indirectly to wage payment. Hence, the true result of relief works and so on is not to leave the aggregate amount of unemployment in the country unaltered, but to diminish that amount. (1908, pp. 27–8)

In other words, and in the modern parlance of the balanced budget multiplier, the taxpayer's marginal propensity to consume is smaller than 1, while the government's marginal propensity to consume is unity: the net effect of such a tax increase is clearly expansionary. Pigou's failure to assess his argument quantitatively (in a multiplier-like fashion), his scepticism about the degree of labour mobility between the private and the public sectors and the resulting weak impact of his argument on policymakers do not detract however from his originality. Public works, even without any budget deficit, can lessen unemployment.

This became a standard argument for most economists, well before the First World War. Robertson gave his 'cordial support' to Pigou's analysis and, for the first time brought forward in his *Industrial Fluctuation* the symmetrical idea that, through public works, governments would 'in times of depression [use] savings [that] are *not* otherwise so applied' (1915, p. 253).

With the notable exception of Hawtrey in the 1920s, most British economists followed Pigou's lead even if they were bitterly arguing about the best way to close the gap between saving and investment. Hawtrey for his part never departed from his early critical position against the *Minority Report* outlined in *Good and Bad Trade* (1913, p. 260). He reiterated many times, most notably in his 1925 article, that the public works doctrine 'overlook[s] the fact that the Government by the very fact of borrowing for its expenditure is withdrawing from the investment market savings which would otherwise be applied to the creation of capital' (1925, p. 104). As an adviser to the Chancellor of the Exchequer, and despite the broad professional consensus in favour of public works, Hawtrey won the day in the British Treasury. Under successive Conservative and Labour Governments, the 'Treasury View' remained official wisdom for years (for a detailed discussion of that evolution see Hutchison 1953, pp. 409–23 and Winch 1969, pp. 94–113). Similarly, during the 1932 US presidential election Roosevelt kept attacking the outgoing Hoover administration for not balancing the budget. It is only with the rearmament in Germany and with the Second World War in other Western countries that the 'Treasury View' all but disappeared from the politicians' standard set of arguments.

In his famous 1931 multiplier article, Kahn managed once and for all to dispose of this 'Treasury View'. Kahn's intentions were, however, empirical, not theoretical. He set out not so much to point out the then generally accepted argument that an increase in government investment would generate 'secondary employments' but to provide 'a stronger case' for public works than that which 'had always been recognized' by giving a precise estimate of this multiplier effect. The ratio of secondary employment to primary employment was thus given its first formal expression (1931, p. 12)

However, and to dispel a very common confusion, with a multiplier equation strictly in the

Pigovian tradition, Kahn did not anticipate the theoretical core of Keynes's *General Theory,* that is, the principle of effective demand. In Kahn's model, even if additional public spending has a multiplier effect on output and employment, such public works do not affect the discrepancy between saving and investment: as for Pigou and Robertson, previously, 'unused' savings are simply brought back into circulation. In short, for Kahn 'the whole point of a policy of public works is that it enables an increase in the rate of home investment . . . without that *fall* in the rate of interest that would be necessary if we were relying on private enterprise' (1931, p. 26).

In the *General Theory,* with his principle of effective demand, Keynes added a new theoretical dimension to Kahn's multiplier approach to the public works doctrine. An increase in public investment not only leads to an increase in employment and output but *generates* an excess of income over that required for consumption (via a marginal propensity to consume smaller than 1) so that the volume of savings will increase until saving once again equals investment. Furthermore, it is clear that since saving and investment are brought into equality by variations in the level of income, and not by changes in interest rate, there need not be full employment. In Keynes's theoretical framework, public works and government investment are thus no longer seen as temporary remedies to cyclical fluctuations in private investment, but as a necessary component of an aggregate demand the deficiencies of which are no longer automatically cared for, even in the long run, by an interest-rate mechanism.

This proposition (and the income-adjustment principle underlying it) could of course find no place in the traditional analytical framework. However, systematic short-term counter-cyclical public works policies were soon to be integrated by mainstream economists within the so-called neoclassical synthesis and played in most countries a major role in post-war economic policies. Victim of its success during the 1950s and 1960s, this Keynesian (as opposed to Keynes's) public works doctrine ran into serious practical and theoretical problems in the early 1970s. The growing size of public sectors, the inflationary wave resulting largely from an excessive use of expansionary fiscal policies and a rapidly growing theoretical dissatisfaction of the economic profession with the neoclassical synthesis brought back the 'Treasury View' onto the theoretical agenda. However even if with the successive advent of the monetarist school and the 'governmental impotence' theorem of the New Classical School, the 'crowding out' hypothesis is currently enjoying a new lease of life, few economists and even fewer politicians would dispute today the importance of modulating government spending in the course of the cycle.

Pufendorf, Samuel von (1632–1694)

Arild Sæther

Abstract

Pufendorf studied in Leipzig and Jena. His first work, *Elementorum Jurisprudentiae Universalis* (1660), earned him a professorship at Heidelberg. In 1668 he moved to Lund. His works *De Naturae et Gentium* (1672) and *De Officio Hominis et Civis* (1673) were translated, spread all over Europe, and entered the curricula at most Protestant universities. Pufendorf's natural law writings include ethics, jurisprudence, government and political economy. A society in which individuals exchange to satisfy their needs brings with it growth, commerce, markets, prices and money. This theory laid the foundation for the progress of economics as a science.

Pufendorf was born in Dorfchemitz, Saxony, Germany on 8 January 1632. He matriculated at Leipzig University in 1650. First he studied theology, but found it dogmatic and turned to philosophy, philology and history. After two years he moved to Jena, concentrating on mathematics, the Cartesian demonstrative method and the natural law writings of Grotius and Hobbes.

After completing his Magister degree in 1658 he secured an engagement as a tutor in the family of the Swedish ambassador in Copenhagen. Shortly thereafter hostilities broke out between the two Nordic rivals. Disregarding diplomatic privileges, the Danes seized the Swedish retinue and accused Pufendorf of espionage. During eight months of harsh captivity, with no access to learned books, he reflected on his university studies and wrote down a system of jurisprudence. After his liberation, he journeyed with his pupils to the Netherlands, where his work was published in 1660 as *Elementorum Jurisprudentiae Universalis* (Elements of Universal Jurisprudence). This work is considered the first useful textbook on natural law and it earned Pufendorf an enviable reputation and a professorship at the University of Heidelberg.

Here he published, anonymously, his historical and political work *De Statu Imperii Germanici* (On the Constitution of the German Empire). It contains a devastating criticism of the condition of public law within the Empire resulting from the Thirty Years' War, and suggested a path to its regeneration through a European commonwealth of sovereign states based on natural and international law. The imperial censor banned the book, but it was reprinted time and again, translated into several languages, and distributed across Europe. By 1710, some 300,000 copies had been printed in Germany alone. Pufendorf's reputation was now extended to nonacademic circles. He achieved both fame and criticism.

In 1668 Pufendorf moved to the newly established university in Lund, Sweden. In 1672 he published his magnum opus *De Naturae et Gentium* (On the Law of Nature and Nations) in eight books, and the year after an abridged popularized version, *De Officio Hominis et Civis* (On the Duty of Man and Citizen), in two books.

In all, 44 editions of his major work have been published. It has been translated into English, French, German and Italian. His popularized version became, in modern parlance, an international bestseller. It has been translated into nine European languages, published in more than 150 editions in tens of thousands of copies. For more than 100 years they were among the most read academic books. The classicists Locke, Montesquieu, Rousseau, Hutcheson, Hume, Smith and countless more all studied and built on his works. Due to Pufendorf's works and reputation, natural law became part of university studies in jurisprudence, philosophy and ethics at most Protestant universities.

A new war resulted in the closing of Lund University in 1677. Pufendorf became royal historiographer in Stockholm. In the following years, he introduced empirical studies of the archives, and published 33 volumes of historical studies. He is regarded as a progenitor of 19th-century historicism.

In 1688 Pufendorf moved to Berlin as historiographer and judicial councillor at the court of Prussia. He continued his works on historical and theological issues. He died on 16 October 1694 of blood poisoning, contracted on a return journey from Stockholm, where he had been elevated to the nobility as a baron. He is buried in St. Nikolai Church in Berlin.

Pufendorf attempted in his works on natural law to mediate and unify Hobbes's natural law doctrine of 'egoism' and 'a war of all against all' with Grotius's natural law doctrine of 'man's inclination towards society'. His writings include ethics, jurisprudence, government, and political economics. These are seen as integral parts of a totality.

The foundation for his treatment is his theory of human behaviour, where the driving force is the interaction between man's self-interest and his existence as a social being. Man seeks society with his fellow man for the fulfilment of his own needs and desires. Man's sociable inclination is not innate; it must be cultivated. He also used his theory of the social man to create his historical account of the rise of property when society changes from hunting and gathering through agriculture to a commercial society. Individuals in a commercial society will need goods and services produced by others, because their own time and resources will fail to give them many necessary goods. On the other hand, individual men can contribute many things to the use of others. However, this will come to nothing if these individuals could not exchange and barter their different goods and services. When a society based on private property grew, it therefore brought with it commerce, the growth of markets, the creation of prices and the introduction of money. The theoretical foundation of a commercial society, in which all individuals attempt to satisfy their own needs and thereby satisfy the need of others, is therefore the cornerstone in his natural law theory.

Price is divided into *ordinary and eminent*. The former is found in the properties of goods and services in so far as they afford service and pleasure for man. The latter is found in money as a common standard for their measurement. The price of a good or service is determined by the interaction between 'the aptitude' (utility) of it and the scarcity of it: in modern parlance, demand and supply. The price will rise towards a level where it covers the normal costs that accrue during production and transport. Lack of need (demand) lowers the price, but price will also be lowered if the number of suppliers increases. Pufendorf therefore comes very close to a Marshallian demand-and-supply analysis. In addition, the price will change if the quantity of money changes. Pufendorf seems to recognise the Snob and Veblen effects, externalities and differences in the elasticity of demand.

Pufendorf also presents his views concerning the state and the distribution of power, the state's right to tax, and the principles of taxation. Here he discusses weighted voting, qualified majorities and what has been known as single-peaked preferences.

It was the diffusion of these theories through popularization which laid the foundation for the progress of economics as a science.

Pump Priming

Leon H. Keyserling

The expression 'pump priming' gained nationwide vogue during the Roosevelt New Deal 1933–9. It referred to US Government spending accompanied by deficit financing to promote economic recovery from the Great Depression, which peaked in 1933 at an unemployment rate of 24.9 per cent and GNP about 30 per cent below 1929 in real terms. The expression suited F.D.R.'s political skills and innate economic and financial conservatism because so many people then used hand pumps and their experience was that pouring in a little bit of water for a short time started a copious and sustained flow in normal fashion. When the US started to become 'the arsenal of democracy' in 1940 and later on entered World War II, the use to the term 'pump priming' ended.

Pump priming cannot significantly be discussed academically as 'theory', but only by specifying what was done and how it worked. Despite factors which limited both size and pace measured against the catastrophic business and human conditions spawned by the Great Crash, the efforts were varied and enterprising; they bespoke the 'experimentalism' and 'try anything' mood of the President and his advisers.

For all practical purposes, the job-oriented programmes started early in 1933 and peaked within about a year. The Civilian Conservation Corps was empowered to employ less than 250 thousand people at $30 a month relief-level wages. The Federal Emergency Relief Administration (FERA) was armed with $500 million for grants in aid to the states, but the required matching grants from the states was a severe limitation, and the means test was applied to ultimate beneficiaries. The National Industrial Recovery Act included $3.3 billion for a Public Works Administration (PWA). The Civil Works Administration (CWA), unlike FERA, could operate works projects directly. This was the swiftest job programme; by January 1934, more than four million jobs resulted, but most CWA funds were drawn from PWA, and thus did not add to net outlays. By early 1934, opposition to CWA placed it within the FERA, where it could finance only state and local activities, help only those previously on relief, and pay only subsistence rather than prevailing wages.

PWA pump priming under Secretary of the Interior Harold L. Ickes dealt with construction, repair, and improvement of highways, public building and any other publicly owned facilities; conservation; low cost housing and slum clearance; and 'any other project of a character previously constructed or carried on by public authority or with public aid to serve the interest of the general public': and loans could be made even to some private corporations. The CWA under Harry

Hopkins dealt, *inter alia*, with roads, airports, school facilities and personnel, playgrounds and swimming pools, sewers, and combating insect pests. The jobs included writers and painters.

The potency of these job programmes must be judged by the gap between the actual size of the 1933 economy and one operating at reasonably full resource use. Measured in uniform dollars, actual GNP in 1933 would have had to be more than 43 per cent higher to close the gap between it and the 1929 performance. But this vastly understates the problem. For without growth to absorb a growing potential in labour force, technology, and know-how, an economy languishes. To be as close to full utilization as the economy was in 1929, GNP in 1933 would have had to be almost 72 per cent higher than it actually was. Looking at the GNP averaged during 1933–7, the gap measured in these two ways was 16 per cent and almost 51 per cent, respectively. And looking at the GNP averaged during 1933–9, the gap was more than 10 per cent and almost 49 per cent, respectively.

Contrasted with these criteria of recovery needs – even if modified considerably – Federal outlays and deficits were minimal, to state it charitably. Outlays were about $4.6 billion in 1933, or less than 8.3 per cent of GNP, and the deficit of $2.6 billion was less than 4.7 per cent of GNP. In 1939, outlays of about $8.8 billion were less than 9.7 per cent of GNP, and the deficit of $3.9 billion was less than 4.3 per cent of it. And only about two-thirds of these outlays, classified as 'extraordinary', were for pump priming *and* for the costs of new 'reform' measures; about one-third, for defence and customary domestic, were classified as 'ordinary'. All in all, increased Federal spending through pump priming outlays was much less than the decline (due to the Great Depression) of state and local outlays for similar purposes.

Despite this spotty and far from adequate performance, the repeated assertion that the New Deal and especially pump priming 'failed' because there were more than 8 million unemployed in 1940 even after the start of the 'arsenal of democracy' is not supportable. Comparing 1937 and 1933, unemployment dropped from 12.830 million to 7.700 million, or 40 per cent (annual average 12.0 per cent). The drop in the rate of unemployment was from 24.9 per cent to 14.3 per cent, or a 42.6 per cent drop (annual average 13.0 per cent). The GNP real growth rate was 45.6 per cent (annual average 9.8 per cent).

The President and the Congress were strongly inclined to reduce pump priming when substantial albeit dismally insufficient recovery occurred. The cutbacks intensified greatly by 1937, and this brought on for two years one of the sharpest economic turndowns on record. Even so, unemployment at 9.480 million in 1939 was 26.1 per cent below 1933 (annual average reduction 4.9 per cent). The unemployment rate fell to 17.2 per cent, a reduction of 30.9 per cent (annual average 6.0 per cent). By 1940, due partly to increased military spending, unemployment was down to 8.12 million. During no periods of comparable length after World War II, despite smaller difficulties and larger know-how, were the rates of reduction in unemployment and real GNP growth nearly as large as during the pump priming era.

'Reform' programmes not called 'pump priming' also aided recovery: bank deposit insurance, regulation of the stock market and other financial practices, farm price supports, stimulation of home building, credit at lower interest rates, and some other measures. Because these 'reform' measures were as much the product of expanded government responsibility as pump priming, pouring public money into the economy and entering into the deficit Budgets, they are not really separable from appraisal of the new public philosophy which pump priming most clearly embodied.

Most important in the long run: although the humanistic new public philosophy, with pump priming setting the tone, emerged because of national disaster, it evoked an *enduring* people's awareness, sensed by political leaders, that *their* Government should exercise immensely enlarged responsibility for economic performance and human well-being; that huge public spending is not anathema; and that balancing the economy should take precedence over balancing the Federal Budget.

World War II did not submerge this heritage. Tremendous war expenditures, claiming almost half of GNP, were financed 50 per cent by deficits, and primed the pump as never before. Thus, during the war years, the average annual real economic growth rate was about 9 per cent, and the unemployment rate dropped to less than one per cent. And because ‘equality of sacrifice’ reflected the social concern of 1933–9 pump priming, living standards rose more rapidly than ever before.

Since the war, national policies and their results have oscillated, but from a plateau of economic and social responsibility far higher than before the pump priming precept and example. Public action to help the unemployed has become a ‘given’; reform programmes have been built upon and new ones added; Federal *domestic* spending during recent years has ranged around 17 per cent of GNP, compared with only 5.5–6.5 per cent during prewar pump priming. Consequently, although there have been frequent recessions, there have been no depressionary downturns which came every seven years or so even before 1929.

However, the most recent years, under both Democratic and Republican Administrations, have brought considerable retrogression. ‘Big Government’ has come to be excoriated and Federal support of vital domestic programme slashed; Federal Budget domestic spending in ratio to GNP has fallen from 17.50 per cent in fiscal 1985 to 15.89 per cent in the President’s 1986 Budget; and pronounced efforts to balance the Budget at the expense of the economy have in fact generated low GNP growth and unparalleled deficits. The goal of full employment, although on the statute books, has in practice been completely surrendered.

To be sure, New Deal pump priming, because it started with 24.9 per cent unemployment, did not within seven years come close to unemployment rates as low as the highest during any year after World War II which provided a postwar starting point of only one per cent unemployment. But the policies and programmes during the pump priming era 1933–9 pressed for and achieved very substantial *reduction* in unemployment, contrasted with the complacency during the mid-1980s despite a rate two-and-a-third times as high as the 2.9 virtually full employment rate in 1953. From 1977 to the second quarter of 1985 (similar in length to 1933–40), the unemployment rate *increased* from 7.1 per cent to 7.3 per cent, and unemployment rose from 7.4 million to 8.4 million. This brought the disgraceful and menacing rate of unemployment among black teenagers up to 39.2 per cent, immensely higher than the overall unemployment rate of 24.9 per cent in 1933 and 17.2 per cent in 1939. And compared with the high real growth rate in GNP during the pump priming era, the real growth rate, punctuated by four recessions, averaged annually less than 3 per cent during the period, and only about 2 per cent from 1979 forward.

The compelling lesson of the more than half a century reviewed is this: we should not underestimate the pump priming era. From it we can learn much and benefit greatly.

Purchasing Power Parity

Lucio Sarno

Abstract

This article expounds the purchasing power parity (PPP) hypothesis as a theory of exchange rate determination. The long history of PPP and its contribution to thinking in international finance is discussed, with reference to implications both for open economy theory and for economic policy. The large literature on empirical testing of the validity of PPP is reviewed, with particular reference to work carried out since 1990.

Purchasing power parity (PPP) is a theory of exchange rate determination. It asserts (in the most common form) that the exchange rate change between two currencies over any period of time is determined by the change in the two countries' relative price levels. Because the theory singles out price level changes as the overriding determinant of exchange rate movements, it has also been called the 'inflation theory of exchange rates'.

The PPP theory of exchange rates has somewhat the same status in the history of economic thought and in economic policy as the quantity theory of money: by different authors and at different points in time it has been considered an identity, a truism, an empirical regularity or a grossly misleading simplification. The theory remains controversial, as does the quantity theory of money, because strict versions are demonstrably wrong while soft versions deprive it of any useful content. In between there is room for theory and empirical evidence to specify the circumstances under which and the extent to which PPP provides a useful, though not exact, description of exchange rate behaviour.

The analogy with the quantity theory of money holds particularly in the effects of monetary disturbances. The latter theory fails to hold exactly when disturbances are primarily monetary, for instance in the course of hyperinflations, because changes in the expected rate of inflation generate systematic movements in velocity that break the one-to-one link between money and prices. In the same way, monetary disturbances cause exchange rate movements that at least temporarily deviate from PPP, implying changes in the exchange rate-adjusted relative price levels or 'real' exchange rates. It is true that when the economy, following a major monetary disturbance, has settled down again the cumulative changes in money, prices and the exchange rate will tend to be close to each other. In that sense PPP holds. The same is decidedly not true, however, in the course of the disturbance.

And in the long run, just as changes in real income or financial innovation bring about trend changes in velocity that destroy the one-to-one relationship between the money supply and prices, there also are trend deviations from PPP: productivity growth differentials between countries, for example, lead to trend changes in real exchange rates.

Statement of the Theory

Let *pi* and p_i^* represent the price of the *i*th commodity at home and abroad, stated in home and foreign currency respectively, and *e* the exchange rate. The exchange rate is quoted as the number of units of domestic currency per unit of foreign money. Further, let *P* and *P** be the price level at home and abroad quoted in the respective currencies.

The strong or absolute version of PPP relies on the 'law of one price' in an integrated, competitive market. If we abstract from all frictions, the price of a given good will be the same in all locations when quoted in the same currency, say dollars: $p_1 = ep_i^*$. Consider now a domestic price index $P = f$ $(p_1, \ldots, p_i, ..p_n)$ and a foreign price index $P^* = g$ $\left(p_1^*, \ldots, p_i^*, \ldots, p_n^*\right)$. If the prices of each good, in dollars, are equalized across countries, and, if the same goods enter each country's market basket with the same weights (that is, the homogeneous-of-degree-one $g(\cdot)$ and $f(\cdot)$ functions are the same), then by definition *absolute* PPP prevails. The law of one price in this special case extends not only to individual goods but also to aggregate price levels. Spatial arbitrage then takes the form of the *strong* (or absolute) version of PPP:

$$e = P/P^* = \frac{\$\,\text{price of a standard market basket of goods}}{\pounds\ \text{price of the same standard basket}} \tag{1}$$

where the RHS is the common multiple of the price of each good in one currency and in the other. Specifically, if $p_i/p_i^* = k$ for all *I*, we then have $e = P/P^* = k$. Note now the implication of absolute PPP. Whatever the monetary or real disturbances in the economy, because of instantaneous, costless arbitrage the prices of a common market basket of goods in the two countries, measured in a common currency, will be the same or $P/eP^* = 1$ at all times.

There can be no objection to (1) as a theoretical statement. Objections arise, however, when it is interpreted as an empirical proposition. In fact the (spot) prices of a given commodity will not necessarily be equal in different locations at a given time. Transport costs and other obstacles to trade, especially tariffs and quotas, do exist and hence the location of delivery does matter. Therefore we would not expect the price even of an ounce of gold of a specified fineness always to be the same in New York and in Calcutta. The fact that prices of the perfectly homogeneous commodity are not equalized across space at every point in time does not suggest market failure; it may simply reflect the inability to shift commodities costlessly and instantaneously from one location to the other. Information costs and impediments to trade stand in the way of strictest spatial equalization of price. But these impediments to trade do not preclude the possibility that common currency prices of any given good in different locations should be closely related and, indeed, arbitraged. They just will not be literally equalized. Impediments to trade and imperfection of competition, of course, also make possible spatial price differentiation, thus further limiting strong PPP.

The *weak* (or relative) version of PPP therefore restates the theory in terms of changes in *relative* price levels and the exchange rate: $e = \theta P/P^*$ where θ is a constant reflecting the given obstacles to trade. Given these obstacles an increase in the home price level relative to that abroad implies an equiproportionate depreciation of the home currency:

$$\widehat{e} = \widehat{P} - \widehat{P}^* \tag{2}$$

where $\hat{a}$ denotes a percentage change.

Equation 2 is the statement of PPP as it was applied by Gustav Cassel to an analysis of exchange rate changes during the First World War.

> The general inflation which has taken place during the war has lowered this purchasing power in all countries, though in a different degree, and the rates of exchange should accordingly be expected to deviate from their old parities in proportion to the inflation of each country. At every moment the real parity is represented by this quotient between the purchasing power of the money in the one country and the other. I propose to call this parity '*purchasing power parity*'. As long as anything like free

> movement of merchandise and a somewhat comprehensive trade between the two countries takes place, the actual rate of exchange cannot deviate very much from this purchasing power parity. (Cassel 1918, p. 413)

Absolute PPP in (1) was stated in terms of the relative prices in different currencies and locations of a *given* and common basket of identical goods. Going from there to relative PPP as in (2) may merely be a way of circumventing the qualifications arising from transport costs or obstacles to trade. But often more is involved because the shift, in practice, leads to a use of PPP in terms of particular price indices such as consumer price indices (CPIs), wholesale price indices (WPIs), or gross domestic price (GDP) deflators. Once that is done we go beyond the law of one price because the shares of various goods in the different national indices may not be the same and the goods that enter the respective indices may not be strictly identical as is clearly the case for nontradable goods.

Once shares in the indices differ or commodities are not strictly identical, the appeal to the law of one price can no longer serve as support for PPP. Now PPP can hold, even in the weak form, only if the disturbances satisfy the conditions of the homogeneity postulate of monetary theory. The homogeneity postulate asserts that a purely monetary disturbance, with all equilibrium relative prices left unchanged, will lead to an equiproportionate change in money and all prices, including the price of foreign exchange. In this very special experiment PPP holds even if the law of one price does not apply. The constancy of real variables under the assumption of a purely monetary disturbance (that is, an unanticipated, nonrecurrent increase in money) assures that once the economy has adjusted the exchange rate depreciation matches the inflation of any individual price or the price of any market basket so that (2) applies. To appreciate the difference of this experiment from absolute PPP, note that under these conditions (2) could even be stated in terms of indices of nontradable goods prices.

PPP theory as a theory of equilibrium must be supplemented by an adjustment mechanism. In the case of identical commodities the theory is simply that of spatial arbitrage. But when the goods are not strictly identical more is required. A high degree of substitution in world trade is generally assumed to be the mechanism through which exchange rate-adjusted prices are kept in line internationally. A further point concerns causation. In much of the literature, especially in the writings of Cassel, exchange rates adjust to prices. But there is an important alternative tradition that singles out exchange rate depreciation as an independent source of inflation.

Criticism of PPP focuses on systematic ways in which relative price changes destroy the strict validity of PPP. Keynes, although strongly supporting the idea of PPP as a broad guide, recognized these possible departures from purely monetary disturbances:

> If on the other hand these assumptions are not fulfilled and changes are taking place in the 'equation of exchange', as economists call it, between the services and products of one country and those of another, either on account of movements of capital, or reparation payments, or changes in the relative efficiency of labour, or changes in the urgency of the world's demand for that country's special products, or the like, then the equilibrium point between purchasing power parity and the rate of exchange may be modified permanently. (Keynes 1923, p. 80)

This limitation of PPP led Samuelson to argue: 'Unless very sophisticated indeed, PPP is a misleading, pretentious doctrine, promising what is rare in economics, detailed numerical prediction' (Samuelson 1964, p. 153).

History

Versions of the PPP theory have been traced to the Salamanca School in sixteenth century Spain and to the writings of Gerard de Malynes appearing in 1601 in England. The Swedish, French and English bullionists in the second part of the eighteenth century and in the early nineteenth century present further statements of PPP. Particularly noteworthy is the Bullion Report in England:

> Whether this 13$\frac{1}{2}$per cent, which stands against this country by the present exchange on Lisbon, is a real difference of exchange, occasioned by the course of trade and by the remittances to Portugal on account

> of government, or a nominal and apparent exchange occasioned by something in the state of our currency, or is partly real and partly nominal, may perhaps be determined by what your committee have yet to state. (Great Britain 1810, p. ccxxii)

During the nineteenth century classical economists, including in particular Ricardo, Mill, Goschen and Marshall, endorsed and developed more or less qualified PPP views. This history is reviewed and discussed in Viner (1937), Schumpeter (1954), Holmes (1967), and Officer (1984).

Even though PPP theory was well established by the time of the First World War, the forceful use and development of the theory by the Swedish economist Gustav Cassel has made him the outstanding protagonist of the theory. He turned the theory into a paradigm, with all the necessary trappings: an alleged challenge to gold standard orthodoxy, a catchy name, a formula, and the claim of empirical support for the new view.

Cassel's first contributions to the subject were published in 1916 in the *Economic Journal*. He presented the inflation theory of exchange rates and proceeded to a demonstration using price level and exchange rate data for the belligerent countries, the United States, and Sweden. J.M. Keynes as the editor appended a footnote drawing attention to the contribution and noting his surprise that, war disturbances notwithstanding, PPP should hold. A further challenge was the implication of PPP that the pre-war par with gold might not be re-established or, more guardedly, might require a powerful deflation in a country like Britain.

Cassel never abandoned an uncompromising PPP view of exchange rates even though he already in 1918 started recognizing the possibility that exchange rates might transitorily diverge from PPP. A decade later he made a clear statement of his final position:

> The fact that the rate of exchange corresponding to Purchasing Power Parity possesses such a remarkable stability is a sufficient reason for regarding Purchasing Power Parity as the fundamental factor determining the rate of exchange and for classifying all other factors that may influence the rate and perhaps make it deviate from the Purchasing Power Parity as factors of secondary importance, most suitably grouped under the head of 'disturbances'. (Cassel 1928a, p. 16)

He identified three groups of disturbances: actual and expected inflation or deflation, new hindrances to international trade, and shifts in international movements of capital. Although these disturbances are recognized, their quantitative effect on deviations from PPP is invariably seen as 'confined within rather narrow limits' (Cassel 1928a, pp. 28–9). In insisting on the proposition that deviations from PPP are limited and transitory, Cassel neglected to pay close attention to the determinants of purchasing power disparities. Even though he recognized that inflation first leads to undervaluation, and stabilization leads later to an overvaluation (Cassel 1928b, p. 26), he never took these ideas further. His emphasis was on PPP. But he pointed out with some merit (Cassel 1928b) that, without some quantifiable concept of PPP, a sensible discussion of over and undervaluation could hardly begin.

Keynes (1923, ch. 3) took up PPP, crediting Ricardo with the invention and Cassel with the name. Keynes recognized PPP as an important empirical possibility. Giving it all the right qualifications he still endorsed it for all practical purposes:

> This theory does not provide a simple or ready-made measure of the 'true' value of the exchanges. When it is restricted to foreign-trade goods, it is little better than a truism. When it is not so restricted, the conception of purchasing power parity becomes much more interesting, but is no longer an accurate forecaster of the course of the foreign exchanges. Thus defined 'purchasing power parity' deserves attention, even though it is not always an accurate forecaster of the foreign exchanges. The practical importance of our qualifications must not be exaggerated. (Keynes 1923, pp. 77–8)

Cassel received support for PPP from the monetary disturbances of the 1913–1928 period. Extensive PPP studies were conducted for the US government (see Young 1925) and for the League of Nations. PPP emerged in the discussion of the resumption of the pre-war gold par in Britain in 1925, and Jacques Rueff used wage-based PPP to calculate an appropriate par for France's stabilization under Poincaré in 1926–1928. But while it became a regular tool of applied macroeconomics, there was also plenty of controversy. Viner (1937) challenged the doctrinal view that classical economists had a concept of PPP, arguing that without the notion of a price level PPP could not be conceived. In fact Viner had little patience with PPP. The opposition is easily recognized today: Viner and other critics always reacted to the overstated claim that PPP must hold as a matter of fact or of theory, pointing out that only a purely monetary disturbance provided the theoretical or practical experiment in which PPP would apply. For them PPP as a theory was simply misstated and as a practical proposition overrated.

A new wave of interest in PPP emerged at the end of the Second World War, when once again exchange rates had to be set following the wartime suspension of trade and convertibility. Renewed interest in PPP followed in the late 1950s and early 1960s. Yeager (1958) and Haberler (1961) emphasized the practical usefulness of PPP and highlighted the role of high price elasticities in international trade as the factor supporting PPP. High elasticities in world trade would ensure that real disturbances had only small effects on relative prices, thus establishing more nearly the conditions under which exchange rate movements predominantly reflect differences in monetary experiences.

In the late 1930s Harrod had drawn attention to the fact that divergent international productivity levels could, via their effect on wages and home goods prices, lead to permanent deviations from Cassel's absolute version of PPP. This idea had already been developed by Ricardo and has now become central to work on international real income comparisons. Balassa (1964) and Samuelson (1964) elaborated similar ideas to argue that there are systematic trend deviations from PPP. This 'productivity bias' to PPP is discussed in more detail below.

PPP had yet another intellectual upturn with the move to flexible exchange rates in the early 1970s. The then fashionable 'monetary approach to the balance of payments' developed by Robert Mundell (1968, 1971), Harry Johnson and their students readily adapted to become a PPP-based monetary approach to the exchange rate (see Frenkel and Johnson 1975, 1978; Mussa 1979). The exchange rate under strict PPP conditions was interpreted as a monetary phenomenon. The absolute version of PPP in (1) above combined with the quantity theory of money for each country ($MV = PY$ and $M^*V^* = P^*Y^*$) yielded the key equation determining exchange rates by relative money supplies, velocities and real incomes:

$$e = (M/M^*)(V/V^*)(Y^*/Y). \qquad (3)$$

Empirical research on the 1920s and on the very early data of the 1970s initially seemed to lend support to PPP and the monetary approach.

But large movements in real exchange rates of the 1970s led to the currently dominant PPP scepticism. The new direction following the Mundell–Fleming model (Mundell 1968; Fleming 1962) of the 1960s emphasized fluctuations in real exchange rates or the terms of trade (import prices relative to export prices) arising from the discrepancies between flexible, forward-looking asset markets and asset prices, and short-run sticky prices and wages. Work on exchange rate dynamics (Dornbusch 1976) developed these ideas about transitory deviations from PPP in a rational expectations context.

Concern with PPP continued to be very active in the late 1970s and the early 1980s. The real exchange rates of the main currencies underwent large, persistent fluctuations with important effects on trade flows and resource allocation. At the same time currency experiments in Latin America involved dramatic real appreciations with ruinous consequences for several countries. Sometimes in history there was bafflement as to how, all things considered, PPP could work so closely. This time, however, the surprise was on the other side: how could real exchange rates get that far out of line? We now review in more detail the theory and the evidence for deviations from PPP.

Purchasing Power Disparities

Qualifications to PPP take one of several forms. Departures from PPP can be 'structural' in the sense that they arise systematically in response to new and lasting changes in equilibrium relative prices. Alternatively, they occur in a 'transitory' fashion as a result of disturbances to which the economy adjusts with differential speeds in goods and assets markets. These qualifications imply that even the weak or relative form of PPP cannot be expected to hold closely.

These disparities arise primarily for the following reasons. First, the terms of trade may change as a consequence of changes in trade patterns. Second, economic growth systematically affects the relative price of home and tradable goods. Third, monetary and exchange rate changes bring about transitory deviations in real price ratios and in PPP as a consequence of imperfectly flexible wages and prices.

Structural Departures

The literature is replete with qualifications to PPP singling out particular real disturbances that change equilibrium relative prices. Thus it has been recognized since Ricardo that real prices of home goods are high 'in countries where manufactures flourish'. It also has been argued that the 'price level is high in borrowing countries'. The Ricardo–Harrod–Balassa–Samuelson theory provides a framework for these ideas.

Consider a Ricardian model where the law of one price applies to tradable goods and where there is also a home good. With perfect competition and constant returns, prices are given by unit labour costs. We define as *R* the relative consumer price levels of two countries measured in a common currency:

$$R \equiv P/eP^*. \tag{4a}$$

With identical homothetic tastes and the law of one price the international component of price indices is the same in both countries and hence cancels out in (4a). The relative price level is then determined by the relative prices of home goods in the two countries, measured in a common currency. Let h and h^* be the levels of productivity in tradable goods (at the competitive margin) relative to home goods in each country. It is easily shown (see Dornbusch et al. 1977) that the relative price level then reduces to:

$$R = R(h/h^*), R' > 0. \tag{4b}$$

A uniform rise in tradable goods productivity at home would bring about a rise in the relative price level of the home country or a real appreciation. The mechanism is the following: with the law of one price applying to tradable goods, increased productivity in the tradable goods sector increases wages in that industry and hence raises economy-wide wages. But, without accompanying productivity gains in the home goods sector, costs and prices there must rise and hence the growing country's relative price level increases as shown by (4b).

In (4b) above the national productivity relatives h and h^* are measured in the tradable goods sector at the competitive margin. Shifts in technology, tastes, commercial policies or labour force growth will all change the equilibrium competitive margin and hence will change the real exchange rate. Thus real factors, as the literature since Ricardo has recognized, will introduce systematic departures from PPP. For example, a shift in world demand towards the home country's goods would raise the relative wage and reduce the range of goods produced by the home country. The rise in the relative wage, given productivity, raises the relative price level of the home country. Likewise an increase in spending relative to income (that is, borrowing or a current account deficit) will lead to a rise in the relative price level of the spending country.

A variant of the Ricardian productivity differential model as an explanation for the relatively low price of non-tradables in poor countries has been advanced by Kravis and Lipsey (1983) and Bhagwati (1984). They rely on differences in factor endowments and factor rewards rather than differences in production functions. In the poor labour-abundant country, the labour-using non-tradable services can be produced at a lower cost than in the rich, capital-abundant country. Whichever is the model, this effect, as we discuss below, has found ample support in empirical research on international real income and price comparisons.

Transitory Deviations

There is no difficulty in accepting that prices of close substitutes or even identical goods could diverge across space at any point in time. This would be the case because, in the shortest time period, transportation and information costs make arbitrage difficult or even impossible. These difficulties would explain that PPP holds up to a constant and white noise error (see Aizenman 1986). But in fact we have to explain relatively *persistent* and often *large* deviations from PPP. These can arise from divergent speeds of adjustment of the exchange rate compared with wages and prices. Particularly when flexible exchange rates behave like asset prices while wages are determined by long-term contracts, there is room for relative prices to show relatively persistent deviations from PPP.

Theoretical approaches to support the relative stickiness of prices can rely on the presence of long-term labour contracts combined with oligopolistic pricing in goods markets. A model of imperfect competition is essential because the less-than- perfect degree of substitution is a key ingredient in PPP deviations. Less-than-perfect substitution means that we are not dealing with the law of one price and arbitrage but with firms' decisions to set relative prices. A suggestive framework is the Dixit and Stiglitz (1977) model of product diversification with imperfect competition. Given constant returns and labour as the only factor each firm will set prices as a fixed and common markup over wages. In the world market for the products of a particular industry the relative price of domestic and foreign variants of the product is determined by relative unit labour costs measured in a common currency:

$$p/ep^* = w/w^*e \tag{5}$$

where w and w^* denote unit labour costs at home and abroad in the respective currencies. Given sluggish wages, for contract reasons or otherwise, exchange rate movements will be one-for-one reflected in changes in the real exchange rate.

The assumption that firms base their pricing entirely on home cost, as appears in this model, leaves no room for the alternative of spatial price differentiation. There is as yet no definitive or even large body of literature that develops the industrial organization aspects of pricing under flexible and volatile exchange rates (see Dornbusch 1987).

Early Empirical Evidence

There is little doubt that the prices of primary commodities traded on major organized exchanges in different locations are fully arbitraged when literally all adjustments for contracts (maturity, delivery terms and location, and so on) are made. But much available evidence suggests that PPP in the strong or weak version does not apply in the same fashion to manufactured goods. This lack of close conformity with PPP is as true for individual commodity prices as it is for aggregate price indices. Moreover, the absence of a very tight PPP relation appears to hold especially during major monetary dislocations.

Studies of high-inflation episodes appear to offer support for PPP in that they show close *cumulative* movements of internal prices and the exchange rate. But even here the evidence is deceptive, as becomes clear when one looks at relative prices, which do show large variations. Indeed, particularly during high inflation the differing frequencies of adjustments of wages, prices and the exchange rate introduce considerable variability in relative prices which disappears only in the most intense stages of hyperinflation where all pricing comes to be based on the exchange rate. Kravis and Lipsey (1978) and Isard (1977) have shown tests of the law of one price at the level of narrowly defined manufactured goods. These studies established that for the same good (or highly substitutable goods) there are quite definitely persistent price discrepancies between domestic and export prices, between domestic and import prices, and between export prices to different markets.

Empirical studies on time series PPP relationships for aggregate price indices since the mid-1960s also show evidence of persistent deviations. Once relative prices are not strictly constant PPP will perform differently depending on the particular price index chosen for comparison.

Commonly the choice is among CPIs, WPIs, and GDP deflators. WPIs are often ruled out on the argument that conceptually they are poorly defined, being neither producer nor consumer price indices. The preference is most often given to CPIs and GDP deflators, which have a clear methodological definition.

As a measure of the departure from PPP, research shows that, for the post Bretton Woods period since 1971 or so, bilateral comparisons of exchange-rate-adjusted inflation rates (that is, comparisons of inflation rates measured in a common currency) reveal that the correlation coefficients are much lower than unity, which is the theoretical value implied by the weak form of the PPP hypothesis.

The strong deviations from PPP can likewise be found by looking at relative prices, in which case one would compare the variability of relative price indices (the standard deviation expressed as a fraction of the mean), measured in a common currency and using the United States as the numeraire country. The data for these relative price variability measures show a large increase in variability in the shift from fixed (Bretton Woods period) to flexible (post-Bretton Woods) exchange rates, suggesting that real exchange rates are approximately as volatile as nominal exchange rates (Baxter and Stockman 1989).

The evidence on deviations from PPP leaves little doubt that they have been large and persistent. To pin down the major sources of these movements, however, is significantly more difficult. Among the chief explanations are capital flows induced by internationally divergent monetary–fiscal mixes interacting with sluggish wages and prices. Thus it would appear that a country that shifts in the direction of tight money and easy fiscal policy, for example, will experience real appreciation.

Besides these dominant macro-shocks there is, of course, a host of other factors. Jacob Frenkel has observed in this context:

> The experience during the 1970s illustrates the extent to which real shocks (oil embargo, supply shocks, commodity booms and shortages, shifts in the demand for money, differential productivity growth) result in systematic deviations from PPP ... It should be noted, however, that to some extent the overall poor performance of the purchasing power parities doctrine is specific to the 1970s. During the floating rate period of the 1920s, the doctrine seems to have been much more reliable. (Frenkel 1981, pp. 694–5)

The lack of solid empirical evidence in support of PPP extends to the assumption that divergent price developments ‘cause’ exchange rate depreciation. From the study of experiences of high inflation it is clear that in some instances capital flight and exchange depreciation precipitated increases in inflation. In fact Nurkse (1944) makes much of the point that expectations acting via capital flight on the exchange rate, and not actual money and prices, often initiate an inflationary episode.

With respect to structural PPP deviations, there is some evidence that establishes that over time real exchange rates, rather than showing constancy or a tendency to fluctuate around a constant level, in fact exhibit a distinct trend. Productivity levels or real incomes influence systematically the relative prices of tradable and non-tradable goods within a country and hence international relative price levels across countries and across time.

In the context of an international income comparison project, Kravis and associates have constructed indices of relative national price levels using an absolute price comparison approach. Drawing on a detailed sample of prices they construct matched sets of the price of individual commodity groups in a particular country relative to a reference country. For commodity i the relative price is p_i/p_i^*, where the $p's$ are measured in the respective countries’ currencies with an asterisk denoting the reference country. Using an arithmetic average with weights a_i, given by final expenditure shares, a PPP index is defined:

$$\mathrm{PPP} \equiv \sum a_i \left(p_i/p_i^* \right). \qquad (6)$$

The expenditure shares a_i used in the weighting may be those of either one of the countries or some other appropriate weighting scheme. The Kravis real price level of a country (relative to the reference country) is defined as the PPP index in (6) divided by the actual exchange rate:

$$\text{Kravis real price level} \equiv \text{PPP}/e. \tag{7}$$

This real price level definition represents a measure of the deviation from the law of one price at the aggregate level.

Kravis and Lipsey (1983, p. 21) report the results of a cross-section study of 34 countries where the 1975 real price level as defined in (7) of the sample of countries (relative to the United States) is explained by the countries real income compared with that of the United States. The evidence shows that the higher a country's relative income is, the higher is its relative price level. Work by Hsieh (1982) using a time series approach further supports the extensive evidence on divergent productivity trends as a source of structural PPP deviations. It must be noted, though, that the evidence on structural deviations continues to be challenged by Officer (1984).

Implications of Purchasing Power Disparities

The possibility that exchange rate movements do not conform to tight PPP patterns poses important issues for macroeconomic measurement, linkages, and policy. We review here several implications.

Real Income Comparisons

With strict PPP based on the law of one price, the purchasing power of a given income in one country and currency can be compared with the purchasing power of the income of any other country by simply measuring incomes in a common currency. If one income is 20 times larger than the other, measured in the same currency at actual exchange rates, then its command over goods and services is 20 times larger. But the fact that PPP does not hold leads to systematic biases in the comparisons. Specifically, as the work of Kravis and associates (1978, 1982, 1983) has shown, the real income of poor countries is severely underestimated when actual exchange rates are used to make the comparison. The low relative price of non-tradables in poor countries (due to the productivity differential discussed earlier) yields for poor countries true purchasing power of income significantly above what exchange rate-converted income suggests.

Note that the biases are particularly large for countries whose incomes are only a small fraction of the US levels, so that productivity differential effects play a maximal role. The poorer a country, the lower is the real price level. An interesting point is that these real price level differences apply both to goods and to services. One reason they also apply to goods is that these always have a local retail component which, on account of labour costs (though perhaps not transport), will tend to be low in poor countries. For low-income countries actual real income is two to three times what exchange rate-converted incomes suggest. These structural deviations from PPP, of course, would be invariant under a purely monetary disturbance so that the weak form of PPP still applies.

Interest Rate Linkages and PPP

Under perfect international mobility of capital and risk-neutral speculation there is a linkage between nominal interest rates and the anticipated rate of depreciation, which is given by the open economy Fisher equation:

$$i = i^* + x \tag{8a}$$

where i and i^* are the nominal interest rates at home and abroad and x is the anticipated rate of depreciation of the home currency. Adding and subtracting anticipated inflation rates on both sides yields an equation in terms of inflation-adjusted or real interest rates:

$$r^* = r - \dot{R}/R. \tag{8b}$$

Real interest parity, according to (8b), prevails when the real interest differential equals the expected rate of real appreciation, $\dot{R}/R$. From the real interest parity condition it is clear that under exact PPP the real exchange rate is constant. In the absence of restrictions on capital flows, real interest rates must therefore be strictly equalized across countries.

The real interest parity equation has two interesting implications. A first one is the linkages between the level of real exchange rates and monetary policy. Suppose that in a medium-term macroeconomic context, following a disturbance, the actual real exchange rate adjusts only gradually to the trend level R' according to the process: $R/R = (1/\lambda)$ $(R' - R)$. Here $1/\lambda$ is the speed of adjustment, which depends among other things on the extent to which wages and prices are sticky. Combining this process with (8b) yields an equation for the equilibrium real exchange rate:

$$R = R' + \lambda(r - r^*). \tag{9}$$

The result shown here is that, when real interest rates at home exceed those abroad, the real exchange rate will be low or appreciated relative to its trend value. A tightening of monetary policy, by raising real interest rates, would thus bring about a (transitory) real appreciation. Equation 9 emerges from the dynamic Mundell–Fleming models and is often thought to explain real exchange rate movements and their tendency to return only gradually to their long-run value.

A second way to look at (8b) draws on the fact that the tradable–non-tradable goods distinction has implications for real exchange rates. Suppose the law of one price holds for tradable goods and that shares in the two countries' price indices are the same. Then, as argued before, the real exchange rate is equal to the relative price of non-tradable goods (in a common currency) in the two countries. Structural disturbances such as differential productivity growth or changes in aggregate demand will now have a systematic impact on relative non-tradable goods prices and hence real interest-rate differentials. Specifically, the country with the higher growth rate of productivity has a rising relative price of home goods and thus has a lower real rate of interest. As another example consider a country where aggregate demand is transitorily high. The real price of home goods will be high, but falling. Accordingly, the real interest rate will be higher than that abroad. Deviations from PPP, trend or short-run, thus introduce an equilibrium international interest-rate differential.

PPP deviations affect interest differentials another way. In (8a) above we assumed risk neutrality. But, once risk-averse speculators are admitted, the possibility that exchange rate movements could deviate from a strict PPP pattern introduces portfolio risk associated with the currency composition of the portfolio. PPP deviations are thus one basic motive for international portfolio diversification. A risk premium will appear and among the determinants of this premium is the variability of the real exchange rate. The risk premium will be an increasing function of real exchange rate uncertainty.

Exchange Rate Policy

In Cassel's view even small deviations from PPP would bring about large changes in trade flows and hence a rapid discipline to move prices back into line internationally. But the reversion towards PPP has often not been quick and deviations from PPP have taken more nearly the pattern of persistent swings in a country's external competitiveness. The changes in competitiveness in turn have implied large swings in external balances, in output and in employment in the tradable goods sector. Changes in exchange rates that deviate from PPP at the same time influence the path of a country's inflation: real depreciation increases inflation and real appreciation dampens inflation. These effects of purchasing power disparities make the exchange rate an important issue in macroeconomic policy.

Countries with high inflation cannot afford a fixed exchange rate since the loss in external competitiveness would soon lead to excessive and growing external deficits and high unemployment. If freely fluctuating rates are deemed too unstable the policy answer is often a crawling peg. In a crawling peg regime the rate of depreciation follows a PPP path such that over time the real exchange rate remains constant (see Williamson 1965, 1982). Such a policy is an important advance over a system of occasional devaluations (too little, too late), but it is not without risks, for two reasons. First, freezing the real exchange rate may be a bad policy when disturbances in fact call for a path of, say, real depreciation. Second, there is a tradeoff between stability of the real exchange rate and price stability. A policy of fully accommodating any and all price or cost disturbances by an offsetting depreciation may in fact remove price stability altogether (see Dornbusch 1982).

PPP issues enter exchange rate policy also when a country seeks to gain macroeconomic advantages by a deliberate policy of driving the exchange rate away from PPP. A real depreciation serves to gain competitiveness and shift employment toward the depreciating country. In the 1930s this was called a 'beggar-thy- neighbour' policy, and in post-Second World War Europe it became 'export-led growth'. A policy of real appreciation, by contrast, serves to reduce inflationary pressure as the rate of increase of tradable goods prices is pushed below the prevailing rate of inflation. These macroeconomic effects of purchasing power disparities are not difficult to bring about: easy money, in the short and medium term, serves to depreciate the exchange rate and thus create employment. This policy is more effective and more lasting the more sticky wages are and the smaller the connection between wages, prices and the exchange rate is. By contrast, in an economy that is strongly indexed and in particular with exchange rate influences on indexation, an attempt at creating employment via easy money would be frustrated as exchange depreciation precipitates offsetting wage and price inflation.

Deviations from PPP have also been used as a disinflation policy. Deliberate fixing of the exchange rate or pre-announced rates of depreciation below the prevailing rates of inflation have been adopted in various countries to break inflation. The experience has been almost uniformly disappointing and worse. The resulting overvaluation very often has led to excessive external deficits, borrowing and capital flight, and ultimately only moderate success at disinflation. The cases of Chile and Argentina in the late 1970s were particularly extreme. Exchange rate policies led to extreme overvaluation. But these economies had been opened to unrestricted trade or free capital flows. The public therefore could speculate against the overvalued currency by massive imports or capital flight while the governments financed the resulting deficits by external borrowing. In the end the scheme collapsed, leaving the private sector with foreign goods or foreign assets and the governments with huge foreign debts.

PPP disparities are relevant for the exchange rate choice between flexible and fixed or managed rates. In a world where exchange rate movements conform strictly to PPP and monetary policy governs prices there is no issue. Flexible rates then allow a country to choose its preferred rate of inflation. But once disparities are possible both as a result of structural trends and perhaps as a consequence of shortterm capital movements the fixed versus flexible rate choice becomes more difficult. Flexible rates are preferable because there is no risk that the government pegs a rate that no longer corresponds to equilibrium. But flexible rates suffer the handicap that disequilibrating capital flows can drive the real exchange rate away from the level warranted by the fundamentals of the goods market. In particular, if exchange rates respond more to asset markets than price levels, persistent real appreciation or depreciation become a possibility. When this occurs there is invariably a call for PPP-based foreign exchange market intervention to bring rates back to 'fundamentals'. Explicit target zones have been proposed as a means of maintaining the advantages of flexible rates within limits to maintain approximate PPP (see Williamson 1983).

Flexible rates are also a concern because disequilibrating capital flows can provoke large changes in the rate of inflation. A loss of confidence, whether warranted or not, induces a capital outflow and a real exchange rate depreciation, as the experience of many East Asian countries in the late 1990s has demonstrated. If domestic financial policies are linked via the budget or indexation to the exchange rate, the real depreciation can initiate a sharp increase in inflation. Much of the discussion of the merits of flexible rates has concentrated on the question of whether speculative capital flows 'cause' the inflation or whether they merely respond to an inflationary situation, bringing about exchange depreciation in line with prevailing inflation. The Graham–Nurkse–Robinson view asserts, contrary to Milton Friedman, that destabilizing capital flows are the central element in the outbreak of major inflation experiences. Exchange stabilization, similarly, is seen as an essential step in stopping a runaway inflation and initiating a stabilization programme.

PPP is also relevant in the context of devaluation of a fixed rate. In the monetary approach to the balance of payments a firm tenet is the proposition that a devaluation cannot exert a lasting effect on relative prices or the balance of trade. Exchange rate depreciation raises the prices of all tradable goods in the same proportion and any effect then must be limited to a temporary depression of home goods prices due to reduced absorption. As money responds to the external surplus, real absorption rises and the initial real equilibrium is restored. This approach has the disturbing implication that devaluation does not appear to be an effective means of coping with trade or employment problems. In practice devaluation will work well when it is designed to speed up the adjustment from an initial disequilibrium in a situation where wages and prices are less than fully flexible downward. But a devaluation is likely to be ineffective if it is accompanied by a monetary expansion and wage increases, thus eliminating any real effects.

More Recent Developments

During the 1990s PPP attracted an enormous amount of interest. Presumably driven by the disbelief that such an intuitively appealing proposition about exchange rate behaviour had found little support in the data, researchers embarked in a 'search' for PPP using increasingly sophisticated time series methods. The early 1990s saw a proliferation of studies testing for PPP over the long run either by testing whether nominal exchange rates and relative prices move together (co-integrate) or by testing whether the real exchange rate has a tendency to revert to a stable equilibrium level over time (is stationary). The latter approach is motivated by the fact that the real exchange rate may be defined as the nominal exchange rate adjusted for relative national price levels and is, therefore, a measure of the deviation from PPP.

Regardless of the great interest in this area of research, the validity of long-run PPP and the properties of PPP deviations have remained the subject of an ongoing controversy. Unit root and co-integration studies generally report the absence of significant mean reversion of the real exchange rate for the recent floating experience (recent surveys include Taylor and Taylor 2004; Sarno 2005). However, the literature has been able to identify an important pitfall in studies of the long-run behaviour of PPP deviations. Specifically, one well-documented explanation for the inability to find clear-cut evidence of PPP is the low power of conventional tests to reject a false hypothesis of a unit root in (non-stationarity of) the real exchange rate (that is, the hypothesis that PPP is invalid) with a sample span corresponding to the length of the recent float (Frankel 1990). Put simply, conventional time series methods would not be able to detect the reversion of exchange rates towards PPP even if PPP were indeed valid unless very long samples of data were made available.

Researchers have sought to overcome the 'power' problem in testing for PPP in various ways. One logical reaction to tackle this problem was to test for mean reversion in the real exchange rate using long spans of data. Lothian and Taylor (1996), for example, use two centuries of data on dollar–sterling and franc–sterling real exchange rates and provide evidence supporting PPP in the recent floating period. This evidence is 'indirect' in the sense that PPP was found to hold over the full sample, which includes the recent float. Lothian and Taylor could not find any significant evidence of a structural break between the pre- and post-Bretton Woods period, and argue that the widespread failure to detect mean reversion in real exchange rates during the recent float may simply be due to the shortness of the sample.

Long-span studies have, however, been subject to some criticism in the literature. One criticism relates to the fact that, because of the very long data spans involved, various exchange rate regimes are typically spanned. Also, real shocks may have generated structural breaks or shifts in the equilibrium real exchange rate. This is a necessary evil with long-span studies of which researchers are generally aware. The long samples required to generate a reasonable level of power with standard univariate unit root tests may be unavailable for many currencies (perhaps thereby generating a 'survivorship bias' in tests on the available data) and, in any case, may potentially be inappropriate because of differences in real exchange rate behaviour both across different historical periods and across different nominal exchange rate regimes (for example, Baxter and Stockman 1989).

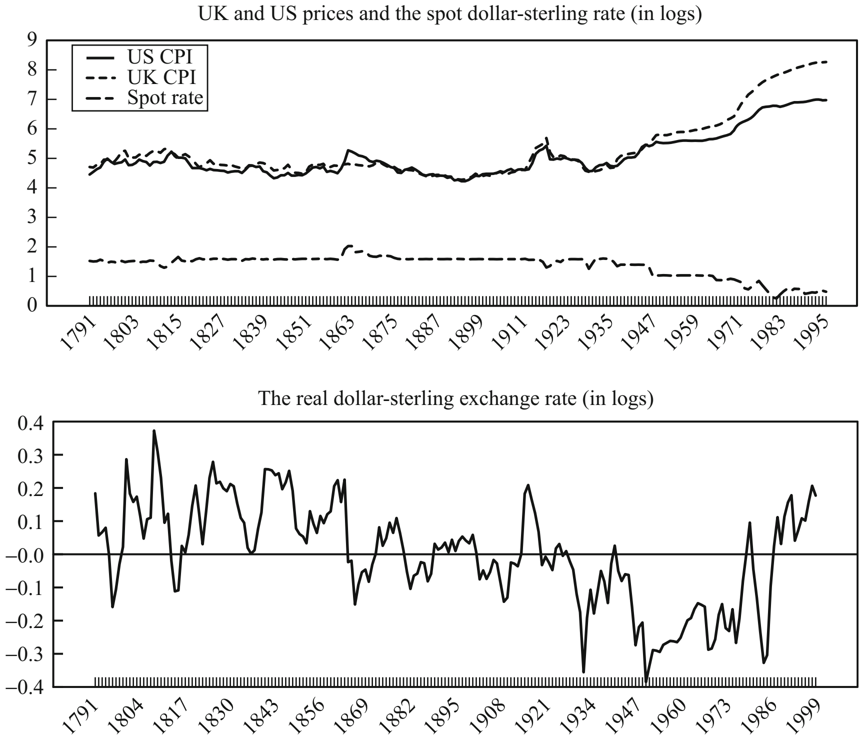
In light of the evidence provided by this literature, there remain several unresolved puzzles, among which two are prominent. First, it is still controversial whether long-run PPP is valid during the recent floating exchange rate regime from 1973 or so. Second, it is puzzling why the majority of studies which favour long-run PPP, such as the long-span studies, find empirical estimates of the persistence of PPP deviations that are too high – the half-life of shocks, that is, the time it takes for a shock to the real exchange rate to dissipate by one half, ranges between 3 and 5 years – to be explained in light of conventional nominal rigidities and to be reconciled with the large short-term volatility of real exchange rates (Rogoff 1996).

A source of potentially important bias in estimates of the half-life is caused by cross-sectional aggregation in moving from the law of one price for individual goods to PPP deviations based on price indices. Imbs et al. (2005) demonstrate how such bias is bound to be present in estimates of the real exchange half-life and provide empirical evidence that the bias is substantial. Crucini et al. (2005) adopt a similar approach to understanding the behaviour of deviations from the law of one price and PPP by examining micro-data on absolute prices of goods. They study good-by-good deviations from the law of one price for over 5000 goods and services between European Union countries for the years 1975, 1980, 1985 and 1990, and report that between most countries there are roughly as many overpriced goods as there are underpriced goods so that PPP holds to a good approximation, particularly after wealth differences are controlled for.

It is instructive to graph the real exchange rate and its components over a long span of time to speculate on its low-frequency properties. The top panel of Fig. 1 plots the time series for prices in the UK and the United States as well as the nominal dollar–sterling exchange rate over the sample period 1791–2000, with all time series expressed in logarithms.

It is quite interesting how the price series move together – even without being adjusted by the exchange rate to express prices in a common currency – over such a long period. It is also apparent how the bigger and more persistent wedge between the two prices seems to occur in the post-Bretton Woods period, essentially from the 1970s onwards. This wedge also coincided with the beginning of a corresponding trend in the nominal exchange rate, exactly as one would expect under PPP. The bottom panel of Fig. 1 then graphs the real exchange rate constructed from these time series (in deviation from the mean). The real exchange rate appears to have a tendency to return to its long-run mean (consistent with the PPP hypothesis), although the mean is crossed only 20 times in more than 200 years of data, indicating a remarkable degree of persistence in departures from PPP. Furthermore, the real exchange rate appears to be more persistent when it is in the proximity of the long-run mean, whereas reversion towards the mean happens more rapidly when the absolute size of the PPP deviation is large. This eyeball analysis of 200 years of real dollar–sterling exchange rate therefore suggests that this real exchange rate may be stationary, albeit persistent, and that it is very persistent in the neighbourhood of PPP, while being mean-reverting at a faster speed when the deviation from PPP gets larger. This is consistent with the existence of nonlinear dynamics in the real exchange rate, implying that the speed of mean reversion is state dependent.

In fact, the empirical literature on PPP has pursued formally the idea of nonlinearities in real exchange rate dynamics since the second half of the 1990s, providing several insights. In essence, the procedures conventionally applied by researchers to examine long-run PPP assume that the real exchange rate follows a linear process and depends on its own past values. In turn, this means that adjustment to the PPP equilibrium is assumed



Purchasing Power Parity, Fig. 1 200 years of prices and exchange rates (Sources: 1791–1991: Lothian and Taylor (1996); 1992–2000: International Financial Statistics database of the International Monetary Fund)

to be both continuous and of constant speed, regardless of the *size* of the past deviation from PPP. However, the presence of transactions costs may imply a nonlinear process, which has important implications for the conventional tests of long-run PPP. A number of authors have developed theoretical models of nonlinear real exchange rate adjustment arising from transactions costs in international arbitrage (for example, Dumas 1992). In most of these models proportional or ‘iceberg’ transport costs (‘iceberg’ because a fraction of goods is presumed to ‘melt’ when shipped) create a band for the real exchange rate within which the marginal cost of arbitrage exceeds the marginal benefit. Assuming instantaneous goods arbitrage at the edges of the band then typically implies that the thresholds become reflecting barriers.

Drawing on recent work on the theory of investment under uncertainty, some of these studies show that the thresholds should be interpreted more broadly than as simply reflecting shipping costs and trade barriers per se, but also as resulting from the sunk costs of international arbitrage and the resulting tendency for traders to wait for sufficiently large arbitrage opportunities to open up before entering the market.

Taylor (2001) has shown that empirical estimates of the half-life of shocks to the real exchange rate may be biased upwards because of two empirical pitfalls. The first pitfall identified by Taylor relates to temporal aggregation in the data. Using a model in which the real exchange rate follows an AR(1) process at a higher frequency than that at which the data is sampled, Taylor shows analytically that the degree of upward bias in the estimated half-life rises as the degree of temporal aggregation increases, that is, as the length of time between observed data points increases. The second pitfall highlighted by Taylor concerns the possibility of nonlinear adjustment of real exchange rates. On the basis of Monte

Carlo experiments with a nonlinear artificial data generating process, Taylor shows that there can also be substantial upward bias in the estimated half-life of adjustment from assuming linear adjustment when in fact the true adjustment process is nonlinear.

Overall, the theoretical models based on non-zero transactions costs of arbitrage in international goods markets suggest that the exchange rate will become increasingly mean-reverting with the size of the past deviation from the PPP equilibrium level. In other words, the speed at which the real exchange rate reverts to PPP depends on the size of the past deviation from PPP itself. When the real exchange rate is arbitrarily close to PPP, the real exchange rates may move randomly next period since agents have no arbitrage opportunities available in international goods markets. At the other extreme, when the real exchange rate deviates from PPP by a very large extent, it is likely that arbitrage forces will imply movements of goods and changes in prices (expressed in a common currency) that induce fast reversion to PPP.

Note that these arguments rationalize mean reversion in the real exchange rates based on ideas that relate to the law of one price in the sense that refers to tradable goods only. However, we argue that this is reasonable given that Engel (1999), in a study that measures the proportion of dollar real exchange rate movements that can be accounted for by movements in the relative prices of non-tradable goods, finds that relative prices of non-tradable goods appear to account for essentially none of the movement of dollar real exchange rates. Hence, much of the explanation for the time series properties of PPP deviations is likely to reside in the behaviour of deviations from the law of one price, that is, movements in the relative prices of tradable goods.

To turn to the empirics of nonlinear reversion to PPP, models that capture the nonlinear behaviour described above have shed light on several aspects of the behaviour of the real exchange rate. For example, Michael et al. (1997) apply a nonlinear model to monthly interwar data for the French franc–US dollar, French franc–UK sterling and UK sterling–US dollar as well as for the Lothian and Taylor (1996) long-span data-set described in Fig. 1. Their results clearly reject the linear framework in favour of a nonlinear process. The systematic pattern in the estimates of the nonlinear models provides strong evidence of mean-reverting behaviour for PPP deviations, and helps explain the mixed results of previous studies.

Using data for the recent float alone, Taylor et al. (2001) provide strong confirmation that the four major real bilateral dollar exchange rates obtaining among the G5 economies are well characterized by nonlinearly mean-reverting processes. Their estimated model implies an equilibrium level of the real exchange rate in the neighbourhood of which the behaviour of the real exchange rate is close to a random walk, becoming increasingly mean-reverting with the absolute size of the deviation from equilibrium, consistent with the theoretical literature on the nature of real exchange rate dynamics in the presence of international arbitrage costs.

Impulse response functions based on these nonlinear real exchange rate models suggest that the speed of real exchange rate adjustment is typically much faster than the very slow speeds of real exchange rate adjustment often recorded in the literature. For example, the estimated half-lives (in months) for dollar–sterling and dollar–yen are the following

Shock (%)	40	30	20	10	5	1
Dollar–sterling	10	20	22	26	29	32
Dollar–yen	14	18	24	32	38	42

where the first row reports the size of the shock (in percentage terms) to the real exchange rate. The estimated half-lives of these major real dollar exchange rates illustrate the nonlinear nature of the response to shocks, with larger shocks mean-reverting much faster than smaller shocks. The dollar–sterling rate displays quite fast mean reversion, ranging from a half-life of less than 1 year for the largest shocks of 40% to just under 3 years for small shocks of one percent; for shocks of 5–10%, the half-lives are just over 2 years. The dollar–yen displays higher persistence, with half-lives ranging from 14 to 42 months. These results therefore seem to shed some light on the PPP puzzles. Only for small shocks occurring when the real exchange rate is near its equilibrium do nonlinear models consistently yield half-lives in the range of 3–5 years, which Rogoff (1996) terms 'glacial'. For dollar–sterling, even small shocks of 1–5% have a half-life less than 3 years; for larger shocks, the speed of mean reversion is even faster.

An interesting experiment in terms of gauging the extent to which market integration and the reduction of trade costs impacts on the degree of mean reversion in real exchange rates is provided by the advent of the euro in 1999. Koedijk et al. (2004) provide empirical evidence that the introduction of the euro and, more generally, the process of economic integration in Europe have accelerated convergence to PPP, consistent with a transactions-costs goods-market arbitrage view of the mean reversion properties of the real exchange rate.

The vast empirical literature briefly reviewed here suggests that there are at least three features that are potentially important in designing a suitable model for the deviations from PPP. The first feature is that the model needs to allow for the fact that adjustment towards PPP is likely to occur at different speeds via nominal exchange rates and prices. The majority of empirical studies on PPP are based on univariate representations of the real exchange rate. This approach is valid only if certain (common factor) restrictions in the process linking exchange rates and prices are satisfied. Employing a model which does not impose these restrictions increases the power of the econometrics methods employed, while allowing us to shed light on the relative importance of nominal exchange rates and prices in restoring the PPP equilibrium. The second desirable feature is that the model allows explicitly for the possibility that different monetary and exchange rate regimes generate regime shifts in the structural dynamics of PPP deviations, especially when one uses long spans of data. The third feature is that the model might be nonlinear, in accordance with the growing evidence that exchange rate dynamics displays statistically and economically important nonlinearities.

To account for these three features, Sarno and Valente (2006) extend the long- span data used by Obstfeld and Taylor (2004) and apply a general modeling methodology in which regime changes and nonlinearities in the dynamic relationship between exchange rates and prices are explicitly allowed for, without imposing common factor restrictions. They examine the G5 countries across different exchange rate regimes, including the gold standard, the Bretton Woods period, and the floating regime since the 1970s. Over the sample period examined, the economic history of the countries involved has seen a number of fundamental changes in monetary and exchange rate regimes, institutional structure and policy targets which, in addition to the continuous evolution of the financial system and various nominal and real shocks, represent serious potential pitfalls to researchers attempting to find an empirical model of the deviations from PPP that is stable over the full sample.

Sarno and Valente's results are supportive of long-run PPP for each of the four major exchange rates examined and of a simple basic conjecture: under fixed exchange rate regimes relative prices adjust to restore deviations from long-run equilibrium, while nominal exchange rates bear most of the burden of adjustment under flexible exchange rate regimes. This is consistent with the general notion that the relative importance of exchange rates and relative prices in restoring the long-run equilibrium level of the exchange rate varies over time and is affected by the nominal exchange rate arrangement in operation. Further, the estimated half-lives of the nonlinear exchange rate models are sensibly different for fixed and floating regimes. Under fixed exchange rate regimes, shocks to the PPP equilibrium relationship may be very persistent, implying half lives – on average across the exchange rates considered – from over 5 years for large real exchange rate shocks of 20% to almost 10 years for small shocks of 1%. However, the corresponding half-lives during floating exchange rate regimes are drastically shorter, since the nominal exchange rate is allowed to operate and contribute to restoring PPP. In fact, shocks will last for less than 1 year on average for 20% shocks. The properties of PPP deviations under floating exchange regimes implied by their model appear to be fairly consistent with standard models of open economy macroeconomics and with their dynamic properties under conventional nominal rigidities (for example, Chari et al. 2002). It is only under fixed exchange rate regimes, when the burden of adjustment towards PPP relies exclusively on relative prices, that we observe remarkably long half-lives of PPP shocks.

Concluding Remarks

PPP remains an essential element of open economy macroeconomics for at least two reasons. First, it is a benchmark by which to judge the level of an exchange rate. Cassel argued that without PPP there would be no meaningful way of discussing overvaluation or undervaluation. That recognition has found a very concrete expression in the real exchange rate series now routinely calculated and reported by governments, international organizations and financial institutions. These series show exchange-rate-adjusted price relatives for a country relative to its trading partners. The series are constructed on the basis of GDP deflators, unit labour costs, manufacturing prices and wholesale prices for all major industrialized countries and increasingly for developing countries, too. They are used to judge changes in a country's external competitiveness, thus implicitly assuming, as Cassel did, that movements in *equilibrium* relative prices are negligible. Changes in real exchange rates then (and only then) unambiguously translate into changes in competitiveness from which to expect changes in trade flows and net exports. There is no question that these data provide a useful benchmark or starting point for policy discussion.

The second use of PPP is to serve as a simple prediction model for exchange rates at medium and long horizons. Under perfectly flexible wages and prices a monetary expansion would lead to equi-proportionate increases in wages, prices and the exchange rate, leaving all real variables unchanged. This combination of the quantity theory and PPP is an important insight in guiding policy. Expansionary monetary policy can be effective only if wages and prices are less than fully flexible and will be more effective the more flexible the exchange rate is. The essential channel is the real depreciation of the exchange rate that served to create employment, at least for a while. Similarly, exchange depreciation can be effective only if money wages and prices are unresponsive. Policy can be effective only if PPP fails to hold. Macroeconomic theory goes increasingly in the direction of sound microfoundations, information, contracting, and pricing models under transactions costs to explore what the basis of PPP failure is in the short run and to determine the resulting extent and persistence of policy effects.

Purification

Stephen Morris

Abstract

Many complete information games have equilibria only in mixed strategies, where players are required to randomize over pure strategies among which they are indifferent according to a fixed probability distribution. Harsanyi showed that, if such a game were perturbed – with each player observing an idiosyncratic independent payoff shock with continuous support – then the perturbed games will have pure strategy equilibria which will converge to the mixed strategy equilibrium as the perturbations become small. We review the strong conditions on perturbations under which Harsanyi's result holds and discuss weaker conditions on perturbations which ensure the existence of pure strategy equilibria without approximating all mixed equilibria of the unperturbed game.

In a mixed strategy equilibrium of a complete information game, players randomize between their actions according to a particular probability distribution, even though they are indifferent between their actions. Two criticisms of such mixed strategy equilibria are (*a*) that players do not seem to randomize in practice, and (*b*), if a player were to randomize, why would he or she choose to do so according to probabilities that make other players indifferent between their strategies?

Since many games have no pure strategy equilibria, it is important to provide a more compelling rationale for the play of mixed strategy equilibria.

Harsanyi (1973) gave a 'purification' interpretation of mixed strategy equilibrium that resolves these criticisms. The complete information-game payoffs are intended as an approximate description of the strategic situation, but surely do not capture every consideration in the minds of the players. In particular, suppose that a player has some small private inclination to choose one action or another independent of the specified payoffs, but this information is not known to the other players. Then the behaviour of such players will look – to their opponents and to outside observers – as if they are randomizing between their actions, even though they do not experience the choice as randomization. Because of the private payoff perturbation, they will not in fact be indifferent between their actions, but will almost always be choosing a strict best response. Harsanyi's remarkable purification theorem showed that all equilibria (pure or mixed) of almost all complete information games are the limit of pure strategy equilibria of perturbed games where players have independent small shocks to payoffs.

There are other inpts of mixed strategy play: Reny and Robson (2004) present an analysis that unifies the purification interpretation with the 'classical' interpretation that players randomize because they think that there is a small chance that their mixed strategy may be observed in advance by other players. But Harsanyi's purification theorem justly provides the leading interpretation of mixed strategy equilibria among game theorists today.

I first review Harsanyi's theorem. Harsanyi's result applies to regular equilibria of complete information games with independent payoff shocks; since many equilibria of interest (especially in dynamic games) are not regular, Harsanyi's result cannot be relied upon in many economic settings of interest; I therefore briefly review what little is known about such extensions.

Harsanyi's theorem has two parts: (*a*) pure strategy equilibria always exist in suitably perturbed versions of a complete information game; and (*b*) for any regular equilibrium of a complete information game and any sequence of such perturbed games converging to the complete information game, there is a sequence of pure strategy equilibria converging to the regular equilibrium. An important literature has ignored the latter approachability question and focused on the former pure strategy existence qst, identifying conditions on an information structure – much weaker than Harsanyi's – to establish the existence of pure strategy equilibria. I conclude by reviewing these papers.

Harsanyi's th

Consider two players engaging in the symmetric coordination game below.

	A	*B*
A	2,2	0,0
B	0,0	1,1

As well as the pure strategy Nash equilibria (*A*,*A*) and (*B*,*B*), this game has a symmetric mixed strategy Nash equilibrium where each player chooses *A* with probability $\frac{1}{3}$ and *B* with probability $\frac{2}{3}$.

But suppose that, in addition to these common knowledge payoffs, each player *I* observes a payoff shock depending on the action he or she chooses. Thus,

	A	*B*
A	$2 + \varepsilon.\eta_{1A}$, $2 + \varepsilon.\eta_{2A}$	$\varepsilon.\eta_{1A}$, $\varepsilon.\eta_{2B}$
B	$\varepsilon.\eta_{1B}$, $\varepsilon.\eta_{2A}$	$1 + \varepsilon.\eta_{1B}$, $1 + \varepsilon.\eta_{2B}$

where $\varepsilon > 0$ is a commonly known parameter measuring the size of payoff shocks and (η_{1A},η_{1B}) and (η_{2A},η_{2B}) are distributed independently of each other, and player *i* observes only (η_{iA},η_{iB}). Finally, assume that, for each player *i*, $\eta_i = \eta_{iA} - \eta_{iB}$ is distributed according to a continuous density *f* on the real line with corresponding c.d.f. *F*.

This perturbed game is one with incomplete information, where a player's strategy is a function $s_i : \mathbb{R} \to \{A, B\}$. In equilibrium, each player will follow a threshold strategy of the form

$$s_i(\eta_i) = \begin{cases} A, \text{ if } \eta_i \geq z_i \\ B, \text{ if } \eta_i < z_i \end{cases}.$$

Under such a strategy, the *ex ante* probability that player *i* will choose action *B* is $\pi_I = F(z_i)$, and the probability he or she will choose *A* is $1 - \pi_i$. Thus we can re-parameterize the strategy as

$$s_i(\eta_i) = \begin{cases} A, \text{ if } \eta_i \geq F^{-1}(\pi_i) \\ B, \text{ if } \eta_i < F^{-1}(\pi_i) \end{cases}.$$

Let us look for a strategy profile (s_1,s_2) of the incomplete information game, parameterized by (π_1,π_2), that forms an equilibrium of the incomplete information game. Since player 1 thinks that player 2 will choose action *A* with probability $1 - \pi_2$ and action *B* with probability π_2, player 1's expected payoff gain from choosing action *A* over action *B* is then

$$2(1 - \pi_2) + \varepsilon.\eta_1 - \pi_2.$$

Thus player 1's best response must be to follow a threshold strategy with threshold

$$F^{-1}(\pi_i) = \frac{3\pi_2 - 2}{\varepsilon}$$

or

$$\varepsilon F^{-1}(\pi_1) = 3\pi_2 - 2.$$

Symmetrically, we have

$$\varepsilon F^{-1}(\pi_2) = 3\pi_1 - 2.$$

Thus, there will be a symmetric equilibrium where both players choose action B with probability π if and only if

$$\varepsilon F^{-1}(\pi) = 3\pi - 2.$$

For small ε, this equation has three solutions tending 0, $\frac{2}{3}$ and 1 as $\varepsilon \to 0$. These solutions correspond to the three symmetric Nash equilibria of the above complete information game, respectively: (*a*) both always choose A, (*b*) both choose B with probability $\frac{3}{2}$, and (*c*) both always choose B.

Harsanyi's purification theorem generalizes the logic of this example. If we add small independent noise to each player's payoffs, then each player will almost always have a unique best response and thus the perturbed game will have a pure strategy equilibrium. There is a system of equations that describes equilibria of the unperturbed game. If that system of equations is regular, then a small perturbation of the system of equations will result in a nearby equilibrium.

I will report a statement of Harsanyi's result due to Govindan, Reny and Robson (2003), which weakens a number of the technical conditions in the original theorem.

Consider an I player complete information game where each player i has a finite set of possible actions A_i and a payoff function $g_i : A \to \mathbb{R}$ where $A = A_1 \times \cdot \times A_I$. An equilibrium $\alpha \in \Delta(A_1) \times \cdot \times \Delta(A_I)$ is a *regular Nash equilibrium* of the complete information game if the Jacobian determinant of a continuously differentiable map characterizing equilibrium is non-zero at α (see van Damme 1991, Definition 1.5.1, p. 39).

The μ-perturbed game is then an incomplete information game where each player i privately observes a vector $\eta_i \in \mathbb{R}^{|A|}$. Player i's payoff in the incomplete information game if action profile a is chosen is then $g_i(a)+\eta_{ia}$; thus η_i is a private value shock. Each η_i is independently drawn according to a measure μ_i, where each μ_i assigns probability 0 to i's expectation of η_i being equal under any pair of i's pure strategies a_i and a_i', given any mixed strategy profile of the other players; Govindan, Reny and Robson (2003) note that this weak condition is implied by μ_i being absolutely continuous with respect to Lebesgue measure on $\mathbb{R}^{|A|}$. A pure strategy for player i in the μ-perturbation is a function $s_i : \mathbb{R}^{|A|} \to A_i$. A pure strategy profile s induces a probability distribution over actions $V_s \in \Delta(A)$, where

$$v_s(a) = \Pr_{\mu}\{\eta : s_i(\eta_i) = a_i \text{ for each } i\}$$

Theorem (Harsanyi 1973; Govindan et al. 2003) Suppose that α is a regular Nash equilibrium of the complete information game and that, for each i, μ_i^n converges to a point mass at $0 \in \mathbb{R}^{|A|}$. Then for all $\varepsilon > 0$ and all large enough n, the μ-perturbed game has a pure strategy equilibrium inducing a distribution on A that is within ε of α, that is,

$$|v_s(a) - \prod_{i=1}^{I} \alpha_i(a_i)| \leq \varepsilon$$

for all $a \in A$.

The pure strategy equilibria are 'essentially strict', that is, almost all types have a strict best response. An elegant proof in Govindan, Reny and Robson (2003) simplifies Harsanyi's original proof.

Dynamic Games

Harsanyi's theorem applies only to regular equilibria of a complete information game. Harsanyi noted that all equilibria of almost all finite complete information games are regular, where 'almost all' means with probability one under Lebesgue measure on the set of payoffs. Of course, normal form games derived from general extensive form games are not generic in this sense. This raises the question of whether mixed strategy equilibria of extensive form games are purifiable in Harsanyi's sense.

Here is an economic example suggesting why this is an important qst. Consider an infinite overlapping generations economy where agents live for two periods; the young are endowed with two units of an indivisible and perishable consumption good, and the old have no endowment. Each young agent has the option of transferring one unit of consumption to the current old agent. Each agent's utility function is strictly increasing in own consumption when young and old, and values smoothed consumption (one when young, one when old) strictly more highly than consuming the endowment (two when young, none when old). Under perfect information, this game has a 'social security' subgame perfect Nash equilibrium where each young agent transfers one unit to the old agent if and only if no young agent failed to do so in the past. But suppose instead that each young agent observes only whether the previous young agent made a transfer, and restrict attention to subgame perfect Nash equilibria. Then Bhaskar (1998) has shown that there is no pure strategy equilibrium with a positive probability of transfers (in fact, this conclusion remains true if all agents only observe history of any commonly known finite length). To see why, suppose there was such an equilibrium: if the young agent at date t does not transfer, then the young agent at date $t + 1$ must punish by not making a transfer; but the young agent at date $t + 2$ did not observe the date t outcome, and so will think that the young agent at date $t + 1$ deviated, and will therefore not make transfers; so the young agent at date $t + 1$ would have an incentive to make transfers, and not to punish as required by the equilibrium strategy.

However, Bhaskar shows that there are mixed strategy equilibria with positive transfers. In particular, there is an equilibrium where the young always transfers in the first period or if he or she observed transfers in the previous period, and randomizes between making transfers or not if he or she did not observe transfers. This strategy profile attains the efficient outcome and involves mixing off the equilibrium path only. It is natural to ask whether this equilibrium can be 'purified': suppose that each young agent obtains a small 'altruism' payoff shock that makes transfers to the old slightly attractive. The mixed strategy might then be the limit of pure strategy equilibria where the more altruistic agents make the transfers and the less altruistic agents do not. However, Bhaskar shows that the mixed strategy equilibria cannot be purified. The logic of Harsanyi's purification result breaks down because the equilibrium is not regular.

Very little is known in general about purifiability of mixed strategy equilibria in extensive form games. Results will presumably depend on the regularity of the equations characterizing equilibria and the modelling of payoff choices in the extensive form (for example, do shocks occur at the beginning of the game or at each decision node?). The best hope of a positive purification result would presumably be in finite dynamic games, where Harsanyi's regularity techniques might be applied. But Bhaskar (2000) gives an example of a simple finite extensive form game where mixed strategy equilibria are not purifiable because of the non-regularity of equilibria even for generic assignment of payoffs to terminal nodes. Mixed strategy equilibria play an important role in recent developments of the theory of repeated games. Bhaskar, Mailath and Morris (2006) report some positive and negative purification results in that context.

Purification Without Approachability

Harsanyi's purification theorem has two parts. First, the 'purification' part: all equilibria of the perturbed game are essentially pure; second, the 'approachability' part: every equilibrium of a complete information game is the limit of equilibria of such perturbed games. For the first part, Harsanyi's theorem uses the assumption of sufficiently diffuse independent payoff shocks. Only the second part required the strong regularity properties of the complete information game equilibria.

Radner and Rosenthal (1982) addressed a weaker version of the purification part of Harsanyi's theorem, asking what conditions on the information system of an incomplete information game will ensure that for every equilibrium (perhaps mixed) there exists an outcome equivalent pure strategy equilibrium. Thus they did not ask that every equilibrium be essentially pure and they did not seek to approximate mixed strategy equilibria of any unperturbed game. Each agent observing a signal with an atomless independent distribution is clearly sufficient for such a 'purification existence' result (whether or not the signal is payoff relevant). But what if there is correlation?

A simple example from Radner and Rosenthal (1982) illustrates the difficulty. Suppose that two players are playing matching pennies and each player i observes a payoff-irrelevant signal x_i, where (x_1,x_2) are uniformly distributed on $\left\{(x_1,x_2)\in\mathbb{R}_+^2 \mid 0\le x_1\le x_2\le 1\right\}$. In any equilibrium, almost all types of each player must assign probability $\frac{1}{2}$ to his or her opponent choosing each action (otherwise, that player would be able to obtain a payoff greater than his or her value in the zero sum game). Yet it is impossible to generate pure strategies of the players that make this property hold true. Another illustration of the importance of correlation for purification occurs in Carlsson and van Damme (1993), where it is shown that, while small independent noise leads to Harsanyi's purification result, small highly correlated noise leads to the selection of a unique equilibrium (the comparison is made explicitly in their Appendix B).

Radner and Rosenthal (1982) show the existence of a pure strategy equilibrium if each player observes a payoff-irrelevant signal with an atomless distribution and each player i's payoff-irrelevant signal and payoff-relevant information (which may be correlated) are independent of each other player's payoff-irrelevant signal. This result extends if players observe additional finite private signals which are also uncorrelated with others' atomless payoff-irrelevant signals. Their method of proof builds on the argument of Schmeidler (1973) showing the existence of a pure strategy equilibrium in a game with a continuum of players. Radner and Rosenthal (1982) also present a number of counter-exs – in addition to the matching pennies example above – with non-existence of pure strategy equilibrium. Milgrom and Weber (1985) show the existence of a pure strategy equilibrium if type spaces are atomless and independent conditional on a finite valued common state variable with payoff interdependence occurring only via the common state variable. Their result – which neither implies nor is implied by the Radner and Rosenthal (1982) conditions – has been used in many applications. Aumann et al. (1983) show that, if every player has a conditionally atomless distribution over others' types (that is, his or her conditional distribution has no atoms for almost every type), there exists a pure strategy ε-equilibrium. Their theorem thus covers the matching pennies example described above.

The existence of such purifications deals with one of the two criticisms of mixed strategy equilibria raised above: people do not appear to randomize. In particular, in any such purification the 'randomization' represents the uncertainty in a player's mind about how other players will act, rather than deliberate randomization. This interpretation of mixed strategies was originally emphasized by Aumann (1974).
