Bequests play a central role in numerous economic models and as such have long attracted the attention of economists. The strength of the desire to leave bequests and the motivation behind these transfers have direct implications for such fundamental behaviours as life-cycle savings and consumption. From a public policy point of view, bequests affect the accumulation of the capital stock, the distribution of income, and the ties across generations. They also provide a source of tax revenue. Furthermore, estimates suggest that an enormous amount of wealth could be bequeathed in the coming decades, making the issues quite timely.

In attempting to understand the motivation behind bequests economists have offered several theoretical models, all of which have some intuitive appeal. Although no agreement has been reached on the most plausible theory or their relative importance, the recent availability of richer data-sets and the use of administrative records provide some hope that patterns of intergenerational transfers will be better understood. Gaining insight into the motivation behind transfer behaviour will help us to assess the potential impacts of tax policies and public transfer programmes, and to understand more completely the impact of population ageing.

Inheritance Taxes

Joseph A. Pechman

Taxes on property left by individuals to their heirs are among the oldest forms of taxation. In societies in which property is privately owned, the state protects the property rights of the individual and supervises the transfer from one generation to the next. Consequently, the state has always regarded property transfers as appropriate objects of taxation. However, taxes on bequests and gifts raise very little revenue in modern tax systems.

I

Forms of Death Taxes

Taxation of property transfers can take several forms, depending on when the transfers are made. *Estate* taxes are taxes on the privilege of transferring property to one's heirs at death. *Inheritance* taxes are levied on the privilege of inheriting property. Most estate and inheritance taxes are levied at graduated rates (sometimes reaching high levels), with high exemptions.

Taxes at death could be avoided simply by transferring property by gifts *inter vivos* (between living persons). Accordingly, estate taxes are usually associated with a *gift* tax on the donor, and inheritance taxes are associated with a gift tax on the donee. In the United States, the United Kingdom, and other countries, the estate and gift taxes have been unified into one tax. In such cases, the tax is levied on the accumulated bequests and gifts, with instalments paid on the incremental gifts as they are made and the bequest treated as the final gift.

State governments of the United States and many countries levy taxes on inheritances separately from gift taxes or without gift taxes. A unified tax on gifts and inheritances, called *accessions tax*, is not used anywhere.

Some people regard an inheritance or accessions tax as more equitable than an estate tax, because taxes are graduated according to the total wealth received by any one person. On the other hand, most countries use the estate tax because it is easier to administer.

Bequests and gifts, like income from work or investments, are a source of ability to pay. In theory, therefore, they should be taxable to the recipient as income when received. However, bequests and gifts are taxed separately from income in all countries.

History

Death taxes pre-date both income and sales taxes as a source of government revenue. The first inheritance tax was levied in the Roman Empire beginning in AD 6. During the Middle Ages, various feudal taxes resembled inheritance taxes. Such taxes were in use in several Italian commercial cities by the end of the 14th century and in England, France, Germany, the Netherlands, and Portugal by the end of the 17th century. Estate or inheritance taxes are now levied in practically all industrial countries and in many developing countries, but the type of tax and the degree of progression differs greatly among them.

England's death tax, which dates from the year 1694, took its modern form in 1779, when a flat duty was replaced essentially by a proportional tax; graduation was introduced in 1894. France adopted its inheritance tax in 1796 and introduced graduation in 1902. Italy modelled its tax after the French system in 1862 and made it progressive in 1902. Germany's tax, which was based on the Prussian inheritance tax of 1873, was graduated in 1905. The federal government of the United States levied temporary inheritance taxes during the Civil War and the Spanish–American War, but the tax was already in use in many of the states before the modern, graduated estate tax was adopted in 1916.

Rationale

Adam Smith was ambivalent about death taxes, mainly because they bear heavily on families having deaths spaced at short intervals. (This problem is now handled by providing a credit or rebate for taxes on an estate which was recently subject to tax, say, within the last five or ten years.) Smith and David Ricardo believed that death taxes would reduce the funds available for investment. Jeremy Bentham and John Stuart Mill attacked the ethical justification of the institution of inheritance, and supported a limitation on the amount any one person could acquire from others without working. Henry Sidgwick, Alfred Marshall, A.C. Pigou, and many other economists in the classical tradition supported the taxation of wealth transfers to promote greater equality of opportunity, even though some were concerned about the effect on capital accumulation. Josiah Wedgwood (1929), Hugh Dalton, James Meade (e.g. 1976) and others emphasized the objective of reducing the concentration of wealth as a justification for state or inheritance taxation. Henry Simons, who argued strongly for the taxation of what he called 'gratuitous receipts' as income, also supported a supplementary tax on wealth transfers to control the size of inheritances.

Some Keynesian economists in Britain have supported death taxes in order to raise the propensity to consume, but this rationale had no influence either on the development of these taxes or on the public's attitude toward them. Keynes himself mentioned that death taxes would probably increase the propensity to consume more than other taxes of equal yield, but did not recommend that such taxes be enacted for this reason.

Death taxes have been supported by people in all wealth classes. One of their strongest supporters was the American steel magnate, Andrew Carnegie, who had doubts about the institution of inheritance (because it impairs children's incentives) and felt that wealthy persons are morally obliged to use their fortunes for social purposes. While this view is not widely held, many people believe that the existing distribution of wealth and control of business enterprise should not be perpetuated through succeeding generations and that

taxation of bequests and gifts is the most effective method of achieving this objective. Although data are scarce, the available information suggests that inherited wealth is a major reason why the distribution of wealth is highly unequal in market economies.

Opinions about the impact of death taxes on private incentives vary. Some believe that these taxes reduce saving and undermine the economic system. But even they might concede that death taxes have less adverse effects on incentives than do income taxes of equal yield. Income taxes reduce the return from effort and risk-taking as income is earned, whereas death taxes are paid only after a lifetime of work and accumulation and are likely to be given less weight by individuals in their work, saving, and investment decisions. This distinction was emphasized by many economists in the classical tradition (including Mill, Sidgwick, Marshall, and Pigou).

Proposals have been made from time to time to tax inherited wealth more heavily than wealth accumulated out of an individual's own saving. In some plans (for example, a plan proposed by Eugenio Rignano, 1924), inherited wealth would be taxed at progressively higher rates in succeeding generations. Such proposals have never been given serious consideration because of the difficulties of tracing inherited wealth, the harshness of the tax when there are quick successions, and the problems of record-keeping and administration. It is possible to accomplish Rignano's objective by varying the tax on the basis of the number of years during which donors hold their wealth. Such a plan, which was devised by William Vickrey (1947) and later proposed in modified form by a commission headed by James E. Meade (1976), tends to be complicated (because it requires interest adjustments to equate the taxes on bequests and gifts over a given number of years) and no country has shown any interest in this type of tax.

Structural Problems

Since wealth transfers take many forms, estate and gift taxation is inherently complicated. The bases of the estate and gift taxes are intended to consist of all property transferred by gift or death, but only a small fraction of total property transfers is subject to tax. In the United States, less than one per cent of all the estates of those who die in any one year is subject to estate or gift taxes.

The estate and gift tax exemptions tend to be relatively high in most countries and concessions for transfers to children and grandchildren (consanguinity rates) are frequently excessive. The tax base is also eroded by undervaluations of farm and small business properties. Works of art and other personal property often escape taxation. In the United States, family foundations may be used to remove wealth from the estate tax base without relinquishing control of the business enterprise.

The most difficult problems in estate and gift taxation have arisen from the use of trusts to transfer wealth to future generations. Children and grandchildren may receive the income from a trust while they are living, but no tax is due on the property when the trust terminates at their death, thus avoiding tax for one or more generations. In the United States and the United Kingdom, the trust property is treated as if it is owned by the income beneficiaries, but significant tax avoidance possibilities through the use of trusts remain.

Even if the estate and gift taxes are unified, wealthy people may reduce their taxes by transferring property by gifts during their lifetimes. Usually, an annual exclusion is allowed to avoid the need to account for small gifts, but such exclusions permit large amounts of property to be transferred free of tax over a period of years. In addition, the gift tax itself is not included in the tax base, whereas the estate tax is computed on the basis of the donor's entire property, including the tax. Despite the advantage of making gifts, data for the United States suggest that wealthy people prefer to retain the bulk of their property until death.

Another device used by wealthy people to avoid estate taxes is to manipulate the ownership of various classes of stock in a corporation so as to

funnel increasing equity values to children or grandchildren. For example, by recapitalizing the equity structure of the business, the owner of a successful closely-held corporation might give his children all the common stock, which is initially given a low value, and retain the preferred stock, which is given a high value. As the corporation prospers, the common stock rises in value to reflect the increased earnings of the corporation, but this increase in wealth never shows up in the estate tax base.

Because of the practical problems of taxes on wealth transfers, some have proposed the enactment of an annual wealth tax to reach property that is not now subject to death (or income) taxes. Annual taxes on net wealth have been enacted in a number of European countries, but these taxes raise very little revenue and are regarded as supplements to estate or inheritance taxes, rather than as substitutes.

Revenue Yield

Despite the appeal of estate and gift taxes on social and economic grounds and despite the use of relatively high rates, taxes on property transfers have never provided significant revenues anywhere and have had only modest effects on the distribution of wealth. In 1983, estate and gift tax collections amounted to 0.3 per cent of gross domestic product in France, 0.2 per cent in the United States and the United Kingdom, and 0.1 per cent in Germany.

One can only guess why heavier reliance has not been placed on estate and gift taxes. One explanation is that people resent paying taxes on such wealth as the family home or business, works of art, and other personal property. The public is not aware that the major part of the estate and gift tax bases consists of stocks, bonds, and real estate, and that the exemptions remove the wealth of most people from the base. Another explanation is that greater equality in the distribution of wealth is not generally accepted as an objective of tax policy.

More intensive use of estate and gift taxes would add progressivity to tax systems with less impairment of economic incentives than many other taxes. Major obstacles to increased use of these taxes are public apathy and the lack of understanding of their major features and how they apply in individual circumstances. Resistance to higher death duties by wealthy people is also a factor. The merits of wealth transfer taxes will have to be more widely understood and accepted before they can become effective revenue sources.

Canadian economist, historian and university administrator. Born in rural Ontario, Innis was educated at McMaster University, Toronto (BA, MA), and at the University of Chicago (Ph.D.). Having served in the First World War, he joined the faculty of the Department of Political Economy, University of Toronto, in 1920.From 1937 until his death he was head of the department, and from 1947 he was also Dean of the Graduate School; at his death he was President of the American Economic Association.

A prolific and thoughtful scholar, Innis began by scrutinizing Canadian economic history, both in shorter writings and in such major works as *The Fur Trade in Canada* (1930) and *The Cod Fisheries* (1940), where he concentrated his attention on such great 'staple products' as codfish, fur, wheat and timber. In these works, which have been read with interest in other lands whose economic structures appear to be similar, such as Australia, Innis developed a vision of Canadian economic history that centred on the successive development of natural-resource-based industries. The physical characteristics of these industries' products, Innis believed, had shaped not only the economic but the political and cultural history of Canada. Few would now accept Innis's interpretation of Canadian history as the mere reflection of the 'staple products'. Yet for 40 years that interpretation shaped the teaching and writing of economy history in English-speaking Canada, and it affected political historiography as well. Innis's undergraduate education was aimed at the Baptist ministry, and perhaps it was a misfortune that he turned to economics; if he had followed some more speculative vocation, the particular powers of his intellect might have developed more widely and less eccentrically, although Canadian economic history would have been deprived of its most creative practitioner. The broadening of Innis's interests beyond economic history can be detected in his early writings on what he called 'the penetrative power of the price system'–the ability of market mechanisms to reshape social relationships. Uncertain in his grasp of modern economics, Innis ignored the Keynesian Revolution, and he was profoundly sceptical about the potential contribution to rational national policymaking which might come not only from economists but from other scholars; better, he thought, for university folk to concentrate upon the safeguarding of the Western cultural tradition. In his later years Innis wrote almost exclusively about very large questions – the interconnections, over very long periods, among imperial structures and means of communication. These works –*The Bias of Communications, Changing Concepts of Time, Empire and Communications, Minerva's Owl* – have had little impact on economists or economic historians, although they have influenced some students of the humanities –most notably the Canadian literary scholar Marshall McLuhan. Also, during the 1970s and 1980s Innis's writings attracted attention from Canadian nationalists, more or less regardless of discipline; furthermore, in these decades efforts were made to find and explicate new profundities in his writings, or to reinterpret this pessimistic and conservative thinker as an unconscious proto-Marxist. Few economists and fewer historians have found these efforts persuasive.

Innovation

C. Freeman

Economists of all descriptions have accepted that new products and new processes are the main source of dynamism in capitalist development. But relatively few have stopped to examine in depth the origins of such innovations or the consequences of their adoption. Most have preferred, in Rosenberg's (1982) apt description, not to look 'inside the black box', but to leave that task to technologists and historians, preferring to concentrate their own efforts on '*ceteris paribus*' models, which relegate technical and institutional change to the role of exogenous variables.

The classical economists were generally more ready to look inside the black box; Adam Smith and Marx in particular both showed a deep interest in the relationship between scientific research, technical innovation and the market. Smith (1776), pointed already in the 18th century to the growth of specialization in scientific research and to the links between innovation in the machine-building industries and scientists ('philosophers' or men of 'speculation' whose task is 'to observe everything'). Marx and Engels (1848) probably more than any other economist assigned to technical innovation the driving force in economic development and competition – 'the bourgeoisie cannot exist without constantly revolutionizing the means of production.'

But in the first half of the 20th century Schumpeter was almost alone among leading economists in following and developing this classical tradition. Consequently those economists such as Nelson (1977, 1982) and Rosenberg (1976, 1982) who have concentrated much of their attention on the economics of innovation are often referred to as 'Schumpeterian' or 'neo-Schumpetarian', even though their ideas may considerably diverge on many topics.

It is to Schumpeter that we owe the threefold distinction between invention, innovation and diffusion of innovations, which has now become the generally accepted convention in analysis of technical change. *Invention* is generally defined as a novel idea, sketch or model for a new or improved product, process or system. It need not necessarily imply any empirical test of feasibility or prototype experience, but as Jewkes (1958) suggests, it usually does convey the first belief that something should work and often the first rough test that it will in fact work.

Nevertheless, Schumpeter was right to stress the distinction between invention and *innovation*. There is an enormous difference between 'working' under laboratory conditions and working under commercial conditions. Schumpeter used the expression 'innovation' to connote the first introduction of a new product, process, method or system into the *economy*. (This is generally taken to include military or health care applications as well as the more purely commercial innovations.) As Schumpeter pointed out, there is many a slip between cup and lip in the development of an invention to the point of commercial introduction. Problems in scaling up from laboratory scale to works scale lead to the demise of many apparently sound ideas and unanticipated 'bugs' are the rule rather than the exception in the exploitation of inventions. Many (perhaps most) inventions are patented, but most patents are never actually used commercially except perhaps as bargaining counters.

Some ambiguity still surrounds the definition of 'innovation', since the word is used both to indicate the date of *first* introduction of a new product or process (e.g. the float glass process was innovated in 1958) and to describe the whole process of taking an invention or set of inventions to the point of commercial introduction, as in 'management of innovation' – a process which may take many years of development work, trial production and marketing.

In fact the date of launch of an innovation is seldom as precise as might appear at first glance, since false starts and modifications to the design of a radical new product or process are commonplace. Thus many different dates can be found for the innovation of well-known products, such as the radio or the electronic computer. National bias plays a part too, as well as definitional problems.

This point is an important one when we come to consider the third aspect of technical change in the Schumpeterian framework – the *diffusion* of innovations. Although almost all economists would agree that the diffusion of innovations through a population of potential adopters is crucial for the achievement of productivity gains and successful competitive performance more generally, they would also agree with Rosenberg (1976), that the product or process which is being diffused is itself usually subject to further change *during* the diffusion process. Indeed, this has been one of the main criticisms of some studies of diffusion in the 1960s and 1970s (Metcalfe 1981) which tended to make the static assumptions of an unchanged product diffusing through an unchanged environment. Nevertheless, this does not invalidate Schumpeter's analytical distinction, which has proved extremely fruitful both in theoretical and empirical work, as shown notably in the major international conference on diffusion of innovations in Venice in 1986.

When Jewkes and his colleagues (1958) made their original study of the sources of invention, they rightly complained that economists had made very little contribution to the study of invention and innovation, and Rogers (1962) could legitimately make a very similar complaint, in relation to the study of *diffusion* of innovations. However, in the next quarter of a century the picture changed considerably. Following the impetus given especially by Mansfield (1968, 1977) numerous empirical studies in Europe, America and Japan covered much of the territory which Schumpeter sketched out in a preliminary way. Unknown and uncharted territory still remains, however, and its exploration is by no means straightforward (Dosi 1985).

Thus, for example, we now know a good deal about the conditions surrounding success and failure in the competitive struggle of private firms to innovate, but far less is known about the types of government policies which are most likely to encourage innovators and promote their success. The study of the latter is inhibited by the difficulty of isolating any specific single measure, such as a tax incentive, development subsidy or procurement initiative from other more general influences on the behaviour of the firm and numerous factors specific to individual firms (Rothwell and Zegveld 1981).

In the analysis of competitive attempts by individual firms to innovate the problems of multiple causality has been partly overcome by the use of statistical techniques in paired comparisons of success and failure, as for example in project SAPPHO (Freeman 1982; Rothwell et al. 1974) and similar studies in several countries (e.g. Szakasits 1974). By and large these studies agree in highlighting the main factors leading to successful innovation performance: the depth of understanding of the needs of potential users of the innovations and the steps taken to obtain this knowledge (external communications network): the research and development capability to eliminate or minimize 'bugs' prior to launch of the innovation; internal communications adequate to ensure effective links between those responsible for R&D, marketing and production within the firm; entrepreneurs or 'business innovators' with the status and experience to ensure the necessary mobilisation and coordination of resources within the firm. Studies of failure have been particularly illuminating in demonstrating the tendency of some technical innovators to neglect user needs and the lack of communication between various departments in some large firms (Burns and Stalker 1961). However, they also show that even in cases, when firms appear to follow all the 'rules' and 'best practices' which lead to good innovation performance, technical and market uncertainties may frustrate their best efforts.

Indeed, the empirical studies of the management of innovation and firm behaviour have undermined the traditional neoclassical theory of

the firm. Imperfect information, uncertainty, complex institutional linkages, cumulative in-house technology, and searching modes of behaviour are characteristic of innovation, rather than the tidy, rational, optimizing calculations and perfect foresight postulated by neoclassical theory (Dosi 1984, 1985). For this reason contributors to innovation studies have also made major new contributions to a revised theory of firm behaviour, which take into account the findings of the stream of empirical research (Nelson and Winter 1982; Dosi 1984).

Less clear-cut conclusions have emerged with respect to the influence of size and concentration on innovative performance. Schumpeter (1928, 1942) is often known for his emphasis on the advantages of large size and monopoly on innovative performance, whilst traditional theory has continued to stress the advantages of competitive market structures. Clearly large size can facilitate innovative efforts in areas where development costs are unavoidably high because of number and complexity of components, as for example in spacecraft, nuclear reactors, or electronic telephone exchanges. The R&D threshold entry barriers in such areas can sometimes be so high as to limit effective competition to only a few large organizations throughout the world; and often innovation costs are partly met by state subsidies.

Even those economists, such as Jewkes et al. (1958), who have stressed the role of individual inventors and small firms at the stage of *invention*, have accepted that often *development* costs are so high that large firms tend to predominate when it comes to *innovation*. Many of the case studies described by Jewkes et al. illustrate this point, since the small firms or individuals who initiated the inventive work were often obliged to seek the help of larger organizations or were taken over by them before they could launch the new product or process on the market.

However, revolutionary advances in technology, for example the micro-chip, can sometimes lower entry barriers dramatically. In those areas where smaller firms can afford the entry costs they appear to perform relatively well in competition with larger firms. Thus the SAPPHO project did not show size as a variable which discriminated systematically between success and failure.

Schumpeter (1912, 1928) had himself recognized the advantages of new small innovator–entrepreneurial firms, but believed that the general trend of capitalist development and the rising costs of in-house R&D would lead increasingly to the management of innovation by larger bureaucratic organizations. Galbraith (1972) developed this notion of the 'technostructure' in large firms in his 'New Industrial State'. However, empirical evidence suggest that small firms have continued to maintain, or increase their share of innovations, even though large firms do indeed now account for more than two-thirds of R&D and of all innovations (Townsend et al. 1982). The share of small firms in innovations is apparently greater than their share of R&D expenditures, and this phenomenon has been explained partly in terms of motivation and good internal communications leading to greater efficiency in the conduct of R&D, and partly in terms of the 'spin-off' of technical innovators who have left large government, industrial or academic laboratories with the idea for an already partly developed product.

The debate continues but with increasingly general acceptance that both very large and new entrepreneurial firms enjoy advantages in distinct types of invention and at different stages of the evolution of new technologies. The previously observed tendency for R&D intensity to decline in the largest firms has been denied by Soete (1979), who maintains that more recent evidence supports the Schumpeterian hypothesis.

Schumpeter's contention that technological competition was more important than price competition with invariant conditions of production has also found increasing confirmation from empirical and theoretical work in the sphere of international trade. Since Hufbauer's (1966) original demonstration of the role of technical innovation in the explanation of patterns of international trade in synthetic materials, evidence has accumulated to confirm that 'neo-technology' theories have greater explanatory power in relation to international trade performance generally than the Heckscher–Ohlin factor proportions theory (Soete 1981).

The notion that cumulative patterns of advantage in know-how, skills and innovative capability may underlie some of the persistent differences in comparative international trade and productivity performance has also found confirmation in many national studies of innovation and economic development (e.g. Pavitt 1980). These suggest that institutional innovations in education and training systems, as well as in research institutes and organizations have historically played an important part in building up cumulative technological capability. Thus, for example, German strength since the late 19th century in the chemical and engineering industries has been related to the establishment of the 'Technische Hochschulen' and other new developments in German universities, as well as the establishment of in-house R&D in the leading German chemical and electrical firms. Similar arguments have been advanced with respect to Japanese industrial training and technological innovation systems and the more recent outstanding successes of the Japanese economy (Freeman 1983).

To sum up, empirical studies of innovations and their diffusion have provided mounting evidence that mainstream neoclassical theories of firm behaviour, competition, international trade and consumer behaviour are seriously deficient in their assumptions and conclusions. However, the 'neo-Schumpeterian' tradition in economics has only begun the task of substituting a more satisfactory theoretical foundation which would take both technical innovation and institutional factors fully into account (Dosi 1985).

Input–Output Analysis

Wassily Leontief

JEL Classifications
E1

Input–output analysis is a practical extension of the classical theory of general interdependence which views the whole economy of a region, a country and even of the entire world as a single system and sets out to describe and to interpret its operation in terms of directly observable basic structural relationships.

Wassily Leontief, a Russian-born American economist, started the construction of the first input-output tables of the American economy when he joined the faculty at Harvard University in 1932. These tables, for the years 1919 and 1929, were published together with the formulation of a corresponding mathematical model and numerical computation based on it in 1936 and 1937. Thus from the very outset the new methodology – for the development of which Leontief was awarded 40 years later a Nobel prize – emphasized the importance of close mutual alignment of systematic fact finding and theoretical formulation.

In the late 1920s Leontief spent three years at the Institute for the World Economy at the University of Kiel (Germany) on derivation of statistical supply and demand curves. That early experience with curve fitting taught him not to rely on indirect statistical inference as a substitute for painstaking direct factual inquiry.

With its emphasis on disaggregation permitting detailed quantitative description of the structural properties of all component parts of a given economic system, the input–output analysis moved in a direction directly opposite to that of the highly aggregative approach that began, approximately at the same time, to dominate fundamental economic research under the powerful influence of the Keynesian paradigm presented in Keynes's *General Theory*. Hand-in-hand with a disaggregated data base went an equally disaggregated theoretical model, the empirical implementation of which involved numerical computations exceeding in their complexity and scale anything that had been carried out up to that time along these lines in economics or any other social science.

The limited capabilities of the Wilbur linear analog computer used in the first large scale computation forced Leontief to scale down his problem by neglecting some of the detail contained in the disaggregated data base. Subsequent rounds of computation were carried out at first on Howard Aiken's, Mark I and Mark II computers, and later on the early electronic machines. Thirty years later the race between the economists and statisticians compiling more and more detailed factual information, and engineers constructing more and more powerful machines, was won hands down by the latter.

A standard input–output table contains square arrays of figures arranged in chess-board fashion. Each row and the corresponding column bears the name of one particular sector, say, steel industry, automobile industry, electric power utilities, advertising services, and so on. Each individual entry represents the amount (which can, of course, be zero) of the commodity or service produced by the sector – identified by the name of the row in which it appears – that has been delivered to the sector named at the head of the column in which that entry is placed. The small schematic input–output table presented below (Table 1) describes intersectoral transactions between the three sectors of the elementary economy described by it.

Input–Output Analysis, Table 1

	Agriculture	Manufacturing	Households	Total
Agriculture	25	20	55	100 bushels
Manufacturing	14	6	30	50 yards of cloth
Households	80	180	–	260 man-years

Input–Output Analysis, Table 2

	Sector 1	Sector 2
Sector 1	0.25	0.40
Sector 2	0.14	0.12
Household	0.80	3.60

Examining these figures, one finds that to produce one bushel of wheat, agriculture requires 0.25 bushels of wheat (seed), 0.14 tons of steel and 0.80 man years of labour. A similar set of technical coefficients – 0.40 units of agricultural and 0.12 of manufactured products – describe the input requirements for production of one yard of cloth. Listed column by column these sets of technical input coefficients represent the structural matrix at the producing part of the given economy. While the figures in Table 2 were derived from the input–output table (Table 1), estimates of the magnitudes of the technical coefficients could be, and in some instances actually are, obtained directly from technical, engineering data sources.

The structural matrix of an economy provides a basis for determination of total sectoral output as well as magnitude of inter-sectoral transactions that would enable the producing sectors to deliver to households and to other so-called final users a specified 'bill of goods'. Considering the vector of final demand, consisting of 55 bushels of wheat and 30 yards of cloth, as given, the following set of balanced equations can be used to determine the total amounts of wheat (x_1), of cloth (x_2), as well as the total amount of labour (L) needed to balance under these particular technological conditions the outputs and inputs of both producing sectors,

$$\begin{aligned}(1-0.25)x_1 - 0.14x_2 \\ = y_1 - 0.40x_1 + (1-0.12)x_2 = y_2\end{aligned} \quad (1)$$

The general solution of these two equations:

$$\begin{aligned}1.457y_1 + 0.662y_2 = x_1\, 0.232y_1 + 1.242y_2 \\ = x_2\end{aligned} \quad (2)$$

permits us to compute the total levels of output of wheat, x_1 and cloth, x_2 required directly and indirectly to satisfy any given vector (y_1, y_2) of 'final demand'.

An increase in the final deliveries of agricultural products, y_1 by one unit would for instance require a rise of total agricultural output, x_1, by 1.1457 units, 0.1457 of which will have to be used to satisfy the additional input requirements of the agricultural and manufacturing sectors.

Formulated in short-hand matrix notation, the balance equations (1), describing the relationship between the column vector of final demand, y, and the column vector, x, of total outputs of all producing sectors can be written as:

$$(I - A)x = y \quad (3)$$

where A represents the upper, square part of the structural matrix describing the material input requirements of all producing sectors, x is the column vector of total outputs and y, the column vector of final deliveries of both goods. The general solution of that linear equation is,

$$x = (I - A)^{-1}y \quad (4)$$

where $(I - A)^{-1}$ represents the so-called inverse of matrix $(I - A)$. Total labour requirement can be computed in a separate step,

$$L = l'x = l'(I - A)^{-1}y \quad (5)$$

where l' is a row vector of technical labour coefficient representing the technologically determined amounts of labour that each industry employs per unit of its total output.

The same set, A, of structural coefficients that controls the physical flows, determines also the relationship between the prices of goods and services produced by different industries and the 'value added' payments (expressed in the monetary units) made by each industry per unit of its output. These include wages, profits, taxes, etc. In short, all payments other than those made for goods and services purchased from other producing sectors.

This set of value added–price equations, (often referred to as a 'dual' to set (3) of physical input–output relationships) can be formulated as follows,

I

$$(I - A')P = V \tag{6}$$

and its solution for the unknown prices as,

$$P = (I - A')^{-1}V \tag{7}$$

where P is the column vector of prices of all sectoral outputs and V is the given column vector of values added (per unit of their respective outputs), in different sectors.

In the schematic input–output table considered above all amounts entered along a particular row are measured in the same appropriately selected physical unit, for instance, wheat – in bushels; cloth – in yards; labour – in man years. No column totals are entered, since adding amounts measured in incomparable physical units would make no sense. In most published input–output tables, all transactions are measured however in value terms – usually in 'base year' prices. Since these are assumed to satisfy the price-value added equations described above – each column total, including the value added per unit of total output, must naturally be equal to the total output figures entered at the end of the corresponding row.

Value figures entered along a particular row can, however, also be interpreted as representing physical amounts of the good in question, provided the physical unit in which they are measured is implicitly defined as the quantity of that good purchasable for, say, one dollar.

In the case of a table, some rows of which are presented in conventional physical amounts, say kwh of electric power, or tons of copper, while some other rows are presented in monetary units, appropriate 'equilibrium prices' can be computed through solution of the corresponding 'dual' Eq. (7). To do so it would suffice to re-define the physical unit of the products of each sector as the amount purchasable for, say, one dollar, or some other monetary unit, at the price actually used in determination of the value figures entered on the base year table. These prices might of course be different from the equilibrium prices.

From the outset the development of input–output analysis was marked by a succession of empirical applications. In Leontief's early volume, *The Structure of American Economy, 1919–1929* (1941), this was the computation of the effects of changes in the input structure of different industries on levels of output and prices of their products, and in particular on the 'standard of living' of households.

With the onset of Second World War, attention was centred on the transition from peacetime to a war economy: in particular, on the effects of changes in the level and composition of final demand on the intersectoral distribution of output and employment. The first official US input–output table – for the year 1939, compiled for the US Bureau of Labor Statistics – provided a basis for preparation of a detailed multisectoral projection of postwar production and employment levels. Correctly predicting serious steel shortages, instead of large surpluses anticipated by leading economic and industry experts, this report gained wider interest in the new approach, not only in government circles, but among large industrial corporations as well. The Western Electric Company (the manufacturing arm of A. T.&T.) having successfully employed input-output analysis to anticipate impending shortages of lead, one of its principal raw materials, even produced an educational film describing the methodology used.

In one of the early applications of the same modelling technique as that which later on became known as operations research, the small input–output team organized – under the name Project Scoop – by the US Air Force constructed a detailed structural matrix of its far-flung material procurement and training operations. It was not a square, but rather a rectangular matrix showing for some sectors not one but several input vectors corresponding to two or more alternative technologies that could be used to produce a particular weapon or to provide a particular type of pilot training. Confronted with the problem of optimal choice between alternative 'cooking recipes', Dr. George Dantzig, a young mathematician on the Project's staff, invented the still very widely used Simplex method of linear programming, which consists of a series of inversion of structural input–output matrices with sequential substitution at alternative vectors of technical coefficients.

Not unlike research conducted in modern natural sciences, input–output analysis was from the outset most successfully conducted by closely coordinated teams rather than individual investigators. The first of such academic research groups was the Harvard Economic Research Project directed by Leontief over a period of nearly thirty years. Another centre was organized by Richard Stone in the Department of Applied Economics at the University of Cambridge. He was responsible for formal incorporation of input–output tables in the United Nations system of national accounts designed by him.

Many of the young foreign economists who came to the United States to complete or postgraduate studies spent from a few months up to several years at the HERP, and after returning home introduced input–output analysis not only as a subject of academic instruction and research but also as a new field of governmental statistics.

In Norway, Canada, Japan and in many other countries governmental planning agencies and central statistical offices compile national input–output tables and carry out practical applications of input–output analysis, but also engage in fundamental methodological research. In Soviet Russia this was the first non-marxist, mathematical approach to economics adapted, on the recommendation of Oscar Lange, after World War II as a subject of academic instruction and as a tool of economic planning.

The first International Conference on Input–Output Analysis organized by Professor Tinbergen was held in Dreibergen, Holland in 1950; the eighth has been held in Japan in 1986. Proceedings of these and of other similar scientific meetings published in book form provide a good account of the current state of the art in the general field of input–output analysis and its various applications.

One of the fundamental theoretical questions that came up in connection with the early input–output computations concerned the conditions under which none of the elements of the inverse $(I - A)^{-1}$ can be negative. The answer to it was provided by Herbert Simon – the future Nobel prizewinner – and David Hawkins, a philosopher, in the form of the following theorem:

The necessary and sufficient conditions for some of the elements of $(I - A)^{-1}$ to be positive, and all to be non-negative, are:

$$|1-\alpha_{11}|>0,\begin{vmatrix}(1-\alpha_{11}) & -\alpha_{12}\\ -\alpha_{21} & (1-\alpha_{22})\end{vmatrix} >0,\ldots\begin{vmatrix}(1-\alpha_{11}) & -\alpha_{12}\ldots & -\alpha_{1n}\\ -\alpha_{21} & (1-\alpha_{22})\ldots & -\alpha_{2n}\\ -\alpha_{n1} & -\alpha_{n2} & \ldots(1-\alpha_{nn})\end{vmatrix}>0 \tag{8}$$

If these conditions are satisfied for any particular numbering of sectors it will necessarily be satisfied for any other numbering sequence too. The economic interpretation of this theorem is that for a system, in which each sector functions by absorbing directly or indirectly outputs of some other sectors, to be able not only to sustain itself but also to make some positive deliveries to final demand, each one of the smaller and smaller subsystems contained within it has to be capable of sustaining itself and yielding a surplus deliverable to outside users as well.

An example of a system unable to sustain itself in this sense could be an economy so badly damaged by some natural catastrophe or war that only external assistance, taking the form of an import surplus, could prevent it from complete collapse. Exports are entered in a standard input-output table and in the corresponding set of balance equations, as positive and exports as negative components of the final bill of goods. The negative elements of the inverse $(I - A)^{-1}$ multiplied into such negative components of the vector y of final demand would yield in this case positive total outputs x.

In an attempt to reconcile at least to some extent the so-called fixed coefficient assumption of linear input–output models with the neoclassical production functions allowing for input substitution, Kenneth Arrow, Tjalling Koopmans and Paul Samuelson provided independently from each other three different proofs of the 'non-substitution theorem'. They considered a multisectoral economy in which each productive sector operates on the basis of a neoclassical production function and all sectors use the same single

primary factors of production, say labour. The input combinations used by different sectors are chosen so as to minimize the total amount of labour that has to be employed by that economy in order to enable it to deliver to final users an exogenously specified bill of goods. The non-substitution theorem states that the combination of the relative amounts of different inputs chosen in each sector will be independent of the composition of the final bill of goods. That means that even if the structure of final demand changes all producing sectors will behave as if they were operating on the basis of fixed coefficients of production.

Restrictive assumptions – particularly those postulating invariability of production functions that control the operations of all sectors – deprive the non- substitution theorem of much of its practical significance. However, it calls attention to the difference between the ways in which the terms technology, and technological change, are used in neoclassical and in input-output theory. In input–output modelling the technology used in any particular sector is described as a given column vector of coefficients, and a change in any element of that vector is called technological change. In neoclassical modelling the state of the technology employed by a particular sector is described by a much more general – and because of that much more complex – kind of functional relationship that in input–output analysis would have to be viewed as a set of many (strictly speaking, infinitely many) different technologies, each described by a different column vector of input coefficients. While providing a convenient basis for deductive reasoning, the neoclassical terminology makes the task of actual observation of the technological structure of a particular economy and empirical description of processes of technological change extremely, not to say prohibitively, difficult.

Since direct observation of a set of isoquants is hardly ever possible, empirical implementation of standard neoclassical models involves nearly exclusive reliance on more and more sophisticated methods of indirect statistical inference.

Neither of the two definitions of technology and technological change can be said to be more correct than the other. The employment of the simpler definition however permitted input–output analysis to advance in the direction of systematic detailed factual inquiry, while reliance on a definition, much less serviceable for purposes of empirical description but much richer in its theoretical implications, propelled neoclassical economics towards construction of elaborate theoretical models erected on a narrow, fragile data base or even on quite arbitrary, purely theoretical assumptions.

In static input–output models, additions to the stocks of building, machinery, and other kinds of productive stocks are treated as a component part of the final demand vector, entered in the right-hand side of the balance Eq. (6). In the following formulation of a simple dynamic model these terms are transferred to its left-hand sides and described explicitly as serving technologically determined capacity expansion required for a rise in the level of output.

$$(I - A)X_t - B(X_{t+1} - X_t) = Y_t \qquad (9)$$

B is a square matrix of technical capital coefficients, each column of which consists of stock-flow ratios, describing the stocks of products of different industries which the sector in question must have on hand per unit of its capacity output.

If the time unit in terms of which the process is observed and described is relatively long – say, covering a five or even ten year period – the stocks might be engaged in production in the same time period during which they have been produced. In this case, the second term on the left-hand side would be $B(X_t - X_{t-1})$. Current inputs required for maintenance of the existing capital stock have of course to be accounted for by the appropriate elements of the A matrix.

While bringing to the fore the crucial role that a complete set of capital coefficients has to play – in addition to a complete set of current input coefficients – in the detailed description of the structural framework of a given economy, such a set of difference equations is too rigid a tool to be used to describe and project the actual process of economic development and change.

More effective, because more flexible, is an approach which takes the form of a step-by-step construction of complete input–output tables of the economy for successive periods of time, each based on the knowledge of its state in the previous period, of anticipated changes in the final bill of goods and expected technological changes.

In more general terms, the input–output relationship between goods produced and consumed over a sequence of successive years can be formally described exactly in the same terms as relationships between different sectors are presented in an ordinary 'static' input-output table for a single year. The solution of a time-phased system of linear equations describing the intertemporal balances of inputs and outputs of goods and services produced and consumed over a long stretch of successive periods of time can be interpreted as inversion of a large triangular matrix; triangular because outputs of one year can become inputs in later years, but not vice versa. The results of this operation describing the direct and indirect relationships between all appropriately timed inputs and outputs has been called the 'dynamic inverse'. Since the sets of flow and capital coefficients controlling the input–output balances in successive stretches of such an historical process do not have to remain the same, both that dynamic matrix and its inverse can accurately represent all kinds of structural change, including elimination of old and introduction of entirely new goods.

Introduction of capital coefficients permits subdivision of the value-added term, V, on the right-hand side of the dual system (8) into its two parts – the returns on capital and wage income:

$$(I - A')P = \lambda B' cP + 1w \qquad (10)$$

or, solving for P:

$$(I - A')P - \lambda B' P = 1w$$

λ represents the rate of return on invested capital and w, the wage rate. These equations can be used for calculating the 'trade-off curve' between real wages (that is, money wage rate divided by a price index) and the rate of return on capital for any given state of technology. Comparison of such curves, each reflecting a different combination of alternative technologies available in different sectors, provides a base for numerical assessment of the influence of the distribution of income between the return on capital and wages upon technological choice.

Practical concerns led quite early to construction of regional input–output tables. The municipal government of the city of Stockholm was the first to compile a detailed metropolitan table. The complex fact-finding task of putting together a detailed input–output map of a particular region seemed to have been inspired sometimes by the desire to assert distinct identity. In Canada, French-speaking economists were the first to construct a regional table, that of Quebec. In Belgium one was compiled for the autonomy-seeking Flemish provinces. In addition to pressing needs of developmental planning, similar considerations seem to have prompted early compilation of input–output tables of many less developed countries.

The next step was construction of multiregional input–output tables and models in which intraregional transactions were linked with each other by interregional flows of goods and services. While comparison of labour, capital and natural resource 'contents' was the object of some of the earliest input-output studies of domestic and internationally traded goods, neither the theoretical formulation nor the available data base are yet sufficiently advanced to permit input–output modelling of international economic transactional trade to be solidly based on direct empirical implementation of the comparative cost theory. In most multiregional input–output models the structure of international transactions is controlled by sets of empirically determined export and import coefficients. A large multiregional input–output model of the world economy constructed under the auspices of the United Nations was published in 1977. Originally intended to provide a basis for a set of

alternative projections of the future growth of eight groups of developed and seven groups of less developed countries, this large, highly disaggregated model was used in a series of other studies such as the analysis of economic effects of international arms trade, detailed long-run projections of the production and consumption of non-ferrous metals in the United States and construction of alternative multiregional scenarios of future exploration of agricultural and energy resources.

As the range of its practical applications widened, the scope of input–output modelling had to be broadened, along with the contents of the requisite data bases.

Analysis of the petroleum refining industry in the early Fifties required modelling of multiproduct processes. Thirty years later a similar approach was employed to describe within the framework of a national input–output table the generation and elimination of various polluting substances. Modelling devices adapted in description of the allocation of the output of transportation and trade sectors have later on been adapted in modelling the activities of all service industries. Separation of the description of the physical from the price and costing aspects of government operations proved to be useful in construction and theoretical interpretation of input–output tables of simple, not yet fully monetized economies of the less developed economies. Richard Stone offered the conceptual framework of input-output analysis for the formal description of demographic processes.

To the extent to which it can provide a bridge between aggregative analysis and detailed description of production and consumption of specific goods and services, input–output analysis has been incorporated into most of the well-known forecasting econometric models.

The general nature of the approach has made the development of input–output analysis a cumulative process. Each refinement in theoretical structure and each addition to or improvement in the accuracy of factual information incorporated in its data base potentially improved the performance of the general model in application to all special problems.

Inside and Outside Money

Ricardo Lagos

Abstract

A distinction is drawn between outside money, which is either of a fiat nature or backed by some asset that is not in zero net supply within the private sector, and inside money, which is an asset backed by any form of private credit that circulates as a medium of exchange.

Keywords

Banking theory; Bonds; Commitment; Fiat money; Finance theory; Inside and outside money; Money; Open market operations; Patinkin, D; Private credit

JEL Classification

D4; D10

Money is an asset that serves as a medium of exchange.

Outside money is money that is either of a fiat nature (unbacked) or backed by some asset that is not in zero net supply within the private sector of the economy. Thus, outside money is a net asset for the private sector. The qualifier 'outside' is short for '(coming from) outside the private sector'.

Inside money is an asset representing, or backed by, any form of private credit that circulates as a medium of exchange. Since it is one private agent's liability and at the same time some other agent's asset, inside money is in zero net supply within the private sector. The qualifier 'inside' is short for '(backed by debt from) inside the private sector'.

Background

In 1960, John G. Gurley and Edward S. Shaw published *Money in a Theory of Finance*, in which they attempted to develop a theory of finance that encompasses the theory of money and a theory of financial institutions that includes banking theory.

Consider a simple economy similar to the one considered by Gurley and Shaw. The economy has fiat money – an intrinsically useless asset with no backing whatsoever – that is generally accepted as a means of payment. A monetary authority or 'government' has the monopoly over issuing this asset. The economy is closed and consists of three sectors: households, firms and government. Firms issue debt in the form of homogeneous, perfectly safe nominal bonds. (For example, think of these bonds as being promises to pay one dollar at some future date.)

Table 1 shows hypothetical sectoral balance sheets for this economy. In this example, households hold only financial wealth (that is, no real wealth such as houses), in particular money, equity in firms, and the bonds issued by the firms. Here households have no liabilities, so their net worth (NW) is just the sum of the value of their assets. The assets owned by firms consist of cash and physical capital. A part of these assets has been financed with debt (bonds), and another part by issuing equity. The former represent the firms' liabilities toward the bond holders, and the latter represent the firms' liabilities towards share holders. The firms' net worth (net of equity) is

Inside and Outside Money, Table 1

zero. The government has no real assets, but at some point in the past it issued financial assets – money – to pay for expenditures, and from an accounting point of view these outstanding government-issued pieces of paper constitute liabilities. (If the money was backed by a real asset, for example gold, and also fully convertible, then the value of the gold would show up on the government's Assets column. In this case, the money issued is literally a liability representing the government's commitment to redeem the money for gold. In the case of fiat money, there need not be a counterpart on the Assets column of the government's balance sheet.)

Table 2 shows what happens if we consolidate the balance sheets of the private sector. The bonds are debts from private agents (in this example the firms) to other private agents (in this example the households), so they have cancelled out. The only assets left in the balance sheet of the public sector are physical capital and the money issued by the government. Money can be thought of as a 'claim' held by consumers and firms against the government. From the standpoint of the private sector, it is a net external, or outside, claim: it is *outside money*.

Gurley and Shaw (1960) were interested in considering the effects of 'open market operations' whereby the government issues money to purchase private bonds. Suppose, for example, that they purchase \$15 worth of private bonds. The resulting balance sheets are those in Table 3, which should be compared with those in Table 1. The government now has \$15 worth of assets (the private bonds it purchased), and its liabilities have increased by \$15 because of the money issued to pay for these bonds. Households still hold \$350 worth of assets, but the composition of their portfolio has changed: they now hold \$65 in money and \$10 in bonds, as opposed to the \$50 in money and \$25 in bonds of Table 1. The additional \$15 in money holdings comes from the new issue of money, backed by private bonds. These \$15 are government debt, but they are issued in payment for government purchases of private securities. They are a claim of consumers and firms against the world outside the private sector, but they are counterbalanced by private debt to the world outside, that is, to the government. These additional cash balances are based on internal debt, so Gurley and Shaw referred to these \$15 as *inside money*.

To use the terminology of Gurley and Shaw, the \$165 stock of money in the economy of Table 3 consists of \$150 of outside money and \$15 of inside money. Both types of money are really the same physical object, for example, green pieces of paper: The qualifiers *inside* and *outside* refer to the asset counterpart of the money. Inside money is backed by private domestic debt. Outside money is of a fiat nature (or backed by some other asset that is not in zero net supply within

Inside and Outside Money, Table 2

the private sector, such as gold). Note that, if we consolidate the balance sheets of the private sector in Table 3, the net worth of the private sector is still \$350, just as in Table 2. Also, note that inside money is 'endogenous' in that if, for example, firms pay off their whole debt, *ceteris paribus* the money supply would shrink by \$15.

Most likely, Gurley and Shaw were led to stress the distinction between inside and outside money because they viewed money and private debt as assets that played distinct roles in exchange, so that an economy with the balance sheets of Table 1, where households hold \$50 in cash and \$25 in private bonds, would function differently from an economy with the balance sheets of Table 3, where households hold \$65 in cash and \$10 in private bonds. (See Gurley and Shaw 1960, pp. 82–88, the section titled 'Monetary Policy in a Modified Second Model'.) The theoretical analysis throughout the book is predominantly verbal, so it is not clear which are the precise trade-offs that agents consider when making a portfolio decision between money and bonds. The fact that households treat them as different assets is explicit in the Mathematical Appendix, where Alain C. Enthoven assumes distinct reduced-form demand functions for the two financial assets. Note that, since bonds are nominal and riskless in this set-up, it is not obvious why households would not treat them as perfect substitutes for money.)

The contemporary literature on monetary theory in general, and the subfield that deals with inside and outside money in particular, does not take it as given that money and bonds play different roles. Instead, it seeks to understand whether they indeed do, and whether they ought to. The recent emphasis has been on trying to gain a deeper understanding of the precise roles that fiat money and private debt play and ought to play, both as media of exchange and as vehicles to channel resources across economic agents, towards their most efficient use. This change of emphasis has led to a slightly different definition of inside money. The more modern use of the concept does not rely on the type of open market operations of Gurley and Shaw. Inside money need not be defined narrowly as circulating fiat money backed by private debt; the private debt *itself* is regarded as inside money if it circulates as means of payment among the private agents. The more modern definition given at the beginning of this article encompasses both the case where private debt circulates directly and Gurley and Shaw's original example. To illustrate, consider again the economy of Table 1. According to the modern use of the term, there is not enough information in that table to decide how much inside money there is in the economy; there are \$25 of inside assets, that is, assets that are in zero net supply within the private sector, but whether these assets constitute inside money depends on whether they circulate as means of payment. If they do not – for example if lenders merely hold the bonds until maturity to redeem them – then these bonds are not inside money.

Contemporary Perspectives

Gurley and Shaw (1960) simply asserted that agents would want to hold government-issued fiat money (this weakness was stressed by Patinkin 1961), and for their purposes the distinction between inside and outside money was relevant because they implicitly regarded them as imperfect substitutes. The modern literature on monetary theory seeks to identify the fundamental features of the basic economic environment that can make fiat money, or, more generally, any asset that serves as a medium of exchange, valuable and socially beneficial. Modern theory also focuses on the differences and similarities between inside and outside money. When is outside money valued? Under which circumstances does inside money arise? Are inside and outside money substitutes or complements? Under which circumstances can they coexist? Are they *both* needed to achieve efficient outcomes?

Inside money is private debt that also circulates as a tangible medium of exchange. Thus, an economy with inside money must perform a delicate balancing act. On the one hand, it must have enough commitment or enforcement for credit to be feasible, but at the same time credit must not function too well, for otherwise a tangible medium of exchange would be inessential. For

example, Kocherlakota (1998) shows that a tangible medium of exchange is not essential if agents can commit to future actions or if their trading histories are public. Starting from this observation, Cavalcanti and Wallace (1999a) consider an environment where trading histories are public for a subset of agents but private for the rest, and show that a social optimum requires note issue by those agents with public trading histories. In addition, those notes are in turn used in trade among the agents whose trading histories are private. Thus, in their environment an optimum requires inside money.

Kiyotaki and Moore (2002a) instead consider an environment where everyone is anonymous, and emphasize the importance of the agents' ability to make bilateral and multilateral commitments. The degree of (bilateral) commitment a borrower can make to an initial lender when selling a paper claim places a bound on the entire stock of private debt. The degree of (multilateral) commitment a borrower can make to repay any bearer determines the extent to which the borrower's debt can circulate in equilibrium. Kiyotaki and Moore find that only outside money circulates in economies with very low degrees of bilateral commitment. For higher, but still low, degrees of bilateral commitment, outside and inside money circulate alongside each other in equilibrium. For yet higher degrees, only inside money circulates, and, when the agents' ability to make bilateral commitments is large enough, the economy can manage without any money, inside or outside.

Insider Trading

Andrew Metrick

Abstract

Insider trading has two definitions: securities trading by a corporate insider, and securities trading while in the possession of material non-public information about the security. This article reviews the two main strands of economic literature on insider trading. First, scholars on the intersection of law and economics analyse the social-welfare implications of insider-trading regulation. Second, financial economists use empirical evidence on insider trading to analyse the efficiency of stock markets.

Federal securities law defines a 'corporate insider' to be an officer, director, or major shareholder of a corporation. The first definition of 'insider trading' refers to any purchase or sale of public-corporation stock by an insider of that corporation. The second definition does not require the trader to be a corporate insider, but does require that the trader possess material non-public information. Within this article, all uses of the generic term 'insider trading' encompass both of these definitions. When necessary, the two definitions are referred distinctly as 'trading by insiders' (any transaction that is made by a corporate insider) and 'trading on inside information' (a transaction that requires material non-public information but need not be made by a corporate insider).

In the United States, prior to 1934 insider trading was regulated by state-level corporate law. In the first few decades of the 20th century, states used a variety of criteria to adjudicate cases, with a substantial minority of states holding that corporate directors had a duty to disclose material information before buying (but not selling) stock. Federal regulation of insider trading did not begin until the Securities and Exchange Act (SEA) of 1934. Rule 10b of the SEA made it unlawful for any person 'to use or employ, in connection with the purchase or sale of any security registered on a national securities exchange or any security not so registered, any manipulative device or contrivance in contravention of such rules and regulations as the Commission may prescribe (Bainbridge, 2001). This sweeping language does not directly mention either corporate insiders or material non-public information, but later judicial interpretations expanded its scope to these cases. Corporate insiders do appear in Section 16a of the SEA, which requires that open- market trades by insiders be reported to the Securities and Exchange Commission (SEC) within ten days after the end of month in which they took place. These reports, filed on the SEC's 'Form 4', are the source of data for almost all of the empirical studies of trading by insiders.

It was not until 1961 that the SEC took its first administrative action on an insider-trading case (Cady, Roberts, & Co.), and it would be another seven years before the first federal insider-trading case was decided by the courts *(SEC* v. *Texas Gulf Sulphur Co.* (1968)). In the decades since these seminal cases, the courts have reaffirmed and expanded the SEC's role in the regulation of trading on inside information. Despite the long judicial record, there is still considerable confusion and a continuing evolution about the scope of regulation, with debates about the type of information that is considered to be 'non-public' or 'material', and about the necessity of the trader having some fiduciary relationship to the company. A discussion of these issues is beyond the scope of this survey; readers are referred to Bainbridge (2001) for a summary.

The United States was the first country to use securities regulation to prohibit trading on inside information. Other countries were slow to adopt similar regulations: Bhattacharya and Daouk (2002) report that, as of 1990, of 103 countries with stock markets, only 34 had any prohibitions on insider trading, and only 9 had enforced their prohibitions with a prosecution. The same paper, however, reports that, by 1998, 87 countries had prohibitions and 38 had made at least one prosecution.

The remainder of this article reviews the two main strands of economic literature on insider trading. First, scholars on the intersection of law and economics analyse the social-welfare implications of insider-trading regulation. Second, financial economists use empirical evidence of trading by insiders to analyse the efficiency of stock markets. Each of these two topics has developed an extensive literature since the 1960s.

Social Welfare

Prior to the 1960s, scholars gave little thought to the social-welfare implications of insider-trading regulation. With the Cady case of 1961, the first

federal regulation in the United States stimulated a large literature on the topic, beginning with Manne (1966). The economic debate revolves around six main issues: market liquidity, informational efficiency, market manipulation, efficient managerial compensation, the costs of regulation, and the necessity of federal law.

Market liquidity. The pro-regulation side argues that, if trading on inside information were pervasive, then non-insiders would be discouraged from trading, thus reducing market liquidity and all of the other good things that come from having well-functioning capital markets. The logic here is straightforward: if non-insiders perceive that counterparties are likely to possess inside information, then they face an adverse-selection problem, and will demand a discount (if buying) or premium (if selling). The resultant spread between bid and ask prices would then act effectively as a tax on every transaction, which lowers the amount of trade.

In response to this argument, the anti-regulation side argues that the total amount of insider trading is very small, and is thus unlikely to create much of an adverse-selection problem for most stocks. Under the current regulatory regime in the United States, these adverse-selection costs do indeed seem to be low. Jeng et al. (2003) examine all reported trading by insiders in the United States from 1975 to 1996. After estimating the profits earned by insiders on these trades, the authors estimate that non-insiders have expected trading losses of about ten cents per $10,000 trade for non-insider sales and less than one cent per $10,000 trade for non-insider purchases. These results require two caveats. First, the study considers only the trades that were reported to the SEC. If the most profitable trades by insiders go unreported, then non-insiders may face larger expected losses. Second, these costs reflect the regulatory regime in place during the relevant period in the United States. If insider-trading restrictions were significantly loosened, then the frequency and profitability of insider trades might be quite different.

Informational efficiency. A second argument in favour of regulation is that, in the absence of regulation, insiders might be induced to hoard information until such time as it could be exploited in the most profitable way. For example, suppose that the managers of company XYZ have just learned of a major problem at one of their production facilities, which they expect to reduce company value by ten per cent. At the same time, managers also learn that a major research breakthrough has been made on another project, which would have an offsetting effect on firm value. Under these assumptions, if both pieces of information were immediately released, there would be no stock-price reaction. However, if insider trading were always permitted, managers would have an incentive to delay one of these announcements. For example, managers could release the bad news first, decreasing the stock price, and then buy stock in advance of releasing the good news.

The anti-regulation side provides a direct counterargument, claiming that insider trading is likely to speed up the flow of information to the market. As a counter to the example presented above, imagine that managers learn only the bad news about the production facility, with no good news about research. In this case, one can imagine these managers trying to contain this information for as long as possible, perhaps in the hope that the problem can be fixed before it is made public. In a regime without any insider trading, this strategy might be possible. With no restrictions on insider trading, however, managers would have a strong incentive to sell shares. In an extreme case, they could even sell shares they do not own ('short selling'), thus providing a virtually unlimited amount of selling, and driving the price to its 'correct' level. Opponents of regulation argue that this kind of scenario is common, and that insider trading would allow stock prices to adjust more quickly to new information. Unfortunately, there is no empirical evidence to give us more insight into this debate, nor is it easy to imagine a plausible data-set that could provide such evidence.

Market manipulation. Once again, consider the situation of company XYZ, with problems at its production facility and the potential of research breakthroughs. For managers who live through these events, it is only a short leap to imagine the possibilities of market manipulation. For

example, a well-placed rumour – coming from an insider – could move the stock price and allow for profitable trading. Opponents of regulation could counter that market manipulation can be illegal, even if trading on inside information is not. The game can grow more complex, however, if managers engage in real activities that allow for higher volatility and increased trading opportunities. For example, a CEO can increase expenditure on research and development well beyond optimal levels, safe in the knowledge that this combination of projects will increase the real underlying volatility of corporate value. In this case, the manager is manipulating the economic activities of the firm in an economically wasteful manner.

Efficient managerial compensation. Opponents of regulation argue that profitable insider trading is mostly a transfer of wealth from shareholders to managers, and thus can be treated the same as any other form of managerial compensation. For example, if shareholders believe that the CEO of their company can earn about $5 million per year from trading on inside information, then the company can reduce the CEO's other compensation by that same amount. In this scenario, the shareholders are not injured at all by the insider trading. Of course, this argument rests on the absence of the other costs discussed above: market liquidity, informational efficiency, and market manipulation.

The costs of regulation. Opponents of regulation argue that effective enforcement would be prohibitively costly. Insiders have many vehicles to exploit their superior information. In addition to stock trading in their own account, they can tip other traders, sometimes using complex 'tipping chains' that are difficult to detect. Furthermore, insiders may be able to exploit superior information by not trading at all. For example, if a manager of XYZ was planning to buy stock, but then learns bad news about a production problem, he could then decide not to buy. Since the manager has taken no action, there is no conceivable way that this exploitation of inside information could be detected. Of course, these opportunities for insider 'nontrading' are limited, since they presuppose a standing (but reversible) decision to trade.

The importance of this argument is ultimately an empirical question. In the absence of more complete information, it is impossible to know the frequency of different kinds of trading opportunities and the costs of detecting each type. Proponents of regulation can also argue that, even when detection probabilities are low, sufficiently high penalties can still provide effective deterrence.

Necessity of federal law. Prior to the Cady case of 1961, insider trading in the United States was governed by state law. Opponents of regulation argue that these state laws are sufficient, and the regulation of insider trading under federal securities laws is illogical and inefficient. There is much legal scholarship to support this view (Bainbridge, 2001), as the legal theories of insider trading are still struggling for a solid foundation, having adopted and discarded several models in the decades since Cady. The economic justification for leaving insider-trading regulation to the states rests on the identification of insider trading as a private issue between a company and its shareholders, with no externalities to security markets. If it is indeed a private issue, then opponents of regulation are correct that insider trading is the purview of other corporate law, which is left to individual states. If externalities exist – for example due to effects on market liquidity or informational efficiency – then federal regulation can be justified.

Overall, these six issues comprise the main topics of debate between the proregulation and anti-regulation sides. As seen by this survey, the empirical evidence on each of these issues is limited. For the debate as a whole, the best evidence comes from the aforementioned paper of Bhattacharya and Daouk (2002). After surveying the 103 countries with stock markets to assess the existence and enforcement of insider-trading laws, the authors used a variety of methods to estimate the cost of capital in each country. They find significant evidence that the cost of capital falls after the first enforcement of insider-trading laws. In contrast, the establishment of laws (prior to the first enforcement) has no effect on the cost of capital. Thus, for some combination of reasons – liquidity, informational efficiency, and so on – it is cheaper for firms to raise capital in

markets that enforce prohibitions against trading on inside information.

Market Efficiency

While law-and-economics scholars focused on social welfare, financial economists saw a good opportunity to use insider-trading data to test market efficiency. This literature began in earnest with the definitions of the efficient markets hypothesis (EMH) (Roberts, 1967), which comes in three versions: weak, semi-strong, and strong. Weak-form efficiency means that current asset prices incorporate all information contained in past prices; semi-strong efficiency means that current asset prices incorporate all public information; strong-form efficiency means that current asset prices incorporate all relevant information, both public and non-public.

Data on trading by insiders can be used to test both the strong and semi-strong versions of the EMH. If the strong form of the EMH holds, then insiders should not be able to make excess profits on their trades, since any information possessed by insiders would already be incorporated in market prices. One can test this implication of the EMH by analysing the risk-adjusted returns earned by insiders, where the main complication is the definition of 'risk-adjusted returns'. The capital asset pricing model (CAPM) was the first model of risk-adjusted returns to be widely adopted by economists. Finnerty (1976) uses the CAPM to evaluate the equally weighted returns to all insider trades in NYSE stocks from 1969 to 1972. He finds that insider buys overperform and insider sales underperform their CAPM benchmarks, thus providing the first direct evidence against the strong form of the EMH.

In the decades that followed Finnerty's study, researchers developed several other methods of computing risk-adjusted returns. Jeng et al. (2003) test the strong form of EMH using these more modern methods on 25 years of disclosed insider trading: they conclude that insiders earn positive risk-adjusted returns on their purchases but not on their sales. Since both the Finnerty and Jeng, Metrick and Zeckhauser studies focus on transactions reported to the SEC, they may both be underestimating insider profits if the most profitable transactions are unreported. While comprehensive data on unreported transactions is, by definition, unavailable, a unique study by Meulbroek (1992) does provide some evidence. Using proprietary data from SEC investigations of insider trading, then-SEC employee Meulbroek concluded that these transactions earned substantial risk- adjusted profits. Overall, the Finnerty, Jeng, Metrick and Zeckhauser, and Meulbroek studies provide significant evidence against the strong form of the EMH.

While the strong form of the EMH is of interest to regulators and academics, the semi-strong version commands far greater attention from investors; if the semi-strong version is false, then there exist profitable trading strategies based on public information. Economists have focused on insider-trading data as one possible source of such information. The first study of this data is Smith (1941), who finds no trading advantage for insiders, a result that discouraged other researchers until the work of Lorie and Niederhoffer (1968). These authors point out the severe problems of the SEC data, with trade dates often off by several weeks. These data problems invalidated the Smith study and opened the door to a new generation of analyses.

To handle these problems, Lorie and Niederhoffer devised a strategy that has dominated the insider-trading literature to this day: analyse the risk-adjusted returns to firms in relation to the 'intensity' of insiders' purchases and sales over well- defined periods. For example, a stock may be labelled an 'insider buy' for a month if at least three insiders bought the stock and no insiders sold it. In the decades that followed, many authors adopted this methodology, with the most important examples being Jaffe (1974) and Seyhun (1986). These many studies use a variety of intensive-trading criteria for many different sample periods, and are nearly unanimous in concluding that stocks that are intensely bought tend to outperform relevant benchmarks over a subsequent period, and that those that are intensely sold tend to underperform. They provide mixed evidence on whether other investors can profit, after

transactions costs, by using this information. Seyhun (1998) summarizes this evidence and concludes that several different trading rules lead to profits. Overall, this literature provides strong evidence against the semi-strong version of the EMH. As in all tests of the EMH, this conclusion is specific to the time period studied and the models used to estimate risk-adjusted returns. Defenders of the EMH can always propose that the effect will go away once investors learn about it, or that researchers will discover some additional risk factor to explain the results.

Conclusion

After 40 years of intense study, research in insider-trading has made substantial progress. Scholars of law and economics have identified the main arguments for and against the regulation of insider trading, and the limited empirical evidence on these arguments has sharpened the debate for future researchers. Further progress is most likely using data-sets from the many countries that have recently begun to regulate insider trading. For financial economists, the evidence on market efficiency is more straightforward. There is significant evidence that insiders profit on their own trades, and that outsiders can profit by gleaning information from the trades of insiders. Under the assumption that there is no missing risk factor that can explain these results, this evidence argues against both the strong and the semi-strong versions of the efficient markets hypothesis.

Institutional Economics

Warren J. Samuels

Abstract

Institutional economics, also concerned with resource allocation and the level and distribution of aggregate income, is primarily concerned with the organization and control of the economy, that is, its power structure, which governs whose interests count. Institutionalists have a broader or deeper set of explanatory variables, including the fundamental economic role of government, the socialization of the individual, and the consequences of a business system. Thus, prices are a function of demand and supply, these a function of markets and rights, manifest in the actions of firms and governments, and the latter a matter of business control of government.

Apart from Marxism, which has also the character of a social movement, institutional economics has become the principal school of heterodox thought in economics. Originating in and still concentrated largely, but by no means exclusively, within the United States, institutionalism has served the dual functions of providing critiques of mainstream neoclassical (and Marxian) economics and producing an alternative conception of the economy, and of doing economic research and analysis. In so doing, it has represented in part a continuation of the German and English historical traditions, including Max Weber, as well as other writers such as John Hobson.

Early Position

The place of institutional economics thus described applies principally to the post-Second World War period. During the interwar period, the picture was substantially different. For most economists, institutionalist ideas and theories were very much a part of economics. Many economists, typified by Frank William Taussig, John Maurice Clark, Friedrich von Wieser and Joseph A. Schumpeter, did not make a fundamental distinction in their own work between institutional and neoclassical economics or, if they did differentiate the two, nonetheless pursued both modes of doing economics. They could work on aspects of the problem of organization and control and on the institutional foundations of markets pretty much simultaneously with work on the theory of competition and the working of pure abstract markets, with each enriching the other. Some economists were less eclectic in their orientation. They continued the antagonism of Thorstein Veblen, on the one hand, or developed the antagonism of those suspicious of institutionalism as another form of interventionism and as largely unreceptive to the development of mathematical formalism in economic theory, on the other hand. The work of Malcolm Rutherford and others has shown a discipline largely undifferentiated in terms of institutionalism versus neoclassicism during the interwar period.

The precise relationship of heterodox institutional economics to orthodox neoclassical economics in the post-Second World War period is complicated by several considerations: the awkward sociological status of heterodoxy within the discipline; the ambivalence within institutionalism as to the relationship, some institutionalists feeling that the two schools are complementary and others that the two are mutually exclusive; and the presence within institutionalism of two different and to some extent conflicting traditions, one emanating from Thorstein Veblen and continuing through Clarence Ayres, the other starting with John R. Commons. The Veblen–Ayres tradition focuses on the progressive role of technology and the inhibitive role of institutions; the Commons tradition is less

enamoured of the imperatives of technology and approaches institutions, as modes of collective action, more neutrally; both groups accept that actual economic performance is a function, inter alia, of both technology and institutions. Notwithstanding their differences, there is a common core of institutional analysis of perhaps no greater variety of formulation than within neoclassicism or Marxism.

Relation to Mainstream Economics

Mainstream economists maintain that the central economic problems are the allocation of resources, the distribution of income, and the determination of the levels of income, output and prices. In contrast, institutional economists assert the primacy of the problem of the organization and control of the economic system, that is, its structure of power. Thus, whereas orthodox economists have a strong tendency to identify the economy solely with the market, institutional economists argue that the market is itself an institution, comprised of a host of subsidiary institutions, and interactive with other institutional complexes in society. In short, the economy is more than the market mechanism: it includes the institutions which form, structure, and operate through, or channel the operation of, the market. The fundamental institutionalist position is that it is not the market but the organizational structure of the larger economy which effectively allocates resources.

To the extent, then, that institutional and neoclassical economists study the same questions (for example, resource allocation) the institutionalists generally encompass a broader or deeper set of explanatory variables: instead of having price and resource allocation be a function of demand and supply in a purely conceptual market, these latter are in turn related to the structure of power (wealth, institutions) which help form them. Power structure in turn is related to legal rights, thence to the use of government in forming legal rights of economic significance and thereby influencing the allocation of resources, level of income, and distribution of wealth.

Institutionalists are generally less concerned with price and resource allocation per se and more with the problem of the organization and control of the economy: that is, with performance seen as specific to power (rights) structure, as well as to technology. Institutionalists are interested, for example, in the formation and role of institutions, and the interrelations between economic and legal systems and between power and belief systems.

If institutionalists insist that the economy comprises more than the market mechanism, they also object to the equilibrium and presumptive optimality modes of analysis of neoclassical economics. The search for the deterministic technical conditions of stable equilibrium, it is felt, obscures the fundamental power and choice aspects of the economy. The search for optimality, or for optimal solutions, it is also felt, is either formally empty or can be given substance only by the introduction, typically implicitly, of antecedent normative assumptions as to whose interests count, whereas in the real world such questions have to be worked out both within institutions and through contests over institutional adjustment and reformation.

Principal Ideas

The central features of institutional thought are its holism and evolutionism. Thus the further principal themes of institutional economics include the following:

1. A theory of social change, and an activist orientation towards social institutions, through focusing on both the substantive impact of institutions on economic performance and the processes of institutional change, treating institutions not as something to be taken as given but as man-made and changeable, both deliberatively and non-deliberatively.
2. A theory of social control and collective choice, or a theory of institutions, a focus on the formation and operation of institutions as both cause and consequence of the power structure and societized behaviour of

individuals and subgroups, and as the mode through which economies are organized and controlled. Instead of focusing on the mechanics of choice from within opportunity sets, a focus on the formation of opportunity sets; instead of a focus on unfettered market freedom, a focus on the total, complex pattern of freedom and control, that is, on the formation and operation of the system of control through which both actual opportunity sets and multidimensional freedom are formed.

3. A theory of the economic role of government, as a principal social process through which both itself and other institutions of economic significance are in part formed and revised. Instead of treating government, law, and the system of rights as either given and/or exogenous, these are treated as both dependent and independent, and always critical, not merely aberrational, economic variables.
4. A theory of technology, as defining and determining the relative scarcity of all resources, as a principal force in the evolution of economic structure (including the operation of institutions) and performance, and as the basis of the logic of industrialization marking the mentality as well as the practices of modern economies.
5. The fundamental principle that the real determinant of resource allocation is not the market but the organizational – institutional, power – structure of society.
6. An emphasis on facets of the value conception which transcend price, on the values represented in and given effect by the habits and customs of social life, on the pragmatic, instrumental values ensconced in the transcendental notion of the life process of man and society, and on the constructive values latent within and given effect by the working rules of law which are both the foundation and the product of the power structure of society. Included are attempts to understand the process by which values are changed, in contrast to the orthodox assumption of given values; that is, to consider within economics such questions as where the values come from, how they are tested, and how they are changed.

In amplification of these themes one finds, for example, Veblen's emphasis on status emulation as a principal force in the formation of economic behaviour, including (through conspicuous consumption and the making of invidious comparisons) the formation of consumer demands; Commons's analysis of the evolution of the fundamental legal foundations of the modern economy; John Dewey's theory of instrumental logic and social value; John Maurice Clark's analysis of the social control of business; Wesley Mitchell's emphasis on the economy as a pecuniary phenomenon; Commons's and Selig Perlman's analyses of labour unions as a mode of representing worker interests and of generating institutional change; Edwin E. Witte's, and Commons's, efforts at creating new institutions for the embodiment and protection of rising interests and for the creative resolution of social conflict and the development of a body of analysis of institutional genesis and adjustment; and, inter alia, Veblen's and Ayres's analyses of the formation of the human belief system, including that of economists, under the impact of the contest between traditional and new ways of doing things.

Apropos of the last point, institutionalists have freely pointed to the selectivity and typically implicit nature of the operative assumptions of neoclassical analysis. They insist that, by its taking institutional or power structure as given or, more typically, by its selective specification of institutions and power structure, there is a strong tendency towards selective apologetics in orthodox economics, especially in that work which is directed to the identification of 'optimal' solutions. The institutionalist solution to such problems is that of Gunnar Myrdal: to avoid the pretence of value-free economics by making all, or substantially all and certainly the operative, value premises explicit and by generating appraisals thereof.

Accordingly, institutional economists have tended to avoid recourse to methodological individualism and to abstain from puzzle-solving research in the context of models devoid of institutional embodiment and stressing equilibrium, optimality, and purely competitive markets. They have rather attended to theoretical and empirical analyses of real-world problems, such

as the operation of particular institutions, business–government relations, and the conditions of economic development. In so far as they have dealt with economic variables at fundamental conceptual levels, such as government and rights, they have at least tried to do so in both analytically credible and non-presumptive ways.

Internal Conflict

Conflict within institutionalism has largely been on two issues. One involves the putative dichotomy of technology and institutions. The other is between those who call for government planning to modify if not replace private enterprise and those who favour private enterprise but call for strong antitrust enforcement to ensure a competitive market economy.

John Kenneth Galbraith

The best-known contemporary version of the institutionalist conception of the economy has been that of John Kenneth Galbraith. Following the course laid down by Veblen, and grafting it on to a version of Keynesian economics, Galbraith explored the corporate nature and planning modes of the business system and the impact of what he considers to be technological imperatives, the social formation of individual preferences underlying demand functions, the power and continuous interaction of the state and the corporate core of the economy, the factors and forces which influence the formation of opinion and policy in the public sector, and the inevitability of resolving conflicts of interest on the basis of some conception of public purpose.

Widespread Practice

In such fields as labour economics, industrial organization, economic development, law and economics, agricultural and natural resource economics, and macroeconomics, institutionalists, through their primary attention to power structure and belief system, in the context of their overriding concerns with social change and social control, have produced understandings of economic reality quite different from those of neoclassical economists. These contributions have come through the recent work, in addition to Galbraith, of John Adams, Jack Barbash, Kenneth E. Boulding, Dan Bromley, Thomas DeGregori, William Dugger, Daniel R. Fusfeld, Wendell C. Gordon, Allan G. Gruchy, David B. Hamilton, Gardiner C. Means, Walter C. Neale, Kenneth Parsons, Wallace Peterson, A. Allan Schmid, Robert Solo, Ron Stanfield, Paul Strassmann, Marc Tool, Harry M. Trebing and William Waller, among others. Some of this work appears in the *Journal of Economic Issues,* published by the Association for Evolutionary Economics. Also in the United States, institutional economists have joined with Post Keynesian economists and with varieties of political economists to explore empirically and theoretically topics central to those fields. In Europe, Geoffrey Hodgson and others have pursued the development and application of evolution theory to the array of institutionalist topics. Some have studied the formation, use and impact of technology and others, for example, the organizational theory applicable to the corporation. The European Association of Evolutionary Political Economy has become the major forum for European institutionalists, and even for many Americans.

Altogether this work has constituted an alternative analysis of the economic system, especially of capitalism but also of socialism, and a critique of both existing economic systems and orthodox schools of economics.

Institutional Trap

Victor Polterovich

Abstract

One of the main obstacles for successful economic development is the formation of institutional traps, inefficient yet stable norms of behaviour. Domination of barter exchange, arrears, corruption and black market activities are examples of institutional traps that have hampered reforms in transition economies. Institutional traps are supported by mechanisms of coordination, learning, linkage and cultural inertia. The acceleration of economic growth, systemic crisis, the evolution of some cultural characteristics and the development of civil society may result in breaking out of institutional traps. Examples from the history of the United States and Russia are considered.

Institutional trap is a stable but yet inefficient equilibrium in a system where agents choose a norm of behaviour (an institution) among several options. It is usually implied that multiplicity of equilibria prevails in the system, and that an institutional trap is Pareto dominated.

The concept of institutional trap is closely related to the notion of lock-in used by Arthur (1988) and North (1990); these authors showed that inefficient technical or institutional development can be self-supporting. In fact institutional traps have been studied in many papers (see for example Ickes and Ryterman 1992; Tirole 1996; Bicchieri and Rovelli 1995; Jonson et al. 1997; Uribe 1997). In Polterovich (2000, 2005) a general scheme for the formation of an institutional trap was described. The theory developed was successful in explaining a number of important features of wide-scale institutional transformation in Russia and other post-communist countries where the evolution of institutional traps was clearly observable. In particular, it was shown that such different phenomena as barter, mutual arrears, tax evasion, and corruption were intensified and supported during the reforms due to similar mechanisms. Also studied were possible strategies for a country to get out of an institutional trap.

Norm-Fixing Mechanisms and Institutional Trap Formation

A norm is a rule that large groups of people can or must obey. In any area of life and at each moment in time, a multitude of alternative norms is available, and every agent has to make his or her choice. For example, an official may choose either corruption or honest service.

Each agent who interacts with partners within the framework of a certain behavioural norm has to bear the corresponding transaction costs. For example, the possibility of being caught while taking a bribe would cause a transaction cost component for an official who has chosen corruption as the norm.

The costs of transition from one norm to another are called transformation costs. These may be incurred by an individual, a firm or the state. If a firm decides to switch from black market to legal operations, it has to search for new partners. Search expenditure is a part of the transformation cost.

For a behavioural norm to be stable, individuals should feel that it is unprofitable or disadvantageous for them to deviate from it. This means that the present value of the difference between the transaction cost of a prevailing norm and any alternative norms has to be less than the related transformation cost. The main type of stabilizing mechanism is based on the coordination effect, according to which the more consistently a norm is observed in a society the greater are the costs incurred by each individual deviating from it. For example, the coordination effect takes place if a personal probability to be punished for a rule-breaking activity decreases with the number of people involved in the activity. In this respect, institutional traps belong to a broader class of coordination failures (Howitt 2003; see also poverty traps).

With time, the transaction costs of a norm's observance decreases due to learning effect since the agents learn to operate more efficiently. If the payment of taxes is considered a norm within a society, the taxpaying technology improves. If, on the contrary, tax evasion is a norm, the relevant techniques develop. A decrease of the transaction costs fixes the norm.

Another mechanism, referred to as the linkage effect, is also important. With time, an established norm finds itself linked with a multitude of other rules, and becomes part of a system of other norms. Therefore, non-observance of this norm triggers a chain of other transformations and, consequently, leads to high transformation costs. By increasing transformation costs, the linkage effect, too, contributes to a norm's fixation.

There is yet another norm-fixing mechanism, cultural inertia, which denotes agents' reluctance to review those behavioural stereotypes that have already proven viable. Inertia effects may be supported by a formal or informal system of punishments and awards for past behaviour. For example, a person with a good reputation tries to maintain that reputation by following respectable norms of conduct.

As with any other norm, an institutional trap's stability means that a system absorbing a small external impact will remain in the institutional trap, having perhaps slightly changed its parameters, and will return to the former equilibrium state once the source of destabilizing pressure is removed. An individual or a small group of people loses if it deviates from an institutional trap. However, the simultaneous adoption by all agents of an alternative norm may be Pareto improving. Thus the lack of coordination is the main cause of the institutional trap stability.

The emergence of institutional traps is an important source of risk associated with any reform process. The universal norm-fixing mechanisms described above, the coordination, learning and linkage effects, as well as cultural inertia, are responsible for institutional trap formation.

Consider a system with multiplicity of equilibria, and let an efficient norm prevail. Under a strong perturbation, the equilibrium may lose its stability or disappear so that the system moves to an alternative stable equilibrium, a potential institutional trap. After the disturbing factor is removed the system remains in the new equilibrium, which is now inefficient. This is the so-called hysteresis effect, which is a form of a system's dependence on its former path of development (path dependence).

A number of unexpected phenomena observed during the wide-scale reforms of the 1990s, including the rise and persistence of arrears, corruption, black market activity, and barter exchange, may be considered as institutional traps. Using the Russian experience, one can describe barter and corruption traps formation in greater detail.

Example 1: Barter

In modern economies, barter is associated with higher transaction costs than monetary transactions. When the inflation rate increases, paper money loses its value. Economic agents try to diminish their losses and seek to accelerate the rates of money circulation, which means an increase of their transaction costs. The transaction costs of monetary exchanges may grow very rapidly, if the finance system fails to cope with the rocketing number of transactions.

In economies with advanced banking systems the share of barter is rather modest, even when inflation is high. But after price liberalization in 1992, Russia proved to be ripe for barter. With the banking system still unformed, money transfers within Moscow could take up to two weeks, and beyond the capital, over a month. It sometimes made more sense to carry bags of cash from city to city by plane than to transfer money from one bank account to another. Many firms soon found that barter transaction costs were lower than those for monetary exchange. Moreover, the transformation costs of a shift to barter looked acceptable, given the pre-reform direct links between supplier and consumer that had been typical in the centrally planned economy. The search for prospective partners and the process of trade negotiations were facilitated by the spread of sophisticated means of communication. The larger the number of firms choosing barter, the lower the barter transaction costs for a fixed barter volume since it was easier to find partners and put together barter chains (a coordination effect). In those conditions, as the share of barter exchanges increased, even more companies became involved.

Thus the environment conducive to barter had been created by changes in fundamental parameters, such as the rate of inflation and the risk of arrears, which radically increased the ratio of monetary exchange transaction costs to barter exchange transaction costs. The coordination effect triggered a rapid formation of a barter economy. Later, the transaction costs of barter exchanges continued to decrease due to the learning effect: companies learned to design elaborate chains of barter exchanges. The newly established norm gave birth to a new institute of barter exchange intermediaries and proved to be an efficient instrument of tax evasion (linkage effect).

By 1997, inflation in Russia had decreased dramatically, and monetary exchange technology had notably improved. Barter practices, however, were not dropped altogether. Barter-driven behaviour was supported by the coordination effect; it has been fixed through learning, linkage and cultural inertia. Any agent deciding to break out of the barter system would be exposed to inevitable transformation costs. He or she would be forced to sever long-established connections, to look for new partners, and to be ready to come face to face with the tax-collecting authorities. The barter intermediaries, who would lose their main sources of income if barter practices were eliminated, formed a potential group of pressure for perpetuation of the relevant norm. This is the hysteresis effect mentioned above.

Example 2: Corruption

Every potential bribe-taker makes decisions comparing his or her gains from bribes and from honest behaviour. In Russia, income inequality jumped sharply during transition because of uneven transitional rent expropriation. The state was not able to properly adjust the salaries of bureaucrats, so the salaries were insignificant in comparison to bribes from the newly rich. This caused an increase in corruption activity. Inefficient government policy, inadequate legislation, unclear norms for new market behaviour and weak mechanisms of government control contributed to a rise in corruption.

The larger the scale of corruption, the smaller were the chances for a bribe-taker to be caught. Corruption technologies were developed with time, corruption hierarchies arose, and corruption activities were closely linked with other shadow economy mechanisms. Corruption turned out to be habitual for both the bureaucrats and the population. The coordination, learning, and linkage mechanisms as well as cultural inertia made the corruption system even more stable.

One can find institutional traps in the history of many developed countries. The United States of nineteenth century presents a good illustration of the corruption trap (Knott and Miller 1987, pp. 15–31). The time between 1815 and 1840 was a period of intensive transformations of political institutions in the United States. Property ownership requirements were abandoned to allow the lower classes to vote. These democratic reforms had unanticipated consequences, however. The political party machine became an effective instrument for some party bosses to get rich. Such men allocated public service positions (including those of postmaster, customs official, and policemen) among their supporters without taking into account competence or skills. Office workers were forced to pay a proportion of their wage to the political party through whom they had obtained their jobs. The police were a political tool rather than a law enforcement agency. Businessmen paid bribes for franchises. Low-level policemen took payments for 'permitting' local vice operations, and the money was distributed among the police hierarchy and the political bosses. Many people understood that the situation had to be changed, but nobody wanted to make a move. This was a corruption trap.

Once it has fallen into an institutional trap, the system chooses a non-efficient path of development, and, with time, returning to efficient development may be very difficult even if possible.

Escaping from an Institutional Trap

However, there are reasons to believe that some institutional traps are stable in the medium run only and that an economy can gradually develop mechanisms conducive to its escaping from institutional traps. The theory outlined above gives us a framework for the systematic consideration and classification of different mechanisms that may facilitate this transformation.

One has to reach at least one of the following goals: (*a*) to increase the transaction costs of the prevalent inefficient norm; (*b*) to decrease the transaction costs of an alternative efficient norm; (*c*) to bring down the transformation costs of the transition to an efficient norm. The coordination, linkage or/and inertia mechanisms have to be influenced for these purposes.

Below we consider microeconomic measures and macroeconomic policies that may be taken by a government, as well as spontaneous tendencies that are helpful for an economy to escape institutional traps.

Microeconomic Measures and Macroeconomic Policies

The simplest way of increasing the transaction costs of an inefficient norm is the introduction of a high penalty for deviating behaviour: for example, a strong punishment for corruption or a special tax on barter exchange. However, high penalties are very costly. There are at least three sources of penalty costs. First, enforcement of stronger penalties requires larger resources to be spent. Large fees may result in strong resistance on the part of the penalized persons. Second, a penalty directed to decrease the intensity of an inefficient norm may increase the intensity of its even more inefficient substitutes. Fee increasing may shift the system to another institutional trap instead of shifting it to an efficient equilibrium. For example, strong punishment for arrears could create additional incentives for firms to escape into the underground economy. Third, one should take into account the possibility of wrong decisions. The stronger the punishment of an innocent person, the larger the social losses.

The development of reputation mechanisms is another way of increasing the transaction costs of corruption, arrears, or tax evasion (Tirole 1996). These mechanisms also decrease transaction costs of efficient norms, creating incentives to observe them. At the start of the Russian transition, old reputation mechanisms were totally destroyed. New mechanisms arose gradually, due to strengthening of the state and formation of new business networks.

Amnesty is an instrument of weakening inertia effects in the cases of tax evasion, arrears and corruption. Many governments use this measure. The outcome is mixed, however. To be successful the amnesty has to be an unexpected event,

conducted at an appropriate moment when fundamental causes for a trap are exhausted, and it has to be complemented by other measures weakening linkage and coordination effects. The rotation of officials may be an effective measure for destroying unproductive coordination (see a theory of rotation in Ickes and Samuelson 1987).

Macroeconomic policy also influences the evolution of institutional traps. In choosing tax, social, or industrial policies, one has to take into account that they can create incentives or disincentives for participation in black market operations or corruption.

Spontaneous Exit

There are some spontaneous tendencies which, being unintended, may nevertheless facilitate exit from institutional traps.

A number of institutional traps (corruption and tax evasion traps, for example) are connected with rent-seeking behaviour. Each economic agent may invest his or her money and time into production or into rent-seeking activity. The choice depends on the relative efficiency of these two options. If rent-seeking dominates, then many agents choose this option, and an institutional trap may arise.

At a time of major institutional transformation, some economic agents are able to derive additional income – transitional rent – exclusively from their fortunate positions. Price liberalization gives the advantage to suppliers of goods in high demand. Foreign trade liberalization allows importers and exporters to profit from differences between domestic and world prices. The emergence of new stock exchanges and securities markets creates ample arbitrage opportunities for financial intermediaries.

If the state does not take special measures to extract transitional rent, rent-seeking becomes much more profitable than production. An increasing number of economic agents find themselves to be involved in rent-seeking activity, and increasing volumes of resources are diverted from productive activities. The rate of production growth falls, and this makes production even less attractive for investors. Coordination, learning, linkage, and inertia mechanisms start to work and form institutional traps.

If, however, the rate of economic growth substantially increases due to improvements of technology or term of trade, then some agents may decide to increase their investment into production. This supports growth and creates new incentives for the next cohort of agents to switch their efforts from rent-seeking to production. As a result, an institutional trap may disappear. Growth diminishes the transaction costs of 'good behaviour' and facilitates improvement of institutions. This conclusion was corroborated by econometric calculations (Chong and Calderon 2000) as well as theoretical research (Balatsky 2002).

Evolution of Civic Culture

One way out of an institutional trap is disadvantageous for each isolated economic agent but advantageous for society as a whole. The root of the problem is lack of coordination. The ability of agents to coordinate their efforts depends on the prevailing civic culture and the development of civil society.

Most studies of economic growth consider civic culture as a fixed and non-changing factor. However, some important parameters of civic culture may change drastically during a period of 10–20 years; therefore long-term considerations have to take them into account. For example, the proportion of people who revealed political interest in Germany was 27% in 1952 and 50% in 1977; the proportion of affirmative answers on the question 'Can most people be trusted?' increased from 9% in 1948 to 39% in 1976 (Conradt 1989). Political interest and social trust are important preconditions for social activity and the strengthening of civil society. Note that the proportion of respondents who belonged to a voluntary organization grew in Germany from 44% in 1959 to 50% in 1967, and 59% in 1975.

Lack of trust has direct economic consequence: it increases transaction costs and decreases investment (Zak and Knack 2001). If social activity is intensified and the degree of social trust increases, coordination becomes less costly; and there are more chances to escape from institutional traps.

The history of the US corruption trap, mentioned above, demonstrates the importance of the development of civil society (Knott and Miller 1987, pp. 33–53). By the turn of the nineteenth century, a powerful progressive movement had emerged. The movement combined the efforts of several groups of citizens including middle-class taxpayers, small businessmen, farmers, and professionals of various sorts. Their main goal was an administrative reform that would separate politics from administration. They required administration according to rules, the selection of civil officers according to merit and qualification, the standardization and simplification of procedures, the centralization of administrative authority under a single executive in accordance with the principles of hierarchy. Progressives created a number of organizations such as the New York Municipal Research Bureau, New York Citizen's Union, and the Milwaukee Free Press, and occupied leading positions in both Republican and Democratic Parties. The US Republican President Theodore Roosevelt and Democratic President Woodrow Wilson conducted reforms in accordance with progressive ideas and constructed a new system of governance based on independent commissions. The elimination of the corruption trap was a result of these reforms.

Systemic Crises

Sometimes systemic crises can be helpful in helping an economy escape from an institutional trap. (The idea that a systemic crisis may be advantageous has been put forward and studied in a number of papers: see Drazen and Grilli 1993.)

A crisis drastically changes system parameters and even destroys supporting mechanisms so that an economy may find itself outside the attraction area of the inefficient norm. The evolution of the barter trap in Russia serves as a remarkable illustration of this statement.

The barter trap was broken in 1998 due to systemic financial crisis. In consequence of the rouble devaluation the dollar has strengthened against the rouble by about two times in real term. Imports dropped drastically – in 1999 to 56% of the 1997 level. Exports decreased because of the rise in oil prices. Real wage rates also dropped. However, the overall demand for domestic goods increased, labour costs diminished and the economy started to grow. The crisis totally destroyed the government bond market, which diverted money flows from production purposes. Enterprises started to earn money and used it for investments. Their real balances increased. All these changes contributed into a strong decrease in monetary exchange transaction costs. The share of barter in industrial sales fell dramatically. In 2002 it was about 10%. The barter trap disappeared, including the complicated system of barter intermediaries. The crisis achieved what the government had not been able to do.

Conclusion

Institutional traps are serious obstacles to economic development. Many countries have found themselves in institutional traps. Some were able to escape, others have been searching for an exit for a long time.

The main cause of institutional traps is lack of coordination. The market is a powerful coordination mechanism; however, if the market fails, the government may try to prevent an institutional trap or facilitate getting out of it by developing reputation mechanisms, implementing an amnesty, improving administration and choosing appropriate macroeconomic policies. In many cases, however, neither market nor government measures are effective in the short run. Civil society institutions have to be developed to reach the necessary coordination. This is a point that may be helpful in integrating cultural and civil society studies into the theory of economic development.

Institutionalism, Old

Malcolm Rutherford

Abstract

What is now called 'old' institutional economics was a central part of a pluralistic American economics during the inter-war period. It is a tradition that still exists today but as a marginal heterodoxy to a dominant neoclassical mainstream. By the early 1920s it had established itself as an appealing programme with a major presence at leading universities and research institutes. Institutionalist work over the inter-war period included significant contributions to economic measurement and analysis. A number of factors led to the decline of institutional economics after the Second World War, but institutionalism has continued in a modified form, and still attracts adherents today.

What is now often referred to as the 'old' institutional economics was a central part of American economics during the inter-war period, and is a tradition of economics that still exists today.

The explicit identification of something called the 'institutional approach' to economics, or 'institutional economics', goes back to 1918 and to Walton Hamilton's American Economic Association (AEA) conference paper, 'The Institutional Approach to Economic Theory' (Hamilton 1919).

Hamilton's paper was a call for the profession at large to adopt the 'institutional approach'. For Hamilton, anything that 'aspired to the name of economic theory' had to be (i) capable of giving unity to economic investigations of many different areas; (ii) relevant to the problem of social control; (iii) relate to institutions as both the 'changeable elements of economic life and the agencies through which they are to be directed'; (iv) concerned with 'process' in the form of institutional change and development; and (v) based on an acceptable theory of human behaviour, in harmony with the 'conclusions of modern social psychology'. According to Hamilton, only an approach to economics that focused on the institutions that make up the 'economic order' could meet these tests. He identified H.C. Adams, Charles Horton Cooley (his own teachers at Michigan), Thorstein Veblen and Wesley Mitchell as the leaders of this movement. At the same session of the AEA conference, J.M. Clark (Clark 1919), argued for an economics both 'relevant to the issues of its time' and based on an 'ideal of scientific impartiality'. Walter Stewart (Hamilton's friend and colleague) chaired the session, and argued that economics needed to be 'organized around the central problem of control', should utilize the 'most competent thought in the related sciences of psychology and sociology', and combine 'the statistical method and the institutional approach' (Stewart 1919, p. 319).

The exact timing of this effort to promote 'institutional economics' as a distinctive approach probably had much to do with the end of the First World War. The war had impressed upon many the great importance of improved economic data and policy analysis, and of the potential role of government in the economy. The period of reconstruction seemed to offer significant opportunities for bringing changes to the conduct of economic research, education, and policy. The 1918 session of the AEA conference was followed by further efforts to promote institutional economics. Another AEA session critical of traditional theory was organized in 1920. This featured J.M. Clark's paper 'Soundings in Non-Euclidian Economics' (Clark 1921), which criticized orthodox theoretical propositions. In 1924 Mitchell argued in his presidential address to the AEA that quantitative methods would transform economics by displacing traditional theory and leading to a much greater stress on institutions (Mitchell 1925). Lionel Edie called this address 'a genuine manifesto of quantitative and institutional economics', one that stated 'the faith of a very large part of the younger generation of economists' (Edie 1927, p. 417). In the same year Rexford Tugwell edited *The Trend of Economics*, a book again seen as something of an institutionalist manifesto and which included papers from Mitchell and Clark as well as from younger people of institutionalist persuasion such as Tugwell himself, F.C. Mills, Sumner Slichter, Morris Copeland, and Robert Hale (Tugwell 1924).

During the inter-war period institutionalism developed a significant following, with a concentrated presence at a number of major schools and research institutes. In addition to Veblen, Hamilton, Clark, Mitchell, and Commons, who were the most visible proponents of institutionalism, there were many others associated with the movement (Rutherford 2000a, b). The two major centres for institutionalism over the whole inter-war period were Columbia and Wisconsin, at that time among the leading doctoral departments of economics in the country. Wisconsin's department included Commons (until he retired in 1933), E.E. Witte, Harold Groves, Martin Glaeser, Selig Perlman and several others (Rutherford 2006). Columbia was an even bigger centre for institutionalism with Mitchell, Clark, Rexford Tugwell, Mills,

A.R. Burns, Joseph Dorfman, Leo Wolman, Carter Goodrich, James Bonbright, and Robert Hale all in the Economics Department or Business School at various times, and Gardiner Means, Adolf A. Berle, and many other people of related views in other departments (Rutherford 2004). Chicago had an institutionalist contingent at least until Clark left for Columbia in 1926, and Walton Hamilton was at the centre of groups first at Amherst (1915–1923) and later at the Robert Brookings Graduate School (1923–1928). Other institutionalist groups existed at Texas, where Clarence Ayres joined Robert Montgomery in 1930, and in a number of other schools and colleges (Rutherford 2003, 2007).

Among research institutes, the Institute of Economics, which became part of the Brookings Institution, was heavily institutionalist in character (the research staff included Isador Lubin, and Edwin Nourse among others). The National Bureau of Economic Research (NBER) was closely associated with Mitchell's quantitative approach and his programme of business cycle research and employed many of his Columbia colleagues and students. The quantitative and policy orientation of the work done by these organizations attracted funding from foundations such as Carnegie and Rockefeller (Rutherford 2005a).

The Sources and Appeal of Institutional Economics

The elements that went to make up the core of the institutional approach as defined by Hamilton, were all present in American economics before 1918. Institutionalism as it formed in the inter-war period was an approach to economics that derived from several sources. While the single most significant source of inspiration for institutionalism was the work of Thorstein Veblen, it is important to understand that institutionalism was a blending of ideas taken from Veblen with those from others (Rutherford 2001), and was never simply Veblenism.

At the most basic level the most important element in the institutionalist approach is the conception of the economic system as a set of evolving social institutions. In this, institutions are seen as much more than constraints on individual action. Social norms, conventions, laws, and common practices embody generally accepted ways of thinking and behaving, and they work to mould the preferences and values of individuals brought up under their sway. A good part of this orientation came from Veblen, but also from sociologists such as Charles Horton Cooley, and from a previous generation of German-influenced scholars (such as R.T. Ely and H.C. Adams). At this time, in line with the German model, sociology was commonly taught within economics departments.

On a more specific level, Veblen's framework, which stressed the role of new technology in bringing about institutional change (by changing the underlying ways of living and thinking) and the predominantly 'pecuniary' character of the existing set of American institutions, was widely influential among institutionalists. Within this framework Veblen developed his analyses of 'conspicuous consumption'; the effect of corporate finance on the ownership and control of firms; business and financial strategies for profit-making, salesmanship and advertising; the emergence of a specialist managerial class; business fluctuations; and many other topics (Veblen 1899, 1904).

For Veblen, the existing legal and social institutions of America were outmoded and inadequate for the task of the social control of modern large-scale industry. Veblen perceived a *systemic* failure of 'business' institutions to channel private economic activity in ways consistent with the public interest. He attacked the manipulative, restrictive, and unproductive tactics used by business to generate income (including consolidations, control via holding companies and interlocking directorates, financial manipulation, insider dealing, sharp practices, and unscrupulous salesmanship), the 'waste' generated by monopoly restriction, unemployment, conspicuous consumption, and competitive advertising, and he held out little hope of change short of a complete rejection of 'business' principles.

Cooley also analysed pecuniary institutions but in more measured tones, and it must be

emphasized that many institutionalists, including Hamilton, Clark, Commons, and Hale placed a much greater emphasis on the evolution of legal institutions than did Veblen. Both Hamilton and Hale moved into law schools and had close connections with legal scholars of the realist school. The major sources of this emphasis on legal institutions were Ely (who taught Commons) and Adams (who taught Hamilton). This greater emphasis on law and on legal evolution helped to shift the character of institutionalism away from Veblen's radicalism and connect it to a pragmatic philosophy, based primarily on the work of John Dewey, which looked to legislative and legal reform concerning such issues such as business regulation, labour law, collective bargaining, health and safety regulations, and consumer protection. Thus, in the hands of institutionalists such as Hamilton, Clark, Mitchell, and Commons, the problem became one of supplementing the market with other forms of 'social control' of business.

Another important element was the linking of institutional economics with 'modern psychology'. Veblen had provided a particularly penetrating criticism of the hedonistic psychology implicit in marginal utility theory (Veblen 1898) and pointed to an alternative based on instinct/habit psychology. What was important for institutionalists, however, was less Veblen's specific formulation but the impetus he gave to the idea that economics needed to be reconstructed on the basis of a theory of human behaviour in harmony with the conclusions of modern psychology (see Mitchell 1910a, b).

Finally, and of central importance to the attraction of institutionalism, was the claim that it represented the ideal of empirical science. An important influence here was Mitchell's combination of Veblenian ideas concerning the significance of the institutions of the 'money economy' with the quantitative and statistical approach he had absorbed as a student at Chicago. Mitchell's *Business Cycles* (1913) was enthusiastically received and widely regarded at the time as a paradigm for a scientific economics. Mitchell thought of business cycles as a phenomenon arising out of the patterns of behaviour generated by the institutions of a developed money economy (Mitchell 1927), and he explicitly connected quantitative work and the institutional approach, arguing that it is institutions that create the regularities in the behaviour of the mass of people that quantitative work analyses (Mitchell 1924, 1925). Mitchell's quantitative bent was shared by many other institutionalists, but the scientific method, for institutionalists, was not confined to the statistical or quantitative, and included all work that was genuinely 'investigative' in character. It is important to comprehend that at this time it was institutionalists, not neoclassicals, who were claiming to be following the methods of natural science (Rutherford 1999), and seemed to be at one with the general movement in American social science towards greater empiricism and 'realism'.

At its inception, then, institutionalism could be seen as a very promising programme – modern, scientific, pointing to a critical investigation and analysis of the existing economic system and its performance, in tune with the latest in psychological, social scientific, and legal research, established at leading universities and research institutes, and involved in important issues of economic policy and reform (see also Yonay 1998).

The Contributions of Interwar Institutionalism

Mark Blaug has stated that institutionalism 'was never more than a tenuous inclination to dissent from orthodox economics' (Blaug 1978, p. 712), and this view still finds wide currency. In fact, institutionalsm in the inter-war period was a major part of a pluralistic mainstream economics (Morgan and Rutherford 1998). That institutionalists did have a positive programme of research in mind should be clear from the above. Not all elements of this programme were pursued successfully, but there can be no doubt that institutionalists did make important positive contributions to economics, and this is particularly true of the period when institutionalism was at its peak. Just a few of these contributions will be highlighted.

Institutionalist took the task of improving economic measurement seriously. The NBER not only produced many empirical studies relating to business cycles, labour, and price movements, but also played a vital role in the development of national income accounting, through the work of Mitchell's student, Simon Kuznets. In conjunction with the Federal Reserve, the NBER also did much to develop monetary and financial data. Moreover, during the New Deal, institutionalists were heavily involved in the effort to improve the statistical work of government agencies (Rutherford 2002).

As noted above, one of the claims of institutionalists was that a 'scientific' economics would have to be consistent with 'modern' psychology. A typical argument was that economics 'is a science of human behaviour' and any conception of human behaviour that the economist may adopt 'is a matter of psychology' (Clark 1918, p. 4). Clark made one of the most interesting efforts to develop the psychological basis of institutional economics. Building on the work of William James and Cooley, he argued that the 'effort of decision' is an important cost, and one that prevents maximization. Clark was considering both the costs of information gathering and of calculation, and his argument is a clear precursor of more recent conceptions of bounded rationality leading to the use of habits or routines.

Interesting work on the economics of consumption and the household, was pursued by Hazel Kyrk and Theresa McMahon. McMahon made use of Veblen's conception of emulation in consumption, while Kyrk was critical of marginal utility theory as a basis for a theory of consumption and emphasized the social nature of the formation of consumption values. Consumption patterns relate to habitual 'standards of living', and Kyrk undertook to measure and critically analyse existing standards of living, and to create policy to help achieve higher standards of living. In her later work she discussed the household in both its producing and consuming roles, the division of labour between the sexes, employment and earnings of women, adequacy of family incomes, and issues of risks of disability, unemployment, provision for the future and social security, and the protection and education of the consumer (Kyrk 1923; 1933; McMahon 1925).

There was much work dealing with the inadequacy of the standard models of perfect competition and pure monopoly. The soft coal industry received particular attention. In that industry investigators such as Hamilton found little that corresponded to the ideal of a competitive industry. Competition within the industry had resulted not in efficient low-cost production but in persistent excess capacity, inefficiency, irregular operation, poor working conditions and low earnings (Hamilton and Wright 1925). This represented a common institutionalist theme – that, particularly under conditions of high overheads and rapid technological advance, competition could lead to 'disorder' and inefficiency rather than to order and efficiency. Institutionalists also studied such things as common pool problems in the oil industry, production cycles in agriculture, including the cobweb model and its implications for the orthodox view of 'self-regulating' markets, and the vast array of restrictive practices to be found in many industries (Hamilton and Associates 1938).

A related theme was that technological change had altered the structure of costs faced by firms and had altered their behaviour. This argument derived from Clark's *Overhead Costs* (1923). For Clark, the growth of overhead costs as a result of capital-intensive methods of production had resulted in price discrimination, an extension of monopoly and an increase in price inflexibility over the cycle. A little later Gardiner Means (1935) developed his theory of administered pricing, which sparked a vast literature on relative price inflexibility.

On issues of corporate finance and ownership, Bonbright and Means co-authored *The Holding Company*, and Berle and Means *The Modern Corporation and Private Property*, both in 1932. These works much extended Veblen's earlier discussions of corporate consolidation and the separation of ownership and control. Berle and Means's work raised important issues of agency, and whether managers would maximize profits.

On labour market issues, institutionalists concerned themselves with studying unions and the history of the labour movement, developing in

the process both classifications of unions and explanations for the particular pattern of trade union development in America (Perlman 1928). Wage determination was also a problem that attracted the attention of institutionalists. Walton Hamilton's 1923 book *The Control of Wages* (with Stacy May) was praised by Clark for providing not an 'abstract formulation of the characteristic outcome' but a 'directory of the forces to be studied' in any particular case (Clark 1927, pp. 276–7). Discussions of trade unions and wage bargaining were provided by other institutional labour economists such as Commons (1924) and Sumner Slichter (1931). In this work much attention was given to issues of collective bargaining and systems of conciliation and mediation.

Public utilities, including issues relating to the valuation of utility property and the proper basis for rate regulation, were major areas of institutionalist research. Both Clark and Commons devoted considerable attention to the concept of intangible property, goodwill, and valuation issues (Commons 1924; Clark 1926). Bonbright dealt with the difference between commercial and social valuation in connection with public utilities. Bonbright, Hale, and Martin Glaeser all wrote extensively on issues of public utility regulation, with Hale probably having the greatest impact with his campaign of criticism of the 'fair value' concept as a basis for rate regulation (Hale 1921; Bonbright 1961, p. 164).

In his *Social Control of Business* (1926) Clark argued that business cannot be regarded as a purely private affair. This idea of private business being broadly 'affected with a public interest' was absolutely central to the institutionalist argument for regulation of business. Clark expresses the idea in his claim that 'every business is "affected with a public interest" of one sort or another' (Clark 1926, p. 185), and the argument also appears in as a central theme in Tugwell's early work on regulation (Tugwell 1921, 1922), and in Walton Hamilton's and Robert Hale's extensive writings on law and economics (Rutherford 2005b; Fried 1998).

More general interconnections between law and economics and the operation of markets were addressed by Hale, Commons, and Hamilton. Commons's approach was the most developed and was built on his notions of the pervasiveness of distributional conflicts, of legislatures and courts as attempting to resolve conflicts (at least between those interest groups with representation), and of the evolution of the law as the outcome of these ongoing processes of conflict resolution. He developed his concept of the 'transaction' as the basic unit of analysis (later adopted by Oliver Williamson). In turn, the terms of transactions were determined by legal rights and by economic (bargaining) power. Market transactions always involved some degree of 'coercion', in the sense of some degree of restriction upon alternatives (Commons 1924, 1932; Hale 1923). He also provided a theory of the behaviour of legislatures based on 'log-rolling', and a theory of judicial decision-making based on the concept of 'reasonableness', a concept that included, but was not limited to, a concern with efficiency (Commons 1932; 1934).

The institutionalist programme dealing with business cycles, in the period before the depression, was centred on Wesley Mitchell's work and that he promoted through the NBER. As noted above, Mitchell explicitly placed his work on business cycles within an institutional context by associating cycles with the functioning of the system of pecuniary institutions. Mitchell's 1913 volume *Business Cycles*, with its discussion of the four-phase cycle driven by an interaction of factors such as the behaviour of profit seeking firms, the behaviour of banks, and the leads and lags in the adjustment of prices and wages, became the standard institutionalist reference. At the NBER, Mitchell focused heavily on promoting work that would add to the understanding of business cycles, generating a stream of research studies far too long to list here, but contributing to the development of national income measures, business cycle indicators, and much more. In addition, Clark developed his concept of the accelerator out of his study of Mitchell's 1913 work, and the accelerator mechanism soon became a standard part of cycle theory (Clark 1917). Mitchell's work was not the only approach to business cycles to be found within institutionalism. Many

institutionalists, including Hamilton, had an interest in the work of J.A. Hobson, and Hobson's underconsumptionism became popular among institutionalists in the 1930s (Rutherford 1994).

On issues of market failure, broadly conceived, Clark (1926) discussed a large number of types of market failure in his *Social Control of Business*. These included monopoly, maintaining the ethical level of competition, protecting individuals where they are unable to properly judge alternatives, problems of agency, relief for people displaced by rapid economic and technological change, relief of poverty (including social security and minimum wages), regulation of advertising and the provision of information and standards, increasing equality of opportunity, externalities ('unpaid costs of industry'), public goods ('inappropriable services'), the wastes of 'arms race' types of competition (such as competitive advertising), unemployment, the interests of posterity or future generations, and any other discrepancy between private and social accounting. Slichter (1924) provided a list of problems almost as long, including the pro-cyclical behaviour of banks, overexploitation of natural resources, discrimination in employment, advertising and salesmanship, lack of market information, pollution and other external effects, uncertainty and unemployment, economic waste and inefficiency, and economic conflict. All these problems were seen as justifying some additional 'social control' of business activity.

Finally, and intimately related to the above, institutionalists made important contributions to policy in their roles in the development of unemployment insurance, workmen's compensation, social security, labour legislation, public utility regulation, agricultural price support programmes, and in the promotion of government 'planning' to create high and stable levels of output. Commons had pioneered public utility regulation, unemployment insurance, and workmen's compensation in Wisconsin, and the Wisconsin model was widely influential. Many institutionalists were active members of the American Association of Labor Legislation (AALL), and the AALL promoted many reforms to labour legislation. Medical insurance programmes were also pursued by the AALL, and also by the Committee on the Cost of Medical Care, which involved both Hamilton and Mitchell.

Institutionalists had significant influence within the New Deal. Many of Commons's students played leading roles in the development of the federal social security programme. Berle and Tugwell were two of Roosevelt's original 'Brains Trust', and Tugwell, Means, and Mordecai Ezekiel were the leading advocates of the 'structuralist' or planning approach that had influence in the early part of the New Deal (Barber 1996). Hamilton and several others were deeply involved in the labour legislation and consumer protection aspects of the New Deal. Hamilton later worked with Thurman Arnold in developing their case by case approach to anti-trust (Rutherford 2005b).

Institutional Economics After 1945

Institutionalism attained a significant position in American economics in the interwar period, both in academia and in government, but then declined in position and prestige after the Second World War. At this point institutionalism fell out of the mainstream of American economics to become a heterodox tradition on the margins of the discipline. There are quite a number of overlapping reasons for this, some of which reach back into the 1920s and 1930s, but the focus here will be limited to just a few of the more important issues.

Institutionalism clearly did not live up to its own early promise, particularly in its failure to pin down exactly what foundations in 'modern psychology' it was supposed to have. After the mid-1920s, psychologists abandoned the instinct/habit approach in favour of a behaviourism that became increasingly narrow and difficult to see as an adequate foundation for economics. In this climate, the enthusiasm for new psychological approaches that had played such a role in the institutionalist movement's beginnings could not be sustained. Institutionalism probably played a part in ridding economics of explicitly hedonistic language, but it did not develop the alternative

basis to convince the profession as a whole to abandon its traditional views of rationality (Lewin 1996).

It must also be said that institutionalists failed to develop their theories of social norms, technological change, legislative and judicial decision-making, transactions, and forms of business enterprise (apart from issues of ownership and control) much beyond the stage reached by Veblen and Commons. The reasons for this lack of development relate partly to the focus of interwar institutionalists on immediate and pressing policy problems, like business cycles, labour law, and social security. In addition, from the late 1920s on, sociology separated itself from economics and became established in separate departments, taking much of the subject matter of social norms and institutions with it.

It is also the case that, from the 1930s onwards, many new developments in theory and methods occurred within economics: developments that tended to displace institutionalist ideas and methods. Hicks's revision of demand theory seemed to free economics from the shifting basis of psychology, while the work of Joan Robinson and Edward Chamberlin provided treatments of imperfect competition more amenable to neoclassical approaches. The discussion of externalities in terms of market failure was also much clarified. Neoclassicism developed a language capable of encompassing at least some of the issues of concern to institutionalists; issues that had formerly fallen outside the neoclassical theoretical compass.

Moreover, institutionalist approaches to business cycles were replaced by Keynesian ideas. In many respects, Keynesian economics took over the role of the exciting 'new' economics that institutionalism had played in the early 1920s. In addition, neoclassical and Keynesian economics gained an empirical component with the rise of econometrics. Institutionalists could no longer claim greater 'scientific' standing because of their empiricism; indeed, they were accused by Koopmans (1947) of 'measurement without theory'; a much exaggerated view, but one often repeated and widely accepted.

In these ways more 'orthodox' economic theory took over those aspects of institutionalism amenable to 'model analysis' (Copeland 1951) while other aspects were absorbed into what became applied field areas, such as industrial organization, labour economics, and industrial relations. At least until the 1960s these field areas had only loose ties to the theoretical core of the discipline, and maintained a substantial institutional component.

Finally, a significant part of the institutionalist agenda of social reform had come to pass, both removing some of the original causes of the institutionalist movement, and prompting a reaction in the form of critiques of the expanded role for government that institutionalists had done so much to put forward.

Under these circumstances, it is not difficult to see why institutionalism slipped from being a central part of American economics to a more marginalized position. This change did not happen overnight, but was hastened by the significant amount of new hiring on the part of American universities immediately after the Second World War. These new faculty were predominantly Keynesians or neoclassicals equipped with the latest in mathematical and econometric tools. The retirement of the last of the older generation of institutionalists in the 1950s completed the process.

American institutionalism did not disappear, but it certainly changed. Insitutionalists formed the small 'Wardman Group' in 1959, an organization that later became the Association for Evolutionary Economics, still the primary organization of 'old' institutionalists in America, and the publisher of *The Journal of Economic Issues*. Institutionalism disassociated itself from the positivism that had gained popularity elsewhere (a positivism that, ironically, Mitchell and the NBER had played an important part in creating), and turned away from the methods and the core areas of the discipline that had been taken over by neoclassical and Keynesian economics. Institutionalists continued to work in applied areas, and to argue for more active government regulation and 'planning' of the economy (Gruchy 1974), but there was also something of a movement back to the broader institutional themes found in Veblen and Commons.

This tendency was especially promoted by Clarence Ayres, in his *Theory of Economic Progress* (1944). Ayes attempted to renew the Veblenian emphasis on technology as the driving force behind institutional change, and developed the Veblenian distinction between business and industry into a general dichotomy between the ceremonial and instrumental aspects of culture. Ayres's charismatic personality attracted a number of students to the institutionalist ranks, and they spread his version of institutionalism to many south-western universities. The University of Texas, too, retained its institutionalist character longer than most, and in the 1960s was still the home of a substantial institutionalist group. Other institutionalist groups existed at Maryland and at Michigan State. J.K. Galbraith produced widely read and distinctly Veblenian analyses in his *Affluent Society* (1958) and *New Industrial State* (1971), while the Commons tradition in law and economics has been kept alive by Daniel Bromley, Allan Schmid, and Warren Samuels (Samuels 1971; Schmid 1978; Bromley 1989).

Perhaps the most important recent development within the 'old' institutionalist tradition has been the growing interest in the work of Veblen and Commons among a new generation of European economists attracted to institutional and evolutionary ideas. One outstanding example of this is to be found in the work of Geoffrey Hodgson, who has argued forcefully for the development of an institutional economics along lines he sees as having been originally pioneered by Veblen in his evolutionary and Darwinian approach to institutions and institutional change (Hodgson 1988; 2004).

Instrumental Variables

Charles E. Bates

Abstract

Instrumental variables methods are an essential tool in modern econometric practice. The method itself is of ancient lineage and historically is closely connected with the econometrics of simultaneous equations. This article describes the statistical foundations of instrumental variables methods with a focus on their classical development.

Keywords

In one of its simplest formulations the problem of estimating the parameters of a system of simultaneous equations with unknown random errors reduces to finding a way of estimating the parameters of a single linear equation of the form $Y = X\beta_0 + \varepsilon$, where β_0 is unknown, Y and X are vectors of data on relevant economic variables and ε is the vector of unknown random errors. The most common method of estimating β_0 is the method of least squares:

$\hat{\beta}_{\mathrm{OLS}} \equiv \arg\min \varepsilon(\beta)'\varepsilon(\beta)$, where $\varepsilon(\beta) \equiv Y - X\beta$. Under fairly general assumptions $\hat{\beta}_{\mathrm{OLS}}$ is an unbiased estimator of β_0 provided $E(\varepsilon_t|X) = 0$ for all t, where ε_t is the tth-coordinate of ε.

Unfortunately for the empirical economist, it is often the case that the basic orthogonality condition between the errors and the explanatory variables is not satisfied by economic models, due to correlation between the errors and the explanatory variables. Particularly relevant examples of this situation include (1) any case where the data contain errors introduced by the process of collection (errors in variables problem); (2) the inclusion of a dependent variable of one equation in a system of simultaneous equations as an explanatory variable in another equation in the system (simultaneous equations bias); and (3) the inclusion of a lagged dependent variable as an explanatory variable in the presence of serial correlation. For all of these cases,

$$E\left(\widehat{\beta}_{\mathrm{OLS}}\right) = E\left[(X'X)^{-1}X'Y\right]$$
$$= \beta_0 + E\left[(X'X)^{-1}\sum_{t=1}^{n} X_t' E(\varepsilon_t|X)\right] \neq \beta_0$$

in general, and the bias introduced cannot be determined because the errors ε are unknown. Furthermore, in every case the bias fails to go to zero as the sample size increases. Clearly the method of least squares is unsatisfactory for many situations of relevance to economists.

In 1925 the US Department of Agricultural published a study by the zoologist Sewall Wright where the parameters of a system of 6 equations in 13 unknown variables were estimated using a method he referred to as 'path analysis'. In essence his approach exploited zero correlations between variables within his system of equations to construct a sufficient number of equations to estimate the unknown parameters. The idea which underlies this approach is that, if two variables are uncorrelated, then the average of the product of repeated observations of these variables will approach zero as the number of observations is increased without bound except for a negligible number of times. Thus if we know that a variable of the system Z_i is uncorrelated with the errors ε, we can exploit the fact that $n^{-1}\sum_{t=1}^{n} Z_{ti}\varepsilon_t \equiv n^{-1}\sum_{t=1}^{n} Z_{ti}(Y_t - X_t\beta_0)$ approaches zero to construct a useful relationship between parameters of the system by setting such averages equal to zero. Provided a sufficient number of such relationships can be constructed which are independent, this

provides a method for estimating the parameters of a system of simultaneous equations which should become more accurate as the number of observations increases.

Since the 1940s, when Reiersøl (1941, 1945) and Geary (1949) presented the formal development of this procedure, the variables Z which are instrumental in the estimation of the parameters β_0 have been called 'instrumental variables'. Associated with each instrumental variable Z_i is an equation formed as described in the previous paragraph, called a normal equation, which can be used to form the estimates of the unknown parameters. Frequently there are more instrumental variables than parameters to be estimated. As the equations are formed from relationships between random variables, generally no solution will exist to a system of estimating equations formed in this manner using all possible instrumental variables. As each estimating equation contains relevant information about the parameters to be estimated, it is undesirable just to ignore some of them. Thus we can define a fundamental problem in the application of this method: how can we make effective use of all the information available from the instrumental variables? This problem will occupy the rest of this article.

Let $\varepsilon_t(\theta) \equiv F_t(X_t, Y_t, \theta)$ be a $p \times 1$ vector-valued function defined on a domain of possible parameter values $\Theta \subseteq \mathbb{R}^k$ which represents a system of p simultaneous equations with dependent variables Y_t, a $p \times 1$ random vector, and an $m \times s$ random matrix of explanatory variables X_t for all $t = 1, 2, ..., n$. Standard formulations of $F_t(X_t, Y_t, \theta)$ are the linear model $\varepsilon_t(\theta) \equiv Y_t - X_t\theta$ and the nonlinear model $\varepsilon(\theta) \equiv Y_t - f_t(X_t, \theta)$. Let $W_t(\theta)$ be a $p \times r$ random valued matrix defined on Θ for all $t = 1, 2,..., n$. Assume that there exists a unique value θ_0 in Θ such that $E\left(\varepsilon_1^0 | W_1^0\right) = 0$ for all $t = 1, 2, \ldots, n$, where $\varepsilon_t^0 \equiv F_t(X_t, Y_t, \theta_0)$ and $W_t^0 \equiv W_t(\theta_0)$. Finally, let $Z_t(\theta)$ be a $p \times 1$ random matrix such that $E(Z_t(\theta)|W_t(\theta) = Z_t(\theta)$ for all θ in Θ. Any such variables $Z_t(\theta_0)$ may serve as instrumental variables for the estimation of the unknown parameters θ_0 since

$$E\left(Z_t^{0\prime}\varepsilon_t^0\right) = E\left(E\left(Z_t^{0\prime}\varepsilon_t | W_t^0\right)\right) = E\left(Z_t^0 E\left(\varepsilon_t^0 | W_t^0\right)\right) = 0$$

for all $t = 1, 2, \ldots, n$, as long as the functions F_t and W_t and the data generating process satisfy sufficiently strong regularity assumptions to ensure that the uniform law of large numbers is satisfied, that is

$$n^{-1}\sum_{t=1}^{n} Z_t(\theta)'\varepsilon_t(\theta) \to n^{-1}\sum_{t=1}^{n} E\left[Z_t(\theta)'\varepsilon(\theta)\right]$$

uniformly in θ on Θ.

Identification of the unknown parameters θ_0 requires that there be at least as many instrumental variables as there are parameters to be estimated, that is, $l \geq k$. On the other hand, if there are more instrumental variables than parameters to be estimated, there will be no solution to $n^{-1}\sum_{t=1}^{n} Z_t(\theta)'\varepsilon_t(\theta) = 0$ in general for finite n as indicated above. One possible solution to this problem is simply to use k of the instrumental variables in the estimation of θ_0. The omitted instrumental variables may then be used to construct statistical tests of the $l - k$ overidentifying restrictions of the unknown parameter vector. A drawback of this approach is that not all of the information available to us is used in the estimation of the unknown parameters and hence, the estimates will not be as precise as they should be. An alternative approach which effectively uses all of the available instrumental variables is to be preferred.

Even though in general the moment function $n^{-1}\sum_{t=1}^{n} Z_t'(\theta)\varepsilon_t(\theta) \neq 0$ for any value of θ, its limiting function $n^{-1}\sum_{t=1}^{n} E\left[Z_t'(\theta)\varepsilon_t(\theta)\right]$ does vanish when $\theta = \theta_0$. This suggests estimating θ_0 with that of Θ which makes $n^{-1}\sum_{t=1}^{n} Z_t'(\theta)\varepsilon_t(\theta)$ as close to zero as possible. The criterion of closeness is of some interest to the econometrician. It affects the size of the confidence ellipsoids of the estimator about θ_0 and hence the precision of the estimate. The nonlinear instrumental variables estimator (NLIV), $\hat{\theta}_{n,\mathrm{NLIV}} = \mathrm{argmin}_{\theta \in \Theta}$

$$\left[\sum_{t=1}^{n} Z_t'(\theta)\epsilon_t(\theta)\right]' \cdot \left[\mathrm{Var}\sum_{t=1}^{n} Z_t'(\theta_0)\epsilon_t(\theta_0)\right]^{-1} \cdot \left[\sum_{t=1}^{n} Z_t'(\theta)\epsilon_t(\theta)\right]$$

is the optimal instrumental variables estimator in this respect (Bates and White 1986a).

The NLIV estimator simplifies to well-known econometric estimators in a variety of alternative specifications of the underlying probability model which generated the variables. When the data generating process is independent and identically distributed, $\hat{\theta}_{n,\mathrm{NLIV}}$ is the nonlinear three-stage least squares estimator of Jorgenson and Laffont (1974). The additional restriction of consideration to a single equation ($p = 1$) results in the nonlinear two-stage least squares estimator of Amemiya (1974). Furthermore, if the model $\varepsilon(\theta)$ is linear in $\theta, \hat{\theta}_{n,\mathrm{NLIV}}$ then simplifies to the three-stage least squares estimator of Zellner and Theil (1962) for a system of simultaneous equations and to the two-stage least squares estimator of Theil (1953), Basmann (1957) and Sargan (1958) for the estimation of the parameters of a single equation. On the other hand, if we allow for heterogeneity by restricting the data generating process only to be independent, $\hat{\theta}_{n,\mathrm{NLIV}}$ simplifies to White's (1982) two-stage instrumental variables estimator of the parameters of a single linear equation.

As indicated above, it is desirable from consideration of asymptotic precision to include as many instrumental variables as are available for the estimation of the unknown parameters θ_0. This raises the question of the existence of a set of instrumental variables $\{Z^*\} \in \Gamma$ that renders the inclusion of any further instrumental variables redundant, where Γ is the set of all sequences of instrumental variables such that $\hat{\theta}_{n,\mathrm{NLIV}}$ is a consistent estimator of θ_0 with an asymptotic covariance matrix. Bates and White (1986b) provide conditions which imply that such instrumental variables exist, though it may not be possible to obtain them in practice. Suppose there exists a sequence of k instrumental variables $\{\mathcal{L}\}$ such that for all $\{Z\}$ in Γ

$$E[\mathcal{L}(\theta_0)'\nabla_\theta \varepsilon(\theta_0)] = E\left[\mathcal{L}(\theta_0)'\varepsilon(\theta_0)\varepsilon(\theta_0)'Z(\theta_0)\right].$$

Then $\mathcal{L}(\theta_0)$ is optimal in Γ in the sense of asymptotic precision. Suppose it is also the case that Σ is an $np \times np$ matrix with representative element $\sigma_{th\tau g} = E(\varepsilon_{\mathrm{th}}(\theta_0) \cdot \varepsilon_{\tau g}(\theta_0) \quad | W_{th}(\theta_0), W_{\tau g}(\theta_0))$, is nonsingular a.s. and that

$$E\left[E(\nabla_\theta \varepsilon_{th}(\theta_0)|\, W_{th}(\theta_0))|\, W_{\tau g}\right] = E(\nabla_\theta \varepsilon_{th}(\theta_0)|\, W_{th}(\theta_0))$$

for all t, τ=1,2,..., n and h, g = 1,2,..,p such that $\sigma^{th\tau g} \equiv 0$, where $\sigma^{th\tau g}$ is a representative element of Σ^{-1}. Let Z^* be an $np \times k$ matrix with rows

$$Z^*_{th} \equiv \sum_{\tau=1}^{n}\sum_{g=1}^{p} \sigma^{th\tau g} E\left[\nabla_\theta \varepsilon_{\tau g}(\theta_0)|\, W_{\tau g}(\theta_0)\right].$$

If $\{Z^*\}$ is in Γ then $\{Z^*\}$ is optimal in Γ.

In many situations it will not be possible to make use of such instrumental variables in practice. However, for some important situations optimal instrumental variables are available. Suppose that $\varepsilon(\theta) \equiv Y - X\theta$ and the explanatory variables X are independent of the errors $\varepsilon(\theta_0)$. If the errors are independent and identically distributed for all $t = 1, 2,...,n$ and $h = 1, 2, \ldots, p$, then $Z^* = X$. Thus the optimal instrumental variables estimator is given by

$$\hat{\theta}_{n,\mathrm{NLIV}} \equiv \arg\min_{\theta \in \Theta} \varepsilon(\theta)'X\left[\sigma^2 E(X'X)\right]^{-1}X'\varepsilon(\theta),$$

where $\sigma^2 \equiv \mathrm{var}[\varepsilon_{\mathrm{th}}(\theta_0)]$ is a real, nonstochastic scalar for all t and h. If it is also the case that $n^{-1}E(X'X) - n^{-1}X'X \to 0$ as $n \to \infty$, $\hat{\theta}_{n,\mathrm{NLIV}}$ is asymptotically equivalent to $\arg\min_{\theta \in \Theta}\varepsilon'(\theta)X(X'X)^{-1}X'\varepsilon(\theta)$, that is ordinary least squares is the optimal instrumental variables estimator. If there is contemporaneous correlation only, that is, $\mathrm{var}(\varepsilon_t(\theta_0)) = \Omega$, a $p \times p$ nonstochastic matrix, then Zellner's (1962) seemingly unrelated regression estimator (SURE), is the optimal instrumental variables estimator. If we further relax these assumptions so that $\mathrm{var}(\varepsilon(\theta_0))$ is an arbitrary positive definite $np \times np$ matrix, the generalized least squares (Aitken 1935) is the optimal instrumental variables estimator.

Since the development of the two-stage least squares estimator in the mid-1950s, the method of instrumental variables has come to play a prominent role in the estimation of economic relationships. In turn, in modern econometric practice, the use of instrumental variables methods has been very much influenced by the evolution of

economic theory as well as the evolution of the relationship between theory and empirical practice. Within macroeconomics, the standard approach to structural economic analysis, Hansen's (1982) generalized method of moments estimation (GMM) procedure, which is a generalization of nonlinear instrumental variables estimation, typically relies on economic theory to identify validinstruments. The most prominent application of GMM methods is to Euler equations estimation, in which valid instruments are defined by a theoretical specification of how one set of variables may be understood to be the expected value of another set.

While economic theory can identify instruments that are, in principle, valid, it typically does not provide insights into whether such instruments are strongly or weakly correlated with the variables that are to be instrumented. Concern over the problem of weak instruments was stimulated by the demonstration in Bound, Jaeger and Baker (1995) that the failure to account for weak instruments called into question findings on the return to schooling in the work of Angrist and Krueger (1991). Important analyses of the effects of weak instruments on estimation and inference include Dufour and Taamouti (2005), Staiger and Stock (1997) and Stock and Wright (2000). This new literature is well surveyed in Dufour (2003) and Andrews and Stock (2006). This work demonstrates how lack of attention to the possibility of weak instruments can lead to very misleading inferences for a broad range of contexts. Furthermore, it provides new ways for conducting inference with respect to the parameters of interest.

When economic theory identifies valid instruments, it may be the case that the set of potential instruments is unbounded. This is evident in Euler equation contexts, where the validity of the instrument vector Z_{t-k} usually implies the validity of Z_{t-k-l}, $l > 0$. This has led to research on the properties of estimators where the number of available instruments grows with the number of observations. Donald and Newey (2001) and Hahn (2002) are examples of analyses of this type.

Other developments in the use of instrumental variables have occurred because of a desire to avoid the use of structural models in developing substantive economic claims. In particular, the literature on TREATMENT EFFECTS may be understood as an effort to show how the causal effects of alternative policies may be uncovered outside the context of a structural model. A part of this literature has focused on the analysis of data from natural experiments and quasi-natural experiments, but, as argued by Heckman (1996), such analyses are in fact forms of instrumental variable estimation. Perhaps unsurprisingly, the effort to develop causal claims based on statistical rather than economic assumptions has led to controversy since the two types of assumptions are in fact interrelated. See Angrist et al. (1996) as well as the discussion of this paper for different perspectives. Heckman (1997) provides a wide-ranging critique of the use of instrumental variables in contemporary research; Roy model describes constructive ways to proceed.

Finally, it is important to remember that instrumental variable estimates are normally evaluated on the basis of asymptotic properties, that is, the law of large numbers and the central limit theorems. Since in general it is not possible to know how much data are required to arrive at acceptable estimates, conclusions derived from instrumental variables estimates should be tempered with a healthy dose of scepticism.

Instrumentalism and Operationalism

Lawrence A. Boland

Abstract

Instrumentalism and Operationalism are the methodological doctrines associated respectively with Milton Friedman and Paul Samuelson. Each has a long philosophical history. Instrumentalism was the 18th-century doctrine created to deal with the Newton mechanics; Operationalism was the early 20th-century doctrine created to deal with Einstein' general relativity. With Instrumentalism one can say that theories do not have to be true, just

useful – as Friedman argued in 1953. With Operationalism one is required to express theories only in terms of observable and measurable variables. Samuelson's early work was designed to demonstrate how theory can be made operational and thus potentially refutable.

For any reader familiar with economic literature, the conjunction of the two methodological doctrines of Instrumentalism and Operationalism immediately calls to mind the methodological pronouncements of Milton Friedman (1953) and Paul Samuelson (1947, 1965, 1983). Interestingly, when making their methodological pronouncements, neither Friedman nor Samuelson mentions a philosopher to support his methodological viewpoint or to indicate an inspiration. Nevertheless, each of these methodologies is intended to solve a philosophical problem. Each has a philosophical history.

Friedman's Instrumentalism

Historically, Instrumentalism was a response to the success of Newton's laws of physics that were claimed to explain facts of nature and in particular explain the movements of the planets. Given the success of Isaac Newton's physics, the problem was thought to be that ordinary people would look to science instead of the church for true explanations of nature. Thus, the fear was that any recognized authority of science might undermine faith. Bishop George Berkeley in the early 18th century promoted the idea that we should allow science to be seen *only* as instruments or tools to solve practical problems (for example, instruments to calculate movements of the planets and thus make astronomical predictions). In this way, scientific explanations should not be considered true, only useful. If people would accept the doctrine of Instrumentalism then science and religion could comfortably coexist.

Friedman's Instrumentalism has nothing to do with religion. Instead it is a response to the demands of the critics of neoclassical economics and in particular criticism of the assumptions of perfect competition. In the 1930s and 1940s, the climate of philosophical opinion concerning any claim to scientific knowledge was that it must be realistic in the sense that any scientific claim can be verified as true. With this in mind, critics of neoclassical economics claimed that the assumptions of neoclassical theory would have to be shown to be true if they are claimed to be the basis of true explanations of economic behaviour – or, perhaps more importantly, if they are used to form economic policy such as that involving labour and employment (for example, Lester 1946, 1947). The key question was: must the assumptions of economic theory be true in order to be useful? In his 1953 article 'The Methodology of Positive Economics', Friedman argues that useful theories do not have to be based on true assumptions, or can even, in some cases be based on assumptions that are known to be false.

Few economists today would think any theory should have to be absolutely true for any serious consideration of that theory, whether or not it is to be used for the formation of an economic policy (for example, Aumann 1985). That is, few today think we should be concerned with the question of the absolute truth status of any scientific theory. Instead, all that is hoped is that the theory is the best available as determined by the current scientific conventions. Instrumentalism is an answer to a different question: 'What is the *role* of scientific

theories?' As noted above, Bishop Berkeley had long ago answered this question. Scientific theories should not be considered true or false, simply because, so long as they are useful tools of analysis or prediction, their truth status does not matter. Instrumentalism will never be seen as a satisfactory methodology to economists who think the truth status of economic theory matters (for example, Lawson 1997, 2003).

As it turns out, Instrumentalism can be a very useful tool for the defense against any competing methodological doctrine that claims either that scientific theories are true or that scientific theories must be proven true before they can be used to deal with real practical problems. Proponents of Instrumentalism can always respond to critics by merely claiming that the use of Instrumentalist methodology has proven to be very useful.

Samuelson's Operationalism

Operationalism is usually attributed to physicist Percy Bridgman's 1927 book, although several writers may have taken similar positions before (see Mirowski 1998; Hands 2004). Bridgman's contribution was apparently a response to the growing interest in Albert Einstein's general relativity-based theory of physics that was being seen as the successor to the classical physics of Newton. Einstein's physics was a challenge for most people of the day to understand. Bridgman was seen to be offering a common-sense view of physical theory and methodology that fitted better with what most people understood.

The basic idea of Operationalism is that explanations should be based only on concepts and variables that can be defined by the operations used to measure them. Interestingly, Einstein in 1905 started out trying to explain his theory of special relativity by showing how what we mean by 'simultaneous' is not as obvious as we might think should we try to operationalize it, that is, try to define it in terms of the operations used to measure it. However, he ultimately rejected such an operationalist approach as it made the development of his theory of general relativity paradoxical or impossible (Schilpp 1949).

Apparently, in the 1930s Operationalism was seen as a plausible means of implementing positivism. Supposedly, if every concept used in one's theory can be operationally defined and is thereby observable, then any empirical verification of a scientific theory would be beyond dispute. Moreover, in the 1930s it was commonly believed that scientific theories were meaningful while philosophical or religious theories were not. And the basic notion to support this was that one could verify scientific theories but not philosophical or religious theories. Operationalism was seen by some to be an avenue to make the common verificationist methodological perspective plausible.

About the same time as Bridgman was arguing for Operationalism, there was a movement towards behaviouralism in psychology. The motivation there was that we should avoid constructs such as consciousness or mind and use only observable behaviour. Being observable behaviour means that one could in principle define operations such that one would be able to measure human behaviour. And this is exactly what can be seen in Samuelson's advocacy of Operationalism in economics. What Samuelson wanted to purge from economic theory and in particular from the theory of the consumer was psychology (1938). That is, in Marshallian neoclassical theory, the consumer is thought to be maximizing utility whenever making a decision about what to buy; however, we cannot observe, let alone measure, the level of utility achieved. So how do we know that it is maximized? Do we have to turn our analysis of consumer decisions over to the psychologists? Samuelson thought not. Perhaps his motivation was only the recognition that, if one were to promote mathematical formulations of economics, everything would need to be quantifiable. But the advocacy of Operationalism goes beyond this by requiring the use of only observable variables to derive the fundamental laws of economics, such as the so- called Slutsky equation and the consumer's demand curve. Samuelson claimed that one did not have to assume the existence of a utility function for the consumer but only that the consumer makes well-defined and consistent observable choices. These choices and whether they are consistent is completely and

directly observable and are so without any reference to psychology or utility.

Samuelson went on in his Ph.D. thesis (published in 1947; see also 1998) to say that it is possible to construct all of the important ideas in economics in such a manner that they can be shown to be in principle falsifiable. He called empirically falsifiable statements 'operationally meaningful statements'. It should be noted, however, that by 1947 he was no longer taking the extreme view taken in 1938, which required that all assumptions of a theory be directly observable, but instead said that a theory need only be shown to have implications that are falsifiable with observable data. Any theory or model that has such implications would henceforth be deemed to be 'operationally meaningful'.

This invocation of Operationalism is somewhat suspect. At the time Samuelson was promoting the use of mathematics in economics, critics, particularly some of the Austrian School, were claiming that all mathematical propositions are tautologies (see Hutchison 1935, 1938). Samuelson, by requiring any theory or model to be 'operationally meaningful' (that is, falsifiable), was really just avoiding the critics, for there is no conceivable evidence that can refute a tautology. So, when he showed that falsifiable statements can be derived from his mathematical model of an economic theory, he proved that his mathematical model is not a tautology. Thus, Operationalism offered a means of dealing with the critics of the use of mathematics in economics.

The Methodological Failures of Friedman and Samuelson

By 1950 Samuelson had to admit that his original operationalist programme to purge psychological concepts such as utility from consumer theory was a failure. Consistency of today's choice with past choices presumes no change in tastes. When he revisited his version of consumer theory in 1948, he introduced preferences into the discussion. His key assumption was to be called the weak axiom of revealed preference. However, once it was recognized that the weak axiom was not sufficient for the purposes of consumer theory, the introduction of a strong version revealed that his revealed preference analysis was logically equivalent to old fashioned utility- based analysis (see Wong 1978, 2006). This undermined any further interest in promoting Operationalism in economics.

Friedman's version of Instrumentalism begs many questions. Who decides what is meant by 'useful' or which empirical facts need to be predicted with one's economic model? What one economist might think an obviously successful policy that justified the use of obviously false assumptions might not be accepted as successful by critics of the realism of those assumptions. So some may think that Instrumentalism can be used to defend its use in a self-referential form by economists, others can just as easily say that the primary and perhaps sole use of Instrumentalism is to avoid criticism of theories and hence of policies recommended on the basis of those theories. Instrumentalism still lives in economics, although in a somewhat muted form (see Boland 2003, Chaps. 4 and 5). The dominance of formal mathematical modelling has often been supported by appeals to Instrumentalism (for example, Aumann 1985, pp. 31–2). Rarely, however, will a promoter of mathematics in economics refer to Friedman's essay, but the methodological position taken is the same.

Insurance

J. J. McCall

Insurance is an ancient institution. It is impossible to reflect on evolutionary processes without recognizing the intrinsic role of insurance. Any species that relied on nature's harmony and regularity and ignored its stochastic whims was soon extinct. The position adopted here is that uncertainty is one of the decisive determinants of individual behaviour. 'Individual' includes not only early and modern man, but also plants and animals. Furthermore, the response to uncertainty is both adaptive and dynamic. Martingale models are ideally suited to portray these responses. The goal of the individual is to maximize expected utility and for early man this was roughly equivalent to maximizing the probability of survival. In order to achieve this goal, he devised a variety of insurance mechanisms he established institutions that included a large element of flexibility so they could readily adjust to nature's stochastic quirks. Insurance and the ensuing flexibility were key components of his decisionmaking. Aggregating these individual responses over the entire group reveals one critical aspect of the society's culture. The individual quickly perceived that some of the most effective devices for mitigating uncertainty entailed *cooperative arrangements*.

At the same time that individuals and bands are designing mechanisms for coping with a fluctuating environment, nature is inexorably monitoring these activities and eliminating those individuals and bands who respond too slowly to adversity or are unlucky, and despite their best efforts, are overcome by misfortune. These Job-like extinctions are more likely in harsh and highly variable environments. We expect that those who survive in these environments are quite distinct from survivors where nature is relatively benevolent. The excellent study by Minnis (1985) indicates how persistent misfortune affects existing social institutions and induces significant modifications. Minnis examined three periods of environmental stress and shows the enhanced survival value of innovation and flexibility.

Insurance also manifests itself in unconscious natural selection. Lowell (1985) has shown that as the predictability of the environment decreases, the safety factory of the biological structure increases. Roughly speaking, the organism adapts to the distribution of the maximum stress, rather than to the distribution of the actual stress. In other

words, the difference between the stress-capability of the organism and the actual stress encountered, measures the 'slack'. The presence of 'slack' or flexibility enhances the survivability of the organism. Thus a fairly conservative way of handling unanticipated shocks is to imitate nature and use the distributions of the extremes (maximum period of drought or minimum density of prey). Leadbetter et al. (1983) is a fine, comprehensive treatment of extreme value distributions. Flocking (Morse 1970) is another of the almost endless variety of insurance mechanisms that evolved in response to the threat of extinction. The study of extinction is a discipline in itself. A good sampling of recent research is the book edited by Nitecki (1984) with Diamond's paper on isolated populations an outstanding contribution. Martin's piece on catastrophic extinctions is the most pertinent. Also see Mangel and Ludwig (1977) for a stochastic analysis of extinction in competitive struggles among species. The classic studies by Slobodkin (1961) and MacArthur (1972) are illuminating. An elegant model of extinction could be devised using the contact process methods in Liggett (1985).

The Basic Elements of Insurance

We have already described the essential aspects of insurance. The remaining task is to translate them into the modern language of economics and probability. The original research on the economics of insurance was conducted by Arrow (1971) and Borch (1968). Hirshleifer and Riley (1979) contains a fine survey of insurance; also see Lippman and McCall (1982). The neatest presentation of stochastic dominance in an insurance setting is the paper by Lippman (1972) that has gone unnoticed in spite of its excellence.

Individuals in modern societies are unable to predict the time and magnitude of events that profoundly affect their well-being. Insurance, in all its guises, is the institution that mitigates the influence of uncertainty. The individual invests in a host of activities *now* to insure that the timing and magnitude of unfortunate future events will be less harmful. These activities enable firms and individuals to trade risks among themselves. The most familiar of these transfers is the ordinary insurance contract. The essence of this contract is the payment of a fee by the insuree in exchange for the insurer's promise to pay a certain sum of money provided a stipulated event occurs.

One of the simplest insurance contracts has the following structure. The insured pays a fixed premium y to avoid the small probability p of incurring L, a large loss. For simplicity, ignore loading charges (i.e. the charge to cover the administrative costs associated with writing and overseeing the insurance contract), and set this premium equal to the actuarial value of the loss plus an amount c, the compensation to the insurer for assuming the risk:

$$y = pL + (1-p)0 + c = pL + c. \quad (1)$$

Such a policy is advantageous to both the insured and insurer. The insured possesses a concave utility function and is therefore eager to pay y to dispense with this risk. The insurance company is able to pool independent risks and via the law of large numbers converts risky contracts into almost 'sure' things.

Because of its fundamental importance we state a simple version of the law of large numbers, namely, the weak law of large numbers for a fair Bernoulli random variable. (This version applies when $L = 1$ and $p = 1/2$.) A fair coin is flipped n times. Let the random variable X_n be given by

$$X_n = \begin{cases} 1, & \text{if a head occurs on } n\text{th flip} \\ 0, & \text{if a tail occurs on the } n\text{th flip,} \end{cases}$$

and S_n is defined by

$$S_n = \sum_{i=1}^{n} X_i.$$

The proportion of heads in the first n trials is simply S_n/n.

At first one might think that the probability of exactly n heads in $2n$ trials should be high because $p = 1/2$, but

$$P(S_{2n} = n) = \binom{2n}{n} 2^{-2n} \simeq 1/\sqrt{\pi n}. \quad (2)$$

Thus, the probability of exactly n heads in $2n$ trials goes to zero as n gets large.

The weak law of large numbers states that the probability of $S_n|n$ deviating from $\frac{1}{2}$ by any fixed positive quantity goes to zero as n goes to infinity. More precisely,

$$\lim_{n\to 0} P\left(\left|S_n/n - \frac{1}{2}\right| > \varepsilon\right) = 0, \quad \text{for any } \varepsilon > 0. \quad (3)$$

Proof Letting $\widehat{\Sigma}$ designate the sum over the set of integers k such that $|k/n - \frac{1}{2}| > \varepsilon$, we have

$$\begin{aligned} P\left(\left|S_n/n - \frac{1}{2}\right| > \varepsilon\right) &< \widehat{\Sigma}\left[\left(k/n - \frac{1}{2}\right)/\varepsilon\right]^2 \binom{n}{k} \\ \times 2^{-n} &\le \varepsilon^{-2} \sum_{k=0}^{n} \left(k/n - \frac{1}{2}\right) 2 \binom{n}{k} 2^{-n} \\ &= \varepsilon^{-2} \mathrm{Var}(S_n/n) = p(1-p)/n\varepsilon^2 \\ &\le 1/4n\varepsilon^2. \end{aligned}$$

where the first inequality follows from the fact that $\left(k/n - \frac{1}{2}\right)^2 > \varepsilon^2$, the second inequality from the fact that additional non-negative terms are being summed, and the final inequality from the fact that $x(1-x)$ is maximized at $x = \frac{1}{2}$. Q.E.D.

Note that the law of large numbers does not say that if you and I play a game of chance with a fair coin, I will lead approximately half the time. In fact, if I win the game, I am likely to have led for most of the game.

By this law S_n/n converges in probability to $\frac{1}{2}$. Thus, an insurance company has considerable control over its average loss.

When contracting (risk transfer) transpires in an uncertain environment, two basic problems present themselves: *moral hazard* and *adverse selection*. Both are founded on imperfect information. The prototypical example of these problems is the insurance contract between an insurance company (the principal) and the insured (the agent). By paying a premium the agent transfers the risk associated with a particular activity to the principal. This risk transfer affects the incentives and behaviour of the agent. It is these incentive effects that are commonly referred to as the moral hazard problem. It has its roots in the inability of the principal to costlessly observe the actions of the agent. Hence when the untoward event occurs, the principal is not sure whether it was caused by the agent's carelessness or by chance. Moral hazard can be reduced by requiring the agent to bear some of the costs of the contingency and/or by monitoring the agent's behaviour. Adverse selection is similar to moral hazard in that the problem arises because the principal does not have costless access to information possessed by agents and vice versa. For example, some purchasers of health insurance have more information about their health status than insurance companies. Because the insurance company cannot discriminate perfectly between healthy and sickly agents, the latter will pose as healthy agents and be 'adversely selected' (insured) by the principal. Insurance companies can and do cope with these informational asymmetries by (a) experience rating, that is, continually adjusting premiums to reflect the size and incidence of each agent's claims and (b) designing policies that elicit the information necessary for partitioning agents into distinct categories.

These problems have received an enormous amount of study by economic theorists. Much of the analysis is static and, of course, gives rise to many perplexes. When properly formulated as dynamic stochastic control problems the perplexities diminish and the solutions accord with those that have been used for centuries by business firms.

Alternative Insurance Mechanisms

The insurance contract is only one of a multitude of devices that have been created for coping with the risks that afflict any economic system. These risks include not only fire, theft, sickness, and death but also fluctuating prices, equipment malfunctions, zero inventory levels causing unsatisfied demands, and failure of basic research ranging from falsely 'proved' theorems to unisolated viruses. The existence of futures

contracts permits the farmer or food processor to specialize in production, while the speculator specializes in risk-bearing. The risks of equipment failure can be reduced by improved design and maintenance procedures like redundancy and frequent inspection. The probability of an unfulfilled demand can be diminished by maintenance of larger inventories. The costs of research failure are frequently insured against by initiation of a large number of relatively independent projects (self-insurance), or, where the costs are large and uncertain, by adoption of inefficient contractual procedures like the cost-plus, fixed-fee contract (government insurance).

The basic institution for shifting the risks of business from entrepreneurs to the general public is the securities market. Individuals can diversify their portfolio of stocks to achieve an acceptable level of expected return for a given level of risk. This ability of individuals to spread risks thereby permits firms to engage in projects which otherwise would be unacceptable. Consequently, society is better off.

These insurance arrangements are, however, far from ideal. It is usually impossible for a firm to transfer *only* rights to the outcomes of its highly risky ventures. In contrast with the futures market, the stock market is usually incapable of separating production and risk, leaving the former to the entrepreneur and transferring the latter to the general public. Instead, the stock certificate is a relatively blunt instrument for disentangling risk and production. The fact that society has not created a sharper instrument attests to the refractory nature of this problem.

The Probability of Bankruptcy

The goal of many firms and indeed of many organisms is to maximize the probability of survival.

Consider the following simple version of the bankruptcy problem. An entrepreneur begins with wealth $W_0 = 0$ and acquires \$1 with probability p and loses \$1 with probability $1-p$. If he reaches $\$ - b$ before he reaches a wealth of \$a, he is bankrupt; whereas if he reaches a before $-b$, he can issue stock and essentially reduce his ruin probability to zero. Let z be the probability of hitting a before $-b$, and Y_n the position of the entrepreneur after n periods (trials). Then

$$X_n = \left(\frac{1-p}{p}\right)^{Y_n}$$

is a martingale with $E(X_n) = 1$, all n. Hence, the probability of survival, z, is the solution to:

$$z\left(\frac{1-p}{p}\right)^{a} + (1-z)\left(\frac{1-p}{p}\right)^{-b} = 1$$

which implies that

$$z = \frac{b}{a+b}.$$

When survival is the criterion function in a finite horizon problem, it is easy to show that the optimal policy is conservative (timid) for the first few trials (the entrepreneur has control over the size of the bet at each trial), but becomes bold as the horizon approaches and success has not yet been achieved. Using standard terminology, the stochastic behaviour of the entrepreneur would switch from risk aversion to risk preference at some critical point. This problem is solved in Lippman and McCall (1980) and Houston and McNamara (1985).

Insurance Mathematics

James C. Hickman and Edward W. Frees

Abstract

Insurance mathematics is concerned with the valuation of obligations arising from insurance contracts. At contract initiation, valuation is known as premium determination or ratemaking, whereas, for a contract already in force, valuation is known as reserve determination. Updating these values as information is revealed involves important techniques known as experience adjustment. Models of insurance mathematics are based on probability theory and financial economics. These models are calibrated with insurance experience and present values from returns on investments in asset markets.

Mathematics and insurance have developed along parallel paths during the past 350 years. It is difficult to identify an economic activity more closely tied to mathematics than insurance. Since the genesis of probability ideas in the mid-17th century, there have been times when mathematical developments were ahead of insurance practice. At other times, commercial necessity required improvisations that did not rest on solid mathematical foundations. In general the science and the application moved together.

Reserves and Premiums: Long-Term Coverages

Two related valuation problems are to establish a price, or premium, and to estimate the liability created by a contract. The basic tools for solving these problems are expected values and compound interest combined with an economic concept, the equivalence principle. The equivalence principle requires, at the time the coverage is activated, that the expected present value of premiums equals to expected present value of benefits. Following the issuance of the coverage, the principle can be extended to define the liability of the insurer as the expected present value of future benefits less the expected present value of future premiums.

Long-term insurance contracts have the possibility of extending for many years. The time of benefit payment, and for some contracts the amount of payments, often depend on the length of the survival time of the insured. Specifically, let T denote the random variable time until death. One example of a long-term coverage is life insurance with a single payment of benefits at time T Another example is a life annuity with many payments of benefits paid during survival, up to time T The life insurance model would apply to financing the replacement of equipment from light bulbs to generators. The mathematics of annuities would apply to funding equipment maintenance costs.

To illustrate, consider a life insurance policy paying a benefit b at death to be funded by a premium π, paid at a continuous annual rate until death. For the time until death random variable, let $\mathrm{s}(t) = \Pr(T > t)$ be the survival function. Then the equivalence principle determines the premium π by the equation

$$-b\int_0^\infty e^{-\delta t}\mathrm{s}'(t)dt = \pi \int_0^\infty e^{-\delta t}\mathrm{s}(t)dt. \qquad (1)$$

Here, $-\mathrm{s}'(t)$ is the probability density function of time until death and δ is the continuous interest rate, also called the force of interest. It will be assumed constant for simplicity. It is defined through the relation $1 + i = e^{\delta}$, where i is the annual effective rate of interest. The premium rate π is known as a 'benefit premium'; it is computed assuming that firms are risk neutral and that there are no transactions costs. In commercial practice, the benefit premium π will be increased to a contract premium G , $G > \pi$. The contract premium will contain provisions for expenses, profits and risk. The equivalence principle can be extended to include these elements.

The liability of the insurer, denoted by ${}_sV$ given survival to s , $s \geq 0$, would be given by the equivalence principle as

$$\begin{aligned} {}_sV + \pi\int_s^\infty e^{-\delta(t-s)}\mathrm{s}(t-s|\, s<T)dt \\ = -b\int_s^\infty e^{-\delta(t-s)}\mathrm{s}'(t-s|\, s<T)dt. \end{aligned} \qquad (2)$$

In words, the liability is the expected present value, also called the actuarial present value, of future benefits less the actuarial present value of future premiums. In this equation, the conditional survivorship function is $\mathrm{s}(t-s|\, s<T) = \mathrm{s}(t)/\mathrm{s}(s)$.

In Eq. (1) for the premium rate and Eq. (2) for the reserves, making benefits and premiums a function of time survived, $\mathrm{b}(t)$ and $\pi(t)$, creates no conflict with the equivalence principle. There are practical reasons for requiring ${}_sV \geq 0$. This prevents a voluntarily withdrawing insured from

leaving the insurer with a negative liability, a non-collectable asset.

As another special case, we now consider a life annuity with benefits at an annual rate b starting at retirement time r, funded by a continuously paid premium rate π paid during survival to r. Such a contact would be a building block of a pension plan. The equivalence principle yields

$$\pi \int_0^r e^{-\delta t} \mathrm{s}(t) dt = b \int_r^\infty e^{-\delta t} \mathrm{s}(t) dt, \qquad (3)$$

allowing us to compute the premium rate π based on survivorship and interest information.

To illustrate how other contracts can be accommodated, we consider the life annuity case that also includes a so-called 'return of premiums' feature. With this feature, there is an additional benefit consisting of the accumulated premiums (with interest) that are paid at death before time r. The benefit side of formula (3) is increased by

$$\begin{aligned} &-\pi \int_0^r \left(\int_0^t e^{\delta x} dx \right) e^{-\delta t} \mathrm{s}'(t) dt \\ &= -\pi \left(\mathrm{s}(r) \int_0^r e^{-\delta t} dt + \int_0^r e^{-\delta t} \mathrm{s}(t) dt \right), \end{aligned} \qquad (4)$$

where the right-hand side is from an integration by parts. With this additional benefit, from formula (3) we have

$$\pi \mathrm{s}(r) \int_0^r e^{-\delta t} dt = b \int_r^\infty e^{-\delta t} \mathrm{s}(t) dt,$$

a result that might have been derived by general reasoning from the equivalence principle.

We return to the life annuity premium displayed in formula (3). The equivalence principle yields a reserve liability at time s, $0 \le s$, of

$$\begin{aligned} &sV + \pi \textstyle\int_s^r e^{-\delta(t-s)} \mathrm{s}(t-s \,|\, s < T) dt \\ &= b \textstyle\int_s^\infty e^{-\delta(t-s)} \mathrm{s}(t-s \,|\, s < T) dt \; 0 < s < r_s V \\ &= b \textstyle\int_s^\infty e^{-\delta(t-s)} \mathrm{s}(t-s \,|\, s < T) dt \; r < s. \end{aligned}$$

The key role played by the survival function and the assumed interest rate in these typical formulas is clear.

Reserves and Premiums: Short-Term Coverages

Short-term coverages include most individual property/casualty, health and group insurance policies. They are characterized by the reduced role of present values. In addition, the benefit amount is typically a random variable. Its value will depend in health insurance on the services provided, and in property insurance on the extent of the property damage. Premiums and reserves will continue to be determined by the equivalence principle. In the time period between the occurrence of a loss event and its settlement, available information about the loss event will determine reserve amounts.

The expected value of benefit payments for short-term coverages is given by

$$\begin{aligned} \pi &= \mathrm{E}\left(\sum_{i=1}^N X_i \right) = \mathrm{E}\left(\mathrm{E}\left(\sum_{i=1}^N X_i \right) | N = n \right) \\ &= \mu \mathrm{E}(N), \end{aligned}$$

where N denotes the random number of losses during the insurance period, X_i is the loss amount arising from loss i and $\mathrm{E}\, X_i = \mu$.

If the distribution of N is Poisson and N and the loss amounts are independent, then

$$S = X_1 + \ldots + X_N \qquad (5)$$

has a compound Poisson distribution. Clearly many distributions, such as the binomial or negative binomial, could be used for the distribution of N.

The reserve liability for short-term coverages uses information about loss events and the loss reserve is

$$\mathrm{E}(X_1 + \ldots + X_N | N = n) = n\mathrm{E}(X) = n\mu$$

and n is the number of losses incurred.

Risk theory is the study of the distribution of total losses and the management of their inconvenient consequences. The earliest contributions to risk theory build on the model for long-term coverages. We start with loss variables

$$L_j = b_j e^{-\delta T_i} - \pi_j \int_0^{T_i} e^{-\delta s} ds,$$

and study the distribution of $S = L_1 + \ldots + L_n$. Here, T_i is a random variable representing the future lifetime of an individual. This study is known as individual risk theory because the variable S is based on n individual loss variables. If the loss variables are assumed to be mutually independent, then

$$Z = \frac{S - \mathrm{E}(S)}{\sqrt{\mathrm{Var}(S)}}$$

will have, as a result of an extension of the central limit theorem, an approximate normal distribution, with mean zero and variance one. In contrast, the direct study of the distribution of S as in formula (5) is called collective risk theory. Approximating the distribution of S has been an active topic in actuarial research since early in the 20th century.

Experience Adjustment: Long-Term Coverages

Valuation of long-term coverages requires assumptions about the realizations about interest rates and mortality in the distant future. In this dynamic world it is almost certain that the results expected by an insurance system will not be obtained. For many contracts, it has become customary for insurers to make assumptions that many financial analysts would view as conservative for pricing at contract initiation. As better than anticipated experience is realized, excess funds are realized that can be directed to the insured in a mutual insurance organization or to owners of the insurance company. For the insured, these are additional (non-contractual) benefits; depending on the regulatory environment, these additional benefits come in the form of dividends or bonuses.

Reconciling anticipated to actual experience is done periodically, not just at the conclusion of the contract. Because of this periodic reconciliation, recursion relationships are important tools for measuring and adjusting for deviations from expected results.

Specifically, let ${}_{s-1}F$ be the fund, possibly the insurance reserve, at the end of policy year s-l. Define ${}_sP$ to be the premium paid at the beginning of policy year s , $\mathrm{E}({}_sB)$ the expected benefits paid at the end of policy year s and ${}_sF$ the expected fund at the end of policy year s. We simplify and assume that $E({}_sB) = b\, q_s$. A basic recursive relationship is

$$({}_{s-1}F + {}_sP)(1+i) - bq_s = {}_sF\, p_s, \qquad (5a)$$

where i is the expected annual interest rate and $p_s = 1 - q_s$. Formula (5) can be written as

$$({}_{s-1}F + {}_sP)(1+i) - q_s(b - {}_sF) = {}_sF. \qquad (6)$$

If the actual experience yields i' and q_s', then formula (6) can be written as

$$({}_{s-1}F + {}_sP)(1+i') - q_s'(b - {}_sF) = {}_sF + D, \qquad (7)$$

where D is a deviation of actual from expected results. If $D > 0$, the amount might be paid to the insured in a mutual insurance organization or to owners of the insurance company.

Subtracting formula (6) from (7), yields

$$D = (q_s - q_s')(b - {}_sF) + (i' - i)({}_{s-1}F + {}_sP). \qquad (8)$$

The first term on the right-hand side of formula (8) is called the mortality contribution and the second term the interest contribution. Formulae used in practice also contain a term for the difference between expense loading and actual expenses.

To study life annuities, the general formula (6) can be modified during the benefit payment period to yield

$${}_{s-1}F(1+i) - p_S b = p_{SS} F. \qquad (9)$$

Replacing the expected parameters with experience parameters, we have

$$ {}_{s-1}F(1+i') - p'_s b = p'_s({}_sF + D). \qquad (10) $$

Subtracting formula (9) from formula (10) yields

$$ {}_{s-1}F(i'-i) + \left(p_s - p'_s\right)(b + {}_sF) = p'_s D. $$

If $D > 0$, this expression could be the basis of a dividend to surviving annuitants.

These recursion relationships are also the basis for flexible coverages where premiums and benefits can be changed by the insured within contractual limits.

Experience Adjustment: Short-Term Coverages

In the first decade of the 20th century industrial accidents were a leading cause of death, a source of much litigation and a major social concern. The advent of workers' compensation insurance replaced litigation with a system based on defined benefits. Employers, in most cases, were required by statute to provide workers' compensation benefits. Because of great variation in the hazards faced in different industries and the lack of loss statistics, initial premiums were set by judgement. The goal was to develop a self-correcting rate estimation process that would also provide incentives to employers to improve industrial safety.

The solution came from the formula

$$ \begin{aligned} (\textit{New rate}) = {} & Z(n) \\ & \times (\textit{observed average losses}) \\ & + [1 - Z(n)] \times (\textit{Initial Rate}), \end{aligned} $$

where the credibility factor is $Z(n)$, n a measure of exposure and $0 \le Z(n) \le 1$. To provide intuition, consider the case where $Z(n) = 1$, known as the 'full credibility' case. Here, the employer's next period premium would consist entirely of observed average losses from the prior period. If the employer had introduced practices to improve industrial safety then this would be reflected in a lower premium. In contrast, consider the case where $Z(n) = 0$. Here, the premium would consist of an initial *rate* that presumably would reflect industry results but not the employer's actual experience. The case $Z(n) = 0$ is the standard for individual coverages. Many employers would fall in the intermediate case, $0 < Z(n) < 1$, known as 'partial credibility'. Premiums for employers in this category would reflect their own industrial safety records as well as benefit from the pooling of risks within an industry.

For the credibility factor, one typically requires $Z'(n) > 0$ and $Z''(n) < 0$. Thus, other things equal, employers with larger exposure (n) enjoy larger credibility but the rate of increase decreases with exposure. A typical credibility function is of the form $Z(n) = n/(n+k)$, $k > 0$. The establishment of k with a satisfactory intellectual foundation has come from Bayesian statistics after its introduction into practice. The credibility idea for experience adjustments is now used in many short-term coverages.

Another type of insurance plan available for groups is known as 'stop-loss' or 'excess of loss' coverage. Large group insurance plans, usually based on employee groups, have distinctly different risk characteristics from individual policies. The sponsor, usually a large organization, is typically willing and able to absorb some variation in benefit payments. Only large and unexpected payments are financially inconvenient to the sponsor. The insurance company is paid to adjudicate and pay benefit claims, and to absorb large and inconvenient benefit payments. Typically, the sponsor maintains an internal account of losses known as an 'experience account'. This account records premiums as income and losses and expenses as expenditures.

We let X be the losses in an experience period and d be the stop loss amount (or d for 'deductible'). The experience account is charged for losses up to d. If $X > d$, then X-d is not charged to the experience account of the sponsor. A risk premium for this experience adjustment is charged on the basis of

$$ \int_d^\infty (x-d) f(x) dx. $$

Model Calibration: Experience Studies

The models introduced suggest that extensive work must be done in estimating survival functions in implementing long-term insurance models. For short-term models, the distribution of the number of losses N, per policy period, and the distribution of X, the loss amount, must be estimated. These efforts are in most applications special cases of statistical estimation.

These estimation projects are generally observational studies. The data come from insurance experience and the subjects have purchased insurance or gained insurance as an employee benefit. The use of general population statistics for insurance purposes has hazards because of potential biases. To illustrate, when studying annuitant mortality, it is well-known that mortality is substantially lower than the general population mortality. This is a selection bias issue; seldom do those in substandard health purchase a life annuity.

Rapid increases in the cost of health services and jury awards in some areas have increased the need to estimate time trends for the distribution of X, loss costs. Because of longer settlement time in some coverages, this estimation has become a major project in loss reserve determination. The rate of increase in health care costs in recent years has been such that estimates of the distribution of X, benefit amount random variable, using information from previous years would result in a distribution significantly to the left of the distribution for the current year. The rate of growth of health care costs is the most important single pricing decision for health insurance.

Model Calibration: Classification

The distributions that enter insurance models are all conditional distributions. Clearly, the distribution of X, loss amount, depends on the time, location and other facts surrounding the insurance loss incident. The distribution of T, time until death, in life insurance depends on a set of classification variables. The purpose of observing these classification variables is to increase the likelihood that the assumed distribution of T will be approximately realized.

The selection of these classification variables may be constrained by law and expense. For example, a determination of the degree of aggression of an applicant for automobile insurance might have a significant impact on the distribution of N, but the expense of collecting the information might be greater than its value in reducing variability.

Model calibration: financial economics

The critical role played by the force of interest δ in premiums and reserves for long-term coverage is clear. The use of an assumed force of interest for an extended period of time will lead, according to common experience, to serious deviations between actual and expected results. Options for moderating these deviations are numerous.

- A statistical model for the force of interest, estimated from past data, could be constructed and the equivalence principle extended to take expectations over the joint distribution of δ_T and T. The joint distribution might also be used to fix an interest rate risk loading into premiums to minimize the inconvenient consequence of variations in δ.
- Arrange the timing of investment cash flows to approximately match the expected cash flows from the insurance operations.
- Pass variations in interest earnings directly to the policy owner as indicated in the section on Experience adjustment, long-term coverages. The insured's account F would absorb variation in investment earnings.
- Use a program of financial derivative contracts to stabilize, for a price, variations in investment income.

Financial economics has not only enriched insurance mathematics by providing risk management tools for the investment risk in conventional insurance contracts, it has also created the possibility of absorbing many traditional insurance risks into special securities traded in worldwide

investment markets. The idea is to use the capital in investment markets, and not just the capital held by insurance companies, to manage risk.

The idea of special securities with contractual payments that approximately match payments from an insurance system has already been developed for several coverages –for example, catastrophe bonds with modified payments following a catastrophe, fitting the definition of the security. A second example is a survivorship bond with regular coupon payments proportional to the number of survivors in a defined group. Such bonds could spread the risk if mortality improvement exceeds the capacity of the sponsor of a pension system.

The market for such special securities is determined, in part, from ideas in financial economics. Portfolio theory would predict that investors would seek securities that have cash flows that are not positively correlated with the regular business cycle. Tying security payments to natural disasters, such as earthquakes and hurricanes, might achieve the sought for independence.

Intangible Capital

Daniel E. Sichel

Abstract

Intangible capital has played an increasingly important role in economic growth, although firm-level financial and national income accounting practices provide little information about intangibles and do not count many purchases of intangible capital as investment.

Economists have long understood that advances in knowledge and technology play a crucial role in economic growth. An important recent contribution to this literature is research on the magnitude and role of intangible capital. As defined by Corrado et al. (2005a, 2006), intangible investment is expenditures by businesses that are intended to boost output in the future but that are not traditional, tangible physical capital; examples include outlays for computer software, research and development, training, brand equity, and improvements in organizational structure and efficiency.

Recent interest in intangible capital was generated by a sense in some quarters that official statistics may not be capturing the full dynamism of the US economy as well as by the resurgence of US productivity growth in the mid-1990s. That resurgence led many researchers, including Oliner and Sichel (2000, 2002), Jorgenson and Stiroh (2000), and Jorgenson et al. (2002), to focus on

the contribution of information technology (IT) to economic growth. And that focus on IT, as well as the run-up in equity valuations that occurred at about the same time, turned researchers' attention to intangible capital. Many analysts observed that firms using IT effectively did more than simply install it; they made sizable collateral investments to revamp their operations in order to exploit the new technologies. For example, Walmart developed a more efficient supply chain, Dell linked demand and production more tightly, Amazon pioneered a new distribution channel, and Google and eBay developed entirely new businesses. In each case, the collateral investments consisted largely of expenditures on intangible inputs. Many observers believe that these intangible investments, as well as intangible investments that may not be tied to IT, are playing an increasingly important role in the economy.

Despite the apparent importance of investments in intangible capital, relatively little is known about these investments. At the firm level, financial accounting provides little information about such expenditures and the return earned by them. Moreover, these outlays are considered a current-period expense, not an investment creating an asset on the firm's balance sheet. Because of this lack of information, Lev (2004) argues that managers may make poor investment decisions and financial markets may incorrectly value firms and therefore may inefficiently allocate capital. At the level of the National Income and Product Accounts (NIPAs) used to measure gross domestic product (GDP) in the United States, historical practice has classified such expenditures as intermediate inputs, and thus they are not counted as investment in GDP. (The inclusion of business software as an investment in the NIPAs is a notable exception to this practice.) Moreover, the GDP accounts, like firm-level financial accounts, provide very little information about most intangible expenditures.

Research has begun to fill this gap with three broad approaches to measuring intangible capital. The first uses financial market valuations to gauge the value of intangible capital, inferring a measure of intangible capital from the gap between the market and book value of firms. As summarized in Hall (2005), such an estimate was quite large around 2000, about equal to the stock of tangible capital. At the firm level, Brynjolfsson and Hitt (2005) regress market value on capital and labour inputs as well as various proxies for intangible capital. Their work highlights the link between intangible investments and investments in computers, and suggests that intangible investments may exceed tangible investments in computers by as much as a factor of ten. Considerable controversy has surrounded estimates of intangible capital that are derived from financial market valuations.

The second broad category of research relies on other performance measures (such as productivity or earnings) to gauge the magnitude of intangible capital; for examples, see McGrattan and Prescott (2005), Cummins (2005), and Lev and Radhakrishnan (2005). Lev (2004) summarizes a methodology for estimating the value of intangibles at the level of individual firms, starting from earnings. This literature also finds a large role for intangibles.

The third broad category of research uses expenditure data to develop measures of intangible capital. Nakamura (1999, 2001, 2003) was the first to develop expenditure measures. Corrado et al. (2005a) expanded on Nakamura's work and more tightly integrated estimates of intangible investment with the NIPAs. Marrano and Haskel (2006) applied the methodology of Corrado et al. (2006) to the United Kingdom, and obtained similar results.

Corrado et al. (2006) classify business spending on intangibles into three broad groups: computerized information, innovative property and economic competencies. Computerized information consists mainly of computer software. Innovative property includes scientific R&D and non-scientific R&D such as product development expenditures in financial services and in the entertainment industry. Economic competencies include brand equity (advertising) and firm-specific resources such as training and organizational capital. Corrado, Hulten, and Sichel use a variety of data sources to develop time series of nominal expenditures for each category. These

figures suggest that nominal intangible business investment from 2000 to 2003 averaged $1.2 trillion per year, about $1 trillion of which was not counted as investment in the NIPAs.

This research highlights the magnitude and importance of intangibles but does not quantify their contribution to economic growth. This question is taken up in Corrado et al. (2006), which extends their earlier paper, and embeds intangibles in a conventional growth accounting framework. Specifically, Corrado, Hulten, and Sichel develop time series of the real stock of intangible capital for the United States, using their earlier estimates of investment in intangibles. According to their numbers, the nominal stock of intangible capital was about $3.6 trillion in 2003, about $3.1 trillion of which is not included in official measures. These figures imply that official measures may be understating the stock of business capital by roughly 20 per cent.

Corrado et al. (2006) embed their estimates of intangible capital into a standard growth accounting decomposition and present estimates for the period from 1973 to 2003 for the United States. They compare a decomposition based on data that exclude intangibles to one based on data that include intangible assets. Several important results emerge from this analysis. First, the inclusion of intangibles as investment boosts the estimated growth rate of labour productivity in the non-farm business sector by 10–20 per cent relative to a baseline case that completely ignores intangibles. Second, the contribution of intangibles to economic growth has increased dramatically since 1995, and including intangibles has a considerable effect on the composition of the mid-1990s pickup in labour productivity growth. Third, once intangibles are included, greater use of capital (including both tangible and intangible capital) becomes a more important source of growth. This contrasts with the traditional result (when intangibles are largely excluded), where total factor productivity – the residual after accounting for the contributions from labour and capital – plays a larger role. Finally, the majority of the contribution of intangibles comes from categories of intangibles that have received relatively little attention in the past, such as non-scientific R&D and firm- specific resources. Scientific R&D – perhaps the most studied and most 'traditional' category of intangibles – accounts for only about one-tenth of the contribution of intangibles to labour productivity growth.

Taken together, the research indicates that business investment in intangible capital is quite sizable and has played an important role in the US economy. Moreover, these results indicate that both firm-level and national income accounting practice miss some important features of economic activity. Nevertheless, the quantitative estimates discussed here are clearly provisional, and this area appears to be a fruitful one for further research.

Integer Programming

Egon Balas

Integer programming is the youngest branch of mathematical programming: its development started in the late 1950s. A (linear or nonlinear) *integer program* is a linear or nonlinear program whose variables are constrained to be integer. We will consider here only the linear case, although there exist extensions of the techniques to be discussed to nonlinear integer programming.

The integer programming problem can be stated as

$$(\mathrm{p}) \times \min\{cx | Az \geq b, x \geq 0, x_j \text{integer}, j \in N_1 \subseteq N\},$$

where A is a given $m \times n$ matrix, c and b are given vectors of conformable dimensions, $N = \{1,\ldots, n\}$, and x is a variable n-vector. (P) is called a *pure integer program* if $N_1 = N$, a *mixed integer program* if $\varphi \neq N_i \neq N$. Integer programming is sometimes called *discrete optimization*.

Modelling Potential

Integer programming is the most immediate and frequently needed extension of linear programming. Integrality constraints arise naturally whenever fractional values for the decision variables do not make sense. A case in point is the *fixed charge problem*, in which one wants to minimize a function of the form $\Sigma_j c(x_i)$, with

$$c(x_j) = \begin{cases} f_j + c_j x_j & \text{if } x_j > 0 \\ 0 & \text{if } x_i = 0 \end{cases}$$

subject to linear constraints. Such a problem can be restated as an integer program whenever x is bounded by setting

$$c(x_i) = c_i x_i + f_i y_i$$
$$x_i \leq U_i y_i, \quad y_i = 0 \text{ or } 1$$

where U_i is an upper bound of x_i.

By far the most important special case of integer programming is the *0–1 programming problem*, in which the integer-constrained variables are restricted to 0 or 1. This is so because a host of frequently occurring nonlinearities, like logical alternatives, implications, precedence relations, etc., or combinations thereof, can be formulated via 0–1 variables. For example, a condition like

$$x > 0 \Rightarrow (f(x) \leq a \vee f(x) \geq b),$$

where a and b are positive scalars, x is a non-negative variable with a known upper bound M, $f(x)$ is a function whose value is bounded from above by $U > b$ and from below by $L < a$, while the symbol '$\vee$' means disjunction (logical 'or'), can be stated as

$$x \leq M(1 - \delta_1)$$
$$F(x) \leq a + (U - a)\delta_1 + (U - a)\delta_2$$
$$F(x) \geq b + (L - a)\delta_1 + (L - b)(1 - \delta_2)$$
$$\delta_1 \delta_2 = 0 \text{ or } 1$$

A linear program with *logical* conditions (conjunctions, disjunctions and implications) involving inequalities is called a *disjunctive program*, since it is the presence of disjunctions that

makes these problems nonconvex. Bounded disjunctive programs can be stated as 0–1 programs and vice versa, but the disjunctive programming formulation has led to new methods.

Nonconvex optimization problems like bimatrix games, separable programs involving piecewise linear nonconvex functions, the general (nonconvex) quadratic programming problem, the linear complementarity problem and many others can be stated as disjunctive or 0–1 programming problems.

A host of interesting combinatorial problems can be formulated as 0–1 programming problems defined on a graph. The joint study of these problems by mathematical programmers and graph theorists has led to the recent development of a burgeoning area of research known as *combinatorial optimization*. Some typical problems studied in this area are: edge matching and covering, vertex packing and covering, clique covering, vertex colouring; set packing, partitioning and covering; Euler tours; Hamiltonian cycles (travelling salesman problem).

Applications of integer programming abound in all spheres of decision making. Some typical real-world problem areas where integer programming is particularly useful as a modelling tool include: facility (plant, warehouse, hospital, fire station) location; scheduling (of personnel, machines, projects); routing (of trucks, tankers, airplanes); design of communication (road, pipeline, telephone) networks; capital budgeting; project selection; analysis of capital development alternatives.

Solution Methods

Integer programs are notoriously hard to solve. Unlike linear programs, which are always solvable in a number of steps bounded by a polynomial function of the length of the data input, integer programs often require a number of steps that grows exponentially with problem size. However, sometimes an integer program (P) can be solved as a linear program; i.e., solving the linear program (L) obtained by removing the integrality constraints from (P), one obtains an integer solution. In particular, this is the case when all basic solutions of (L) are integer. For an arbitrary integer vector b, the constraint set $Ax \leq b$, $x \geq 0$ is known (Hoffman and Kruskal 1958) to have only integer basic solutions if and only if the matrix A is totally unimodular (i.e. all nonsingular submatrices of A have a determinant of 1 or -1).

The best known instances of total unimodularity are the vertex-edge incidence matrices of directed graphs and undirected bipartite graphs. As a consequence, shortest path and network flow problems on arbitrary directed graphs, edge matching (or covering) and vertex packing (or covering) problems on bipartite graphs, as well as other integer programs whose constraint set is defined by the incidence matrix of a directed graph or an undirected bipartite graph, with arbitrary integer right-hand side, are in fact linear programs.

Apart from this important but very special class of problems, and a few other special classes, the difficulty in solving integer programs lies in the nonconvexity of the feasible set, which makes it impossible to establish global optimality from local conditions. The two main approaches to solving integer programs try to circumvent this difficulty in two different ways.

The first approach, which in the current state of the art is the standard way of solving general integer programs, is *enumerative* (branch and bound, implicit enumeration). It partitions the feasible set into successively smaller subsets, calculates bounds on the objective function value over each subset, and uses these bounds to discard certain subsets from further consideration. The procedure ends when each subset has either produced a feasible solution, or was shown to contain no better solution than the one already in hand. The best solution found during the procedure is a global optimum. Two early prototypes of this approach are due to Land and Doig (1960) and Balas (1965).

The second approach, known as the cutting plane method, is a *convexification* procedure: it approximates the convex hull of the set F of feasible integer points, by a sequence of inequalities that cut off (hence the term ‘cutting planes’) parts of the linear programming polyhedron, without

removing any point of *F*. When sufficient inequalities have been generated to cut off every fractional point better than the integer optimum, then the latter is found as an optimal solution to the linear program (L) amended with the cutting planes. The first finitely convergent procedure of this type is due to Gomory (1958).

Depending on the type of techniques used to describe the convex hull of *F* and generate cutting planes, one can distinguish three main directions in this area. The first one uses algebraic methods, like modular arithmetic and group theory. Its key concept is that of subadditive functions. It is sometimes called the algebraic or group theoretic approach. The second one uses convexity, polarity and propositional calculus. Its main thrust comes from looking at the 0–1 programming problem as a disjunctive program. It is known as the convex analysis/disjunctive programming approach. Finally, the third direction applies to combinatorial programming problems, and it combines graph theory and matroid theory with mathematical programming. It is sometimes called polyhedral combinatorics.

Besides these two basic approaches to integer programming (enumerative and convexifying), two further procedures need to be mentioned, that do not belong to either category, but can rather be viewed as complementary to one or the other. Both procedures essentially *decompose* (P), one of them by partitioning the variables, the other one by partitioning the constraints. The first one, due to Benders (1962) eliminates the continuous variables of a mixed integer program (P) by projecting the feasible set *F* into the subspace of the integer-constrained variables. The second one, known as Lagrangean relaxation, removes some of the constraints of (P) by assigning multipliers to them and taking them into the objective function.

Each of the approaches outlined here aims at solving (P) exactly. However, since finding an optimal solution tends to be expensive beyond a certain problem size, approximation methods or *heuristics* play an increasingly important role in this area.

At present all commercially available integer programming codes are of the branch and bound type. While they can *sometimes* solve problems with hundreds of integer and thousands of continuous variables, they cannot be *guaranteed* to find optimal solutions in a reasonable amount of time to problems with more than 30–40 variables. On the other hand, they usually find feasible solutions of acceptable quality to much larger problems.

A considerable number of specialized branch and bound/implicit enumeration algorithms have been implemented by operations research groups in universities or industrial companies. They usually contain other features besides enumeration, like cutting planes and/or Lagrangean relaxation. Some of these codes can solve general (unstructured) 0–1 programs with up to 80–100 integer variables, and structured problems with up to several hundred (assembly line balancing, multiple choice, facility location), a few thousand (sparse set covering or set partitioning, generalized assignment), or several thousand (knapsack, travelling salesman) 0–1 variables.

At the current state of the art, while many real-world problems amenable to an integer programming formulation fit within the stated limits and are solvable in useful time, others substantially exceed those limits. Furthermore, some important and frequently occurring realworld problems, like job shop scheduling and others, lead to integer programming models that are almost always beyond the limits of what is currently solvable. Hence the great importance of approximation methods for such problems.

Integrability of Demand

Donald W. Katzner

Abstract

Integrability of demand arguments start with consumer demand functions having properties that would be implied by constrained utility maximization were they generated from that source. Using a process of mathematical integration, the arguments then proceed to demonstrate the existence of utility functions from which those demand functions could be derived.

Keywords

Demand function; Integrability of demand; Marginal rate of substitution; Revealed preference; Slutsky substitution functions; Utility function

The lines of reasoning linking individual (ordinal) utility functions (or preference orderings) to individual demand functions run in both directions. Progressions from the former to the latter often begin with assumptions about the characteristics of a consumer's utility function and the requirement that he or she always chooses so as to maximize utility subject to a budget constraint, and then go on to derive the demand functions and the properties of those demand functions that logically ensue from such premises. Depending on context, certain of the properties of the demand functions so derived are expressed in differential terms (that is, symmetry and negative definiteness of matrices of Slutsky substitution functions where the latter are defined) or in discrete revealed preference form (for example, weak and strong axioms of revealed preference). The reverse course takes the individual's demand functions and their properties as given and determines the existence of a utility function from which, upon constrained maximization, the original demand functions could have been generated. In this second case, when the starting point includes the differential rather than revealed preference properties of demand, the argument often involves (in part) the integration of a system of one or more differential equations. Hence the name 'integrability of demand' affixed to it.

There are several ways to structure an integrability of demand argument. Perhaps the most straightforward approach (the only one considered in detail here) is simply to backtrack over the path that yields demand functions from utility functions via the theorem of Lagrange on maximization subject to constraint. That path may be summarized as follows. Begin with a utility function $\mu = u(x)$ defined over the commodity space $\{x : x \geq 0\}$, where $x = (x_1,\ldots,x_I)$ is a vector of quantities of commodities x_i and $x \geq 0$ means $x_i \geq 0$ for every $i = 1,\ldots, I$. Let $u_i(x)$ be the partial derivative of the utility function u with respect to its i^{th} argument. For each vector $(p, m) > 0$, where $p = (p_1,\ldots, p_I)$, p_i is the price of good i, and m is a scalar denoting the consumer's income, vectors $x > 0$ that maximize $u(x)$ subject to the budget constraint $\sum_{i=1}^{I} p_i x_i = m$ are, according to Lagrange's theorem, characterized by

$$\frac{p_i}{p_I} = \frac{u_i(x)}{u_I(x)}, \qquad i = 1,\ldots,I-1, \tag{1}$$

$$\frac{m}{p_I} = x_I + \sum_{i-1}^{I-1} \frac{u_i(x)}{u_I(x)}\, x_i. \tag{2}$$

Equations (1) state that, at a constrained maximum, the marginal rates of substitution or the negatives of the partial derivatives of indifference functions equal the price ratios, and Eq. (2) is a form of the budget constraint. Equations (1) and (2) together may be thought of as a system of inverse functions which are solved to secure demands x_i as functions h^i, of prices and income:

$$x_i = h^i\left(\frac{p_1}{p_I},\ldots,\frac{p_{I-1}}{p_I},\frac{m}{p_I}\right), \quad i = 1,\ldots,I. \tag{3}$$

Evidently, (3) may be written in the equivalent form

$$x_i = H^i(p,m), \qquad i = 1,\ldots,I,$$

where $H^i(p, m) = h^i(p_1/p_I,\ldots,p_{I-1}/p_I, m/p_I)$ and H^i is homogeneous of degree zero. Of course, sufficient properties have to be imposed on u so as to ensure the existence of a usually unique constrained maximizing x for each $(p, m) > 0$, and these properties, in turn, imply the well-known characteristics of the h^i or the H^i.

Consider now an integrability of demand argument that reverses the above steps. Start with the demand functions (3) having all of the properties that would be implied by constrained utility maximization were they determined as previously described. The aim is to show the existence of a utility function generator of these demand functions. Clearly, for this latter utility function to generate the h^i, it must exhibit properties such as those stated above that yield unique constrained maxima. Backtracking from (3), solve for price–price and income–price ratios as functions, g^i, of x:

$$\frac{p_1}{p_I} = g^i(x), \qquad i = 1,\ldots I-1, \tag{4}$$

$$\frac{m}{p_I}\, g^I(x). \tag{5}$$

If the h^i are to be derivable from constrained utility maximization, then the g^i of (4) should indicate the negatives of the partial derivatives of appropriate indifference functions and g^I should be related to the budget constraint; that is, Eq. (4) should correspond to Eq. (1), and Eq. (5) to Eq. (2). But to say that the g^i are the negatives of the partial derivatives of indifference functions means that

$$\frac{\partial x_1}{\partial x_i} = -g^i(x), \quad i = 1,\ldots,I-1. \tag{6}$$

Thus, at every $x > 0$, the 'slopes' of the indifference surface through x in the direction of each of the coordinate axes are given by the g^i, for $i = 1,\ldots,I-1$. Integrating the differential equation system (6) 'fits' all of these slopes for each surface together to form an indifference map from which a utility function is deduced (It is possible to integrate alternative, though related, systems of differential equations which yield the utility function directly). It should be noted, however, that the mathematics employed in this integration process usually shows only that such an indifference map, and hence a utility function, exists and typically does so without providing the means to specify the exact forms it will take. Lastly, the appropriate general characteristics of this utility function and the fact that its constrained maximization produces the original demand functions (3) are established.

Naturally, the properties of the demand functions h^i are crucial for such an integrability of demand argument to hold up. Among other things, these properties must permit the inversion of the h^i into the g^i and must ensure that the integration step can be carried out. Invertibility means that the h^i specify a 1–1 correspondence between values of the vectors $x = (x_1,\ldots,x_I)$ and $(p_1/p_I,\ldots,p_{I-1}/p_I, m/p_I)$. For the integration of (6) it is necessary that the g^i be continuous and, when $I > 2$, that a certain 'integrability' condition be satisfied. This guarantees that at least one indifference surface passes through every $x > 0$. To make certain that no more than one indifference surface passes through each x, a Lipschitz condition has to be in force. It turns out that the g^i are continuous as long as the h^i are continuous, that the integrability condition is equivalent to the existence and symmetry, for all $(p, m) > 0$, of the matrix of Slutsky substitution functions, and

that the Lipschitz condition is implied if certain partial derivatives of the g^i are bounded. All of these properties of demand functions except the last two are derivable from the constrained maximization of utility functions that are twice continuously differentiable, increasing, strictly quasiconcave, and whose indifference surfaces do not touch the boundaries of the commodity space (Although such utility-function characteristics imply symmetry of the matrix of Slutsky substitution functions, they do not guarantee that those functions, and hence the matrix, will be defined everywhere). Even so, the properties of demand functions obtained from such utility functions are still 'roughly' sufficient to support the integrability of demand argument outlined above.

Problems arise when the properties of demand functions are derived from utility functions with modified characteristics. For example, the previously mentioned 1–1 correspondence may not appear in the h^i and hence invertibility from the h^i to the g^i may break down. In such a situation it is possible to restructure the integrability of demand argument to avoid the invertibility issue at the level of the h^i altogether. Since it turns out that the demand functions $H^i(p, m)$ may also be viewed as partial derivatives with respect to p_I of the expenditure or income compensation function (obtained in the progression from utility to demand by minimizing expenditure for a given level of utility)

$$m = E(p, \mu),$$

where μ varies over all utility levels and p ranges over all vectors $p > 0$, this is accomplished by integrating the system

$$\frac{\partial m}{\partial pi} = H^i(p, m), \quad i = 1, \ldots, I, \tag{7}$$

and converting the resulting expenditure function into a utility function. Once again the appropriate characteristics of the derived utility function have to be established, constrained maximization of it has to produce the given H^i, and enough properties of the H^i need to be present to sustain the argument.

Antonelli (1886) is usually credited with introducing economists to the integrability of demand argument. He began with the functions g^i and obtained a utility generator by integrating a system of differential equations related to (6). Many years later in a mathematical appendix, Samuelson (1950) inverted the h^i and then secured an indifference map by integrating another differential equation related to (6). In between, Antonelli's work seems to have been almost forgotten. Fisher (1892) independently 'rediscovered' the integrability problem in his doctoral dissertation, and various aspects of it were taken up subsequently by Pareto (1906a, b), Volterra (1906), Allen (1932), Georgescu-Roegen (1936), Wold (1943, 1944), and others. It is interesting that Volterra's contribution was to point out that, in Pareto's initial (1906a) discussion of integrability for the case of more than two goods (that is, in the first edition of his *Manuale*), the integrability condition had been conspicuously omitted. More detailed history is given by Samuelson (1950) and Chipman et al. (1971, intro. to Part II). Hurwicz and Uzawa (1971) were the first to structure an integrability of demand argument based on the integration of (7).

Intellectual Property

Michele Boldrin and David K. Levine

Abstract

Intellectual property refers to patents, copyrights, trademarks and other forms of ownership of ideas. It results in monopoly power that has significant consequences for discouraging as well as encouraging innovation and growth. The discouragement effect is especially important when ideas are used as building blocks for other ideas. The economics literature has examined the need for intellectual property; optimal systems of intellectual property; the optimal duration of intellectual property; how innovation takes place in the absence of intellectual property; and the rent-seeking behaviour induced by intellectual property.

Intellectual property refers to patents, copyrights, trademarks and other forms of ownership of ideas. While property and ownership are not controversial topics among economists, patents and copyrights have long been. By contrast, trademarks – serving merely to identify individuals and businesses – are not controversial. The economic analysis of patents and copyrights applies also to a variety of private contractual arrangements that are used to enforce 'intellectual property' such as non-disclosure agreements, no-compete contract clauses, and software shrink-wrap agreements.

The controversy surrounding patents and copyright has both theoretical and policy relevance. The theoretical relevance arises because models of economic growth, trade, and industrial regulation all put innovative activity at their core. Two fundamental views of innovation have been advanced. In the first, which can be traced back to Arrow (1962) and has recently been developed by Romer (1986, 1990), it is abstract ideas that matter. These are produced subject to fixed costs that cannot be recouped under competition because, once discovered, ideas are non-rivalrous and infinitely reproducible at constant marginal cost, which is often treated as equal to zero. In the second, traces of which are found in Schumpeter (1911), Plant (1934) and Stigler (1956), and is formalized by Boldrin and Levine (2003), it is the concrete embodiment of copies of ideas that has economic value. Embodied ideas are initially characterized by indivisibility, but their reproduction is limited by capacity constraints; the latter generate competitive rents that may cover the indivisibility cost, hence ideas can be produced and traded under competition.

From both perspectives, 'intellectual property' is a grant of monopoly power over the right to make copies of ideas, and not simply the extension of 'normal' property rights to the realm of ideas. The first view argues in favour of intellectual property not because it is property and serves to protect the value of individual investment, but

rather because monopoly over ideas can be a good thing. This argument has recently been linked, by such authors as Aghion and Howitt (1992) or Grossman and Helpman (1991), to a Schumpeterian theme (Schumpeter 1942). It posits a trade-off between 'static efficiency', which requires competition, and 'dynamic efficiency', which can be achieved only through technological progress driven, in turn, by the desire to acquire a monopoly. In this view it is monopoly power that drives the innovative process.

On the policy side, intellectual property has become controversial largely because of three developments. The first is the high price and restrictive policies of pharmaceutical companies, for example with regard to AIDS drugs. Second is the damaging impact of intellectual property on the growth perspectives of the less developed countries, especially when they are denied free trade with the more developed ones unless they adopt strict standards for intellectual property. Third is the impact of the internet on the 'piracy' of music, books and movies.

On one side of the policy debate stand those who benefit from existing monopolies and are eager to protect their way of doing business, arguing typically that their 'property' should be protected from 'theft'. On the other side is a broad array of people who resent having the free use of their copies of ideas restricted by creators.

The central issue is whether the monopoly power achieved through copyrights and patents is truly necessary, in the words of the US Constitution, 'To promote the progress of science and useful arts' or whether it in fact hinders progress and innovation.

Optimal Systems of Intellectual Property

A key question is what an optimal system of intellectual property looks like. Most research has focused on patents, and much attention has been devoted to the issue of the breadth versus the duration of patents – that is, whether long but narrow patents are preferable to short but broad ones. The seminal paper on the subject is that of Gilbert and Shapiro (1990), which models breadth as a price ceiling limiting the patent holder's ability to price at the full monopoly price. In the Gilbert–Shapiro setup, the conclusion is that optimal patents should be as long and narrow as possible. Subsequent authors have contested this conclusion – Gallini (1992), in particular, argues that the model of 'breadth' as a price ceiling does not reflect what 'breadth' is likely to mean in practice, and that a more reasonable model of breadth leads to the opposite conclusion. Subsequent work by Gallini and Scotchmer (2001) concludes that optimal patent protection should probably be broad but short.

Recent research, for example by Hopenhayn and Mitchell (2001), has examined the possibility of providing not a single breadth-cum-duration for all patents, but rather allowing patent applicants to select from a menu of alternatives: some might choose broad but short, others narrow but long. They show that a properly calibrated system of this type can be superior to a one-size-fits-all system.

Many of these models recognize that innovators will earn something even without patent protection, and it is generally true in these models that if enough rents are earned without patents the optimal system is to have no patents at all. From the perspective of designing a system, this answer – no patents – is not interesting, and for understandable reasons this case tends to be underplayed. However, while how not to design a patent system may be less intellectually challenging than how to design one, the case in which adequate rents are earned without patents may well be empirically more relevant.

Optimal Duration of Intellectual Property

Quite apart from the details of system design, the question arises of how much protection an IP system should provide. Why, for example, should monopoly be limited rather than unrestricted? Answering this question requires trading off the monopoly power created by intellectual property against the incentive to innovate. This issue was first studied in the context of

copyrights by Ian and Waldman (1984). They examine a model in which 'innovation' has the dimension of higher product quality. However, they assume away the harmful effects of monopoly power by assuming that demand is completely elastic up to an upper bound. Not surprisingly, in this setting stronger intellectual property is unambiguously good. Beginning with Liebowitz (1985), Stan Liebowitz has also extensively studied copyrights; focusing largely on a single creation, he argues that the indirect appropriability of competitive rents is generally an inadequate incentive to create.

More recently, Grossman and Lai (2004) and Boldrin and Levine (2005a) have examined a general equilibrium setting in which ideas of different quality are produced. Both papers show that optimal protection is generally limited rather than unlimited; and, because markets are growing over time, they consider the consequences of expanded markets for optimal protection. Boldrin and Levine show that optimal protection always declines when the market is large enough. They also give an elasticity condition under which protection should always decline with market size and, based on examination of existing data, conclude that this condition is likely to be satisfied in practice. This empirical analysis builds heavily on an empirical literature, stemming from Pakes (1986), that tries to estimate the distribution of patent values by examining such things as patent renewal rates.

Patent Races

Some time ago, theoretical work focused on patent races, in which firms over-invest in R&D in an effort to obtain a valuable patent before a rival. Fudenberg et al. (1983) and Harris and Vickers (1985) are two of the earliest papers on these lines. Contrary to the traditional problem of too little innovation, this line of research suggests that the desire to acquire the monopoly power that patents confer may encourage too much expenditure in wasteful R&D. These models seem to have fallen out of favour in recent years, perhaps because there is little empirical evidence that patent races are quantitatively important in determining the pace of actual technological innovation. The fact that legal battles over patents have become a persistent feature of contemporary business strategy may well restore currency to a modified version of these models.

Ideas as Building Blocks

One critical element of innovation – and artistic creation as well – is that new ideas are generally built upon existing ideas. That this is true for patentable innovations is fairly obvious (in the realm of copyright see Lessig 2004, and Vaidhyanathan 2003). Scotchmer (1991) points out that strong patent protection can have the dual effect of increasing the return to innovation and at the same time increasing the cost of acquiring the rights needed to innovate. This point is developed further in Boldrin and Levine, who show that under certain conditions a patent system may serve only to discourage innovation (2003), and that, when the innovator is better informed about the value of a new idea than the holders of rights to previous ideas, a patent system serves strictly to discourage innovation (2005b). Intuitively, all the additional profit from the new innovation is absorbed by the existing rights holders; if there are many of them, there is a public goods problem, with each 'little monopolist' setting a price that is too high because much of the cost of decreased likelihood of innovation is borne by the other 'little monopolists'. This type of holdup problem is not dissimilar to the problem pointed out by Chari and Jones (2000) in the context of externalities more broadly; interestingly, in this case externalities are created by the existence of intellectual property, and would be altogether absent without it.

The practical impact of intellectual property in a setting where the use of existing ideas is important is well documented by Bessen and Hunt (2003), who examine the software industry in the United States during the era of personal computers; they find that intellectual property has been antithetical to innovation in this industry.

The role of transactions costs that arise when it is necessary to acquire many rights in order to innovate is underlined by David Friedman's (1994) striking hypothetical example of what

would happen if every word in the English language was copyrighted, so that any writer had to pay for each use of every word.

Competitive Innovation

Since there is a well-documented downside to intellectual property, it is important to understand how markets might function in its absence. Arnold Plant and George Stigler, among others, provide important examples of innovation and creation taking place without the benefit of monopoly. Plant (1934, p. 173) writes that, although in the 19th century English authors could not copyright their works in the United States,

> . . . American publishers found it profitable to make arrangements with English authors . . . English authors sometimes received more from the sale of their books by American publishers, where they had no copyright, than from their royalties in [England].

Similarly, Stigler (1956, p. 274) argues that monopoly is completely unnecessary to provide incentives for innovation.

> There can be rewards – and great ones – to the successful competitive innovator. For example, the mail-order business . . . The innovators . . . were Aaron Montgomery Ward, who opened the first general merchandise establishment in 1872, and Richard Sears . . . Sears soon lifted his company to a dominant position by his magnificent merchandising talents, and he obtained a modest fortune, and his partner Rosenwald an immodest one. At no time were there any conventional monopolistic practices, and at all times there were rivals within the industry and other industries making near-perfect substitutes . . .

In more recent times, Liebowitz (1985), Boldrin and Levine (2003), Quah (2002), Legros (2005), and Hellwig and Irmen (2001) have all examined the competitive rents that accrue to innovators due to 'limited capacity' – the fact that in a competitive market the owners of a fixed factor (first copy of an idea) are the recipients of all downstream rents originating from it, and that an infinite number of copies cannot be made instantaneously. The conclusion is that innovation will take place even without intellectual property – as it often has in the past (see for example the cases mentioned by Moser 2002). While some of this work shows that there may be too little innovation under competition due to the indivisible nature of the initial copy of ideas, it also suggests that the appropriate remedy is unlikely to be a government-granted monopoly.

In modern times, evidence that patents are unnecessary to provide the adequate incentive to innovate can be found in the widespread cross-licensing agreements found in chip manufacturing. The evidence is discussed by Shapiro (2001), who argues that the sharing of information between chip firms is much more important to them than any short-term advantage gained through a patent, and the primary function of patenting in this industry is to block entry by potential rivals.

First-Mover Advantage

Regardless of the presence of competitive rents, an innovator is likely to have a substantial advantage by being first to the market. This is largely what Plant and Stigler had in mind. The important impact of first-mover advantage in the market for new types of financial securities prior to the advent of patents in that industry has been ably documented by Tofuno (1989), and the theory explained carefully, together with further evidence, by Herrera and Schroth (2002, 2003).

Besides the temporary monopoly that results from being first, there are less obvious advantages. Hirshleifer (1971) first, and Anton and Yao (1994) subsequently, show how advance knowledge of an innovation can give an edge in asset markets. This can be illustrated through the example of the 'Segway' scooter – much publicized when it was introduced as a revolution in transportation. Suppose for the moment that these claims were true: how could the inventor have profited from this information without – as he did – surrounding himself with a thicket of patents? The Hirshleifer scheme would see him selling short automobile stocks, which would drop through the floor as soon as he announced his discovery. The Anton–Yao scheme would have the inventor sell the idea to, say, Ford in exchange for a share of the profits. Since he would share the

profits, he would then have no incentive to try to sell the idea to other automobile companies, and so Ford would be happy to pay for the resulting monopoly. If it simply took the idea without paying, Ford would lose the monopoly when the inventor told the other companies how to build Segways. Along similar lines, Baccara and Razin (2004) have developed a bargaining model for the case when the inventor must share the idea with others to implement it, and the latter can 'run away' after the idea is revealed. Even in the absence of any intellectual property, as the idea is revealed to more and more people and market power dilutes, the 'threat of competition' is enough to make the collaborator comply and to guarantee the innovator a substantial (larger than one-third) share of the surplus.

Rent Seeking

The most significant downside of government grants of monopoly is the rent seeking they trigger. For example, although they have a generally favorable view of patents, historical research by Lamoreaux and Sokoloff (2001) shows that tightening of patent law resulted in a large upswing in innovation – presumably because it eliminated the nuisance of 'submarine' and other patents designed to appropriate value from the true innovators.

Outside the direct line of those whose existing way of business is threatened by innovation, enormous concern has been expressed at the consequences of rent seeking for the limitations it imposes on personal liberty and the threat it poses to economic progress. For example, the efforts of large media giants to 'protect' their 'intellectual property' through government-mandated hardware installed in computers poses a significant threat to innovation in the much larger IT industry.

Throughout history governments with little ability to monitor transactions and collect tax revenue have often fallen back on grants of monopoly to private individuals. Current patent and copyright systems seem to be remnants from this era, and many economists wonder if it is not time to replace them with more efficient modern systems of graduated incentives such as tax subsidies.

Intellectual Property, History of

Zorina Khan

Abstract

The evolution of patents and copyrights followed different paths over time and across countries. Initially, intellectual property rules were endogenously determined according to social and economic priorities in each society. International patent laws subsequently were heavily influenced by early American policies that favoured the rights of original inventors. By contrast, US copyrights were among the weakest in the world; international copyright laws converged towards European doctrines that were based on non-economic rationales for inherent authors' rights. The intellectual property system in the 21st century therefore constitutes an anomaly, since previously no country simultaneously adhered to strong patent rights and strong copyrights.

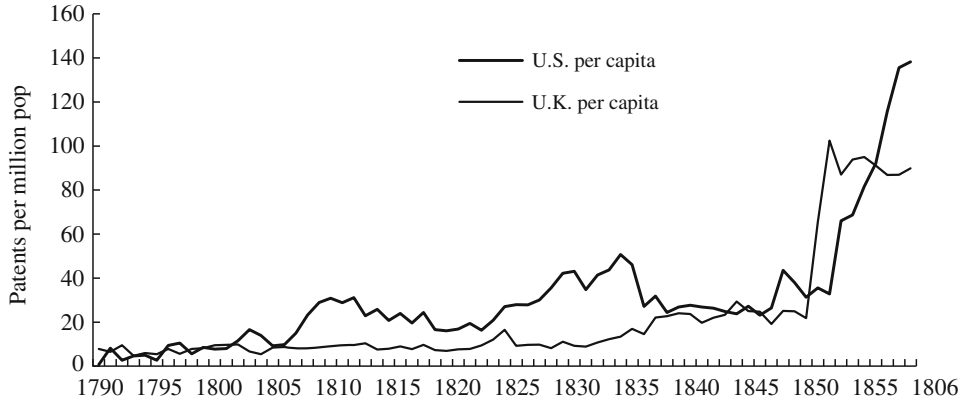
Intellectual property rights primarily have their origins in 15th-century monopoly privileges granted in Europe. Specific features of these rights of exclusion varied enormously and some constituted broad national claims that existed in perpetuity. By the 18th century, such differentiated privileges had evolved into standardized legal rights whose boundaries were delimited by statute. Most notably, the British Statute of Monopolies (1624) and the Statute of Anne (1710) established the longest continuous intellectual property system in existence. In Europe the philosophy and enforcement of intellectual property laws, the structure of patent and copyright systems, and the resulting patterns of invention (broadly defined to include technological and cultural creations) were all consistent with the oligarchic structure of these societies.

European patents were viewed as 'pernicious monopolies', which had to be narrowly interpreted, monitored, and restricted. This perspective was reinforced by the grant of patents to anyone who paid the exceedingly high fees, regardless of whether they were true inventors. The Crown reserved the right to expropriate any innovations that it wished, and kept others secret. Few provisions were made to ensure ready access to information. The legal system was biased against patents in general, and incremental improvements in particular. High transactions and monetary costs, as well as the prevailing prejudices towards non-elites, combined to create barriers to entry that discouraged the poor or disadvantaged from making contributions to technological innovation. Markets in patent rights and in patented inventions were thin and risky. As a result, trade secrecy probably played a more prominent part in protecting new discoveries, diffusion was certainly inhibited, the distribution of inventors and inventions was skewed, and potential inventors faced a great deal of uncertainty.

The elites who were privileged by these biases had little inducement to adopt institutional reforms that might generate social benefits at their expense. Administrators and patent agents lobbied against amendments and many had to be compensated for their lost rents before the system could be revised. Thus, despite their inefficiencies, patent rules and standards in both France and England remained essentially unchanged for stretches of over 100 years. In Britain, patent grants favoured a narrow range of capital-intensive industries and unbalanced growth paths. Clearly, despite these drawbacks, European economies still experienced industrialization and expansion; nevertheless, total factor productivity gains were quite modest and Britain was unable to sustain its initial advantage. Indeed, the record for Britain and other countries suggests that patent systems and their specific rules and standards had a significant effect. As Fig. 1 shows, when Britain reformed its laws in line with the United States in 1852 and 1883, patenting rates immediately increased. Similarly, Swiss patent reforms in the 1880s and Taiwanese revisions in the 1980s changed the rate and direction of their inventive activity (Khan 2005; Lo 2005).

In the United States policymakers were well aware of the European experience. They carefully weighed the grant of intellectual property rights against alternative strategies such as state subsidies and prizes. Legislators did not shrink from novel approaches, which they estimated would increase social welfare, regardless of how great the popular outcry. In accordance with the US Constitution, the utilitarian objective of the intellectual property system was to promote the public welfare. Patent and copyright laws were clearly distinguished in separate statutes in 1790, and developed along diametrically different lines based on a rational assessment of their costs and benefits.

The leading industrial nations acknowledged that patent rights might increase the rate of invention, but it was less conventional to propose that the background or the identity of inventors was irrelevant to their productivity. The US patent system exemplified one of the country's most democratic institutions, offering secure property rights to true inventors, regardless of colour, marital status, gender, or economic standing. Patent data, when linked to biographical information,



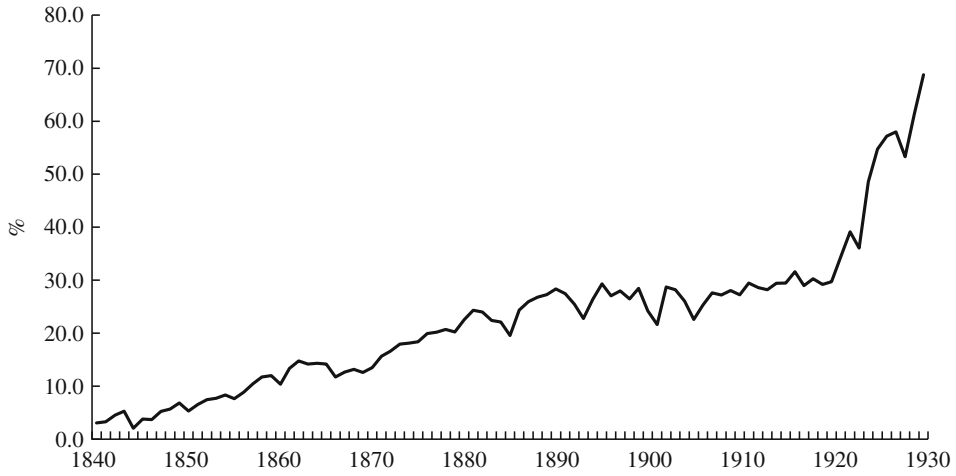
Intellectual Property, History of, Fig. 1 Patents per capita issued in Britain and the United States, 1790–1860 (*Source:* Khan (2005))

show that the expansion of markets and profit opportunities stimulated increases in inventive activity by attracting wider participation from relatively ordinary individuals. The roster of patentees included not only scientists and engineers, but also senators, schoolteachers, housewives, and even economists. The characteristics and patterns of patenting for American ' great inventors' were strikingly similar to those of ordinary patentees, unlike Europe where inventors were much more likely to be drawn from the elites.

Such patterns were due in part to the conscious design of US patent institutions to ensure open access. These included transparent rules and administration, explicit measures for the diffusion of information, low fees, protection of the rights of the first and true inventor, a centralized examination system, and a legal system that balanced the rights of patentees with social welfare. American judges understood that secure private property rights and market competition comprised effective counters to oligarchical tendencies. Unlike the situation England, where the Crown reserved the right to expropriate inventions, in the United States even federal government claims could not trump the patentee's property right. The examination system ensured that all inventors were able to secure the services of professional examiners at minimal cost. Patents helped transform inventive ideas into tradeable assets, and this securitization of invention enhanced market efficiency.

The second industrial revolution from 1870 to 1920 was a transitional period that hinted at future changes in the nature and organization of technology. This era is usually characterized as the age of professional, science-based invention conducted by teams in research laboratories. Indeed, formal college education, human capital accumulation, and financial capital mobilization through corporate ties became more important, but relatively uneducated rural inventors were no less likely to produce valuable inventions. By the 1920s the rate of assignments sharply increased (Fig. 2), even as patenting per capita declined (Fig. 3), in part because inventive activity was increasingly conducted within corporations that appropriated returns through alternative strategies. Fig. 3 indicates that per capita patenting by US residents in the 21st century remains lower than during the second industrial revolution, whereas the so-called 'patent explosion' after the 1980s was largely the result of increases in grants to foreign inventors.

The US patent system was soon acknowledged as the most advanced in the world, and other countries drew causal connections between American achievements and its strong protection of patent property. Follower countries such as Germany and Japan patterned their own patent regime after the American model, but they introduced measures that addressed the particular needs of their own societies. These included the likelihood that patents would predominantly be granted to foreigners, the wish to raise revenues, and the



Intellectual Property, History of, Fig. 2 US patents assigned at time of issue as a proportion of all patents granted, 1840–1930 (*Source:* Khan (2005))

need to foster domestic ingenuity. Their patent policies incorporated exemptions to protect social welfare in crucial industries such as food and pharmaceuticals, and restricted monopolistic tendencies through compulsory licensing and working requirements. Still, despite resistance from follower nations, patent harmonization over the 19th and 20th centuries converged towards the American model.

Copyrights

However much they praised and emulated US patent policies, other countries failed to understand the rationale for its copyright policies. The intellectual property clause of the US Constitution was the common source of both patent and copyright doctrines, and the same individuals were responsible for their formulation and implementation. American patent and copyright policies differed precisely because the objective of both systems was to promote the general welfare. This objective required a judicious balancing of private and public interests, the weighing of costs and benefits, and estimations of incentives and outcomes. Interests, costs and incentives differed across technical inventions and cultural goods, and also altered over time. Intellectual property adapted

endogenously to meet these changing circumstances in a way that contrasted directly with the institutional sclerosis in Europe.

The rationale for US copyrights was not based on European notions of inherent rights of personhood but, rather, on purely pragmatic and utilitarian grounds. Instead of a bona fide property right, American copyrights often mimicked more limited legal mechanisms such as contract, trade restraint or even liability rules. Americans viewed copyright trade-offs with greater concern. First, the economic processes that produced cultural goods differed from technological innovations: many copyrighted items might be produced even in the absence of financial incentives because their producers could benefit from ancillary returns such as enhanced reputations or greater demand for complementary goods. Second, the risk of unwarranted monopolies was higher, because cultural goods incorporated ideas that belonged to the public domain in ways that made it difficult to distinguish between the contributions of the author and those of society in general. Third, the enforcement of copyright had more serious implications for a democratic society. Restrictions on free diffusion could result in significant social costs in terms of knowledge, education and free speech, in ways that promised to bolster the narrow redistributive claims of elites and interest groups. Although policymakers protected property rights, their primary objective was not to benefit authors or publishing companies per se, so the advantages of a privileged few were circumscribed in order to protect the public domain.

It is, therefore, unsurprising that throughout US history patents were treated differently from copyrights. The first copyright statute granted protection to both ' authors and proprietors' for the instrumental purpose of learning, whereas only the first and true inventor could claim patent rights. Similarly, for much of the 19th century, work-for-hire doctrines led to weak employee rights in the case of copyrights, but not in the case of patents. Copyrights were administered in a registration system and were overturned if authors did not strictly comply with the rules; since 1836 patents were granted through an examination system and could not be revoked except for fraud. Patent policies were hostile to compulsory licences and unauthorized use of patent rights. By contrast, US copyright laws enshrine the world's most pervasive 'fair use' doctrines, which allow free unauthorized access for socially justifiable purposes (such as academic research and education) if such access did not significantly reduce the author's returns.

Although they excelled at pragmatic contrivances, 19th-century Americans were advisedly less sanguine about their efforts in the realm of music, art, literature, and drama, and so the USA was initially a net debtor in flows of material culture from Europe. The first copyright statute recognized this when it authorized international copyright piracy that persisted for a century. Proposals to reform the law were repeatedly brought before Congress and rejected because the net effects for Americans would be 'on the wrong side of the ledger'. It was only in 1891, when the balance of trade in cultural goods was more favourable to the United States, that an international copyright law was finally passed. Even then, the bill almost failed, and its passage required protectionist exemptions in favour of American workers and printing enterprises that remained in place until 1986. This policy was a dramatic departure from the evolution of international copyright laws in European countries. Early on in the 19th century France accorded national treatment to all countries, and led the movement for international harmonization towards strong copyright laws, which culminated in the 1886 Berne Convention. While it took a leadership role in patent conventions, the United Stated did not enter the Berne Convention until 1988, and it still has not completely complied with its provisions.

Today intellectual property rights are at the forefront of economic policy issues for developed and developing countries alike. Questions from four centuries ago are still current, ranging from the philosophical underpinnings of intellectual property to proposals for the abolition of all such rights. A 19th-century economist could assess contemporary policies that substituted tariffs and taxes for revenues to copyright owners, and would have

been equally familiar with analyses about whether uniformity in intellectual property rights across countries benefited global welfare. However, throughout their history, patent and copyright regimes have accommodated 'new eras' that were no less significant and contentious for their time than the 'digital dilemmas' of the 21st century.

Economic history indicates that intellectual property institutions best stimulated early economic growth when they enabled flexible endogenous responses to socioeconomic circumstances. However, the movement to harmonize patent and copyright laws encouraged a 'race to the top': it arose from two separate sources that culminated in stipulations for a system of uniformly strong patents and strong copyrights regardless of the level of economic development. Such a system did not exist anywhere in the world before the late-20th century, when countries enjoyed greater freedom to choose appropriate institutions. The more limited menu of choices today – especially for developing countries but even in the United States – constitutes an economic and historical anomaly.

Intelligence

Herbert Gintis

From the latter half of the 19th century to the Great Depression and the rise of fascism in the 1930s, it was fashionable both in and out of scientific circles to stress the contribution of the genetic worth of individuals and groups to their economic success. This stress was to be as often found among progressives, who used the doctrine to affirm birth control, divorce, and equal educational and economic opportunity for women, as among conservatives, who relied upon eugenic arguments to justify the natural superiority of their favoured social classes, ethic groups, and races. Eugenics, for instance, was supported by such radicals as Havelock Ellis, Beatrice and Sydney Webb and George Bernard Shaw, as well as such conservatives as Francis Galton, Leonard Darwin and Charles Davenport.

Brought into disrepute by its association with Nazism, the notion of genetic destiny resurfaced in the United States in the 1960s as a conservative reaction to the civil rights movement of American blacks (Jensen 1969; Herrnstein 1971; Eysenck 1971). The ensuing flurry of invective and empirical research has generated its proverbial quota of heat, and some light. My assessment of the evidence is that it provides no support for the notion that racial differences in economic success can be

attributed to their genetic inferiority with respect to mental functioning, since no acceptable technique of correcting for environmental differences between distinct racial groups has been devised. This same evidence provides some positive evidence for the effect of genes on economic performance in general, but it is so difficult to separate genetic and environmental factors, even among such relatively restricted samples as monozygotic (identical) twins, that the extent of this effect is unknown. It certainly is not enough to justify the use of the notion of genetic differences in any serious way in the formulation of economic policy.

To illustrate this point, consider one of the most careful and powerful examinations of the role of genes in explaining earnings (Taubman 1976a). Taubman uses a sample of 2468 pairs of monozygotic and dizygotic (fraternal) white male twins, attempting to explain differences in earnings at age 50 using such family background variables as parents' earnings and occupational status. This sample should provide the best possible evidence for or against the role of common genes, since monozygotic twins share all their genes, while dizygotic twins are no more genetically similar than two brothers. Assuming no assortive mating, no sex-linked genes, and no dominant and recessive genes, Taubman finds that the combined family environment explains 54% of the variance in earnings, while other influences explain the remaining 46%. However, depending on the extent to which twins share the same family environment more than two genetically unrelated individuals, the family contribution is apportioned so that the ratio of environmental to genetic factors ranges between 8% and 75%. In a related article (Taubman 1976b) using this sample, Taubman shows that not correcting for family background leads to a severe upward bias in estimating the returns to years of education. But the extent to which this bias is due to genetic as opposed to social factors cannot be ascertained.

It has been suggested (Jensen 1969) that individuals who perform badly on standardized cognitive tests be shunted out of the public educational system on grounds of the efficient application of economic resources. Certainly cognitive performance has been a central determinant of educational attainment in most modern societies. Yet one can show using a representative sample white American males (Bowles and Gintis 1976, pp. 110–12) that the economic return to education does not fall appreciably when cognitive performance is controlled in a regression analysis of earnings and occupational status. Moreover, it can be shown that for the same sample, the observed relationship between social class background and earnings is only in small part due to the tendency of families to pass on IQ differences (Bowles and Gintis 1976, pp. 120–22) either genetically or environmentally.

It is thus safe to say that if all differences in economic achievement were eliminated except for differences in IQ, and if the differences in the latter were maintained at their present level, there would be virtually perfect intergenerational economic mobility. In this sense, arguments which justify economic inequality, either among individuals or between races, on the basis of presumed intellectual differences, must be incorrect.

Interacting Agents in Finance

Cars Hommes

Abstract

Interacting agents in finance represent a behavioural, agent-based approach in which financial markets are viewed as complex adaptive systems consisting of many boundedly rational agents interacting through simple heterogeneous investment strategies, constantly adapting their behaviour in response to new information and strategy performance, and through social interactions. An interacting agent system acts as a noise filter, transforming and amplifying purely random news about economic fundamentals into an aggregate market outcome exhibiting important stylized facts such as unpredictable asset prices and returns, excess volatility, temporary bubbles and sudden crashes, large and persistent trading volume, clustered volatility and long memory.

Interacting agents in finance represent a new behavioural, agent-based approach in which financial markets are viewed as complex adaptive systems consisting of many boundedly rational, heterogeneous agents interacting through simple investment strategies, constantly learning from each other as new information becomes available and adapting their behaviour accordingly over time. Simple interactions at the individual, micro level cause sophisticated structure and emergent phenomena at the aggregate, macro level. Recent surveys of this approach are Hommes (2006) and LeBaron (2006).

The traditional approach in finance is based on a representative, rational agent who makes optimal investment decisions and has rational expectations about future developments. Friedman (1953) made an early, strong argument in favour of rationality, arguing that 'irrational' agents would lose money whereas rational agents would earn higher profits. This is essentially an evolutionary argument saying that irrational agents will be driven out of the market by rational agents. In a perfectly rational world, information is transmitted instantaneously, asset prices reflect economic fundamentals and asset allocations are efficient. In the traditional view, agents interact only through the price system.

In contrast, Keynes earlier stressed that prices of speculative assets are not solely driven by market fundamentals, but that 'market psychology' also plays an important role. Another early critique on perfect rationality is due to Simon (1957), who emphasized that agents are limited in their computing abilities and face information gathering costs. Therefore individual behaviour is more accurately described by simple, suboptimal 'rules of thumb'. Along similar lines, Tversky and Kahneman (1974) in psychology argued that individual decision behaviour under uncertainty can be better described by simple *heuristics* and *biases.* Since the 1990s the traditional view of financial markets has been challenged through developments in bounded rationality (for example, Sargent 1993), behavioural finance (for example, Barberis and Thaler 2003) and computational, agent-based modelling (for example, Tesfatsion and Judd 2006).

Fundamentalists Versus Chartists

Most interacting agents models in finance include two important classes of investors:

fundamentalists and *chartists.* Fundamentalists base their investment decisions upon market fundamentals, such as interest rates, growth of the economy, company's earnings, and so on. Fundamentalists expect the asset price to move towards its fundamental value and buy (sell) assets that are undervalued (overvalued). In contrast, chartists or technical analysts look for simple patterns, for example, trends in past prices, and base their investment decisions upon extrapolation of these patterns. For a long time, technical analysis has been viewed as 'irrational' and, according to the Friedman argument, chartists would be driven out of the market by rational investors. Frankel and Froot (1986) were among the first to emphasize the role of fundamentalists and chartists in real financial markets. Evidence from survey data on exchange rate expectations (for example, Frankel and Froot 1987; Allen and Taylor 1990) shows that at short time horizons (say, up to three months) financial forecasters tend to use *destabilizing*, trend-following forecasting rules, whereas at longer horizons (say 3–12 months or longer) they tend to use *stabilizing,* mean- reverting, fundamental forecasts. Frankel and Froot (1986) argue that the interaction of chartists and fundamentalists amplified the strong rise and subsequent fall of the dollar exchange rate in the mid-1980s.

Another simple interacting agent system with chartists and fundamentalists driven by *herding* behaviour is due to Kirman (1991, 1993). This model was motivated by the puzzling behaviour of ants observed by entomologists. A colony of ants facing two identical food sources distributes asymmetrically, say 80–20 per cent, over the two sources. Moreover, at some point in time the distribution suddenly reverses to 20–80 per cent. Kirman (1993) proposed a simple stochastic model explaining ants' behaviour and applied it to a financial market setting (Kirman 1991). Agents can choose between two investment strategies – a fundamentalist or a chartist strategy– to invest in a risky asset. Two agents meet at random and with some interaction-conversion probability one agent will adopt the view of the other. There is also a small self-conversion probability that the agent will change her view no matter what the other agent believes. It turns out that, when the interaction- conversion probability is relatively high compared with the self-conversion probability, the distribution of agents is bimodal. The behaviour of the agents is very persistent and the market tends to be dominated by one group for a long time, but then the majority of agents suddenly switches to the other view, and so on.

But what about the Friedman argument? Will not 'irrational' technical trading rules be driven out of the market by rational investment strategies? DeLong et al. (1990) presented one of the first models showing that this need not be the case. Their model contains two types of traders, *noise traders,* with erroneous stochastic beliefs, and rational traders who are perfectly rational and take into account the presence of noise traders. Noise traders create extra risk and risk-averse rational traders are not willing to fully arbitrage away the mispricing. Noise traders bear more risk and can earn higher realized returns than rational traders, and therefore noise traders can survive in the long run. Lux (1995) presents a herding model with fundamentalists and chartists, whose behaviour is driven by imitation and past realized returns, leading to temporary bubbles and sudden crashes. Furthermore, Brock et al. (1992) showed empirically, using 90 years of daily Dow Jones index data, that technical trading rules can generate significant above-normal returns.

Markets as Complex Adaptive Systems

Since the end of the 1980s, multidisciplinary research as done at the Santa Fe Institute (SFI) (for example, Anderson et al. 1988) has stimulated a lot of work on interacting agents in economics and finance. Models of interacting particle systems in physics served as examples of how local interaction at the micro level may explain structure, for example a phase transition, at the macro level. This has motivated economists to study *the economy as an evolving complex system.*

Arthur et al. (1997) consider the so-called SFI artificial stock market consisting of an ocean of different types of agents choosing among many

simple investment strategies. Agents' investment decisions are affected by their expectations or beliefs about future asset prices. Beliefs affect realized prices, which in turn determine new beliefs, and so on. Prices and beliefs about prices thus *co-evolve* over time, and agents continuously adapt their behaviour as new observations become available, replacing less successful strategies by more successful ones. Are simple forecasting strategies irrational and will rational traders outperform technical traders in such an artificial market? In general, no. The reason is that a speculative asset market is an *expectations feedback system.* Imagine a situation where an asset price is overvalued and the majority of traders remains optimistic expecting the rising trend to continue. Aggregate demand will increase and as a result the asset price will rise even further. Optimistic expectations thus become *self-fulfilling* and chartists will earn higher realized returns than fundamental traders who sold or shortened the asset because they expected a decline in its price. As long as optimistic traders dominate the market and reinforce the price rise, fundamentalists will lose money. Even when the fundamentalists may be right in the long run, there are 'limits to arbitrage', for example due to short selling constraints, preventing them from holding their positions long enough against a prevailing optimistic view, as stressed by Shleifer and Vishny (1997).

Emergent Phenomena and Stylized Facts

The interacting agents approach has been strongly motivated by a number of important stylized facts observed in many financial time series (for example, Brock, 1997): (*a*) unpredictable asset prices and returns; (*b*) large, persistent trading volume; (*c*) excess volatility and persistent deviations from fundamental value, and (*d*) clustered volatility and long memory. According to (*a*) asset prices are difficult to predict. New information is absorbed quickly in asset prices and there is 'no easy free lunch', that is, arbitrage opportunities are difficult to find and exploit. The traditional rational, representative agent framework can explain (*a*), but has difficulty in explaining the other stylized facts (*b*)–(*d*). In particular, in a world with only rational, risk-averse investors with asymmetric information there can be no trade, because no trader can benefit from superior information since other rational traders will anticipate that this agent must have superior information and therefore will not agree to trade (for example, Fudenberg and Tirole 1991). These no-trade theorems are in sharp contrast to the huge daily trading volume observed in real financial markets, which suggests that there must be other types of heterogeneity such as *differences in opinion* about future movements. Stylized fact (*c*) means that fluctuations in asset prices are much larger than fluctuations in underlying market fundamentals. This point has been emphasized by, for example, by Shiller (1981). When markets are excessively volatile, prices can deviate from their fundamental values for a long time. Stylized fact (*d*) means that price fluctuations are characterized by irregular switching between quiet, low volatility phases, with small price fluctuations and turbulent phases of high volatility and large swings in asset prices. Interacting agent models have been able to explain these stylized facts simultaneously (for example, LeBaron et al. 1999; Lux and Marchesi 1999).

Evolutionary Selection of Strategies

Blume (1993) and Brock (1993) present a general probabilistic framework for strategy selection motivated by results from interacting particle systems in physics (see also Föllmer 1974). The probability of agents using strategy h changes over time according to a random utility fitness measure of the general form

$$U_{ht} = \pi_{ht} + S_{ht} + \varepsilon_{ht}. \tag{1}$$

Here π_{ht} represents *private utility,* for example given by (a weighted average of) realized profit, realized utility or forecasting performance. S_{ht} represents *social utility* measuring herding behaviour or social interactions (see Brock and Durlauf 2001a, b). For example, agents may behave as conformists, that is, they are more likely to follow

strategies that are more popular among the population (global interaction) or among their neighbours (local interaction). Agents observe the performance of each strategy with some idiosyncratic errors, represented by ε_{ht}.

A frequently used model for the probabilities or fractions of the different strategy types is the *discrete choice* or *multinomial logit model*

$$n_{ht} = e^{\beta U_{h,t-1}}/Z_{t-1}, \tag{2}$$

where $Z_{t-1} = \sum_j e^{\beta U_{j,t-1}}$ is a normalization factor so that the fractions add up to one. When the errors ε_{ht} in (1) are independently and identically distributed according to a double exponential distribution, the probability of choosing strategy h is exactly given by (2). The crucial feature of (2) is that, the higher the fitness of trading strategy h, the more agents will select strategy h, and therefore it is essentially an *evolutionary selection* mechanism. Agents are *boundedly rational* and tend to follow strategies that have performed well in the (recent) past. The parameter β is called the *intensity of choice* and is inversely related to the variance of the noise ε_{ht}. It measures how sensitive agents are to selecting the optimal strategy. The extreme case $\beta = 0$ corresponds to noise with infinite variance, so that differences in fitness cannot be observed and all fractions will be equal to 1/H, where H is the number of strategies. The other extreme $\beta = +\infty$ corresponds to the case without noise, so that the deterministic part of the fitness is observed perfectly, and in each period *all* agents choose the optimal forecast. An increase in the intensity of choice β represents an increase in the degree of rationality concerning strategy selection.

Brock and Hommes (1997, 1998) propose a simple, analytically tractable heterogeneous agent model to show how non-rational strategies can survive evolutionary selection. Brock and Hommes (1997) consider a market with an *endogenous evolutionary selection* of expectations rules described by the multinomial logit model (2), with fitness given by past realized profits. Agents choose between a set of different forecasting rules and tend to switch to forecasting strategies that have performed well in the recent past. When agents face information gathering costs, because sophisticated rational strategies are more costly to obtain, simple rule of thumb strategies can survive in this market. In Brock and Hommes (1998) this evolutionary selection of strategies is applied to a standard asset pricing model similar to but much simpler than the SFI artificial stock market. Agents choose between fundamentalists' and chartists' investment strategies. When the sensitivity to differences in past performance of the strategies is high (that is, the parameter β is high), evolutionary selection of strategies destabilizes the system and leads to complicated, possibly chaotic asset price fluctuations around the benchmark rational expectations fundamental price. The fluctuations are characterized by an irregular switching between a quiet phase with asset prices close to the fundamentals and a more turbulent phase with asset prices following (temporary) trends or bubbles. In contrast with Friedman's argument, chartists can survive in this evolutionary competition and may on average earn (short-run) profits equal to or even higher than (short-run) profits of fundamentalists.

A common finding in these models is that more rationality, that is, a larger intensity of choice, leads to *instability.* The intuition is that random choice leads to stability, because agents will be evenly distributed over the strategy space without systematic biases. In contrast, correlated choice may cause instability when, for example, many traders switch to a profitable trend-following strategy. Another common finding is that, when the social interaction effect is strong, multiple equilibria exist and it depends sensitively on the initial state to which of the many equilibria the market system will settle down (for example, Brock and Durlauf, 2001a, b).

Summary and Future Perspectives

Although the approach in finance is relatively new, interacting agent models have been able to explain important stylized facts simultaneously. An interacting agents system acts as a noise filter, transforming and amplifying purely random news about economic fundamentals into an aggregate

market outcome exhibiting excess volatility, temporary bubbles and sudden crashes, large and persistent trading volume, clustered volatility and long memory. It should be emphasized that at the aggregate level these asset price fluctuations are highly irregular and unpredictable, there exists no easy free lunch, and arbitrage will be very difficult and risky in such a market.

Much more theoretical work is needed in this area, for example, to find the 'simplest tractable model' explaining all important stylized facts. Speculative bubbles have been observed in laboratory experiments of Smith et al. (1988) and more recently in Hommes et al. (2005), showing that coordination on trend-following rules can destabilize a laboratory experimental asset market. Another important topic for future research is estimation of interacting agent models on financial data. Boswijk et al. (2007) is one of the first attempts to estimation of an evolutionary model with fundamentalists versus trend-following chartists using yearly S&P 500 data, suggesting that trend-following behaviour amplified the strong rise in stock prices at the end of the 1990s. More laboratory experiments and estimation of interacting agents models are needed to test the robustness and empirical relevance of the interacting agents approach.

Interdependent Preferences

Peter C. Fishburn

JEL Classifications
D7

Interdependent preferences arise in economic theory in the study of both individual decisions and group decisions. We imagine that a decision is required among alternatives in a set X and that the decision will depend on preferences between the elements in X. If the preferences represent different points of view about the relative desirability of the alternatives, of if they are based on multiple criteria that impinge on the decision, then we encounter the possibility of interdependent preferences.

There are two predominant approaches to interdependent preferences, the synthetic and the analytic. The synthetic approach begins with a set of preference relations on X and attempts to aggregate them into a holistic representative preference relation on X. This is done in social choice theory, where each original relation refers to the preferences of an individual in a social group. The aggregate relation is then referred to as a social preference relation. The synthetic approach also appears in studies of individual preferences, as when an individual rank-orders the alternatives for each of a number of criteria and then seeks a holistic ranking that combines the criteria rankings in a reasonable way.

In contrast, the analytic approach begins with a holistic preference relation on X and seeks to analyse its internal structure. This may involve a decomposition into components of preference, or it may concern trade-offs between factors that describe interactive contributions to overall preferences.

The synthetic approach often considers a list $(\gg_1, \gg_2, \ldots, \gg_n)$ of preference relations on X, where $x \gg_i y$ could mean that person i prefers x to y, or that an individual prefers x to y on the basis of criterion i. The problem may then be to specify a holistic relation $\gg = f(\gg_1, \gg_2, \ldots, \gg_n)$ for each possible n-tuple of individual relations.

The analytic approach often begins with X as a subset of the product $X_1 \times X_2 \times \ldots \times X_n$ of n other sets. It considers a holistic *is preferred to* relation $\gg$ on X and asks how $\gg$ depends on the X_i considered separately or in combination. Under suitably strong *independence* assumptions it may be possible to *define* $\gg_i$ for each i in a natural way from $\gg$ on X, and perhaps to establish a functional dependence of $\gg$ on the $\gg_i$. However, interdependencies among the factors will often preclude such a simple resolution.

Historical Remarks

During the rise of marginal utility analysis in the latter part of the 19th century (Stigler 1950), the utility of each commodity bundle in a set $X = X_1 \times X_2 \times \ldots \times X_n$ was thought of as an intuitively measurable quantity. Founders such as Jevons, Menger and Walras regarded x as preferred to y precisely when $u(x)$, the utility of x, is greater than $u(y)$. Their analytic approach ignored interdependencies since they used the independent additive utility form $u(x) = u_1(x_1) + \ldots + u_n(x_n)$.

Later writers such as Edgeworth, Fisher, Pareto and Slutsky discarded the additive decomposition for the general interdependent form $u(x_1, x_2, \ldots, x_n)$. Their ordinalist view of utilities as a mere reflection of a preference ordering remains dominant, and they considered interactive effects among goods, such as complementarities and substitutabilities. A fine example of interdependent analysis appears in Fisher (1892).

Fisher was also one of the first people to mention explicitly the interpersonal effect on individual utility (Stigler 1950, p. 324). This occurs when one's utility and consequent demand depend on other people's consumption and could generally be expressed by $u_i(x_1, \ldots, x_n)$ as consumer i's utility when x_j denotes the commodity bundle of consumer j. Pigou (1903) considered the interpersonal effect in modest detail, and Duesenberry (1949) explored it in greater depth, but it has never been a prominent concern in economic theory.

Early examples of the synthetic approach in social choice theory come from Borda and Condorcet in the late 1700s. They asked: Given a list of voter preference rankings on a set X of $m \geq 3$ nominees, what is the best way of selecting a winner? Borda's answer was to assign $m, m - 1, \ldots, 1$ points to each first, second,..., last place nominee in the rankings and to elect the nominee with the largest point total.

Condorcet advocated the election of a nominee who is preferred by a simple majority of voters to each other nominee in pairwise comparisons. Black (1958) contains an excellent review of their work and the proposals of later writers. The debate over good election methods continues today (Brams and Fishburn 1983).

The turning point for social choice theory was Arrow's (1951) discovery that a few appealing conditions for aggregating individual preference orders on three or more candidates into social preference orders were jointly incompatible. The avalanche of research set off by Arrow's discovery is represented in part by Sen (1970, 1977), Fishburn (1973), Pattanaik (1971), and Kelly (1978).

In the area of risky decision theory, we envision a risky alternative as a probability distribution x on potential outcomes in a set C and observe that such decisions involve multiple factors since they entail both chances and outcomes. Bernoulli (1738) argued that a reasonable person will choose a risky alternative from a set X of distributions that maximizes his expected utility $\sum x(c)\, u(c)$. He proposed that u be assessed without reference to chance since he held an intuitive measurability view of utility. Consequently, his approach is wholly synthetic.

Little changed in the foundations of risky decisions during the next two centuries. Then, in a complete turnabout, von Neumann and Morgenstern (1944) introduced the analytic approach by beginning with a preference relation $\gg$ on X. Axioms for $\gg$ on X were shown to imply the existence of a real valued function u on C such that, for all x and y in X, $x \gg y$ precisely when x has greater expected utility than y, and u is to be assessed on the basis of comparisons between distributions. With a few exceptions, most notably Allais (1953), subsequent research has adopted the von Neumann-Morgenstern approach.

In the rest of this essay we comment further on multiattribute preferences under 'certainty', interdependent preferences in risky decisions, and social choice theory.

Multiattribute Preferences

We assume throughout this section that $\gg$ is a strict preference relation on $X = X_1 \times X_2 \times \ldots \times X_n$. A given X_i could represent amounts of commodity i, consumption bundles available to

person i, levels of income and/or consumption in period i, or values that elements in X might have for criterion i. Also let u on X and u_i denote real valued functions.

A non-empty proper subset N of $\{1, 2, \ldots, n\}$ is defined to be $\gg$-*independent* if, for all x_N and y_N in the product of the X_i over N and for all $z_{(N)}$ in the product of the X_i over i *not* in N,

$$(xN, z(N)) \gg (yN, z(N)) \gg (xN, w(N)) \times \gg (yN, w(N)).$$

Most research for $\gg$ on X involves $\gg$-independence for some N, but this need not exclude elementary notions of preference interdependencies. Two models that presume all N to be $\gg$-independent are the additive model (see Krantz et al. 1971)

$$x \gg y \Leftrightarrow u_1(x_1) + \ldots + u_n(x_n) > u_1(y_1) + \ldots + u_n(y_n),$$

and the lexicographic model (Fishburn 1974a) that places a value hierarchy on the factors.

Relationships between factors in the additive model and the more general model $x \gg y \Leftrightarrow u(x) > u(y)$ with u continuous, are often characterized by indifference maps or iso-utility contours. Interdependence arises in the lexicographic model from the fact that a small change in one factor overwhelms all changes in factors that are lower in the hierarchy.

Situations in which only some of the N are $\gg$-independent are reviewed by Keeney and Raiffa (1976, ch. 3) and Krantz et al. (1971, ch. 7). Among other things, these models allow complete reversals in preferences over one factor at different fixed levels of the other factors. This, of course, is a very strong form of interdependence under which all N may fail to be $\gg$-independent.

Other general models for interdependent preferences are discussed by Fishburn (1972) for finite sets, and by Dyer and Sarin (1979) when u is viewed in the intuitive measurability way.

Models that explicitly incorporate the interpersonal effect in economic analysis have been investigated by Pollak (1976) and Wind (1976), among others. Pollak explores the influence of several versions of interdependence among individuals on short-run and long-run consumption within a group. Using models of demand that are locally linear in others' past consumption, he concludes that the distribution of income need not be a determinant of long-run per capita consumption patterns. Wind's work is representative of empirical approaches to the influence of others on an individual's choice behaviour.

Risky Decisions

Interdependent preferences in risky decisions fall into two categories. The first concerns special forms for $u(c) = (c_1, c_2, \ldots, c_n)$ in the context of von Neumann- Morgenstern expected utility theory when the outcome set C is a subset of a product set $C_1 \times C_2 \times \ldots \times C_n$. The second focuses on changes in the basic model that occur when the independence axiom that gives rise to the expected utility form $\sum x(c)u(c)$ is relaxed or dropped.

Decompositions of $u(c_1, c_2, \ldots, c_n)$ in the expected utility model have been axiomatized by various people. Reviews and extensions of much of this work appear in Keeney and Raiffa (1976) and Farquhar (1978). The simplest independent decompositions are the additive form and a multiplicative form. The first of these requires x and y to be indifferent whenever the marginal distributions of x and y on X_i are the same for every i. The multiplicative form arises when, for each non-empty proper subset N of $\{1, \ldots, n\}$, the preference order over marginal distributions on the product of the C_i for i in N, conditioned on fixed values of the other factors, does not depend on those fixed values.

An example of a more involved interdependent decomposition is the two-factor model (Fishburn and Farquhar 1982) $u(c_1, c_2) = f_1(c_1)g_1(c_2) + \ldots + f_m(c_1)g_m(c_2) + h(c_1)$, which clearly allows a variety of interactive effects.

In the basic formulation for expected utility, assume that X is closed under convex combinations $\lambda x + (1 - \lambda)y$ with $0 < \lambda < 1$ and x and y in

X. The *independence axiom* for expected utility asserts that, for all x, y and z in X and all $0 < \lambda < 1$.

$$x \gg y \Rightarrow \lambda x + (1 - \lambda)z \gg \lambda y + (1 - \lambda)z.$$

Systematic violations of this axiom uncovered in experiments by Allais (1953), Kahneman and Tversky (1979), and MacCrimmon and Larsson (1979) among others, have led to new theories of risky decisions (Kahneman and Tversky 1979; Machina 1982; Chew 1983; Fishburn 1982) that do not assume independence. Machina (1982) proposes a model that approximates expected utility locally but not globally. Fishburn (1982) weakens the usual transitivity and independence assumptions to obtain a non-separable model $x \gg y \Leftrightarrow \varphi(x, y) > 0$ that allows preference cycles.

Related interdependent generalizations of Savage's subjective expected utility model for decisions under uncertainty are developed by Loomes and Sugden (1982) and Schmeidler (1984).

Social Choice

Many problems in social choice theory are related to Condorcet's phenomenon of cyclical majorities. This phenomenon occurs when voters have transitive preferences yet every nominee is defeated by another nominee under simple majority comparisons. The simplest example has three nominees and three voters with $x \gg_1 y \gg_1 z$, $z \gg_2 y$ and $y \gg_3 z \gg_3 x$; x beats y, y beats z, and z beats x. Borda's point- summation procedure can fail to satisfy Condorcet's majority-choice principle, and it is notoriously sensitive to strategic voting. Moreover, all summation procedures based on decreasing weights for positions in voters' rankings are sensitive to nominees who have absolutely no chance of winning, but whose presence can affect the outcome.

Various problems and paradoxes for multicandidate elections that arise from combinatorial aspects of synthetic methods are discussed by Fishburn (1974b), Niemi and Riker (1976), Saari (1982) and Fishburn and Brams (1983). Analyses of strategic voting, which suggest that no sensible election method is immune from manipulation by falsification of preferences, are reviewed in Kelly (1978) and Pattanaik (1978).

Arrow's (1951) theorem offers a striking generalization of Condorcet's cyclical majorities phenomenon. Suppose X contains three or more nominees, each of n voters can have any preference ranking on X, and an aggregate ranking $\gg = f(\gg_1, \gg_2, \ldots, \gg_n)$ is desired for each list $(\gg_1, \gg_2, \ldots, \gg_n)$ of individual rankings. The question addressed by Arrow is whether there is any way of doing this that satisfies the following three conditions for all x and y in X:

1. Pareto optimality: if $x \gg_i y$ for all i, then $x > y$;
2. Binary independence: the aggregate preference between x and y depends solely on the voters' preferences between x and y;
3. Non-dictatorship: there is no i such that $x \gg y$ whenever $x \gg_i y$. Arrow's theorem says that it is impossible to satisfy all three conditions.

Several dozen related impossibility theorems have subsequently been developed by others. Many of these are noted in Kelly (1978) and Pattanaik (1978). As well as multi-profile theorems, like Arrow's, that use different lists of preference rankings to demonstrate impossibility, there are single-profile theorems (Roberts 1980) that use only one list with sufficient variety in the rankings to establish impossibility.

Impossibility theorems, voting paradoxes, and results on strategic manipulation highlight the difficulty of designing good election procedures. Recent research to alleviate such problems (Dasgupta et al. 1979; Laffont and Moulin 1982) focuses on the design of preference-revelation mechanisms (generalized ballots) and aggregation procedures that encourage people to vote in such a way that the outcome will agree with some theoretically best decision based on the true but unknown preferences of the voters. Other work, such as that on approval voting (Brams and Fishburn 1983), continues to search for simple synthetic methods that minimize the problems that beset these methods.

Interest and Profit

Carlo Panico

The analysis of the relationship between the rates of interest and profit deals with how to integrate the theory of money with the theory of value and distribution. Different views on this subject reflect alternative positions expressed in the debates over these theories. They describe how changes in the financial markets affect the production process and vice versa, and have different policy implications.

The dominant view on the relation between the rates of interest and profits since Adam Smith has been that while monetary factors affect the *daily* variations of the 'money' or 'market' interest rate, in equilibrium the interest rate can only be equal to its 'average' or 'natural' or 'real' value (as alternatively named in the literature), which is determined, independently of monetary factors, by the same forces that determine the general rate of profits on the capital invested in the production process. This view, though dominant, is not the only one put forward in the literature. Indeed some outstanding economists (e.g., J.M. Keynes) have proposed alternative views according to which monetary factors are relevant, both temporarily and permanently, in determining the equilibrium level of economic variables.

The distinction between the notions of 'money' or 'market' interest rate and 'average' or 'natural' or 'real' interest rate can be traced in the writings of most economists dealing with this subject. Ricardo, for instance, drew a clear-cut distinction between these rates and provided a coherent analysis of how to relate them. The rate of profits was determined on the basis of a 'surplus' theory, in the tradition of the English classical political economists. He took as given the social product, the available technology and the real wage rate, disallowing any direct influence of monetary factors in the determination of the rate of profits. The 'average' or 'natural' interest rate was in his writings a *portion* of the rate of profits and was determined by the latter. As to the 'market' interest rate, it could undergo daily variations around its 'natural' level, on account of the changing conditions of competition between lenders and borrowers in the money markets.

Ricardo's writings clarify the role played by the analysis of the money markets in the treatment of this subject. He provided several examples to show how changes in the market interest rate occur and how this rate tends to move towards its natural level. The analysis of money markets, therefore, has to support the view that the rate of profits ultimately determines the interest rate by describing how competitive market forces make the natural level of the interest rate assert itself in the money markets.

Ricardo presented a coherent analysis of how the theory of the interest rate and of money has to be integrated with the classical theory of value and distribution, when the real wage rate is taken as given. Yet he did not provide a detailed analysis of the working of the money markets. Soon after his death some attempts to develop the latter analysis were presented by Tooke and J.S. Mill. Both used this analysis to criticize Ricardo's view and to claim that the interest rate can be determined both temporarily and permanently by causes which are independent of what happens to the rate of profits.

Tooke's and Mill's positions were stimulated by the sharp variations in the interest rate which occurred during and after the Napoleonic wars. These long-lasting variations in the interest rate were, according to them, the result of the policy followed to finance the Government debt, rather than the result of a change in the conditions of production implying a higher level of the rate of profits. The analysis of the interest rate they put forward had a strong influence on the economic literature. It failed, however, to give a correct account of the competitive market forces relating the rates of interest and profits. This led to the unconvincing view that the average interest rate and the rate of profits can move independently of each other.

A similar point of view was expressed some years later by Marx, who studied monetary issues at length both at a theoretical and at an empirical

level, with particular reference to the experience of the British financial system. By looking at this system, Marx developed the view that the most powerful pressure-groups operating in the financial markets were able to affect the interest rate permanently (and consequently their share of surplus-value produced) through the introduction of financial innovations and through their influence on State interventions regulating the legal and institutional arrangements of the financial markets.

To support this idea Marx presented a detailed analysis of the working of these markets and of the determination of both the average and the market interest rates in terms of supply and demand for liquid means. He stressed the need to reject the notion of a 'natural' rate of interest determined on the basis of technological or material laws of production, and pointed out the analytical conditions allowing a determination of the interest rate independent of the rate of profits and based on historical, conventional elements.

Yet, like Tooke and Mill in the 1820s, Marx failed to correctly relate these two rates. He maintained Ricardo's determination of the rate of profits in terms of a given real wage rate within a surplus theory of value and distribution, and failed to work out the effects of the operation of competitive market forces coming into action when a divergence between the rates of interest and profits comes about.

However, from Marx's writings some insights can be derived for analysing these forces, even if he did not carry them out himself. He pointed out that the banking sector, like the other industrial sectors, has to earn at least the general rate of profits on the wages and capital anticipated to carry on its activity. Changes in the interest rates affect the revenues (interest received on bank loans and financial assets) and the costs (which include payments for wages, interest on deposits and the rate of profits on the capital advanced) of the banking firms. This produces adjustment processes tending to restore the conditions of equilibrium between revenues and costs, which set some constraints linking the movements of the rates of interest and profits.

The economic literature of the years during which Marx was developing Ricardo's surplus theory of value and distribution shows the progressive abandonment of this theory, which implied an inverse relationship between the rate of profits and the real wage rate. The general trend in this literature was to determine instead these two rates independently of each other, as the specific contributions of capital and labour to production. Leading historians of economic thought have argued that it is not possible to claim that a *new* theory of value and distribution was actually presented in those years. The analyses were not clearly spelt out, particularly those which dealt with the concept of capital.

This new trend was reflected in the analysis of the relationship between the rates of interest and profits. The tendency prevailed to identify interest and profit and use them as synonyms. Tooke, Fullarton and James Wilson claimed in those years that a *permanent* variation in the interest rate affects the costs of production and the prices in the same direction. For them a permanent change in the interest rate was *the same thing* as a change in the rate of profits. No one spoke any longer of independent movements of these two rates. Indeed, the whole analysis of the relation between the average interest rate and the rate of profits faded away. The only issue left for discussion was the temporary fluctuations of the market interest rate. Besides, the abandonment of the surplus theory of value and distribution, the confusions as to the definition of capital, and the tendency to identify demand for and supply of *money*- or *banking*-capital with demand for and supply of *real* capital – all these made impossible at that time the development of a monetary theory of the rate of profits, of a theory, that is, which recognizes the influence of monetary factors on this rate.

The concept of capital and its analytical role were more precisely spelt out by the economists who introduced the marginalist or neoclassical theory of value and distribution in the 1870s and later. In this new theory too, the natural interest rate and the general rate of profits were *the same thing*. The money rate of interest could vary independently only temporarily. In equilibrium it had

to be equal to its natural value determined as the rate of return to be made on the *real* capital employed in production.

Walras explicitly stated that money markets, so relevant in the real world, are a 'superfetation' in marginalist theory. Later on, Wicksell, having presented a rather developed analysis of the role played by monetary factors in disequilibrium, concluded that the money interest rate depends in the last analysis upon the supply of and the demand for real capital. In equilibrium no room can be allowed for the action of monetary forces.

An example of the marginalist view of the relationship between the rates of interest and profits can be found in *A Treatise of Money*, published by Keynes in 1930. This book is based upon the marginalist separation between the 'real' department and the 'monetary' department of economics. In the real department, in line with the marginalist theory of value and distribution, the equilibrium or natural level of the distributive variables, the relative prices and the level of output (which turns out to be full employment) are simultaneously determined. In the monetary department, as analysed in *A Treatise on Money*, equilibrium values are taken as given (or rather known from the real department). The fluctuations of the price level are then analysed by looking at the variations in the evaluations of the expected yields of investment goods and at the fluctuations of the money interest rate around its natural level.

In *A Treatise on Money* the instability of the demand for investment and the analysis of liquidity preference are both present. The latter analysis, presented in this book in the form of 'bear and bull positions', describes the working of the money markets and how changes in the interest rate come about. Their presence, however, does not imply the abandonment of the marginalist approach, which asserts itself in the determination of the natural interest rate.

An alternative view was presented by Keynes a few years later in the *General Theory*. In this book Keynes took a critical attitude towards the marginalist theory. From 1932 on, he denied the validity of the separation between real and monetary departments, proposing instead a 'monetary theory of production', where monetary factors were directly relevant to determine the equilibrium level of output, of the interest rate and of other distributive variables. According to this view, the traditional causal relation between the rates of interest and profits was reversed. The level of the latter rate depended upon the former.

The introduction of the concept of a 'monetary theory of production' coincided in Keynes's writings with the abandonment of the concept of 'natural interest rate'. A new 'monetary' theory of the interest rate was instead proposed to determine the 'average' or 'durable' (as Keynes named it: 1936, p. 203) level of this rate. Presenting this theory, Keynes stressed its historical, conventional character by claiming that *any* level of interest which is accepted with sufficient conviction as *likely* to be durable, *will* be durable (Keynes 1936, p. 203). He pointed out that the policy of the monetary authority is a major determinant of the 'common opinion' as to the future value of the interest rate. But he also added that other elements of an economic or institutional character can affect this 'common opinion', for instance by persuading the public that the monetary authority will not be able to maintain its present policy.

However, the *General Theory* did not introduce any alternative analysis of how changes in the interest rate come about. The analysis of liquidity preference was represented in this book as dealing with the daily variations in the market interest rate and describing how the level of the interest rate, which is expected to be durable, tends to assert itself.

To support his new view as to the causal link between the rates of interest and profits, Keynes also presented in the *General Theory* an analysis of how competitive market forces tend to affect productive processes when temporary or persistent changes occur in the financial markets. This analysis was best framed in chapter 17 of this book. According to Keynes, investors in the financial and industrial sectors pay great attention to the rates of return of the different assets. They allow for certain differentials between these rates, which take into account the liquidity premium offered by the different assets. The equilibrium structure of the rates of return (that is the equilibrium differentials) is so determined. When

the actual differentials do not correspond to the equilibrium ones, competitive market forces come into action, producing adjustment processes which affect the prices of the assets. Autonomous variations of the interest rates – as Keynes argued in the *General Theory* – if persistent can thus cause changes in the same direction in the rate of profits.

The analysis of the competitive forces tending to relate the rates of interest and profits, proposed by Keynes in the *General Theory*, can be considered as complementary to that hinted by Marx and described above. They point out two different market mechanisms which tend to relate the movements of these two rates. Combined together, these two analyses provide a base to argue for a monetary determination of the rate of profits. Those who accept a historical conventional determination of the interest rate, can claim the existence of a causal relationship moving from this rate to the rate of profits. Monetary factors can therefore be directly allowed in the determination of the rate of profits.

Sraffa's recent rehabilitation of the surplus theory of value and distribution moves along these lines. Taking advantage of the possibility offered by this theory to determine one distributive variable independently of the others, he suggests that it is preferable in order to analyse the present conditions of capitalist economies, to consider the rate of profits as an independent variable (determined by the level of the rates of interest on money), instead of following the classical political economists of the last century who took the real wage rate as independently determined (Sraffa 1960, p. 33).

A new way to relate the rates of interest and profits, and consequently the theory of money, and that of value and distribution is therefore proposed within the recent rehabilitation of the surplus approach. This proposal can refer to the writings of outstanding economists to find theoretical support and to spell out its analytical implications.

The reconstruction of this analysis appears particularly relevant in the face of the present state of the neoclassical approach. As outstanding neoclassical economists have themselves recognized, no satisfactory integration between monetary and real variables has yet been presented within modern versions of neoclassical theory, that is, those developed after the work of Hicks (1939) and the subsequent works of Arrow, Debreu and Malinvaud. On account of this unsatisfactory integration, neoclassical economists still refer, as they themselves say, to the works of Wicksell and Fisher, that is, to those earlier versions of the neoclassical theory, whose internal consistency has been denied by the debate on capital theory of the 1960s and the 1970s.

The relationship between the rates of interest and profits can thus be considered one of the most open and controversial subjects of political economy.

Interest Rates

J. E. Ingersoll

Interest is payment for use of funds over a period of time, and the amount of interest paid per unit of time as a fraction of the balance is called the interest rate. In some contexts, economists have found it conceptually useful to refer to a single number, the interest rate. In fact, at any point in time there are many prevailing interest rates. The

rate actually charged will depend on such factors as the maturity of the loan, the credit-worthiness of the borrower, the amount of collateral, tax treatment of interest payments for both parties, and special features such as call provisions or sinking fund requirements.

A complete treatment of interest rates would account for all of these factors, but in fact it is hard enough to handle any one of them adequately. This entry considers one factor, the term to maturity for default-free bonds. This analysis of the *term structure of interest rates* will be approached from the partial equilibrium perspective of finance: the determinants of interest rates and the impact of changing short and long interest rates on the macroeconomy are not discussed.

Merton (1970 and other unpublished work) was the first to formulate the term structure problem using the continuous- time no-arbitrage framework exposited here. Cox et al. (1985a, b), Dothan (1978), Richard (1978), and Vasicek (1977) solved term structure problems of this type for different stochastic processes.

Interest Rates in a Certain Environment

Historically, the theory of interest rates has been burdened with cumbersome notation designed to distinguish among spot rates, forward rates and rates of different terms. Notation and terminology will be kept to a minimum here. The instantaneous spot rate of interest at time t for a loan to be repaid an instant later will be denoted by $r(t)$. $R(t, T)$ will denote the continuously compounded interest rate for a zero coupon bond sold at t to be repaid at T, and $P(t, T)$ will be the price or present value per \$1 face value of such a bond. The relation between these three quantities is

$$r(t) \equiv \lim_{T \downarrow t} R(t,T) \tag{1a}$$

$$P(t,T) \equiv e^{-R(t,T)(T-t)}. \tag{1b}$$

An investor who has funds to invest until time T could buy a T-period zero coupon bond with a guaranteed annualized return of $R(t, T)$. Alternatively, the investor could roll over a series of shorter bonds or buy a longer bond with the intention of selling it at time T. In the absence of uncertainty, all of these plans would have to realize the same final return to avoid the possibility of arbitrage. In particular

$$\frac{1}{P(t,T)} = \exp\left[\int_t^T r(s)\mathrm{d}s\right] \tag{2}$$

or the continuously compounded long rate must be the average of the instantaneous rates,

$$R(t,T) = \frac{1}{T-t}\int_t^T r(s)\mathrm{d}s. \tag{3}$$

(Note that with discrete compounding one plus the long rate is equal to the geometric mean of one plus the single-period rates. See Dybvig et al. (1986) for a catalogue of related results in both continuous and discrete time.)

One-Factor Models of Interest Rates in an Uncertain Environment

When future interest rates are not known in advance, these relations need not be realized, even on average, but the equilibrium that obtains will still depend on the trade-offs between different bond portfolio strategies. The resulting equilibrium relation among the interest rates will depend primarily on the information structure perceived by investors and, in particular, on the temporal resolution of uncertainty.

In this section we will assume that the information structure is Markov in the currently prevailing short rate, which is assumed to capture all currently available information relevant for pricing default-free bonds. $P(r, t, T)$ denotes the price at t of a zero coupon bond maturing at T with a face value of \$1, given that the currently prevailing short rate is r. The evolution of the interest rate is assumed to follow a diffusion process.

$$\mathrm{d}r = f(r,t)\mathrm{d}t + g(r,t)\mathrm{d}\omega. \tag{4}$$

Here $f(\cdot)$ measures the expected change in the interest rate per unit time, $g(\cdot)$ measures the standard deviation of changes in the interest rate per unit time, and $d\omega$ is the increment to a Wiener process.

The price of a zero coupon bond evolves according to

$$dP(r,t,T)/P(r,t,T) = \alpha(r,t,T)dt + \delta(r,t,T)d\omega \quad (5)$$

where $\alpha(\cdot)$ is the bond's (endogenous) instantaneous expected rate of return and $\delta(\cdot)$ is its instantaneous standard deviation. By Itô's lemma

$$\alpha(r,t,T)P(r,t,T) = \frac{1}{2}g^2(r,t)P_{rr} + f(r,t)P_r + p_t \quad (6a)$$

$$\delta(r,t,T)P(r,t,T) = g(r,t)P_r \quad (6b)$$

where subscripts denote partial differentiation.

Equation (6a) is a partial differential equation relating the prices of a given bond at different points of time and with different prevailing short rates. Together with the known value of a bond at its maturity [$P(r, T, T) = 1$] and mild regularity conditions, (6a) is equivalent to the integral

$$P(r,t,T) = E\left[\exp\left\{-\int_t^T \alpha[r(s),s,T]ds\right\}\right] \quad (7)$$

(Friedman 1975, Theorem 5.2). This integral demonstrates that when the source of uncertainty is a stochastically varying discount rate rather than a random cash flow, it is generally improper to discount by using the expected discount rate. Rather, we should use the geometric mean across states of the discount rate.

To price bonds using (6a) or (7), we must know $\alpha(\cdot)$. Intuitively, $\alpha(\cdot)$ will be equal to the risk-free rate plus a risk premium. As there is but a single source of uncertainty, the returns on all bonds will be perfectly correlated; therefore, the risk premium on any bond will be proportional to its exposure to the risk, and knowing $\alpha(\cdot)$ for one bond (for all interest rate levels) is sufficient. We can specify $\alpha(\cdot)$ by fiat, or it can be derived from an equilibrium model.

One equilibrium condition that is often imposed is the 'local' expectations hypothesis, $\alpha(r, t, T) = r$ (Cox et al. 1981). Under the local expectations hypothesis the partial differential equation for bond pricing derived from (6a) and the integral in (7) are fully determined given the distribution of interest rate changes. The local expectations hypothesis is a strong assumption, but for assest pricing purposes it is the only case that needs consideration. It can be shown that the absence of arbitrage implies that we can artificially reassign probabilities so that the local expectations hypothesis holds without changing any asset prices. The artificial probabilities are called the risk neutral probabilities or the equivalent martingale measure. Here is an informal proof in our context.

Consider any two zero coupon bonds. From (6a) their realized returns are perfectly correlated. Therefore, to ensure the absence of arbitrage possibilities, their expected excess returns must be proportional to their standard deviations

$$\begin{aligned}\alpha(r,t,T) - r &= \pi(r,t)\delta(r,t,T) \\ &= \pi(r,t)(P_r/P)g(r,t).\end{aligned} \quad (8)$$

The risk premium term $\pi(\cdot)$ cannot depend on the bond in question, which is why it does not depend on T. We can now write the equivalent diffusion process under the martingale measure. Because we can infer the variance of any diffusion from its sample path and because the martingale measure has the same set of possible events as the original probability measure, the martingale standard deviations must be the same i.e., $g(\cdot)$. The drift under the martingale measure must equate expected returns across assets. Therefore, the drift term under the equivalent martingale measure must be $f^*(r, t) \equiv f(r, t) - \pi(r, t)\, g(r, t)$. Using the martingale measure (6a) therefore becomes

$$rP = \frac{1}{2}g^2(r,t)P_{rr} + f^*(r,t)P_r + P_t \quad (9)$$

and its solution analogous to (7) is

$$P(r,t,T) = E^*\left\{\exp\left[-\int_t^T r(s),\mathrm{d}s\right]\right\}. \quad (10)$$

where $E^*[\cdot]$ denotes expectation under the modified process with f^* as the drift term.

To illustrate how these tools are used, consider the simplest model in Cox et al. (1985b). The stochastic process for the interest rate is

$$\mathrm{d}r = \kappa(\mu - r)\mathrm{d}t + \sigma\sqrt{r}\ \mathrm{d}\omega. \quad (11)$$

For this process, the interest rate is attracted elastically toward its mean value μ and is influenced by a noise term whose variance is proportional to the prevailing level of the interest rate. As a consequence, the interest rate cannot become negative. Assuming logarithmic utility, the drift term for the equivalent process is $f^* = \kappa\mu - (\kappa + \lambda)r$.

With this specification of f^*, (9) or (10) is solved by

$$P(r,t,T) = A(T-t)e^{-B(T-t)r} \quad (12)$$

where

$$A(\tau) \equiv \left[\frac{2\eta e^{(\kappa+\lambda+\eta)\tau/2}}{b(\tau)}\right]^{2\kappa\mu/\sigma^2}, B(\tau) \equiv \left[\frac{2(e^{\eta\tau}-1)}{b(\tau)}\right]$$
$$\times b(\tau) \equiv 2\eta + (\kappa+\lambda+\eta)(e^{\eta\tau}-1),$$
$$\eta \equiv \sqrt{(\kappa+\lambda)^2 + 2\sigma^2}.$$

The resulting zero coupon yield has a limit of

$$R_\infty = 2\kappa\mu/(\eta + \kappa + \lambda)$$

regardless of the current short rate. (The constancy of the long rate may seem like a severe restriction of this model. Actually, it is a property that is to be expected of any recurrent model. See Dybvig et al. 1986.) If the current short rate is below R_∞, then the yield curve is upward sloping. If the current rate is greater than μ then the yield curve slopes downward. For interest rates between these two levels the yield curve has a single hump.

Brown and Dybvig (1986) have estimated a reduced form of this model, yield curve by yield curve, to obtain a time series of parameter estimates. They found that the implied variance tracks actual interest rate volatility well. They also find some evidence of misspecification, including what appears to be a tax effect.

Bond Pricing with Multiple Sources of Uncertainty

One criticism of previous models is that they permit only a single source of uncertainty. As a result of this assumption all bonds are perfectly correlated and all yield curves are characterized by a single parameter. Typically there would be factors that influence long and short rates differently. However, the basic techniques for bond pricing remain the same.

Suppose for simplicity that interest rates are determined by the short rate and one other state variable, x. The assumed dynamics for the two state variables are

$$\begin{aligned} \mathrm{d}r &= f(r,x,t)\mathrm{d}t + g(r,x,t)\mathrm{d}\omega_1 \\ \mathrm{d}x &= \phi(r,x,t)\mathrm{d}t + \gamma(r,x,t)\mathrm{d}\omega_2. \end{aligned} \quad (13)$$

The resulting partial differential equation for bond pricing is

$$rP = \frac{1}{2}g^2P_{rr} + \rho g\gamma P_{rx} + \frac{1}{2}\gamma^2P_{xx} + f^*P_r + \phi^*P_x + P_t \quad (14)$$

where as before $f^*(\cdot)$ and $\varphi^*(\cdot)$ denote the modified (risk adjusted) drift terms under the equivalent martingale measure, and ρ is the correlation between the two Wiener processes. Solving this problem requires a specification of the joint stochastic process and the necessary modification of the equivalent martingale measure.

If the second state variable, x, is the price of some asset, then the risk premium, $-\pi_2(\cdot)\gamma(\cdot)$, associated with ω_2 is $rx - \varphi(\cdot)$ giving $\varphi^* = rx$ as in the Black–Scholes option pricing model. We can also infer the risk premium if x is functionally related to an asset's value and time. For example suppose that x is the yield-to-maturity on a zero coupon bond maturing at s. The price of this bond, $P(r, x, t, s)$, must itself satisfy the pricing equation.

As $P(r, x, t, s) \equiv \exp[-x(s-t)]$, we know all of its required partial derivatives. Substituting them into (14) and solving for $\varphi^*(\cdot)$ gives

$$\phi^*(r,x,t) = \frac{r - x - \frac{1}{2}\gamma^2(\cdot)(s-t)^2}{t-s} \tag{15}$$

(Ingersoll 1987). Of course, if x is not known to be related to a marketed asset, we can still specify the second risk premium arbitrarily or by reference to an equilibrium model.

Brennan and Schwartz (1979) used a finite difference numerical approximation to analyse a two factor model. In a test with US Government bonds, they concluded that the two factor model predicted bond prices much better than did a one factor model and on the whole was an adequate description of bond prices.

The traditional forecasting models using geometrically smoothed averages of past short rates as predictors of future rates can also be viewed as two (or more) factor models of this sort. (See Dobson et al. (1976) for a survey of the forecasting models.) For example, consider the model of Malkiel (1966) in which the short rate tends to return to a 'normal level', measured by a geometric average of past interest rates

$$x(t) \equiv \beta \int_0^\infty e^{-\beta s} r(t-s)\mathrm{d}s. \tag{16}$$

The dynamics of this model are

$$\mathrm{d}r = \mathsf{K}(x-r)\mathrm{d}t + \sigma(\cdot)\mathrm{d}\omega \tag{17a}$$

$$\mathrm{d}x = \beta(r-x)\mathrm{d}t. \tag{17b}$$

As changes in the state variable x are locally deterministic, no risk adjustment is required. The modification to the stochastic process for r is handled in the usual fashion.

No closed form solution is known for this model when $\sigma(\cdot) = \sigma\sqrt{r}$ as in the Cox et al. (1985b) model. A solution for this and similar problems with other lag structures is given in Cox et al. (1981) when the variance is a constant.

Another form of two factor model uses real interest rates and expected inflation as its two state variables (Richard 1978; Cox et al. 1985b). Besides providing more flexibility for a better empirical fit, this formulation permits an identification of real and nominal effects for separate consideration.

Applications of Interest Rate Models

This continuous-time no-arbitrage method of pricing bonds is an outgrowth of the option pricing literature which gives it certain advantages over more traditional approaches. One advantage is the provision of a fully specified model of bond prices for empirical work. Another major advantage of term structure models of this type is that they provide a framework for valuation that is consistent with all of our other models based on the absence of arbitrage.

Thus, in addition to pricing zero coupon bonds and determining the term structure, this method can handle any other interest rate valuation problem. For example Cox et al. (1985b) value call options on interest rates. Applications to futures contracts, variable rate instruments, mortgages, loan commitments, etc. have also been published. Equation (9) or a multiple factor version such as (14) remains the fundamental relation among interest rate contingent claims. To value a particular claim the appropriate boundary condition is used in place of $P(r, t, T) = 1$.

Another advantage of such models is that they give an explicit measure of the risk characteristics of the priced assets. These risk measures can be used in immunizing bond portfolios or in relative performance measurement. Because they are derived in models based on the absence of arbitrage they are not subject to the same criticisms that have been made of traditional duration measures (see Ingersoll et al. 1978).

Of theoretical interest is the relation between these models and the risk neutral or equivalent martingale valuation procedure. With a constant interest rate it can be shown that the value of a derivative asset that pays $H(S_T)$ at time T, contingent on the value S_T of its primitive asset and makes no other disbursements, is

$$V(S,t) = \mathrm{e}^{-r(T-t)E*}[H(S_T)]. \quad (18)$$

The expectation $E^*[\cdot]$ is taken with respect to the risk neutral process for the primitive's price under which the actual expected rate of return is replaced by the risk-free interest rate. With a stochastic interest rate, the valuation is

$$V(S,t) = E^*\left\{\exp\left[-\int_t^T r(s)\mathrm{d}s\right]H(S_T)\right\}. \quad (19)$$

This equation generalizes both equations (18) and (10). The expectation in (19) is over the joint distribution under the martingale measure of interest rate paths and S_T. That is, the expectation assumes that

$$\mathrm{d}S(t) = r(t)S\ \mathrm{d}t + \sigma(\cdot)S\ \mathrm{d}\omega_S \quad (20a)$$

$$\mathrm{d}r(t) = f(\cdot)\mathrm{d}t + g(\cdot)\mathrm{d}\omega_r \quad (20b)$$

plus the modified processes of any other state variables that determine the term structure.

Interests

Albert O. Hirschman

'Interest' or 'interests' is one of the most central and controversial concepts in economics and, more generally, in social science and history. Since coming into widespread use in various European countries around the latter part of the 16th century as essentially the same Latinderived word (*intérêt, interesse*, etc.), the concept has stood for the fundamental forces, based on the drive for self-preservation and self-aggrandizement, that motivate or should motivate the actions of the prince or the state, of the individual, and later of groups of people occupying a similar social or economic position (classes, interest groups). When related to the individual, the concept has at times had a very inclusive

meaning, encompassing interest in honour, glory, self-respect, and even after-life, while at other times it became wholly confined to the drive for economic advantage. The esteem in which interest-motivated behaviour is held has also varied drastically. The term was originally pressed into service as a euphemism serving, already in the late Middle Ages, to make respectable an activity, the taking of interest on loans, that had long been considered contrary to divine law and known as the sin of usury. In its wider meanings, the term at times achieved enormous prestige as key to a workable and peaceful social order. But it has also been attacked as degrading to the human spirit and corrosive of the foundations of society. An inquiry into these multiple meanings and appreciations is in effect an exploration of much of economic history and in particular of the history of economic and political doctrine in the West over the past four centuries.

The concept, moreover, still plays a central role in contemporary economics and political economy: the construct of the self-interested, isolated individual who chooses freely and rationally between alternative courses of action after computing their prospective costs and benefits to him or herself, that is, while ignoring costs and benefits to other people and to society at large, underlies much of welfare economics; and the same perspective has yielded important, if disturbing contributions to a broader science of social interactions, such as the Prisoner's Dilemma theorem and the obstacles to collective action because of free riding.

Two essential elements appear to characterize interest-propelled action: *self-centredness*, that is, predominant attention of the actor to the consequences of any contemplated action for himself; and *rational calculation*, that is, a systematic attempt at evaluating prospective costs, benefits, satisfactions, and the like. Calculation could be considered the dominant element: once action is supposed to be informed only by careful estimation of costs and benefits, with most weight necessarily being given to those that are better known and more quantifiable, it tends to become self-referential by virtue of the simple fact that each person is best informed about his *own* satisfactions and disappointments.

Interest and Statecraft

Rational calculation also played the chief role in the emergence of the concept of interest-motivated action on the part of the prince in the 16th and 17th centuries. It accounts for the high marks interest-governed behaviour received during the late 16th- and early 17th-century phases of its career in politics. The term did duty on two fronts. First, it permitted the emergent science of statecraft to assimilate the important insights of Machiavelli. The author of *The Prince* had almost strained to advertise those aspects of politics that clashed with conventional morality. He dwelt on instances where the prince was well advised or even duty bound to practise cruelty, mendacity, treason, and so on. Just as, in connection with money lending, the term interest came into use as a euphemism for the earlier term usury, so did it impose itself on the political vocabulary as a means of anaesthetizing, assimilating and developing Machiavelli's shocking insights.

But in the early modern age, 'interest' was not only a label under which a ruler was given *new latitude* or was absolved from feeling guilty about following a practice that he had previously been taught to consider as immoral: the term also served to impose *new restraints* as it enjoined the Prince to pursue his interests with a rational, calculating spirit that would often imply prudence and moderation. At the beginning of the 17th century, the interests of the sovereign were contrasted with the wild and destructive passions, that is, with the immoderate and foolish seeking of glory and other excesses involved in pursuing the by then discredited heroic ideal of the Middle Ages and the Renaissance. This disciplinary aspect of the doctrine of interest was particularly driven home in the influential essay *On the Interest of Princes and States of Christendom* by the Huguenot statesman the Duke of Rohan (1579–1638).

The interest doctrine thus served to release the ruler from certain traditional restraints (or guilt

feelings) only to subject him to new ones that were felt to be far more efficacious than the well-worn appeals to religion, morals, or abstract reason. Genuine hope arose that, with princely or national interest as guide, statecraft would be able to produce a more stable political order and a more peaceful world.

Interest and Individual Behaviour

The early career of the interest concept with regard to statecraft finds a remarkable parallel in the role it played in shaping behaviour codes for individual men and women in society. Here also a new license went hand in hand with a new restraint.

The new license consisted in the legitimation and even praise that was bestowed upon the single-minded pursuit of material wealth and upon activities conducive to its accumulation. Just as Machiavelli had opened up new horizons for the Prince, so did Mandeville two centuries later list a number of 'don'ts' for the commoner, in this case primarily in relation to money making. Once again, a new insight into human behaviour or into the social order was first proclaimed as a startling, shocking paradox. Like Machiavelli, Mandeville presented his thesis on the beneficial effects on the general welfare of the luxury trades (which had long been strictly regulated) in the most scandalous possible fashion, by referring to the activities, drives and emotions associated with these trades as 'private vices'. Here again, his essential message was eventually absorbed into the general stock of accepted practice by changing the language with which he had proclaimed his discovery. For the third time, euphemistic resort was had to 'interest', this time in substitution for such terms as 'avarice', 'love of lucre', and so on. The transition from one set of terms to the other is reflected by the first lines of David Hume's essay 'On the Independency of Parliament':

> Political writers have established it as a maxim, that, in contriving any system of government and fixing the several checks and balances of the constitution, every man ought to be supposed a *knave*, and to have no other end, in all his actions, than private interest. By this interest we must govern him, and, by means of it, make him, notwithstanding his insatiable avarice and ambition, cooperate to public good (Hume, 1742, vol. I, pp. 117–18, emphasis in the original).

Here interest is explicitly equated with knavishness and 'insatiable avarice'. But soon thereafter the memory of these unsavoury synonyms of interest was suppressed, as in Adam Smith's famous statement about the butcher, the brewer, and the baker who are driven to supply us with our daily necessities through their interest rather than their benevolence. Smith thus did for Mandeville what the Duke of Rohan had done for Machiavelli. His doctrine of the Invisible Hand legitimated total absorption of the citizen in the pursuit of private gain and thereby served to assuage any guilt feelings that might have been harboured by the many Englishmen who were drawn into commerce and industry during the commercial expansion of the 18th century but had been brought up under the civic humanist code enjoining them to serve the public interest *directly* (Pocock 1982). They were now reassured that by pursuing gains they were doing so *indirectly*.

In fact, Adam Smith was not content to praise the pursuit of private gain. He also berated citizens' involvement in public affairs. Right after his Invisible Hand statement he wrote 'I have never known much good done by those who affected to trade for the public good' (1776, p. 423). Ten years before, Sir James Steuart had supplied an interesting explanation for a similar aversion toward citizens' involvement in public affairs.

> . . . were everyone to act for the public, and neglect himself, the statesman would be bewildered . . . were a people to become quite disinterested, there would be no possibility of governing them. Everyone might consider the interest of his country in a different light, and many might join in the ruin of it, by endeavouring to promote its advantages (1767, vol. I, pp. 243–44).

In counterpart to the new area of authorized and recommended behaviour, these statements point to the important *restraints* that accompanied the doctrine of interest. For the individual citizen or subject as for the ruler, interest-propelled action

meant originally action informed by rational calculation in any area of human activity – political, cultural, economic, personal and so on. In the 17th century and through part of the 18th, this sort of methodical, prudential, interest-guided action was seen as vastly preferable to actions dictated by the violent, unruly and disorderly passions. At the same time, the interests of the vast majority of people, that is of those outside of the highest reaches of power, came to be more narrowly defined as economic, material or 'moneyed' interests, probably because the non-elite was deemed to busy itself primarily with scrounging a living with no time left to worry about honour, glory, and the like. The infatuation with interest helped bestow legitimacy and prestige on commercial and related private activities, that had hitherto ranked rather low in public esteem; correspondingly, the Renaissance ideal of glory, with its implicit celebration of the public sphere, was downgraded and debunked as a mere exercise in the destructive passion of self-love (Hirschman 1977, pp. 31–42).

The Political Benefits of an Interest-Based Social Order

The idea that the interests, understood as the methodical pursuit and accumulation of private wealth, would bring a number of benefits in the political realm took various distinct forms. There was, first of all, the expectation that they would achieve at the macrolevel what they were supposed to accomplish for the individual: hold back the violent passions of the 'rulers of mankind'. Here the best-known proposition, voiced early in the 18th century, says that the expansion of commerce is incompatible with the use of force in international relations and would gradually make for a peaceful world. Still more utopian hopes were held out for the effects of commerce on domestic politics: the web of interests delicately woven by thousands of transactions would make it impossible for the sovereign to interpose his power brutally and wantonly through what was called '*grands coups d'autorité*' by Montesquieu or 'the folly of despotism' by Sir James Steuart. This thought was carried further in the early 19th century when the intricacies of expanding industrial production compounded those of commerce: in the technocratic vision of Saint-Simon the time was at hand when economic exigencies would put an end, not just to *abuses* of the power of the state, but to any power whatsoever of man over man: politics would be replaced by administration of 'things'. As is well known this conjecture was taken up by Marxism with its prediction of the withering away of the state under communism. An argument that a century earlier had been advanced on behalf of emergent capitalism was thus refurbished for a new, *anti*-capitalist utopia.

Another line of thought about the political effects of an interest-driven society looks less at the constraints such as society will impose upon those who govern than at the difficulties of the task of governing. As already noted, a world where people methodically pursue their private interests was believed to be far more predictable, and hence *more governable*, than one where the citizens are vying with each other for honour and glory.

The stability and lack of turbulence that were expected to characterize a country where men pursue singlemindedly their material interests were very much on the minds of some of the 'inventors' of America, such as James Madison and Alexander Hamilton. The enormous prestige and influence of the interest concept at the time of the founding of America is well expressed in Hamilton's statement:

> The safest reliance of every government is on man's interests. This is a principle of human nature, on which all political speculation, to be just, must be founded (Hamilton 1784), cited in Terence Ball 1983, p. 45).

Finally, a number of writers essentially extrapolated from the putative personality traits of the individual trader, as the prototype of interest-driven man, to the general characteristics of a society where traders would predominate. In the 18th century, perhaps as a result of some continuing disdain for economic pursuits, commerce and money-making were often described as essentially innocuous or 'innocent' pastimes, in

contrast no doubt with the more violent or more strenuous ways of the upper or lower classes. Commerce was to bring 'gentle' and 'polished' manners. In French, the term innocent appended to commerce was often coupled with *doux* (sweet, gentle) and what has been called the thesis of the *doux commerce* held that commerce was a powerful civilizing agent diffusing prudence, probity and similar virtues within and among trading societies (Hirschman 1977, 1982a). Only under the impact of the French Revolution did some doubt arise on the direction of the causal link between commerce and civilized society: taken aback by the outbreak of social violence on a large scale, Edmund Burke suggested that the expansion of commerce depended itself on the *prior* existence of 'manners' and 'civilization' and on what he called 'natural protecting principles' grounded in 'the spirit of a gentleman' and 'the spirit of religion' (Burke 1790, p. 115; Pocock 1982).

The Invisible Hand

The capstone of the doctrine of self-interest was of course Adam Smith's Invisible Hand. Even though this doctrine, being limited to the economic domain, was more modest than the earlier speculations on the beneficent *political* effects of trade and exchange, it soon came to dominate the discussion. An intriguing paradox was involved in stating that the *general* interest and welfare would be promoted by the self-interested activities of innumerable decentralized operators. To be sure, this was not the first nor the last time that such a claim of identity or coincidence or harmony of interests of a part with those of a whole has been put forward. Hobbes had advocated an absolute monarchy on the ground that this form of government brings about an identity of interest between ruler and ruled; as just noted, the writers of the Scottish Enlightenment saw an identity of interest between the general interests of British society and the interests of the middle ranks; such an identity between the interests of one class and those of society became later a cornerstone of Marxism, with the middling ranks having of course been supplanted by the proletariat; and finally, the American pluralist school in political science returned essentially to the Smithian scheme of harmony between many self-interests and the general interest, with Smith's individual economic operators having been replaced by contending 'interest groups' on the political stage.

All these *Harmonielehren* have two factors in common: the 'realistic' affirmation that we have to deal with men and women, or with groups thereof, 'as they really are', and an attempt to prove that it is possible to achieve a workable and progressive social order with these highly imperfect subjects, and, as it were, behind their backs. The mixture of paradoxical insight and alchemy involved in these constructs makes them powerfully attractive, but also accounts for their ultimate vulnerability.

The Interests Attacked

The 17th century was perhaps the real heyday of the interest doctrine. Governance of the social world by interest was then viewed as an alternative to the rule of destructive passions; that was surely a lesser evil, and possibly an outright blessing. In the 18th century, the doctrine received a substantial boost in the economic domain through the doctrine of the Invisible Hand, but it was indirectly weakened by the emergence of a more optimistic view of the passions: such passionate sentiments and emotions as curiosity, generosity, and sympathy were then given detailed attention, the latter in fact by Adam Smith himself in his *Theory of Moral Sentiments*. In comparison to such fine, newly discovered or rehabilitated springs of human action, interest no longer looked nearly so attractive. Here was one reason for the reaction against the interest paradigm that unfolded toward the end of the 18th century and was to fuel several powerful 19th-century intellectual movements.

Actually the passions did not have to be wholly transformed into benign sentiments to be thought respectable and even admirable by a new generation. Once the interests appeared to be truly in command with the vigorous commercial and industrial expansion of the age, a general lament

went up for 'the world we have lost'. The French Revolution brought another sense of loss and Edmund Burke joined the two when he exclaimed, in his *Reflections on the Revolution in France*, 'the age of chivalry is gone; that of sophisters, economists and calculators has succeeded; and the glory of Europe is extinguished for ever' (1790, p. 111). This famous statement came a bare 14 years after the *Wealth of Nations* had denounced the rule of the 'great lords' as a 'scene of violence, rapine and disorder' and had celebrated the benefits flowing from everyone catering to his interests through orderly economic pursuits. Now Burke was an intense admirer of Adam Smith and took much pride in the identity of views on economic matters between himself and Smith (Winch 1985; Himmelfarb 1984). His 'age of chivalry' statement, so contrary to the intellectual legacy of Smith, therefore signals one of those sudden changes in the general mood and understanding from one age to the next of which the exponents themselves are hardly aware. Burke's lament set the tone for much of the subsequent Romantic protest against an order based on the interests which, once it appeared to be dominant, was seen by many as lacking nobility, mystery, and beauty.

This nostalgic reaction merged with the observation that the interests, that is, the drive for material wealth, were not nearly as 'innocuous', 'innocent' or 'mild', as had been thought or advertised. To the contrary, it was now the drive for material advantage that suddenly loomed as a subversive force of enormous power. Thomas Carlyle thought that all traditional values were threatened by 'that brutish god-forgetting Profit-and-Loss Philosophy' and protested that 'cash payment is not the only nexus of man with man' (1843, p. 187). This phrase – cash-nexus – was taken over by Marx and Engels who used it to good effect in the first section of the *Communist Manifesto* where they painted a lurid picture of the moral and cultural havoc wrought by the conquering bourgeoisie.

Many other critics of capitalist society dwelt on the destructiveness of the new energies that were relased by a social order in which the interests were given free rein. In fact, the thought arose that these forces were so wild and out of control that they might undermine the very foundations on which the social order was resting, that they were thus bent on self-destruction. In a startling reversal, feudal society, which had earlier been treated as 'rude and barbarous' and was thought to be in permanent danger of dissolution because of the unchecked passions of violent rulers and grandees, was perceived in retrospect to have nurtured such values as honour, respect, friendship, trust and loyalty, that were essential for the functioning of an interest-dominated order, but were relentlessly, if inadvertently, undermined by it. This argument was already contained in part in Burke's assertion that it is civilized society that lays the groundwork for commerce rather than vice versa; it was elaborated by a large and diverse group of authors, from Richard Wagner via Schumpeter to Karl Polanyi and Fred Hirsch (Hirschman 1982a, pp. 1466–70).

The Interests Diluted

While the interest doctrine thus met with considerable opposition and criticism in the 19th century, its prestige remained nevertheless high, particularly because of the vigorous development of economics as a new body of scientific thought. Indeed, the success of this new science made for attempts to utilize its insights, such as the interest concept, for elucidating some non-economic aspects of the social world. In his *Essay on Government* (1820), James Mill formulated the first 'economic' theory of politics and based it – just as was later done by Schumpeter, Anthony Downs, Mancur Olson etc. – on the assumption of rational self-interest. But this widening of the use of the concept turned out to be something of a disservice. In politics, so Mill had to recognize, the gap between the 'real' interest of the citizen and 'a false supposition [i.e., perception] of interest' can be extremely wide and problematic (1820, p. 88). This difficulty provided an opening for Macaulay's withering attack in the *Edinburgh Review* (1829). Macaulay pointed out that Mill's theory was empty: interest 'means only that men,

if they can, will do as they choose . . . it is . . . idle to attribute any importance to a proposition which, when interpreted, means only that a man had rather do what he had rather do' (p. 125).

The charge that the interest doctrine was essentially tautological acquired greater force as more parties climbed on the bandwagon of interest, attempting to bend the concept to their own ends. As so many key concepts used in everyday discourse, 'interest' had never been strictly defined. While individual self-interest in material gain predominated, wider meanings were never completely lost sight of. An extremely wide and inclusive interpretation of the concept was put forward at a very early stage in its history: Pascal's Wager was nothing but an attempt to demonstrate that belief in God (hence, conduct in accordance with His precepts) was strictly in our (long-term) self-interest. Thus the concept of *enlightened* self-interest has a long history. But it received a boost and special, concrete meaning in the course of the 19th century. With the contemporary revolutionary outbreaks and movements as an ominous backdrop, advocates of social reform were able to argue that a dominant social group is well advised to surrender some of its privileges or to improve the plight of the lower classes so as to insure social peace. 'Enlightened' self-interest of the upper classes and conservative opinion was appealed to, for example, by the French and English advocates of universal suffrage or electoral reform at mid-century; it was similarly invoked by the promoters of the early social welfare legislation in Germany and elsewhere toward the end of the century, and again by Keynes and the Keynesians who favoured limited intervention of the state in the economy through countercyclical policy and 'automatic stabilizers' resulting from welfare state provisions. These appeals were often made by reformers who, while fully convinced of the intrinsic value and social justice of the measures they advocated, attempted to enlist the support of important groups by appealing to their 'longer-term' rather than short-term and therefore presumably *shortsighted* interests. But the advocacy was not only tactical. It was sincerely put forward and testified to the continued prestige of the notion that interest-motivated social behaviour was the best guarantee of a stable and harmonious social order.

Whereas enlightened self-interest was something the upper classes of society were in this manner pressed to ferret out, the lower classes were similarly exhorted, at about the same epoch but from different quarters, to raise their sights above day-to-day pursuits. Marx and the Marxists invited the working class to become aware of its *real interests* and to shed the 'false consciousness' from which it was said to be suffering as long as it did not throw itself wholeheartedly into the class struggle. Once again, the language of interests was borrowed for the purpose of characterizing and dignifying a type of behaviour a group was being pressed to adopt.

Here, then, was one way in which the concept of interest-motivated behaviour came to be diluted. Another was the progressive loss of the sharp distinction an earlier age had made between the passions and the interests. Already Adam Smith had used the two concepts jointly and interchangeably. Even though it became abundantly clear in the 19th century that the desire to accumulate wealth was anything but the 'calm passion' as which it had been commended by some 18th-century philosophers, there was no return to the earlier distinction between the interests and the passions or between the wild and the mild passions. Money-making had once and for all been identified with the concept of interest so that all forms of this activity, however passionate or irrational, were automatically thought of as interest-motivated. As striking new forms of accumulation and industrial or financial empire-building made their appearance, new concepts were introduced, such as entrepreneurial leadership and intuition (Schumpeter 1911) or the 'animal spirits' of the capitalists (Keynes 1936, pp. 161–63). But they were not contrasted with the interests, and were rather assumed to be one of their manifestations.

In this manner the interests came to cover virtually the entire range of human actions, from the narrowly self-centred to the sacrificially altruistic, and from the prudently calculated to the passionately compulsive. In the end, interest stood behind anything people do or wish to do and to explain human action by interest thus did turn into the

vacuous tautology denounced by Macaulay. At about the same time, other key and time-honoured concepts of economic analysis, such as utility and value, became similarly drained of their earlier psychological or normative content. The positivistically oriented science of economics that flourished during much of this century felt that it could do without any of these terms and replaced them by the less value- or psychology-laden 'revealed preference' and 'maximizing under constraints'. And thus it came to pass that interest, which had rendered such long and faithful service as a euphemism, was now superseded in turn by various even more neutral and colourless neologisms.

The development of the self-interest concept and of economic analysis in general in the direction of positivism and formalism may have been related to the discovery, toward the end of the 19th century, of the instinctual-intuitive, the habitual, the unconscious, the ideologically and neurotically driven–in short, to the extraordinary vogue for the nonrational that characterized virtually all of the influential philosophical, psychological and sociological thinking of the time. It was out of the question for economics, all based on rationally pursued self-interest, to incorporate the new findings into its own apparatus. So that discipline reacted to the contemporary intellectual temper by withdrawing from psychology to the greatest possible extent, by emptying its basic concepts of their psychological origin–a survival strategy that turned out to be highly successful. It is of course difficult to prove that the rise of the nonrational in psychology and sociology and the triumph of positivism and formalism in economics were truly connected in this way. Some evidence is supplied by the remarkable case of Pareto: he made fundamental contributions both to a sociology that stressed the complex 'non-logical' (as he put it) aspects of social action and to an economics that is emancipated from dependence on psychological hedonism.

Current Trends

Lately there have been signs of discontent with the progressive evisceration of the concept of interest. On the conservative side, there was a return to the orthodox meaning of interest and the doctrine of enlightened self-interest was impugned. Apart from the discovery, first made by Tocqueville, that reform is just as likely to unleash as to prevent revolution, it was pointed out that most well-meant reform moves and regulations have 'perverse' side effects which compound rather than alleviate the social ills one had set out to cure. It was best, so it appeared, not to stray from the narrow path of narrow self-interest, and it was confusing and pointless to dilute this concept.

Others agreed with the latter judgement, but for different reasons and with different conclusions. They also disliked the manoeuvre of having every kind of human action masquerade under the interest label. But they regarded as relevant for economics certain human actions and activities which cannot be accounted for by the traditional notion of self-interest: actions motivated by altruism, by commitment to ethical values, by concern for the group and the public interest, and, perhaps most important, the varieties of non-instrumental behaviour. A beginning has been made by various economists and other social scientists to take these kinds of activities seriously, that is, to abandon the attempt to categorize them as mere variants of interest-motivated activity (Boulding 1973; Collard 1978; Hirschman 1985; Margolis 1982; McPherson 1984; Phelps 1975; Schelling 1984; Sen 1977).

One important aspect of these various forms of behaviour which do not correspond to the classical concept of interest-motivated action is that they are subject to considerable variation. Take actions in the public interest as an example. There is a wide range of such actions, from total involvement in some protest movement down to voting on Election Day and further down to mere grumbling about, or commenting on, some public policy within a small circle of friends or family – what Guillermo O'Donnell has called 'horizontal voice' in contrast to the 'vertical' voice directly addressed to the authorities (1986). The actual degree of participation under more or less normal political conditions is subject to constant fluctuations along this continuum, in line with changes in economic conditions,

government performance, personal development, and many other factors. As a result, with total time for private *and* public activity being limited, the intensity of citizens' dedication to their private interests is also subject to constant change. Near-total privatization occurs only under certain authoritarian governments, for the most repressive regimes do not only do away with the free vote and any open manifestation of dissent, but also manage to suppress, through their display of terrorist power, all *private* expressions of inconformity with public policy, that is, all those manifestations of 'horizontal voice' that are actually important forms of public involvement.

An arresting conclusion follows. That vaunted ideal of predictability, that alleged idyll of a privatized citizenry paying busy and exclusive attention to its economic interests and thereby serving the public interest indirectly, but never directly, becomes a reality only under wholly nightmarish political conditions! More civilized political circumstances necessarily imply a less transparent and less predictable society.

Actually, this outcome of the current inquiries into activities not strictly motivated by traditional self-interest is all to the good: for the only certain and predictable feature of human affairs is their unpredictability and the futility of trying to reduce human action to a single motive–such as interest.

Intergenerational Income Mobility

Gary Solon

Abstract

One important aspect of income inequality is the extent to which position in the income distribution is passed from parents to children. Theoretical models suggest that both intergenerational persistence and equilibrium income inequality increase with the responsiveness of earnings to human capital investment and with the heritability of income-generating traits, and decrease with the progressivity of public investment in children's human capital. A rapidly growing empirical literature is documenting the extent of intergenerational income mobility in many countries and is beginning to explore why intergenerational transmission is as high (and low) as it is.

'Intergenerational income mobility' refers to the degree to which position in the income distribution persists or changes from one generation to the next.

For example, a society in which individuals' adult income is altogether independent of their parents' income is a highly mobile society. A society in which one's percentile in the income distribution is always identical to one's parents' percentile is completely immobile. Neither extreme is ideal, and neither corresponds to the intergenerational patterns typically observed in actual societies. Which intergenerational association between the extremes is desirable depends on the processes generating it. In any case, reasonable and well-informed observers are likely to disagree about the optimal level of intergenerational mobility because of differences in their values, such as feelings about equity–efficiency trade-offs. See Jencks and Tach (2005) for a discussion of some of the normative issues.

Because understanding intergenerational mobility is important for understanding the nature of income inequality, intergenerational mobility has received a great deal of attention from both theoretical and empirical researchers. Since the late 1980s, empirical research describing the extent of intergenerational mobility has made considerable progress. Much work remains to improve our understanding of the causal processes underlying the observed extent of intergenerational mobility.

Theory

The classic theoretical analysis by Becker and Tomes (1979) encompasses a multitude of reasons why relative income status is correlated across generations. In a recent variant of that analysis, Solon (2004) adopts the functional form assumptions consistent with the log-linear intergenerational mobility regression commonly estimated by empirical researchers. In this model, an individual parent divides her income between her own consumption and investment in an individual child's human capital so as to maximize a Cobb–Douglas utility function in which the two

goods are the parent's consumption and the child's adult income. The mapping from the parent's investment in her child's human capital to the child's subsequent income as an adult operates through two functions.

First, a semi-logarithmic human capital production function relates the child's level of human capital to the logarithm of the sum of the parent's investment and public investment (for example, publicly supported education and health care for children) plus a variable representing the human capital endowments children receive regardless of the investment choices of their families and the government. These more mechanically determined endowments to children are, in Becker and Tomes's (1979, p. 1158) words, 'determined by the reputation and "connections" of their families, the contribution to the ability, race, and other characteristics of children from the genetic constitutions of their families, and the learning, skills, goals, and other "family commodities" acquired through belonging to a particular family culture'. The transmission of these endowments is assumed to follow a first-order autoregressive process across generations. Thus, intergenerational transmission occurs both because higher-income parents have greater wherewithal to invest in the human capital of their children and because of the genetic and cultural heritability of human capital. Second, the mapping to the child's income is completed by a semi- logarithmic earnings function that relates the child's log earnings to her level of human capital.

This simple model leaves out some important aspects of intergenerational transmission. For example, it assumes that the parent cannot borrow against the child's prospective earnings and does not bequeath financial assets to the child. See Becker and Tomes (1986) and Mulligan (1997) for analyses that relax this assumption. Also, the model's single-parent/single-child structure ignores the role of assortative mating, which is discussed by Lam and Schoeni (1994) and Chadwick and Solon (2002). Nevertheless, the model is rich enough to illustrate some key aspects of the intergenerational transmission process. These are embodied in the following result concerning the intergenerational income elasticity β, which is the coefficient in the regression of the child's log income on the parent's log income:

$$\beta \cong \frac{(1-\gamma)\theta + \lambda}{1 + (1-\gamma)\theta\lambda} \tag{1}$$

where θ is the elasticity of earnings with respect to human capital investment, λ is the autoregressive parameter representing the genetic and cultural heritability of income-generating traits, and γ is an index of the progressivity of public investment in children's human capital.

This result implies that the intergenerational income elasticity increases with the responsiveness of earnings to human capital investment and with the heritability of income-generating traits, and decreases with the progressivity of public investment in children's human capital. Cross-country differences in intergenerational mobility could arise from differences in any of these factors. So could changes over time in a particular country's intergenerational mobility. Finally, it can be shown that the same factors that increase the intergenerational income elasticity also increase the equilibrium level of cross-sectional income inequality within a generation. Thus, we should not be surprised if societies with particularly high income inequality also exhibit high intergenerational persistence of income status.

Empirical Evidence

If lifetime income data were available for both the parents' and children's generations in a nationally representative sample, estimation of the intergenerational income elasticity β could be performed simply by applying least squares to the regression of the children's log lifetime income on the parents' log lifetime income. In most countries, however, the ideal data are not available. As of the 1980s, data constraints had forced most of the then-small empirical literature to rely on short-term income measures, such as annual income in only one year, for peculiarly homogeneous samples. As summarized in Becker and Tomes (1986, p. S25), the resulting estimates

suggested that 'a 10% increase in father's earnings (or income) raises son's earnings by less than 2%'. As discussed in detail in Solon (1989, 1992), however, these estimates were biased substantially downward. The 'right-side' measurement error from using short-term parental income measures to proxy for parents' lifetime income can serve as a good classroom example for the econometrics textbook analysis of the attenuation bias resulting from 'noisy' measurement of an explanatory variable. And when the estimates were based on relatively homogeneous parent samples, this bias was aggravated by the diminished 'signal variance' in the explanatory variable.

By the 1990s, empirical researchers in the United States had the benefit of better data. By that time, two longitudinal surveys initiated in the late 1960s, the Panel Study of Income Dynamics (PSID) and the National Longitudinal Surveys (NLS) of labour market experience, had generated new data with an intergenerational span. Because these surveys used national probability samples, they were less subject to the problems from homogeneous samples. And because the longitudinal surveys repeatedly collected income information at each re-interview, they enabled exploration of the impact of using longer-term income measures. Many of the new studies, surveyed in Solon (1999), treated the errors-in-variables issue by averaging the parental income measure over several years. A typical finding was that, in a regression of son's log earnings on a multi-year measure of father's log earnings, the estimated slope coefficient was about 0.4 – that is, double the 0.2 value that previously had been described as an upper bound for the intergenerational elasticity. A few studies treated the errors-in-variables problem by performing instrumental variables estimation with parental characteristics like education or occupation used to instrument for measured parental income. That approach usually produced somewhat higher intergenerational elasticity estimates, but, as explained in Solon (1992), the consistency of such instrumental variables estimation depends on the 'excludability' of the instruments from the model for children's income.

Even the new estimates based on multi-year parental income data probably were too low. As emphasized in Solon (1992) and Mazumder (2005), averaging parental income over several years reduces but does not eliminate attenuation bias. Non-random attrition from the longitudinal surveys probably generated a weaker version of the sample homogeneity that had plagued earlier data-sets. And, as discussed in Reville (1995) and Haider and Solon (2006), many of the newer estimates have been biased by 'left-side' measurement error. At the time researchers began to use intergenerational data from the PSID and NLS, the offspring were only about 30 years old or even younger. For workers in their twenties, the log of current income as a proxy for log lifetime income is subject to 'mean-reverting' measurement error, instead of the classical measurement error typically analysed in econometrics textbooks. The mean reversion occurs because the workers who eventually will have high lifetime earnings typically experience steeper earnings growth. As a result, the early career gap in current earnings between workers with high and low lifetime earnings tends to understate their lifetime gap. This sort of mean-reverting measurement error in a dependent variable is still another source of attenuation bias. Once all these downward biases in the estimation of the intergenerational elasticity are considered, it becomes plausible that the intergenerational elasticity in the United States may well be as large as 0.5 or 0.6.

In recent years, researchers have estimated intergenerational elasticities for many other countries, sometimes with much larger samples than are available from the US surveys. As summarized in Solon (2002), the elasticity estimates for the United States and United Kingdom are towards the high end among developed countries, with considerably smaller estimates appearing for Canada, Sweden, Finland and Norway. Some new estimates for developing countries in Latin America (Dunn 2004; Ferreira and Veloso 2004; Grawe 2004) are even higher than the US and UK estimates. By and large, these cross-country comparisons accord with the theoretical prediction of greater intergenerational income persistence in countries with greater income inequality, higher returns to human capital, and less progressive public investment in children's human capital.

A related question is whether the changes in income inequality experienced by many countries since the 1970s have been accompanied by changing intergenerational elasticities. In most of the time-trends research conducted so far, the time spans and sample sizes have been too limited to permit strong conclusions.

Cross-country comparisons have only begun to illuminate *why* intergenerational income associations are as large (and as small) as they are. To what extent does intergenerational transmission occur because higher-income parents invest more in their children's human capital? What are the roles of genetic and cultural heritability? One intriguing line of research seeks clues from comparisons of relatives with varying degrees of genetic and environmental relatedness. Sibling studies of this type (Taubman 1976; Bjorklund et al. 2005) have compared correlations in socioeconomic status among monozygotic twins, dizygotic twins, non-twin full siblings, half-siblings, and biologically unrelated adoptive siblings, and also have compared biological siblings reared together and apart. (A related literature – Solon et al. 2000; Page and Solon 2003a, b; Oreopoulos 2003; Raaum et al. 2006 – has compared sibling correlations and correlations among unrelated children that grew up in the same neighbourhood. The typical finding that the sibling correlations are considerably larger than the neighbour correlations suggests that family influences loom larger than neighbourhood influences in accounting for the effects of origins on socioeconomic outcomes.) Intergenerational studies (Bjorklund et al. 2006; Plug 2004; Sacerdote 2004) have compared parent–child outcome associations in biological and adoptive families. Some empirical patterns consistent with an important role for genetic transmission are as follows: outcome correlations are particularly high among monozygotic twins; correlations for dizygotic twins and non-twin full siblings exceed those for half-siblings and adoptive siblings; correlations for biological siblings are positive even when the siblings are reared apart; intergenerational associations are higher for biologically related parents and children; and adoptive children's outcomes are positively associated with those of their biological parents (even after the adoptive parents' outcomes are controlled for). Empirical patterns consistent with important environmental factors are as follows: outcome correlations are positive among biologically unrelated adoptive siblings; correlations among biological siblings tend to be higher when the siblings are reared together; and adoptive children's outcomes are positively associated with those of their adoptive parents (even after the biological parents' outcomes are controlled for).

Intergenerational Models

Itzhak Zilcha

Recently it has been widely recognized by economists that the extension of the Arrow–Debreu model to a dynamic multi-period economy should not be restricted to models with a finite number of economic agents, each facing an infinite horizon. In analysing many economic problems, it seems natural to consider an open-ended horizon economy with individuals (or households) living for a finite number of periods; thus, at each date the economy consists of consumers of different ages (who interact with each other) and hence are inherently characterized by different economic parameters (such as their current income or planning horizon). In his seminal work, Samuelson (1958–9) attempts to explain, in an overlapping generations (OLG) equilibrium model, Irving Fisher's (1961) theory of interest. This simple model of a market economy characterized by an unbounded horizon, short-lived, overlapping, but essentially identical households, is different from the Arrow–Debreu model in various aspects. We shall concentrate upon similar models which have been successfully used to analyse microeconomic and macroeconomic problems. We shall focus upon the applications of these intergenerational models in: (1) efficient intergenerational and intertemporal allocation of resources, (2) intergenerational transfers (such as social security), and (3) optimal financing of government debt.

The Overlapping Generations Model: Pareto Optimality and Competitive Equilibria

Let us describe the OLG model as it has been frequently used in the literature. Basically this is a formal generalization of Samuelson's (1958) model.

The economy starts in period 1 and continues over periods extending indefinitely into the future, $t = 1, 2, \ldots$. In each period there are l, $l \geq 1$, consumption goods, which are perishable, and an imperishable fiat 'money'. All households (or consumers) in this economy live for two periods, except those households which already exist at the inception of the economy (namely, were born in period 0) and who live out the balance of their lives in period 1. The t th generation, G_t, is the set of all households born at the beginning of period t, $v = 0, 1, 2, \ldots$. Therefore, in each period t, there are just two age groups of households, the older generation, G_{t-1}, and the younger generation, G_t.

In each generation there are n households (or n 'types' of consumers). Each household will be denoted by a pair of indices (i, t), where $i = 1, \ldots, n$ and $t = 0, 1, \ldots$, and will be referred to as the ith household of the tth generation. Household (i, t), $t \geq 1$, has utility function u_i, u_i: $R^l_+ \times R^l_+ \to R$, defined over its lifetime consumption bundle $c_{it} = \left(c^y_{it}, c^0_{it}\right) \in R^l_+ \times R^l_+$, where c^y_{it} is the consumption of (i, t), when 'young', and c^0 is his consumption when 'old'. For $i \in G_0$ the utility function u_{i0} is defined over his consumption in period 1, c_{i0}, and u_{i0}: $R^l_+ \to R$. Each household (i, t) is endowed with physical goods in each period of his life $w_i = \left(w^y_i, w^0_i\right)$ in $R^l_+ \times R^l_+$ for $t \geq 1$. For $t = 0$, $w_{i0} \in R^l_+$ and $w_{i0} = w^0_i$. Households $(i, 0)$ of the oldest generation, G_0, may have initial endowments of money, $m_{i0} \geqq 0$.

Each consumer can trade goods and money in markets in t at (present value) prices denoted as $p_t \in R^l_+$ for goods and $p_m \in R^l_+$ for money, respectively. We also assume that young households can borrow money, free of transaction cost, by means of issuing IOUs as long as there are households in the same generation which will accept the IOUs. Each household (i, t) faces the problem, maximize $u_i(c_{it})$ s.t.

$$p_t c^y_{it} + p_{t+1} c^0_{it} \leqq p_t w^y_i + p_{t+1} w^0_i, \quad \text{for t} \geqq 1 \text{ and } c_{it} \geqq 0.$$

For i in G_0, the problem is maximize $u_{io}(c_{io})$ s.t.

$$p_1 c_{io} \leqq p_1 w_{io} + p_m m_{io}, \quad c_{io} \geq 0.$$

Note that since the economy is stationary, the optimal consumption of (i, t), $c_i(p_t, p_{t+1})$, depends only on (p_t, p_{t+1}), and for each (i, o) the optimal consumption $c_{io}(p_1, p_m)$ depends only on p_1 and p_m. The excess demand function for (i, t), $t \geq 1$, are

$$\begin{aligned} z_i\left(p_t, p_{t+1}\right) &= \left[z^y_i\left(p_t, p_{t+1}\right),\ z^0_i\left(p_t, p_{t+1}\right)\right] \\ &= c_i\left(p_t, p_{t+1}\right) - w_i. \end{aligned}$$

For (i, o) it is defined as $z_{io}(p_1, p_m) = c_{io}(p_1, p_m) - w_{io}$.

A competitive equilibrium is a triplet of positive goods prices, $(p^*_t)^\infty_{t=1}$ a non-negative price of money, p^*_m, and optimal lifetime consumption profiles $\left[(c^*_{it})^n_{i=1}\right]^\infty_{t=0}$ which are feasible, i.e.

(a)
$$\sum_{t=1}^{n} \left[c^{*y}_{it} + c^{*o}_{i(t-1)}\right] \leqq \sum_{t=1}^{n} \left[w^y_i + w^o_i\right], \quad \text{for } t = 1, 2, \ldots$$

and satisfies

(b)
$$c^*_{it} = z_i\left(p^*_i,\ p^*_{i+1}\right) + w_i, \quad \text{for all } i,\ t = 1, 2, \ldots,$$

(c)
$$c^*_{io} = z_{io}\left(p^*_1,\ p^*_m\right) + w_{io}, \quad \text{for all } i,$$

(d)
$$\sum_{t=1}^{n} \left[z^o_i\left(p^*_{t-1},\ p^*_t\right) + Z^y_i\left(p^*_t,\ p^*_{t+1}\right)\right] = 0 \qquad \text{for all } t = 2, 3, \ldots,$$

(e)
$$\sum_{t=1}^{n} \left[Z_{io}\left(p^*_1,\ p^*_m\right) + z^y_i\left(p^*_1,\ p^*_2\right)\right] = 0$$

A competitive equilibrium is called a *monetary equilibrium* if $p^*_m = 0$, and a *non-monetary* equilibrium, if $p^*_m = 0$.

A feasible allocation $\left((c_{it})^n_{i=1}\right)^\infty_{t=0}$ is called *Pareto optimal* (P.O.) if there is no other feasible

allocation $\left((\hat{c}_{it})_{i=1}^{n}\right)_{t=0}^{\infty}$ such that $u_i(\hat{c}_{it}) \geq u_i(c_{it})$ for all (i, t) and for some (h, τ), $1 \leqq h \leqq n$, $u_h(\hat{c}_{h\tau}) > u_h(c_{h\tau})$.

Samuelson analysed stationary allocations only and showed that without some extra-market institution, such as the fiat money already introduced in our presentation, competitive equilibria may not be Pareto optimal. Consider for example the case $l = 1$ $n = 1$, where the initial endowments are $w_i = (3, 1)$. Let $u_i(c^y{}_i, c^0{}_i) = \text{In } c_{io}$. Without fiat money the initial endowments allocation is the only competitive equilibrium when $p_t = 3^t$ for all t. This allocation is not P.O. since it is dominated by the P.O. allocation: $c^*_{i0} = 2$ and $c^*_i = (2, 2)$ for all i. If G_0 'contrives' fiat money, then a monetary equilibrium exists with this allocation and $p^*_t = 1$ for all t.

The main difference between an Arrow–Debreu model and the OLG model is the 'double infinity' of economic agents and commodities in the latter case. The reason for the failure of the second Theorem of Welfate Economics in the OLG models is the non–validity of Walras's Law in these infinite horizon models. This inherent property is due to the fact that, unlike the Arrow–Debreu economy, there is no posibility of trade between generations which do not overlap in their lifetime periods (see Gale 1973).

Extending Samuelson's analysis to the non–-stationary economies it was demonstrated by Cass et al. (1979) that when households are heterogeneous the following situations may occur: (a) there are both barter and monetary equilibria which are Pareto optimal; (b) there are both barter and monetary equilibria but none which is Pareto optimal. The non-optimality case, (b), highlights a fundamental difficulty: the mere creation of fiat money, i.e. the once-and-for-all augmentation of initial wealth, does not imply the second basic theorem of welfare economics; just the presence of money (trading for commodities at any conceivable positive price) may possibly not guarantee the Pareto optimality of competitive equilibrium.

In a non–stationary model, Okuno and Zilcha (1980) obtained a complete characterization of Pareto optimal competitive equilibria using the equilibrium prices. Also it is shown that certain monetary transfers (e.g. when the stock of money is increased at a uniform positive rate) can never achieve a Pareto efficient competitive equilibrium. Similar results have been attained by Balasko and Shell (1981). Cass and Shell (1983) introduced the concept of sunspot equilibria, that is equilibria in which uncertainty extrinsic to the economy operates through expectations to yield a fulfilled expectations competitive equilibrium in which the extrinsic randomness has real effects on prices and allocations. Cass and Shell examine assumptions on market structure and dynamics and find that sunspots can have no influence in a static world with complete markets, but can have effects when an OLG dynamics is introduced.

Intergenerational Transfers

The impact of annuity markets and social security upon savings, bequest and consumption has been studied recently in OLG models with uncertain lifetime. In these models there is a *continuum* of households in each generation. Each household maximizes its lifetime expected utility, where the utility from bequests appears explicitly. Uncertainty about lifetime concerns either the retirement period (as in Sheshinski and Weiss 1981; Eckstein et al. 1985) or may extend to all periods (as in Karni and Zilcha 1986). In the latter case it affects lifetime *earnings* and thus life insurance plays an important role in achieving efficient intergenerational allocations. In this model the first period income of each household depends upon the history of his family. In the presence of social security programmes and annuity markets agents can share death-related risks. When annuity markets operate, a non-discriminatory social security programme affects only the intergenerational allocation of resources. In the absence of private information regarding the survival probabilities, such a programme may lead to a non-optimal intragenerational allocation.

Kotlikoff and Summers (1981) use US data to estimate directly the contribution of intergenerational transfers to aggregate capital accumulation. They show that intergenerational

transfers account for the vast majority of aggregate US capital formation; only a negligible fraction of actual capital accumulation can be traced to life-cycle savings.

Loury (1981) models the dynamics of earnings distribution among successive generations of workers as a stochastic process. The process arises from random assignments of abilities to individuals by nature together with the utility maximizing bequest decisions of their parents. In this OLG model parents cannot borrow to make human capital investments in their offspring. Consequently the allocation of training resources among the young generation depends upon the distribution of earnings among their parents. This implies in turn that the conflict between egalitarian and redistributive policies and economic efficiency is mitigated.

National Debt: Analysis in Olg Models

In recent years the OLG model has been applied to investigate the effects of national debt on real economic activity. Historically, attention has been focused on the question of whether or not individuals perceive government bonds as net wealth, the link between wealth and real activity being as given. Diamond (1965) analyses these questions in an OLG model with production (employing a durable capital good), in which individuals provide for their retirement years by lending to entrepreneurs. Diamond's framework has been used extensively in analysing optimal financing of government expenditures and debt; we shall describe it briefly here. Individuals live for two periods: working period and retirement period. The labour force in each period t, $t = 0, 1, 2, \ldots$, is $L_t = L_0 (1 + n)^t$. The output in period t is given by $Y_t = F(K_t, L_t)$ where K_t is the capital stock in period t. $K_t + Y_t$, should be divided between capital stock K_{t+1} available for production in the date $t + 1$ and aggregate consumption C_t. Unlike the optimal growth models, where the central planner determines the allocation between productive capital and consumption in each date (according to some social welfare function) Diamond considers allocations through the competitive mechanism. Individuals in G_t receive wage W_t which equals the marginal product of labour, $F_L(K_t, L_t)$. This wage is allocated between current consumption $c^y{}_t$ and future consumption $C^o{}_{t+1}$ given the rate of interest on one period loans r_{t+1}, in a way that maximizes his lifetime utility $U\left(c_t^y, c_{t+1}^o\right)$. Therefore, $c_t^y = w_t - s_t$, $c_{t+1}^o = (1 + r_{r=1})s_t$ where $s_t = s(w_t, r_{r+1})$ is given by $U_1 = (1 + r_{t+1})U_2$. The equilibrium interest rate will equal the marginal product of capital, $r_{t+1} = F_K(K_{t+1}, L_{t+1})$, where the capital stock K_{t+1}, is *the sum* of the individual's savings $S_t = L_t s(w_t, r_{t+1})$. The equilibrium condition in the capital market which relates the interest rate to the wage rate of the previous period is ($f(c)$ is the per-capita production function);

$$r_{r+1} = f'\left(\frac{S_t}{L_{t+1}}\right) = f'\left[\frac{s(w_t, r_{t+1}}{1+n}\right] \qquad (1)$$

Given the factor–price frontier $w_t = \varphi(r_t)$ and the initial (w_1, r_1) equations (1) define the equilibrium path. Diamond observes from these relations that the equilibrium need not occur at an interest rate exceeding the Golden Rule level. Thus the competitive solution may be dynamically inefficient. The open-ended nature of this economy is crucial to such analysis. Using this OLG model, Diamond demonstrates that external debt has two effects in the long run, both arising from the taxes needed to finance the interest payments. The taxes directly reduce available lifetime consumption of the individual taxpayer. Further, by reducing his disposable income taxes reduce his savings and thus the capital stock. Internal debt has both of these effects as well as a further reduction in the capital stock arising from the substitution of government debt for physical capital in individual portfolios. Barro (1974), using the same model, assumes that generation t's utility depends on its own consumption and leisure and upon the utility of its immediate offspring's utility. This actually connects generation t to all future generations since its utility depends on the entire future time path of consumption and leisure of its descendants. Barro argued that despite the

limitation of finite lives of consumers in each generation, bonds will not be regarded as net wealth in a system characterized by intergenerational transfers. However, Barro admits that his neutrality result is valid for bonds that are redeemed at a known date. For a growing economy an increase in steady-state per-capita debt will generate net wealth if the rate of growth is greater than the interest rate. Further results concerning national debt were attained by Buiter (1979) and McCallum (1984).

Lucas (1972) uses Diamond's OLG framework, without population growth but including fiat money issued by the government and transferred to the old generation. Lucas shows that equilibrium prices and quantities exhibit what may be the central feature of the modern business cycle: a systematic relation between the rate of change in nominal prices and the level of real output. The relationship, essentially a variant of the well-known Phillips curve, is derived within a framework from which all forms of 'money illusion' are rigorously excluded: all prices are market clearing, all agents behave optimally in light of their objectives and expectations are formed optimally.

Tirole (1985) explores the interaction between productive and nonproductive savings in the model described above with capital accumulation. Some consequences of asset bubbles to asset pricing are derived. Once again the intergenerational interaction in an open-ended economy is important to such analysis.

Intergenerational models have been used in various other domains in economic theory due to their special dynamic characteristics. In international trade, for example, the examination of several questions related to exchange rate regimes has been carried out in an OLG model. Kareken and Wallace (1977) examine in various exchange rate regimes the differences that monetary-fiscal policy make. In the absence of capital controls the equilibrium exchange rate of the floating rate regime is indeterminate.

Bental (1985) applied an OLG model to two countries, two goods and two factors of production to show that in some cases the laissez-faire regime with free international trade and capital mobility is not necessarily a Pareto improvement over a regime in which capital is not internationally mobile. Furthermore, despite the fact that the laissez-faire regime is Pareto optimal and the restricted (portfolio autarky) regime is not, there do not exist simple temporal or intertemporal tax-transfer schemes which render the first allocation Pareto superior to the second.

Intergenerational Transmission

Lance Lochner

Abstract

Intergenerational transmission refers to the transfer of individual abilities, traits, behaviours and outcomes from parents to their children. This article analyses the key theoretical and empirical issues in studies of intergenerational transmission of educational attainment, welfare receipt and fertility. Mechanisms that lead to intergenerational transmission of these outcomes are discussed in detail. The role of government policy in affecting intergenerational transmission is also considered.

Intergenerational transmission refers to the transfer of individual abilities, traits, behaviours and outcomes from parents to their children. Economists have largely focused on the intergenerational transmission of educational attainment, earnings and income, wealth, fertility decisions and welfare receipt. When intergenerational transmission is strong, children turn out much like their parents, and social mobility is low.

Raw intergenerational correlations in education, earnings, teenage childbearing and welfare receipt in the United States are sizable. Correlations between parents'and children's educational attainment and earnings are both around 0.4. Daughters of teenage or welfare mothers are nearly twice as likely to have a child when they are teenagers compared to daughters of older or non-welfare mothers. Mothers who grew up in a welfare family are four to six times more likely to receive welfare themselves than other mothers.

What gives rise to the intergenerational transmission of these outcomes? Parents may genetically pass on abilities, endowments, or preferences to their children that predispose them to choose actions similar to those they themselves chose. This can generate an intergenerational correlation in outcomes even if there is no actual causal effect of a parent's behaviour or outcome on the child. However, parents' actions themselves may encourage their children to take similar actions. For example, parents' schooling choices may directly impact on their children's decisions to stay in school. Intergenerational transmission incorporates both causal and non-causal channels.

Identifying the mechanisms that lead to the intergenerational transmission of education, earnings, fertility, or welfare receipt is central to understanding the role played by economic conditions or government policies in shaping those

relationships. For example, if differences in earnings or welfare receipt primarily reflect differences in genetically endowed abilities, then policies to expand educational opportunities may have little effect on the intergenerational transmission of earnings and welfare. On the other hand, if ability primarily influences earnings by altering individual access to, or the financial rewards from, schooling, then college subsidies for low-income families should weaken the link between parents' and their children's earnings and welfare receipt.

This article offers detailed analyses of the key theoretical and empirical issues in studies of intergenerational transmission of educational attainment, welfare receipt and fertility. See also intergenerational income mobility for a discussion of earnings and income transmission.

Educational Attainment

The economics literature has emphasized the role of skill and human capital development in analysing intergenerational transmission. To begin, consider an overlapping generations economy that generalizes the model of Becker and Tomes (1986) in which parents choose between investing in their children's human capital, their own current consumption, and borrowing or saving in the form of debts or bequests left for their children. Parents care about their own current consumption, but they also care about the consumption of their children and all future generations. While schooling is costly for parents and children, it raises human capital (or skill) levels, which increases subsequent earnings. Suppose that the production of a child's human capital, H_c, depends positively on parental human capital levels, H_p, the child's 'natural' ability, A_c, and the total years of child schooling, s_c, such that $H_c = h(H_p, A_c, s_c)$. Further, assume that both child ability and parental human capital raise the marginal productivity of schooling (that is, $\partial^2 h/\partial s_c \partial H_p \geq 0$ and $\partial^2 h/\partial s_c \partial A_c \geq 0$). These assumptions imply that: (*a*) for any given level of child investment or schooling, an increase in parental education or child ability produces more child human capital and (*b*) more able children from more educated parents will tend to invest more in their skills through schooling. Finally, assume that the abilities of children and parents are positively (but not perfectly) correlated. That is, bright parents tend to have bright children while dull parents tend to have dull children, but there is, on average, regression to the mean.

If parents are free to leave any amount of bequests/debts to their children, optimal child schooling for each generation will be chosen to maximize discounted earnings less investment costs. In this case, a child's schooling, $s_c = \sigma(H_p, A_c, \pi)$ is an increasing function of his parents' human capital and his own ability, while it is decreasing in the price of schooling, π. Importantly, the optimal schooling level will not depend on parental earnings or wealth, although it may be correlated with both since they depend on parental abilities and human capital. In this simple model, a positive correlation in schooling between parents and children arises for two primary reasons: (1) parental human capital directly raises the productivity of child schooling and (2) abilities are positively correlated across generations and ability raises the productivity of schooling. Economists interested in identifying the 'causal effect' of parental schooling on child schooling attempt to estimate effect (1). This reflects the amount child schooling would increase if policy interventions were to raise parental schooling (and all else were held constant).

Effect (2) depends on the intergenerational transmission of ability. As this is driven by genetics, it reflects the main role played by nature. If a child's human capital depended only on his own ability and schooling (so $\partial h/\partial H_p = 0$ as assumed in Becker and Tomes 1986), only effect (2) would matter, and the intergenerational transmission of educational attainment would be driven by the intergenerational transmission of ability. Even in this case, nurture plays a role in that schooling and other family investments are choices made by families. When schools change their prices (or quality), schooling decisions and the intergenerational transmission of educational attainment are affected.

Imperfect credit markets with limited borrowing opportunities also weaken the link between

ability and schooling for poor families. When poor parents cannot borrow against their own future earnings or leave debts for their children, they may be forced to compromise on both their own consumption and schooling for their children (see, for example, Becker and Tomes 1986; Caucutt and Lochner 2006). Among constrained families, schooling choices depend on family income, I_p, so $s_c = \sigma'(H_p, A_c, \pi, I_p)$ where $\partial\sigma'/\partial I_p \geq 0$. Poorly educated (and, consequently, low-income) parents lucky enough to have bright children may not be able to afford the efficient amount of schooling for them. (This need not be true when parental human capital has a very strong effect on the marginal product of schooling; in this case, poorly educated parents may not want to invest much in their children, even when they are bright.) This implies a strong intergenerational transmission of schooling among the least educated who cannot escape their misfortune. Since more educated and wealthier parents can afford efficient investments in their children, their behaviour is driven by the forces described earlier (that is, $s_c = \sigma(H_p, A_c, \pi)$). That the most disadvantaged underinvest in their children (while the most advantaged do not) when borrowing opportunities are limited implies that policies designed to subsidize the schooling of poor children will help to reduce economic inequality while improving aggregate efficiency.

Most researchers agree that the primary reason many college-age children from poor families do not attend college is that they are ill-prepared and not because they are unable to borrow for college. This raises the question as to whether these youths are ill-prepared because their parents have been unable to borrow the resources needed to prepare them for college in the first place. Direct evidence is scant, but indirect evidence suggests that poor parents sometimes fail to make early educational investments in their children that have substantial long-run payoffs. Cunha et al. (2007), therefore, argue that policies promoting early investments (for example, preschool) in children do not face the same equity-efficiency trade-off that late investments (for example, college or post-school training) do.

The intergenerational transmission of preferences (for example, altruism, patience, or risk aversion) and other causal channels (for example, schooling may stimulate intellectual curiosity that is passed on to children) may also play important roles in the intergenerational transmission of education. While Mulligan (1997) explores the implications of endogeneous altruism, most economists have not incorporated these channels into their theoretical models.

The empirical literature typically considers a linearized version of the schooling decision described earlier:

$$S_{ci} = \alpha S_{pi} + \beta A_{ci} + \gamma I_{pi} + X_i\delta + \varepsilon_i, \qquad (1)$$

where X_i reflects variables that may affect the costs or benefits of schooling (for example, parenting skills, neighbourhood characteristics, school quality, or tuition prices) for child i. With ideal data, estimates from this equation inform us about the schooling choice function. Estimates of α tell us the direct effect of an increase in parental schooling, net of any effects parental schooling has on family income (or neighbourhood and school characteristics included in X). To obtain the total effect of parental education ($\alpha_T = \alpha + \gamma\partial I_p/\partial S_p + \delta\partial X/\partial S_p$), one must incorporate its effects through family income and the X variables. These effects are typically referred to as causal effects, since they measure how much a change in parents' education causes children's education to change. Most empirical studies suggest that the difference between α and α_T is small. See Haveman and Wolfe (1995) or Behrman (1997) for surveys of standard multivariate regression estimates of Eq. (1).

Since data do not typically contain reliable measures of child ability, neighbourhood and school peer quality, or parental skills in bringing up children, most regression-based estimates of Eq. (1) are probably upward biased for α. Researchers have begun to exploit three alternative econometric techniques that aim to reduce or eliminate biases arising from these types of unobserved factors: comparisons of children born of twin mothers or fathers, studies of adopted children, and instrumental variable approaches.

Some researchers have estimated how schooling differences between cousins whose parents are

identical twins depend on the educational differences between their twin parents. This approach assumes that schooling differences among twin mothers or fathers are random rather than the result of different abilities or environments – an assumption often questioned. If the effects of unmeasured ability and parenting skill differences are additively separable from the effects of parental schooling, within-twin-parent estimators remove the effects of genetic differences in parental ability (from the twin parent side of the family) as well as any variation in the twins' parenting skills owing to the similarity of their upbringing – two potential sources of bias. Twin-parent-based estimates generally imply an important role for unobserved ability and parenting skills in determining child schooling levels. Using recent US data on the children of twins, Behrman and Rosenzweig (2002) find that within-twin-parent estimates of the effect of father's schooling are positive and statistically significant, while the estimated effect for mother's schooling is not. That is, differences in schooling between cousins with fathers who are twins are positively correlated with the difference between their fathers' schooling. For cousins with twin mothers, differences in child and differences in mothers' schooling are uncorrelated. (Controlling for differences in spouses' schooling or earnings has little effect on these conclusions.) In explaining the finding that a mothers' schooling does not affect child schooling, the authors argue that more educated mothers spend more time working and may, therefore, spend less time bringing up their children. However, this was not true in the 1970s in the United States (Leibowitz 1974) nor is it true today in rural India (Behrman et al. 1999), where women work little outside the home. This shows that the economic environment plays an important role in determining intergenerational relationships.

A different approach estimates the effects of parents' schooling on adopted children. When the effects of nature and nurture are additively separable and adoptees are randomly assigned to adoptive parents, the estimated effects of the adoptive parents' education on adoptees' schooling eliminates any bias due to the genetic transmission of ability. Under these circumstances, the estimated effects from adoptees provide a measure of the role played by nurture. However, they need not reflect the causal effect of parental education if some unobserved parenting skills are correlated with (but not caused by) parents' educational attainment. Bjorkland et al. (2006) use a unique data-set from Sweden that contains educational attainment for adopted children and *both their biological and their adopting parents*. This enables them to regress adoptee schooling on the schooling of both biological parents, both adoptive parents, and even the interaction of biological and adoptive parents' schooling. While their results suggest important effects of the biological and adoptive father's and biological mother's education on their children, evidence of the adoptive mother's role is mixed. Interestingly, they estimate a positive and significant interaction between the biological and adoptive mother's schooling, suggesting an important nature–nurture complementarity. This interaction raises questions about methods that rely on the assumption that genetic and environmental effects are additively separable (for example, twin-parent studies or other adoptee studies that do not use data on both biological and adoptive parents).

Finally, some recent studies use changes in compulsory schooling laws in the United States and Europe as instrumental variables for changes in parental schooling. The legal changes largely affect the educational outcomes of parents at the low end of the distribution; thus, the studies' findings measure the impacts of increasing schooling among less-educated parents. Furthermore, the laws alter the population distribution of schooling, which may impact marriage markets. As such, they do not necessarily measure the effects of changing a single parent's schooling level. A Norwegian study (Black et al. 2005) estimates little causal effect of parental schooling (except for the mother–son relationship) when using an increase in compulsory schooling as an instrument, but the effects are not very precisely estimated. By contrast, a US study (Oreopoulos

et al. 2006) finds that a mother's and father's education has a significant effect on the probability that a young child is a year behind at school.

To summarize, most researchers conclude that parental education has a causal effect on child education, albeit substantially smaller than raw correlations suggest. While a few recent studies that compare children with twin parents or that focus on adopted children suggest that changes in a mother's education may have very small effects, instrumental variables studies do not confirm this pattern. Adoptee studies suggest that the educational outcomes of biological parents are important even when the child is brought up by others. Thus, the genetic transmission of abilities and preferences plays an important role in intergenerational transmission. Bjorkland et al. (2006) estimate an important interaction between nature and nurture that is often neglected in empirical analyses. Finally, even studies that estimate causal effects do not separately identify the mechanisms by which parents' schooling affects child schooling. We are still left wondering whether schooling changes the preferences or information of parents, or whether it changes the marginal productivity of investing in one's children.

Teenage and Non-marital Fertility and Welfare Receipt

Studies of intergenerational fertility transmission have typically focused on non-marital and teenage births, as these are often associated with a wide range of negative outcomes for mothers and their children. Studies of intergenerational welfare receipt invariably discuss intergenerational patterns for education, earnings, and fertility as well. Economic theories of fertility (for example, Becker 1991) generally say little about intergenerational patterns in childbearing and marital decisions. Formal economic models of intergenerational welfare transmission are also notably absent. Despite a lack of formal theory, social scientists have identified a number of factors that may affect the intergenerational transmission of fertility and welfare outcomes, including intergenerational correlations in cognitive ability, age of puberty, education and earnings. Economists are most interested in causal channels, however. Studies of teenage and non-marital fertility often refer to parental rolemodel effects and the impacts of early/non-marital childbearing on subsequent family structure and economic resources. Studies of intergenerational welfare patterns stress that parental welfare receipt may affect children's views about accepting public transfers, inform children about the welfare system, limit connections in and information about the labour market, and augment family resources.

Empirical researchers primarily aim to estimate the causal effects of parental teenage or out-of-wedlock childbearing and welfare receipt on daughters' choices; however, it is difficult to separate causal effects from other factors that contribute to intergenerational correlations. Analyses typically employ multivariate regression techniques to control for measured family and environmental conditions, but concerns about unobserved heterogeneity plague most studies. Unmarried welfare mothers almost certainly differ from married mothers who are not on welfare, even when current family income and other observable characteristics are the same.

Kahn and Anderson (1992) estimate very different roles of teen motherhood on the fertility decisions of black and white children. They find that teen motherhood largely affects white daughters' marital teen childbearing whereas black daughters' non-marital teen childbearing is most affected. Differences in family background drive much of the intergenerational correlation of teen motherhood for whites but not blacks. Biological links related to the age of puberty play no role in teen fertility for either race. Two more studies (Haveman et al. 2001; Wolfe et al. 2001) separate the effects of the mother's age and her marital status at childbirth on the probability that a daughter has an out-of-wedlock birth as a teenager. The first study finds that mother's age is the more important factor, while the second concludes that

marital status is more important. There is no consensus in the literature as to the relative importance of mother's age or marital status at the time of birth on her daughter's subsequent fertility decisions.

Most empirical studies of intergenerational welfare receipt control for parental income levels (or welfare eligibility), and attempt to estimate how parental welfare acceptance itself affects daughters' future welfare receipt. Some studies use instrumental variables (typically, local unemployment rates or state welfare benefit levels) to further account for unobserved heterogeneity in family tastes or productivity levels (for example, Levine and Zimmerman 1996; Pepper 2000). Gottschalk (1996) exploits the timing of parental welfare receipt (while the daughter lives at home and afterwards) in an attempt to control for unobserved permanent family characteristics. These studies generally conclude that parental welfare receipt increases the daughter's subsequent welfare receipt and childbearing, but much (or even most) of the raw intergenerational correlation is attributed to the correlation in both income and unobserved heterogeneity. Recent studies suggest that there is a small positive causal effect of family income on children's educational outcomes (for example, see Dahl and Lochner 2006); however, most intergenerational welfare studies find that income-enhancing effects from parental welfare payments do not reduce the probability of daughter's welfare receipt enough to offset other direct effects on daughters' tastes or information.

Intergovernmental Grants

Nora E. Gordon

Abstract

Intergovernmental grants are payments from one level of government to another, such as from the federal government to a state government, or from a city to a school district. Theoretically, such grants allow more local choice in public goods provision than purely centralized provision would, while still enabling some redistribution across local jurisdictions. Empirical research on these grants has focused on the extent to which these grants ultimately affect spending by receiving jurisdictions, both on the intended programme area and overall, and on other unintended consequences of the grants.

H7

Intergovernmental grants are payments from one level of government to another, such as from the federal government to a state government, or from a city to a school district.

Intergovernmental grants are widely used in the United States across a range of policy functions and are an important tool for redistribution in a federalist context. Under the Tiebout hypothesis, providing public goods locally rather than centrally improves match quality between individual preferences and local provision levels and generates competition in efficiency of public goods provision across communities, limiting bureaucratic capture. In a purely local system, however, any spillovers to public spending across local jurisdictions generate inefficient levels of public spending, and the ability to redistribute is limited to within local borders. Intergovernmental grants provide a mechanism to retain some benefits of local provision, while allowing for more optimal levels of public spending in the presence of interjurisdictional spillovers and increasing the capacity for redistribution.

The economic literature on intergovernmental grants investigates both their fiscal and their non-fiscal effects. Research on the fiscal impact of intergovernmental grants focuses on the extent to which they supplement local revenue formerly dedicated to the programme area, rather than supplanting it. Because intergovernmental grants are used in such a variety of policy functions, they have the capacity – especially if they do not crowd out local revenue – to affect a wide range of non-fiscal outcomes. Before discussing the research on the effects of intergovernmental grants, I briefly discuss the main types of intergovernmental grant structures.

Block Grants and Matching Grants

The most important distinction between block grants and matching grants is that matching grants change the relative prices facing the receiving jurisdiction, making the publicly provided good or service in question relatively cheaper, while block grants provide income but do not change prices. Both types of grant typically are directed to particular agencies or programmes.

Block grants transfer funds from one jurisdiction to another, and are theoretically equivalent to the receiving jurisdiction facing a positive income shock from any source. A conditional block grant requires that the receiving jurisdiction spend at least the grant amount on the governmental activity targeted by the grantor jurisdiction. The extent to which the condition is binding depends on the preferences of the receiving jurisdiction. Despite this constraint, the fungibility of grant income makes it difficult to force receiving jurisdictions to increase spending by the full grant amount. Grantor jurisdictions often attempt to address this issue through 'maintenance of effort' requirements,

by which receiving jurisdictions are required to continue funding the programme to which the grant is dedicated at some set percentage of previous years' levels in order to receive the grant.

When a grantor jurisdiction offers matching grants, it sets a rate at which it will match contributions from the grantee jurisdiction. These rates may vary depending on the level of contributions. Matching grants differ from block grants in fundamentally changing incentives for spending on education by making education spending 'cheaper' than other spending.

Data on Intergovernmental Grants in the United States

The Census of Governments, conducted every five years in years ending in 2 and 7, collects data from states, counties, cities and other municipalities, independent schools districts, and special districts on all revenues and expenditures, including intergovernmental grants. For intergovernmental grants, the Census of Governments details the source of revenue or destination of payments (federal, state, or local) and the policy function to which it is dedicated (for example, health, education, or fire).

Evidence of Fiscal Impacts: the Flypaper Effect

Economic theory predicts that a jurisdiction receiving an intergovernmental lumpsum grant targeted to a particular function of government will view the grant as income and spend it as such, with a fraction going to the targeted function, and the remainder going to other projects or to private consumption through reductions in tax rates. Many empirical studies, however, have observed that the marginal propensity to spend an intergovernmental grant on public expenditures is higher than the marginal propensity to spend other income on public expenditures. Arthur Okun called this phenomenon the flypaper effect, because the money 'sticks where it hits' (see Gramlich 1977). There are three main categories of explanation for these observed effects: (*a*) they are real and reflect the preferences of bureaucrats but not of voters; (*b*) they are real and reflect voters' preferences, but voter preferences may reflect some behavioural anomalies, such as loss aversion and lack of fungibility; (*c*) they are not real, but are generated by econometric misspecification. Hines and Thaler (1995) describe more specific cases within these categories in detail.

Given the current and historical prevalence of such grants, whether they ultimately supplement, or 'stick to', local spending is, unsurprisingly, the subject of a lengthy empirical literature, of which Hines and Thaler provide an excellent review. Studies included typically find that intergovernmental grants increase expenditures on the targeted programme by 25 to 100 per cent of the grant amount, with most estimates clustered at the high end of the range. This is much more than the receiving government's estimated propensity to spend on public programmes out of regular income (here Hines and Thaler estimate that only five to ten per cent of new non-grant income would be spent on public programmes), corresponding to a strong flypaper effect. One of the most convincing studies in their review is that of Ladd (1992), which shows that plausibly exogenous increases in state tax bases (stemming from the fact that some states link their tax base definition to the federal one, and exploiting changes in the federal income tax base following the Tax Reform Act of 1986) generate increases of about 40 per cent in state revenue. Many other studies simply correlate intergovernmental grants with spending, often in a cross-sectional context, without regard to potential bias from the fact that the same factors which make some jurisdictions receive more intergovernmental payments in a particular policy area may also make them have higher demand for public spending in that area.

Several recent additions to this literature have focused more explicitly on isolating exogenous variation in grant levels, and in doing so have yielded much less 'sticky' results. Knight (2002) accounts for political endogeneity in the amount of federal highway aid received by states by exploiting variation in legislative bargaining power due to seniority of state representatives in the US House. His technique reveals significant

crowd-out of states' own support of their highway programmes.

A number of recent papers focus on the heterogeneity of flypaper effects. Gordon (2004) shows that governments receiving intergovernmental grants may need time to adjust other revenue sources in response. Federal Title I grants to school districts for compensatory education, based largely on child poverty counts, appeared to stick completely to school spending in the first year following a shock to grant amount after the release of new census poverty data. Three years after the shock, however, there appears to be no effect on spending. Baicker and Staiger (2005) highlight the importance of institutional factors in determining how much receiving jurisdictions are capable of crowding out. In examining state responses to federal Medicaid Disproportionate Share Hospital (DSH) grants, they find that states which allow different levels of government to transfer funds directly between one another crowded out about half the federal grants. In states without this institutional capacity, the DSH funds were much stickier. Strumpf (1998) shows that the share of local spending on administrative overhead (a proxy for bureaucratic power) predicts the extent to which intergovernmental payments stick to local budgets, supporting a bureaucratic capture explanation of the flypaper effect.

Evidence of Non-fiscal Impacts

Intergovernmental grants have a wide range of effects, intended and unintended, on non-fiscal outcomes. The intended effects of intergovernmental grants may be due to the productive use of the grant. For example, Baicker and Staiger (2005) go on to show that federal DSH grants have significant impacts on mortality, despite the substantial crowd-out observed. Their findings suggest that the effects on mortality are due to the sticky part of the grant, which improves quality of hospital care. More often, studies evaluate the effect of the total intergovernmental grant amount rather than the effective or sticky grant amount on the outcome targeted by the grant. Such studies may conclude that public spending in that area is not effective, when in fact other revenue was crowded out so that total public spending in that area did not rise.

Jurisdictions making intergovernmental grants may do so to create incentives for the receiving governments that differ from simply spending the payment as designated. For example, Title I of the Elementary and Secondary Education Act of 1965 strengthened incentives for school districts to desegregate in compliance with the Civil Rights Act of 1964, and school districts responded accordingly (Cascio et al. 2005), though Title I funded compensatory education activities rather than desegregation-related costs. The current incarnation of this programme, the No Child Left Behind Act of 2001, similarly uses the threat of losing compensatory education funds as an incentive for schools to meet criteria for academic achievement growth benchmarks.

Finally, intergovernmental grants may create incentives that generate consequences unintended by the granting jurisdiction. For example, Cullen (2003) attributes 40 per cent of the significant rise in the special education classification of Texas public (government) school students from 1991 to 1996 to increased payments from the state to districts on a per-classified-student basis.

Internal Economies

G. Becattini

Abstract

Marshall introduced the idea of 'internal' economies, which accompany the growth of the 'individual representative firm', as opposed to the 'external' economies accompanying the growth of 'a national or a local industry'. In principle the pursuit of internal economies would lead to a world composed of firms each one producing a great share of a very small range of commodities. But while Marshall shared the classical view of an increasing average size of the business unit, he put it into a dynamical and historical context. Tendencies and countertendencies may result in different outcomes in terms of market structures.

The expression 'internal economies' is considered here solely in terms of Alfred Marshall's own formulation, which is quite different from current terminology referring to internal economies of scale. Modern terminology refers to a reduction in the average cost of production of a well-specified commodity in relation to increases in the quantity produced, assuming, for every given quantity produced, the most appropriate utilization of the optimum productive plant. Marshall's concept of internal economies is analytically looser than this, but richer in empirical content and, possibly, in philosophical insight.

The twin terms, 'internal' and 'external' economies (and diseconomies) were first used by Marshall 'for indicating the fundamental distinction between the "internal" economies and wastes which come with an increase in the size of the individual representative firm; and those "external" economies and wastes which come with an increase in the aggregate volume of a national or a local industry' (Marshall 1890, vol. 2, p. 347).

The main aim of the distinction was to help the applied economist in his attempts to disentangle the intricacies of contemporary socio-economic reality, rather than to provide an integral part of a formal theory of the relative values of the commodities; this is shown clearly enough by the ambiguous references to 'national or local industry' and by the use of such a fuzzy concept as the 'individual representative firm'. We must add that many times Marshall conveys the impression of confining external economies in the straitjacket of a single-product, homogeneous industry. Moreover, we must bear in mind, as Loasby aptly pointed out, that Marshall 'made no clear distinction between the theory of value and the theory of growth' (Loasby 1978, p. 1, n. 1).

This vein of Marshallian thought derives from three sources: his vast and detailed knowledge of the literature on contemporary British and American industry; his own ruminations on the Smith–Babbage arguments on the division of labour and the internal organization of the firm,

and, finally, his own early studies of mental science.

There is a passage in the *Principles* that contains the kernel of the Marshallian ideas on the internal growth of the firm. 'Practice makes perfect', starts Marshall, taking up the well-known Smithian theme:

> physiology, [he continues], in some measure explains this fact. For it gives reasons for believing that the change is due to the gradual growth of new habits of more or less reflex or automatic action. Perfectly reflex actions . . . are performed by the responsibility of the local nerve centre without any reference to the supreme central authority of the thinking power, . . . But all deliberate movements require the attention of the chief central authority: it receives information from the nerve centre or local authorities and perhaps in some cases direct from the sentient nerves, and sends back detailed and complex instructions to the local authorities, or in some cases direct to muscular nerves, and so co-ordinates their action as to bring about the required results. (1890, vol. 1, pp. 250–1)

This quotation helps us put together the scattered pieces of the Marshallian theory of the growth of the firm under competitive conditions.

Under the spell of all the usual drives of the human mind (money-making propensity, 'instinct of the chase, desire for fame', and so on), a business unit, working in a competitive context, is subject to a continual pressure to rationalize its most typical recurring operations and the tools used. So we have, simultaneously, both the development of 'skills' (a 'sort of capital of nerve force'), allowing the saving of time and of physical and, above all, nervous energies, and a rationalization of the process and the tools used. Alert to the danger of sliding to an abstract conception of the industrial process, Marshall makes room for historical and geographical peculiarities of the 'skilling' and 'rationalizing' processes.

But there comes a point 'when the action has thus been reduced to routine [that] it has nearly arrived at the stage at which it can be taken over by machinery' (1890, vol. 1, p. 254) At this point it is very probable that someone will invest the money and the inventive power required for the realization of the appropriate appliance.

When a machine is introduced into a manufacturing firm, its product becomes more uniformly specified and a cumulative process of mechanization and standardization can start. Marshall speaks of 'a great architectonic principle' according to which

> a well-driven machine tool could become the parent of new machine work more exact than itself . . . and so on . . . By successive steps larger and more delicate work is thrown upon the apparatus . . . at last it becomes . . . a thinking acting on hints given from within.. .. When all is in order, the machine is nearly self-sufficient. (1890, vol. 1, pp. 206–7)

The gradual introduction of specialized machinery results in more time and more nervous energies being made free at the hierarchical summit of the firm, in such a way that the entrepreneur can devote more of his time and energies to the 'broadest and most fundamental problems of his trade' (1890, vol. 1, p. 284), that is, to the collection and evaluation of information about general market trends and technological and organizational innovations.

The growing of a business unit above the other units of an industry gives to it the opportunity of taking advantage of a better allocation of skills, of getting hold of 'big brains', of introducing innovations out of reach of the others, of obtaining better terms in buying, selling and borrowing. And consequently, in the words of Marshall: 'lowers the price at which he can afford to sell' (1890, vol. 1, p. 315).

The basic constraint to the development of the individual firm lies in the conflict between the urge of the entrepreneur to decipher the environmental conditions of growth and the organizational requirements of the productive process. From this second viewpoint the best results can be attained by concentrating the entrepreneur's efforts on a narrow range of tasks. The simpler the work of direction, the larger the volume of output which can be efficiently controlled by a single mind, the greater the scope for the introduction of machines and uniform continuous processes. It would seem that the combined effect of these constraints would be a world composed of firms each one producing a great share of a very small range of commodities.

But this outcome would be apparently self-destroying for a world of competitive (albeit

imperfectly) firms, like the Marshallian one. Marshall's answer to this challenge is both complex and stimulating. First of all, to make use of all the possible internal economies, a certain amount of individual volition is needed. The entrepreneur 'works hard and lives sparely . . . subordinates trust him and he trusts them . . . every improved process is quickly adopted .. .'. If this behaviour 'could endure for a hundred years, he and one or two others like him would divide between them the whole of that branch of industry in which he is engaged'. But life is short and those who follow are not always fit to take over the task. The firms of many industries, at least before 'the great recent development of vast joint-stock companies, which often stagnate but do not readily die', like the trees of the forest 'gradually lose vitality and one after another . . . give place to others'.

We must also remember that 'many of the lines of division between the trades which are nominally distinct are becoming narrower and less difficult to be passed . . . A watch factory with those who worked in it could be converted without any overwhelming loss into a sewing-machine factory' (1890, vol. 1, pp. 258–9). This continual trespassing of 'industrial' borderlines systematically frustrates the inner tendencies towards concentration and monopolization.

It must also be taken into account that the continual formation of economies, external to the single firm but internal, either to an industry or to some group of industries, in that they apply even to the smallest firms, systematically erodes part of the advantage of the bigger businesses. A particularly relevant example of this is provided by the case of a localized population (the Marshallian 'industrial district') of medium-small sized firms, which, grouping together and specializing in various stages of the production process, achieve many of the large-scale economies typical of the giant firms.

Marshall shares the classical view of an increasing average size of the business unit, but he is very careful to put it into a dynamical and historical context.

Tendencies and countertendencies may result in different outcomes in terms of market structures. What is necessary for the process to be self-perpetuating is that the system should reproduce the complex of motivations which, given the structural characteristics of the industrial field, nourish the basic tendency of man towards liberation from purely mechanical tasks. In the words of R.A. Jenner: 'external and internal economies thus form counterbalanced forces of competition around which the disturbing thrusts of evolutionary change are held in control' (Jenner 1964, p. 311).

Internal Migration

James R. Walker

Abstract

Migration is a shared topic within social sciences attracting interest from members of all sub-disciplines. This attention reflects both the importance of the flows and the complexity of the behaviour. This article presents a short overview of the basic theoretical perspectives on individual migration decision making, and it considers empirical challenges to bringing these models to the data.

Keywords
Family decision making; Human capital; Internal migration; Labour market search; Learning; Social networks

Migration is a shared topic within social sciences attracting interest from members of all subdisciplines. This attention reflects both the importance of the flows and the complexity of the behaviour. This article presents a short introduction to economic analyses of internal migration.

Theory

Since the seminal work of Sjaastad (1962), economists have recognized that migration is a form of human capital. In the simplest model of wealth maximization the fixed costs of moving are balanced against the net present value of earnings streams available in the alternative location. This framework explains why, as was first noted by Ravenstein (1885), migration is an activity primarily of the young. The young are most likely to move, according to the human capital perspective, for three related but distinct reasons. First, they should move to take advantage of economic opportunities as soon as they are independent economic actors. Second, the young have a longer horizon over which to amortize the fixed cost of migration; hence, relatively small gains in earnings may tip the scales in favour of moving. And third, the young have fewer location-specific investments that serve to tie them to the current location (such as children).

Since its publication, Sjaastad's framework has been extended in a variety of ways (see Greenwood (1997), for a useful summary). Wealth maximization, as a motivation for migration, has given way to utility maximization, with uncertainty, information and local amenities given special attention. Perhaps the richest set of behavioural models appears in the development literature, where models of family behaviour incorporating notions of risk sharing, intergenerational transfers, and household bargaining have been developed. (See Lucas (1997), for a comprehensive summary, and Stark (1991), for several case studies which tailor the model to a particular context or issue.)

Nearly all the research on migration adopts a static framework, usually within a binary mover–stay decision framework. A classic example is Mincer's paper 'Family Migration Decisions' (1978), which is an early contribution to the now popular area of decision making in multiperson households. Mincer assumes wealth maximization and that spouses have separate preferences and different opportunities across locations. His basic insight is that the location of an individual's maximum may not coincide with the location of joint maximum. Indeed, the location of the joint maximum may not coincide with the location of the individual maximum of either spouse. This gives rise to the concepts of 'tied movers' and 'tied stayers' and sharp predictions on who should remain married and who should separate. One of his interesting predictions is that the incidence of migration should increase soon after a divorce or separation as the now independent individuals move from their 'tied' locations. Mincer also predicts that these forces become stronger as women's labour force participation and earnings increase.

The limitations of a static framework are also evident in Mincer's paper. (It is noteworthy that to date no one has extended Mincer's work in a meaningful way.) Mincer presumes marriage and does not investigate who marries whom (forward-looking agents may consider the possible consequences of different spatial opportunities before consummating the match). And, restricted to a single period, the analysis cannot investigate the timing or temporal sequence of separation and migration. Indeed, to study temporal linkages of migration and other important lifecycle choices (such as marriage or retirement) requires a dynamic framework. And, as illustrated above, a static framework begs the question as to the nature of initial equilibrium. Allowing households to make multiple migration decisions substantially increases the model's complexity. Now the model

must determine *where* and *when* to move. Moreover, prior moves influence subsequent opportunities, giving these models their own natural dynamics.

Empirical Implementation

One of the first empirical regularities gleaned from individual migration histories is their diversity (DaVanzo and Morrison (1981), is an early contribution). The richness of the life histories appears in the diverse terminology describing the types of moves. Concepts such as 'repeat' (an individual's second or higher order move), 'onward' (a move to a new location – all first moves are 'onward') and 'return' (movement back to a previous location, most commonly the individual's childhood location or self- identified 'home') appear. At an aggregate level, notions of 'circular' and 'chain' migration are commonly used.

Data from the US National Longitudinal Survey of Youth, 1979 Cohort (NLSY79) (US Department of Labor 2006), can be used to give an estimate of the magnitude of these flows. Data through 1994 when cohort members were in their mid-30s show that roughly 80 per cent of the cross-sectional sample had never moved out of their childhood state of residence, considered as their 'home' state. Of the 20 per cent of movers, more than half move again, and of the repeat movers, approximately 55 per cent ever return to their home state. Interestingly, few differences appear by gender, but the proportion of movers is U-shaped in completed education – individuals with a high school degree move the least, whereas those with some college or less than a high-school education are more likely to move. (Long (1988, 1991, 1992), and the numerous reports of William Frey at the University of Michigan and the Brookings Institute are among the best sources of descriptive evidence on internal migration flows in the United States.)

To study the influence of labour market opportunities on migration, we would like to define locations corresponding to distinct local labour markets. Within the United States, if we define local labour markets crudely as equivalent to counties, the model admits a choice set of approximately 3100 elements. (Models of residential choice and occupation are sometimes said to be isomorphic. From an empirical standpoint they are not. Models of occupation choice typically have relatively few alternatives, say five or ten, and educational or experience requirements or other characteristics offer a natural ordering to the occupational alternatives. See Neal (1999), for a recent contribution.) Consequently, there is a fundamental trade-off between the economic definition of locations and statistical measures available. For this reason many studies of internal migration use the decennial Census. Yet the decennial Census has its limitations, most importantly that virtually all individual and household characteristics are measured as of the date of the census. Census data offer detailed descriptive summaries of migration flows over narrow geographic regions, but, with no measures of pre-migration characteristics, are of problematic use for unravelling cause and effect.

Extending the analysis to panel data and multiple decision periods makes greater demands on the data and the analysis. Opportunities must be measured for each period of time, and some decision must be made on the persistence of economic opportunities. As in models of job search, the analyst must decide whether 'recall' is available: do migrants have the ability to remember and possibly return to a previous wage offer? If so, the size of the state space within the dynamic program formulation increases exponentially with the agent's memory length. And an important empirical challenge for dynamic analyses is sample attrition, as not being able to locate a respondent who has moved is one of the reasons for not securing an interview. (Survey organizations quickly developed expertise in locating respondents in the early years of the large-scale surveys such as the Panel Studies of Income Dynamics and the National Longitudinal Surveys. Most commonly, respondents are not interviewed because they refuse, not because they could not be located by the survey organization. See Olsen and Reagan (2000), for detailed information on the experience for the NLSY79.)

Nevertheless, Bellman's principle can be usefully applied to represent the decision problem of the individual (or household). Kennan and Walker (2005) adopt a dynamic programming approach for analysing the migration histories within the National Longitudinal Survey of Youth, 1979 Cohort. We find that earnings are an important (economic and statistical) determinant of migration flows, and their inclusion significantly improves the model's fit to the migration flows within the NLSY79. Respondents in the NLSY79 are more likely to leave a poor local labour market but do not necessarily move to 'the best' labour market as predicted by the model. Our findings are consistent with the interpretation that economic factors are an important determinant of migration, but not the *only* factor.

Research Frontiers

Research on internal migration flows remains on the frontier. Models and analysis of life-cycle migration are still in their infancy, with plenty of room for growth. An important challenge to decision theorists is developing frameworks for understanding return migration – why it is optimal to leave and return home. (Learning or more generally the resolution of uncertainty will be part of the explanation. For an early investigation based on learning, see Pessino (1991).)

Investigating the timing and the relationship between migration and other lifecycle choices such as marriage and retirement is another likely active research area. Certainly the migration behaviour by baby boomers will be of increasing interest to federal and local policymakers.

There is broad consensus that economic and family factors are the primary determinants of internal migration flows. Yet no analysis satisfactorily combines both factors. The barriers to doing so are more empirical than conceptual. The set of family members who may potentially influence migration choice is large, with no consensus as to which relationships must be surveyed. Except for the central role of parents and children, there is little additional information to guide one's choice. Obtaining information on the spatial distribution of family members and their avenues of influence (for example, income pooling or information sharing) is time consuming and thus costly. The influence of broader social networks need also be considered. The Great Black Migration within the United States during the first half of the 20th century illustrates the importance of social factors for migration streams (Lemann's (1991) classic *The Promised Land: The Great Black Migration and How it Changed America* offers an engaging account of the family, social and economic factors that stimulated these flows). Migration research may offer another avenue to explore the influence of social interactions, and perhaps provide stronger ties among social science disciplines.

Internal Rate of Return

Harald Hagemann

JEL Classifications
E2

The internal rate of return of an investment project is that discount rate or rate of interest Y which makes the stream of net returns x_t associated with the project equal to a present value of zero. It is the solution for i in the following equation in which indicates the physical lifetime of the investment project.

$$C(0,\theta) = \sum_{t=0}^{\theta} x_t(1+i)^{-t} = 0.$$

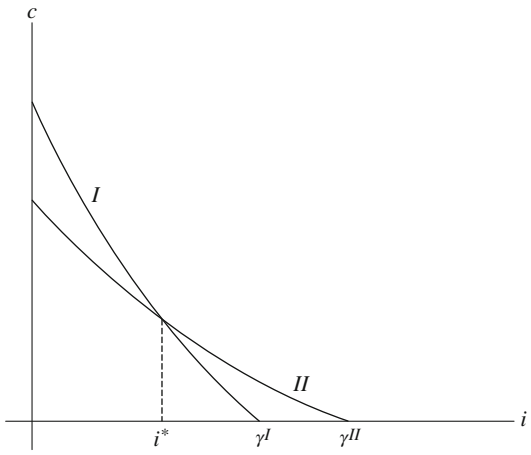
The internal rate of return is compared with the market rate of interest in order to determine whether a proposed project should be undertaken or not.

Among the criteria to be used in determining the profitability of an investment project two others are frequently considered. Whereas the payout-period criterion is a crude rule of thumb which for much of the time ignores pattern of receipts, the net present value criterion is the most relevant 'rule' for optimal investment behaviour. If the present value (using the market rate of interest as the rate of discount) of a project's expected earnings is greater than its cost (including discounted future operating and maintenance costs), that is, if the net present value is positive, the investment project is potentially worth undertaking.

Whereas the net-present-value rule and the internal-rate-of-return rule lead to identical results in the two-period case and in the perpetuity case (which in essence is only a variant of the former), the two criteria may lead to different results in the multiperiod case. Figure 1 illustrates such a case in which the choice between two alternative investment options will lead to identical results for $i > i^*$ whereas the two criteria lead to different results for market rates of interest smaller than the cross-over rate i^* where the present value of i is higher while II has the higher internal rate of return. The failure of the internal rate of return criterion is the consequence of the implicit assumption that all intermediate receipts, positive or negative, are treated as if they could be compounded at the '*internal*' rate of return itself whereas the only appropriate *external* discounting rate is the market rate of interest (reinvestment problem).

When the investment projects are independent and with a perfect capital market (in which the lending and borrowing rates of interest are identical) the net present value is, in general, the only universally correct criterion of appraising investment projects (see Hirshleifer 1958, 1970, ch. 3). For the multiperiod case the internal- rate-of-return rule is not generally correct. Furthermore, there may be *multiple rates of return* that will equate the present value of a project to zero. A necessary condition for non-uniqueness of the internal rate of return is that there be more than one change of sign in the stream of receipts over the lifetime of a project.

The controversy about the multiplicity of the internal rate of return in the late 1950s led to the development of the *truncation theorem.* This



Internal Rate of Return, Fig. 1

theorem turns out to be important for the general problem of choosing the optimal investment period (for a historical survey of truncation theorems see Matsuda and Okishio 1977). In 1969 Arrow and Levhari presented a new version of the truncation theorem which contrasted sharply with the other economists' method of choosing a truncation period so as to maximize the internal rate of return. They rightly pointed out that this criterion would not be adequate for the choice of the truncation period. Instead they advocated the maximization of the present value of the investment project as the proper criterion. It was demonstrated that the possibility of truncating investment projects at any age different from their physical lifetimes and at no extra costs leads to the following results:

(1) The maximized present value of the project is a monotonically decreasing function of the rate of interest. A corollary of this is that the internal rate of return is always unique.
(2) A rise (fall) in the rate of interest will always lower (raise) the present value of the remaining future net returns at all stages of the production process.

Consequently the optimal economic lifetime, too, is a monotonically decreasing function of the rate of interest.

Flemming and Wright (1971) dropped the assumption of a constant rate of discount per unit of time and tried to generalize the theorem to the case of different interest rates over time, a case where the deficiency of the internal-rate-of-return rule is most obvious. However, the 'generalization' does not take us very far because the calculation would require perfect foresight of future rates. The authors emphasize that a 'slight relaxation' of this assumption is allowed because 'a change in expectation which causes' all rates 'to be revised in the same "direction" will alter the present values of all costlessly terminable projects ... in a common direction' (Flemming and Wright 1971, p. 262). But even this proposition holds, in general, only when the change takes place uniformly, so that there is no change in the weights of the time pattern of the stream of net returns.

More interesting is the discussion of the impact of a consequence stream, that is, costs and benefits following from truncation. Whereas a positive *scrap value* can easily be incorporated the range of validity of the truncation theorem is severely limited in the case of *shut down costs.* Shut down costs can occur before and after truncation. Sen (1975) has shown that in the general case of a consequence stream following from truncation only minimal sufficiency conditions can be formulated: non-negative consequence sums (NCS) and non-negative consequence remainders (NCR), that is, the present value of the consequence stream for each t before and after the actual point θ of truncation has to be non-negative. Neither NCS nor NCR requires the present value of the consequence stream at θ to be non-negative, that is, a negative present value of the remaining process does not endanger the monotonicity result. But the conditions are very restrictive, because NCR is violated if the last item or the discounted value of the tail of the consequence stream is negative. This may be the case because of for example, redundancy payments, environmental protection or shut down costs of a nuclear power station.

The truncation theorem was originally developed in a *partial framework.* Nevertheless, Hicks (1973) and Nuti (1973) considered it applicable in a *general framework.* However, Eatwell's (1975)

criticism of these authors has clarified that important propositions of the theorem do not carry over to the general framework (see also Hagemann and Pfister 1978). At the partial level all prices in the economy are taken as given, that is, the individual's stream of net returns is considered not to be affected by changes in the discount rate. This assumption is impermissible when considering investment processes for society as a whole. At the general level the rate of profit is represented by the internal rate of return of the process as a whole for a given real wage. A variation of the discount factor, that is, the profit rate implies an opposite variation of the real wage rate. Because the present value of the whole process is both maximum and zero in competitive equilibrium the slope of the wage–profit curve is negative throughout. This is the only result one can draw under the conditions of the truncation theorem in the general setting. Neither the inverse relationship between the present value of the rest of the process and the rate of profit nor that between the optimal economic process length and the rate of profit invariably hold.

Furthermore, the analysis raises serious doubts as to the existence of an inverse monotonic relationship between interest and investment. The implication for Keynes's concept of the 'marginal efficiency of capital' is close at hand. As is well known, Keynes considered his concept 'identical' with Fisher's definition of the 'rate of return over cost' and stressed that there is no material difference 'between my schedule of the marginal efficiency of capital or investment demand-schedule and the demand curve for capital contemplated by some of the classical writers' (Keynes 1936, pp. 140 and 178). To be sure, there are passages which indicate that Fisher was aware of the fact that prices and therefore not only the present values of the streams of net receipts but the net receipts themselves vary with variations in the rate of interest (see especially the 'more intricate than important' complication discussed in Fisher 1930, pp. 170–71). However, the fixed-price assumption he commonly referred to implies a partial framework where the relationship between interest rates and prices is eliminated. It is therefore impossible to construct a demand curve for investment on the basis of a *ceteris paribus* clause for prices simply by variations of the rate of interest. An inverse macroeconomic relation between interest and investment cannot be derived from monotonicity results reached in a microeconomic framework. The difficulties encountered by Fisher and Keynes are discussed by Alchian and Garegnani from different points of view. Alchian (1955, p. 942) stresses that 'a schedule of investment demand at different market rates of interest requires that one compute the internal rates of return in terms of the prices that would prevail at each potential market rate of interest'. Garegnani (1978–9) brings into focus the problems involved in Keynes's concept of the schedule of the marginal efficiency of capital.

The return of the same truncation period and reswitching of techniques are closely linked phenomena occurring in a general framework. Some authors have tried to draw another analogy between the reswitching problem and the well-known possibility of the existence of multiple rates of return. Apparently the intention was to play down the importance of reswitching. This is reflected by the proposition that 'there is no new thing under the sun' (Bruno et al. 1966, p. 553). However, multiple internal rates of return are a phenomenon related to the partial framework from which a generalization to the general level is not admissible. Truncation ensures the uniqueness of the internal rate of return but cannot rule out reswitching. Therefore, an analogy between the two phenomena does not exist.

International Capital Flows

Shang-Jin Wei

Abstract

Cross-border capital flows may be regarded as either too small (known as the Lucas paradox) or too big (against the Samuelson theorem of factor price equalization). The resolution to the conflicting views may require thinking out of the neoclassical box. In theory, international capital flows can promote economic growth, but the data do not reveal a strong, robust, and causal effect, particularly for developing countries. The theoretical results and the empirical patterns can be reconciled through either a composition effect or a threshold effect. Some emerging evidence suggests that the two effects are related.

Cross-border capital flows worldwide have risen substantially since the mid-1970s, from US$1.2 trillion in 1980 to $5.8 trillion in 2004. The pace of the growth (at an average annual rate of 6.6 per cent) surpasses by a big margin those of the world GDP (at 1.7 per cent per annum) and the world exports (at 3.1 per cent per annum). Developed economies are the most important source countries, accounting for 92 per cent of the aggregate outward capital flows in 2004. They are also the most important recipients, accounting for 91 per cent of the aggregate inward capital flows in 2004. A small number of developing countries – commonly known as emerging market economies – receive the lion's share (nearly 70 per cent) of the remaining international capital flows in 2004. More than 130 other developing economies are more or less bypassed by the surge in the capital flows. (For these calculations, developed countries consist of the following 25 countries: Australia, Austria, Belgium, Canada, Cyprus, Denmark, Euro Area, Finland, France, Germany, Greece, Iceland, Ireland, Italy, Japan, Luxembourg, Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, Switzerland, the United Kingdom, and the United States. Emerging market economies consist of the following 22 economies: Argentina, Brazil, Chile, China, Colombia, Egypt, Hong Kong SAR, Indonesia, India, Israel, Korea, Morocco, Mexico, Malaysia, Pakistan, Peru, Philippines, Singapore, Thailand, Turkey,

Venezuela, and South Africa. Aggregate capital flows for any set of countries are calculated by summing up the values for individual countries in the set.)

The first part of this article, which draws from joint work (Ju and Wei 2006), provides an analytical perspective on the volume of international capital flows, which can be regarded as either too low (known as the Lucas paradox) or too high (when compared with the logic of factor price equalization). The second part, which draws from a different set of recent work (Prasad et al. 2003; Wei 2006; Kose et al. 2006), examines some apparent mismatch between theory and empirics on the economic consequences of international capital flows, and discusses ways to reconcile them.

The Volume of International Capital Flows: Paradoxes and Possible Solutions

The extent of cross-border capital movement can be measured by flows at a given point in time or by stocks accumulated over time. Capital inflows are net purchases of domestic assets by foreign residents, whereas capital outflows are net purchases of foreign assets by domestic residents. These data are well described in the International Monetary Fund's Balance of Payments statistics. For stock data, the IMF reports information for a few countries in recent years. Lane and Milesi-Ferreti (2001, 2005) expand the country and year coverage by combining this information with cumulative flows adjusted for valuation effects.

A country's exposure to international capital flows can be measured either by its government's policies (restrictions or incentives vis-à-vis capital flows) or by the actual amount of capital movement (scaled by the size of the recipient economy). The latter, the *de facto* measure, does not need to agree with the former, the *de jure* measure. For example, some countries may have many legal restrictions on capital movement (and hence a low exposure to capital flows by the *de jure* measure), but massive capital flight (and hence a high exposure by the *de facto* measure). A practical *de facto* measure of a country's exposure to cross-border capital movement is the sum of the country's total foreign assets and total foreign liabilities, divided by the country's GDP. For some economic questions, such as the effect of international capital flows on economic growth, the *de facto* measure may be more meaningful than the *de jure* measure.

Is the volume of capital flows observed in the data consistent with economic theory? Using a one-sector model, Lucas (1990) argues that it is a paradox that more capital does not flow from rich to poor countries. His reasoning goes as follows. Let $y = f(L, K)$ be a constant-returns-to-scale production function, where y is the output produced using labour L and capital K. Let p be the price of the good, and w and r be the returns to labour and capital, respectively. Firm's profit maximization problem gives

$$r = p\partial f(L,K)/\partial K = p\partial f(1,K/L)/\partial K \qquad (1)$$

If the product price is equalized across countries under free trade, the law of diminishing marginal product implies that r is higher in the country with a lower capital–labour ratio. As an illustration, Lucas calculates that the return to capital in India should be 58 times as high as that in the United States based on their factor endowment. Facing a return differential of this magnitude, one should observe a lot more capital flowing from rich to poor countries. That too little is observed in the data has come to be known as the 'Lucas paradox'.

Lucas (1990) discusses three possible explanations (within a one-sector framework): (*a*) a worker in a rich country could be several times more productive than her counterpart in a poor country; (*b*) human capital may be a missing factor and is likely much higher in a rich country; and (*c*) political risk and hence the required risk premium may be substantially higher in a poor country. Reinhart and Rogoff (2004) illustrate the last point for a set of countries with frequent default on their external debt.

Lucas's logic can be turned on its head in a multi-sector model. More precisely, in a standard Heckscher–Ohlin–Samuelson model with two

goods, two factors, and two countries, firms earn zero profit. So one must have:

$$p_1 = c_1(w, r) \text{ and } p_2 = c_2(w, r) \qquad (2)$$

where $c(.)$ is the unit cost function and the numerical subscripts represent sectors. This implies that the factor prices are uniquely determined by product prices, and are independent of factor endowments. Since free trade in goods equalizes the product prices across countries, factor returns must also be equalized even in the absence of cross-border capital and labour movement. This was first pointed out by Samuelson (1948) and has become known as the 'factor price equalization theorem'. Two countries with different capital–labour ratios would simply produce different mixes of outputs, but the marginal returns to physical capital are the same everywhere. In other words, zero capital flow is needed in equilibrium. This is true with or without cross-country differences in effective labour, human capital or political risk. The actual capital flow appears excessive on this logic.

One might think that the theorem of factor price equalization is too naive, requiring restrictive assumptions that surely do not hold in a more realistic setting with many countries, goods and factors. However, Ju and Wei (2006) show that, in a generalized neoclassical framework, relatively weak conditions are sufficient for factor prices to be equalized across countries (without factor movement). In particular, while the United States and India may not appear to satisfy the conditions for the factor prices to be equalized between them in a two-country model, it is nonetheless possible for factor prices to be equalized through a chain of country pairs (for example, the United States and Spain, Spain and Greece, Greece and Thailand, and Thailand and India). This means that it may be more difficult than it first appears to escape from the logic of factor price equalization within a neoclassical framework, and that free trade in goods can completely substitute for capital mobility.

Obstfeld and Rogoff (2001) proposed that the existence of trade costs could explain the low but positive international capital flow. Trade costs do break factor price equalization even in a two-sector, two-factor model. However, as tariffs and transport costs decline over time, factor prices (including returns to capital) should converge across countries. This should lead to a decline in international capital flow (by the logic of factor price equalization), which is contradicted by the data.

Cross-country differences in total factor productivity (TFP) is another influential explanation of the Lucas paradox. While the discussion is usually couched in a one- sector model, it *could* work even in a multi-sector model. In particular, in a two-sector model, if the TFPs in both sectors are many times higher in the United States than in India, then return to capital in the United States could be only slightly lower than in India, justifying the observed small amount of capital flow. What drives the TFP differential across countries can be the quality of institutions, including the protection of property rights and the control of bureaucratic corruption. However, the TFP story can also go in the opposite direction in principle, exacerbating rather than resolving the Lucas paradox. In particular, if the United States has a greater TFP advantage in the labour-intensive sector than in the other sector, then this could further depress the return to capital from what already results from a high capital–labour ratio. This suggests that one has to be precise about the nature of the TFP differences in order to deliver predictions on the sign and the size of international capital flows.

Moving outside the neoclassical box, Ju and Wei (2006) introduce financial contracts and heterogeneous firms into an otherwise standard two-sector, two-factor framework. A key implication of the model is the separation between return to physical capital and return to financial investment. In particular, India could have a high return to physical capital due to its relatively low capital–labour ratio, but a low return to financial investment due to its relatively inefficient financial system. In addition, heterogeneous firms give rise to diminishing marginal returns at the sector level even though every firm has a constant returns technology. As a result, factor price equalization (before factor movement) does not hold in

this model. In equilibrium, it is possible for financial capital to leave India for the United States, and for physical investment to flow in the reverse direction, resulting in a moderate amount of net flow. In this model, the return to capital (before capital flows) is still higher in India (with a lower capital-to-labour ratio) than the United States, but the differential in return is much smaller than in a one sector model. Thus, Ju and Wei's non-neoclassical two-sector, two-factor model partially restores the result of a typical one-sector model (that is, return to capital is determined in part by factor endowment) but does not generate the Lucas paradox.

Effects of International Capital Flows on Economic Growth

The Gap Between Theories and Empirics

International capital flows have the potential to bring a variety of benefits to recipient countries. In theory, financial globalization could raise a country's economic growth rate through a number of direct and indirect channels.

The direct channels include (*a*) augmenting domestic savings, (*b*) reducing the cost of capital through better allocation of risks (Henry 2000; Stulz 1999), (*c*) transferring technology and managerial know-how (Grossman and Helpman 1991), and (*d*) stimulating development of the domestic financial sector (Levine 1996; 2005). The indirect channels include (a) promoting specialization (Brainard and Cooper 1968; Imbs and Wacziang 2003), and (b) committing to better economic policies (Gourinchas and Jeanne 2004; Tytell and Wei 2004).

Yet a massive body of empirical papers has often found mixed results, suggesting that the benefits are not straightforward. Kose et al. (2006) survey 20 scholarly articles written between 1994 and 2005 that have empirically estimated the effect of exposure to international capital flows on economic growth. A majority of these papers (16 out of 20) find no, or at best mixed, effects. This echoes the conclusion in earlier survey articles by Eichengreen 2001 and Prasad et al. (2003) that it is not easy to find a strong and robust causal effect from financial globalization to economic growth, especially for developing countries.

Indeed, one alleged source of collateral damage of financial globalization is an increased propensity for developing countries to experience currency crises or other types of financial turmoil. For example, while the pace of cross-border capital flows picked up in the 1980s, there have also been more financial crises since around 1990, including the crises in Mexico in 1994, the Asian financial crisis during 1997–9, the Russian meltdown in 1999, and the Argentinean and Uruguayan crises of 2001–2. Most such crises tend to set countries back in their growth aspirations for a number of years.

Reconciling Theories with Empirical Patterns

Financial crises do not prove that financial integration is a bad thing. Indeed, almost all developed countries are financially integrated, and very few developing countries, once embarked on a path of integration, would go back to financial isolation. So why do countries aspire to become financial integrated and yet experience so many bumps and potholes along the way? The literature has proposed *independently* two views: a composition hypothesis and a threshold hypothesis.

The composition hypothesis maintains that not all capital flows are equal. International direct investment, and perhaps international portfolio flows, appear to be robustly associated with a positive effect on economic growth (Borensztein et al. 1998; Bekaert et al.2005). In contrast, there is no strong evidence that private foreign debt including international lending has robustly promoted economic growth. Indeed, one sometimes finds evidence that international lending is negatively associated with economic growth. Official aid flows do not robustly support growth either (Rajan and Subramanian 2005).

Composition of capital flows has also been related to a country's propensity to experience a currency crisis. In their study of all episodes of currency crises in emerging markets during 1971–92, Frankel and Rose (1996) report that, while virtually no variable has a strong predictive power for subsequent currency crashes, the

composition of capital inflows is one of the very few variables that are robustly related to the probability of a currency crisis. In particular, the share of foreign direct investment (FDI) in a country's total capital inflow is negatively associated with the probability of a currency crisis. This is confirmed in several subsequent studies including Frankel and Wei (2005). Other dimensions of composition are the maturity structure of external debt (the greater the share of short-term debt, the more likely a crisis), and the currency denomination of external debt (the greater the share of foreign currency debt, the more likely a crisis) (Frankel and Rose 1996; Radelet and Sachs 1998; Rodrik and Velasco 1999).

The threshold hypothesis states that certain minimum conditions have to be met before a country can be expected to benefit from financial globalization. Otherwise, the country could experience more crises and lower growth. The threshold effect comes in various versions. Only countries with reasonably good public institutions (for example, adequate control of corruption) and a minimum level of human capital seem to be able to translate exposure to financial globalization into stimulus to investment and growth on a sustained basis (see the surveys by Prasad et al. 2003; Kose et al. 2006). It is not difficult to imagine why countries with weak institutions may not benefit from financial globalization. In a highly corrupt country, for example, more capital inflows are likely to result in more consumption by a few elite families or in bigger Swiss bank accounts rather than more productive investment. So more capital flows may not result in higher growth rates. If capital inflows help to promote excessively risky projects backed by governments, then more inward capital flows could translate into an increased probability of a financial crisis.

Is the Composition Effect a Consequence of the Threshold Effect?

Rather than viewing the threshold effect and the composition effect as two *rival* hypotheses, Wei (2000a, b, 2001) suggests a concrete connection between the two: countries with better public institutions are likely to attract more international direct investment than international bank loans. Wei derives evidence from data on bilateral FDI reported by OECD source countries, and bilateral international lending reported by Bank for International Settlements (BIS) member countries. In the earlier work, Wei measures quality of public institutions by perception of corruption reported in surveys of firms such as those conducted by the World Economic Forum for its *Global Competitiveness Report* or by the World Bank for its *World Development Report*.

Recent evidence on investment by international mutual funds suggests that better institutions measured by a high degree of government and corporate transparency help to attract more international equity investment than that predicted by the international capital asset pricing model (ICAPM) (Gelos and Wei 2005). So the composition effect and the threshold effect are perhaps just the two sides of the same coin.

Not everyone has found the same result. Hausmann and Fernandez-Arias (2000) report no relationship between share of FDI in total capital inflows and good institutions. In a panel of advanced and developing countries, Albuquerque (2003) finds the share of FDI in total inflows to be negatively related to good credit rating. It is important to note that Albuguerque's measure is about financial development rather than quality of public institutions generally, whereas Haumann and Fermandez-Arias mix measures of financial development and property rights institutions. As Ju and Wei (2006) point out, financial development and quality of public institutions have different effects, in theory, on the composition of capital flows. Furthermore, none of these studies employs instrumental variables to correct for possible measurement errors and endogeneity of the corruption or other institutional measures.

In any case, more recent papers with an instrumental variable approach and arguably better data again affirm the earlier conclusion that there may be an intimate relationship between the institutional threshold effect and the composition effect. Using data from the IMF on balance of payments, Alfaro et al. (2005) find that good institutional quality is a key determinant of total capital inflows. Papaioannou (2005) reports that foreign asset holdings by BIS banks, including their

portfolio assets and direct investments, tend to be higher in destinations with better institutions.

Using recently available data from the IMF on member countries' international investment position (IMF 2002), Faria and Mauro (2004) present evidence that countries with strong institutions are likely to attract more equity-like capital flows (FDI and portfolio equity flows) than other types of capital. Their measure of Einstitutional quality is the average of six indicators – voice and accountability, political stability and absence of violence, government effectiveness, regulatory quality, rule of law, and control of corruption – as computed and reported by Kaufmann et al. (2003). An important feature of the study is that the authors address explicitly the possibility that the composite institutional index may be measured with errors and/or be endogenous. They employ as instrumental variables log settler mortality during the early colonial period as proposed by Acemoglu et al. (2001) and ethno-linguistic fragmentation first used by Mauro (1995). The instrumental variable approach reaffirms their basic conclusion.

Wei (2006) furnishes evidence that the effects of the quality of public institutions and the level of financial development can indeed be different. In particular, weak public institutions strongly discourage FDI, and possibly foreign debt, as shares of a country's total foreign liabilities, but appear to encourage borrowing from foreign banks. In comparison, low financial-sector development discourages inward portfolio equity flows but encourages inward FDI. The finding that poor financial development could encourage FDI may sound surprising. A possible story is set out in Ju and Wei (2006). Essentially, in countries with poor financial systems but also low capital–labour ratios, the return to financial capital is low. Hence domestic households would want to take savings out of the country, and international portfolio investors do not wish to come in. As the same time, as long as the risk of expropriation is not too high, the depression of domestic investment due to poor domestic financial development could raise the return to FDI.

To gain confidence that these patterns reflect causal relations, Wei (2006) employs instrumental variables for the institutional measures based on the economic histories of the countries in the sample, in particular the log mortality rate of the European settlers in former colonies à la Acemoglu et al. (2001), and the origin of legal systems à la La Porta et al. (1998). The instrumental variable approach bolsters the argument that weak institutions are a *cause* of the unfavourable composition of capital inflows.

To summarize, the cumulative evidence points to the strong possibility that weak public institutions tilt the composition of capital flows into a country away from FDI and portfolio equity flows and towards debt, including bank loans, making the country more vulnerable to a currency crisis and less able to translate a given amount of capital inflow into stimulus for economic growth. While the composition and the threshold effects are not identical, they are very likely related.

For an institutionally challenged country, more research is needed to determine whether it should wait for its institutions to be sufficiently improved before opening up to global capital flows, or use exposure to the international capital market as a disciplinary device to improve its institutions.

International Coordination in Asylum Provision

Yuji Tamura

Abstract

This article summarises theoretical studies on asylum provision in multi-country settings. The common feature of their models is the assumption that asylum-related policies of safe countries generate cross-border externalities. The presence of externalities results in inefficiently low provision of asylum. The studies explore ways to increase asylum provision to the efficient level, but reveal more difficulties than a solution.

This article summarises the current state of the theoretical literature on the provision of asylum – the protection of refugees by sheltering them within the provider's territories. The existing studies offer insight into the incentive problem of asylum provision when there is more than one potential host country. The studies show that asylum provision remains inefficiently low even if people in safe countries are humanitarian and care about the welfare of refugees. This is because of the way people in safe countries benefit from asylum provision in the models. The government of a safe country derives a benefit from the protection of refugees because it cares about the welfare of its own citizens who in turn care about the welfare of refugees abroad. However, this benefit accrues to the citizens whether the protection is provided in their own country or in other safe countries. Since hosting refugees is costly, each safe country has an incentive to rely on the asylum provision of other safe countries. Consequently, the provision of asylum remains inefficiently low.

This type of incentive problem in asylum provision was first articulated verbally before the model-based studies appeared, e.g. Suhrke (1998). As a matter of fact, the free-or easy-riding problem (Cornes and Sandler 1996) is not specific to asylum provision but is common to the provision of various public goods that are distinguished from private goods by the degree of non-rivalry and non-excludability in consumption. In our context, the 'consumption' of refugee protection is not rivalrous because when the humanitarian citizens of one country gain from the protection of refugees their gain does not reduce the benefit that accrues to the humanitarian citizens of another country. The 'consumption' of asylum is not excludable either. The provider cannot prevent humanitarian citizens of other countries from enjoying the protection of refugees. The provision of a public good thus generates positive externalities – the benefits enjoyed by people who did not supply the good.

Using an overarching framework where asylum enters as an international public good, we look at how different factors influence asylum provision. The existing studies examine how we could mitigate the incentive problem among potential host countries. However, their searches for ways to increase asylum provision to the

efficient level reveal, instead of a solution, difficulties in resolving the incentive problem. This article omits discussion of the literature in relation to policy coordination in reality, as the non-technical companion article (Suriyakumaran and Tamura 2016) includes it.

Benchmark Model

Consider a fixed number of safe countries indexed by $n = 1, \ldots, N$. They face a mass of identical refugees. Asylum is modelled as an international public good.

Each country's net benefit is defined as follows:

$$u_n(a_n, a_{-n}) = b_n(a_n, a_{-n}) - c_n(a_n)$$

where $a_n \geq 0$ denotes the number of refugees that country n decides to host and $a_{-n} \geq 0$ denotes the number of refugees that the $N-1$ other countries decide to host. The benefit function, $b_n(\cdot)$, is increasing in asylum provision by any country. Here, a_n and a_{-n} are entered separately to allow for the possibility that asylum is an impure public good. That is, a safe country might well regard a foreign country's provision of asylum as an imperfect substitute of asylum provision by itself, although one foreign country's provision is assumed to be a perfect substitute of another foreign country's provision. Reasons for considering asylum provision as an impure public good include the importance of doing it yourself as opposed to reliance on other safe countries (self-satisfaction aspect) and the generation of international prestige through the exhibition of altruistic actions (Andreoni 1989). The cost function, $c_n(\cdot)$, is increasing only in its provision of asylum, as the cost of providing a_{-n} is borne by the other safe countries. The net benefit, $u_n(\cdot)$, is concave in a_n, i.e. $\partial^2 b_n / \partial \alpha_n^2 < 0$ and $c_n'' \geq 0$, or $\partial^2 b_n / \partial \alpha_n^2 < 0$ and $c_n'' \geq 0$.

The absence of international coordination is modelled as a static game of complete information in which each country independently maximises its net benefit by taking others' asylum provision as given and choosing its provision of asylum, i.e.

$$\max_{a_n} u_n(a_n; a_{-n}).$$

The resulting Nash equilibrium is compared with the outcome of

$$\max_{\alpha_1, \ldots, \alpha_N} \sum_{n=1}^{N} u_n(a_n, a_{-n}).$$

Under international coordination, the countries are thus assumed to maximise the utilitarian welfare together. This internalises the positive externalities generated by each country's provision of asylum.

Hatton (2004) analyses this model for two identical safe countries, i.e. $b_1(a_1, a_2) = b_2(a_2, a_1)$ and $c_1(a_1) = c_2(a_2)$. He shows that the internalisation of the positive externalities increases the total provision of asylum by increasing provision in both countries. Since each country's benefit function increases in the total provision while the cost function increases only in its own provision, the net benefit is greater under the utilitarian maximisation than in the Nash equilibrium. Hence the identical host countries should be willing to coordinate to maximise their total welfare, resulting in a Pareto efficient outcome.

This conclusion does not require two potential host countries to be identical. Czaika (2009) shows that both countries can benefit from the utilitarian maximisation as long as they are sufficiently similar to each other in their benefit and cost parameters. In other words, when the countries are sufficiently different from each other, the utilitarian maximisation requires one of the two to be worse off than in the Nash equilibrium. The total welfare maximisation is not beneficial for the country where asylum provision is very costly and/or is not sufficiently appreciated.

Role of Cross-Border Financial Transfers in Increasing Asylum Provision

Facchini et al. (2006) and Czaika (2009) examine the role of financial transfers in enabling two

non-identical countries to increase the total provision of asylum. While Facchini et al. (2006) simply assume that two countries agree to share the total net benefit equally through a financial transfer from one country to another, Czaika (2009) allows two countries to decide on their cross-border financial transfers in a two-stage game with complete and imperfect information. The countries first decide on their transfers simultaneously, and then decide on asylum provision simultaneously. He shows that the total provision of asylum in the subgame-perfect Nash equilibrium can be greater than that in the Nash equilibrium without a financial transfer. The country that benefits more from asylum provision abroad than from domestic provision (in other words, the marginal cost of asylum provision is high) is willing to financially support the other country which benefits more from domestic provision than from provision abroad. However, the possibility of financial transfers is shown to be insufficient to achieve the total welfare maximisation.

Allocating Tradable Asylum Quotas to Achieve the Utilitarian Welfare Maximisation

Fernández-Huertas Moraga and Rapoport (2014, 2015) show that a fixed number of potential host countries can maximise the total net benefit if they can agree with an initial allocation of tradable asylum quotas that can total the utilitarian welfare-maximising level of provision. In this competitive scheme, originally proposed verbally by Schuck (1997), the equalisation of marginal costs of asylum provision across the participating countries determines the price of transferring to another country the obligation to grant asylum to a refugee. Countries that can provide asylum only at high costs reduce their quotas by paying other low-cost countries to host refugees in excess of their initial quotas.

For the countries to willingly participate in the scheme, the initial allocation of tradable quotas must be incentive-compatible. Other things being equal, the scheme should initially allocate larger quotas (larger than the post-trading quotas that achieve the utilitarian maximisation) to countries that derive greater externality-related benefits from the scheme (that is, the externality-related benefit is greater under the scheme than in the Nash equilibrium without tradable quotas). Also, other things being equal, smaller quotas (smaller than the post-trading quotas that achieve the utilitarian maximisation) should be initially allocated to countries that bear higher costs under the scheme (that is, the cost of asylum provision is higher under the scheme than in the Nash equilibrium without tradable quotas). An initial allocation that meets these incentive compatibility constraints enables all participating countries to increase their net benefits through quota trading.

Fernández-Huertas Moraga and Rapoport (2014, 2015) point out the difficulty of identifying incentive compatibility constraints for deriving a correct initial allocation. Relevant benefit and cost parameters are likely to be private information, and a potential participant may lack an incentive to reveal true parameters because the initial allocation can be manipulated to its advantage by giving false parameters.

Fernández-Huertas Moraga and Rapoport (2014, 2015) also show that individual preferences of refugees over the potential host countries and the preferences of those countries over refugees with different characteristics can be taken into consideration through matching mechanisms. For example, in a deferred acceptance algorithm (Roth 1985), safe countries offer asylum to their most preferred refugees, and each of the refugees either accepts one of the received offers or declines all offers according to her/his preference. The process repeats with the remaining refugees until all tradable quotas are met. As we focus on the welfare of host countries in this literature, this algorithm may be attractive because safe countries are likely to benefit from an efficiency gain by filling their asylum quotas with preferred refugees. To justify the use of a matching mechanism, the efficiency gain must outweigh a potential increase in uncertainty that results from untruthful preference revelation by participating countries (Roth 1985).

Introducing Asylum-Seeking Behaviour

So far we have assumed a mass of identical refugees facing a fixed number of safe countries, and each country decides on how many of them to host. Refugees do not have a choice. The assumption seems reasonable for analysing resettlement situations where the mass consists of refugees who are similar to each other in hosting costs-related characteristics (such as language skill and ethnicity) and in the evidence of protection need which every safe country can easily verify.

We now introduce asylum-seeking behaviour. Each refugee chooses whether and where to seek asylum. We adapt Monheim-Helstroffer and Obidzinski's (2010) approach to our framework. (Their model does not regard asylum as an international public good.) Consider two safe countries facing a mass of refugees normalised to one. We assume bi-dimensional heterogeneity among the refugees. They differ in the strength of evidence of protection need and are uniformly distributed over the interval [0, 1]. They also differ in the preferred destination. A fraction, h, of the unit mass prefer to seek asylum in country 1 if they have evidence to exceed the standards of proof in both countries. The rest prefer country 2. The preference parameter, h, summarises the heterogeneity across refugees in all dimensions except the ability to meet each country's standard of proof. For example, a refugee may prefer country 1 to country 2 partly because seeking asylum in country 1 is financially less costly than doing so in country 2. A refugee's preference may also be influenced by the cross-country differences in the existing social network. Let us assume $h \in \left(0, \frac{1}{2}\right)$, i.e. country 2 is more popular than country 1 among the refugees. Each country sets a standard of proof, $s_n \in [0; 1]$, and accepts asylum seekers whose evidence exceeds the standard. Refugees decide whether and where to seek asylum in response to the standards of proof. For simplicity, refugees are assumed unconstrained in all dimensions (such as finance and time) other than the ability to satisfy each country's standard of proof. (See also Giordani and Ruta (2013) who similarly model the destination choice of migrants in response to immigration policies in a multi-country setting, although their study does not deal with refugees.)

To understand asylum seeking behaviour, suppose $s_1 < s_2$, i.e. the more popular country sets a higher standard of proof. Then the unit mass consists of the following four groups:

- s_1 refugees who do not seek asylum because their evidence is weak
- $s_2 - s_1$ refugees who seek asylum in country 1, including $(s_2 - s_1)(1 - h)$ refugees who prefer country 2 but their evidence is not sufficiently strong
- $(1 - s_2)h$ refugees who seek asylum in country 1
- $(1 - s_2)(1 - h)$ refugees who seek asylum in country 2

By applying the same reasoning to the case of $s_1 \geq s_2$, we obtain each safe country's asylum provision as a function of the standards of proof as follows:

$$a_1(s_1, s_2) = \begin{cases} h - s_1 + (1 - h)s_2 & \text{if } s_1 < s_2 \\ (1 - s_1)h & \text{otherwise} \end{cases}$$

$$a_2(s_1, s_2) = \begin{cases} (1 - h) - s_2 + hs_1 & \text{if } s_1 < s_2 \\ (1 - s_1)(1 - h) & \text{otherwise} \end{cases}$$

Each country takes these equations into account in maximising its net benefit with respect to the standard of proof. The equations imply that a country can reduce its asylum provision by increasing its standard of proof. They also imply that a country has to increase its asylum provision when the other country's standard of proof is higher than its standard and increases. Thus, setting a standard higher than the other country's standard is equivalent to redirecting some refugees to the other country. By explicitly incorporating asylum-seeking behaviour, we thus introduce cross-border externalities that are distinct from the positive externalities that result from the assumption that asylum is an international public good.

By substitution, each country's net benefit is now written as

$$u_n(a_n, a_{-n}) = \begin{cases} b_n(a_n(s_n, s_{-n}), a_{-n}(s_{-n})) - c_n(a_n(s_n, s_{-n})) & \text{if } s_n < s_{-n} \\ b_n(a_n(s_n), a_{-n}(s_n, s_{-n})) - c_n(a_n(s_n)) & \text{otherwise} \end{cases}$$

for $n, -n = 1; 2$ and $n \neq -n$: The Nash equilibrium, (s_1^*, s_2^*), is characterised by

$$\frac{\partial b_n}{\partial a_n}\left(a_n\left(s_n^*, s_{-n}^*\right), a_{-n}\left(s_{-n}^*\right)\right) = c_n'\left(a_n\left(s_n^*, s_{-n}^*\right)\right),$$

$$\frac{\partial b_{-n}}{\partial a_{-n}}\left(a_{-n}\left(s_{-n}^*\right), a_n\left(s_n^*, s_{-n}^*\right)\right) = c_n'\left(a_{-n}\left(s_n^*\right)\right) + \frac{\partial b_{-n}}{\partial a_{-n}}\left(a_{-n}\left(s_{-n}^*\right), a_n\left(s_n^*, s_{-n}^*\right)\right)$$

$$s_n^* < s_{-n}^*,$$

for $n, -n = 1; 2$ and $n \neq -n$; or

$$\frac{\partial b_1}{\partial a_1}\left(a_1\left(s_1^*\right), a_2\left(s_1^*, s_2^*\right)\right) = c_1'\left(a_1\left(s_1^*\right)\right) + \frac{\partial b_1}{\partial a_2}\left(a_1\left(s_1^*\right), a_2\left(s_1^*, s_2^*\right)\right),$$

$$\frac{\partial b_2}{\partial a_2}\left(a_2\left(s_2^*\right), a_1\left(s_1^*, s_2^*\right)\right) = c_2'\left(a_2\left(s_2^*\right)\right) + \frac{\partial b_2}{\partial a_1}\left(a_2\left(s_2^*\right), a_1\left(s_1^*, s_2^*\right)\right),$$

$$s_1^* = s_2^*.$$

Note that, say, for $s_1 < s_2$, country 1's first-order condition is not different from the case without asylum-seeking behaviour. That is, the marginal benefit and marginal cost of providing asylum in the country are equalised. This is because country 1 cannot influence country 2's asylum provision so long as s_1 remains lower than s_2.

However, country 2's first-order condition contains an extra term on the right-hand side. It is the marginal benefit that country 2 gains from country 1's asylum provision. Country 1's asylum provision increases when country 2 raises its standard of proof because the refugees who become disqualified in country 2 at the margin will successfully seek asylum in country 1. This additional term on the right-hand side of the first-order condition motivates country 2 to set a high standard that results in the country's asylum provision being lower than without asylum-seeking behaviour.

We can easily confirm that the total provision of asylum in the Nash equilibrium is lower than that under utilitarian maximisation. In other words, total welfare maximisation requires lower standards of proof than in the Nash equilibrium. Whether $s_1 < s_2$ or not, the utilitarian maximisation is characterised by

$$\frac{\partial b_1}{\partial a_1}(a_1(\cdot), a_2(\cdot)) + \frac{\partial b_2}{\partial a_1}(a_2(\cdot), a_1(\cdot)) = c_1'(a_1(\cdot)),$$

$$\frac{\partial b_2}{\partial a_2}(a_2(\cdot), a_1(\cdot)) + \frac{\partial b_1}{\partial a_2}(a_1(\cdot), a_2(\cdot)) = c_2'(a_2(\cdot)).$$

These two conditions show that both types of externality (cross-border benefits from asylum provisions and the cross-border deflection of asylum seekers through the requirement of high standards of proof) must be internalised to maximise total welfare. The internalised cross-border benefit is represented by the second term on the left-hand side of each equation. Recall that, in the Nash equilibrium with $s\ s_1^* < s_2^*$, for example, $\partial a_2/\partial a_1$ was a term on the right-hand side of the second condition, not a term on the left of the first condition, because country 2 used its standard to manipulate country 1's asylum provision to its own advantage.

The total welfare maximisation is incentive-compatible if each country's net benefit is higher than in the Nash equilibrium. However, in this extended framework, even if we assume that the two countries are homogeneous in terms of relevant benefit and cost parameters, i.e. $b(a_1, a_2) = b_2(a_2, a_1)$ and $c_1(a_1) = c_2(a_2)$, the destination preferences of refugees cause their total welfare-maximising standards of proof to diverge. Allowing more popular countries to set higher standards may be inadequate for non-economic reasons in dealing with refugees. Monheim-Helstroffer and Obidzinski (2010) examine two alternative coordination regimes: fixing an internationally common standard and setting the highest standard permitted internationally.

Under the common standard regime, all participating safe countries use the same standard of proof. That is, the standard of proof affects refugees' decisions on whether to seek asylum, but it does not affect the choice of destination among those who decide to seek asylum. The common standard regime removes deflection externalities, and asylum seekers choose their destinations solely according to their preferences. Monheim-Helstroffer and Obidzinski (2010) suggest that participation in the utilitarian maximisation by a common standard is always incentive-incompatible for more popular safe countries because they can increase their net benefits by deviating from the common standard upwards to deflect asylum seekers to less popular countries.

The other alternative coordination regime, the maximum standard regime, sets a standard that the participating safe countries are prohibited from exceeding. This approach leaves each country the room to choose its own standard, but the choice range is capped. The maximum standard is chosen by anticipating how the participating countries set their standards in response to the ceiling. That is, the maximum standard is the subgame-perfect Nash equilibrium of the two-stage game with complete and imperfect information. Like the common standard case, the total welfare-maximising ceiling prevents more popular countries from setting sufficiently high standards to achieve their net benefits as large as in the Nash equilibrium. However, the maximum standard regime is found superior to the common standard regime because the former allows less popular countries to maximise their net benefits with respect to their standards given more popular countries using the ceiling standard. Because the maximum standard regime forces more popular countries to provide more asylum than they would in the absence of the regime, less popular countries benefit through the increased provisions of asylum abroad. Less popular countries are able to use standards lower than the Nash equilibrium in the absence of the regime without attracting more asylum seekers to their countries.

When an Asylum Seeker Is Not Always a Refugee

The framework can easily accommodate the possibility that asylum seekers are not necessarily refugees – the concern held by many people in potential host countries. Suppose that, for any given evidence provided by an asylum seeker, the probability of the person being a true refugee is $r \in (0, 1)$. However, a safe country is unable to verify the falsity of evidence provided by non-refugees. Discounting evidence by probability is inappropriate, so each country hosts asylum seekers so long as they provide evidence (either genuine or falsified) that exceeds the required standard of proof. Let us assume that providing a non-refugee with asylum is as costly as providing a refugee with it, but generates no gross benefit. (Here we focus on non-refugee migrants who enter safe countries with false information, and we ignore the fact that economic migrants often benefit host countries.)

Assuming that the distribution of destination preferences of non-refugees is the same as that of refugees, each country's net benefit is now written as

$$u_n(g_n, a_n, g_{-n}, a_{-n}) = \begin{cases} b_n(g_n, (s_n, s_{-n}), g_{-n}, (s_{-n})) - c_n(a_n(s_n, s_{-n})) & \text{if } s_n > s_{-n} \\ b_n(g_n, (s_n), g_{-n}, (s_n, s_{-n})) - c_n(a_n(s_n)) & \text{otherwise} \end{cases}$$

for $n, -n = 1, 2$ and $n \neq -n$, where $g_n = ra_n$. Since every successful asylum seeker contributes to the benefit function by only a fraction and at the same time fully contributes to the cost function, the chosen standard of proof is higher than in the absence of non-refugee asylum seekers. This applies to both non-cooperative and utilitarian maximisation.

Bubb et al. (2011) were the first to introduce asylum-seeking by non-refugees in a multi-country setting. Their model is not as simple as the modified Monheim-Helstroffer and Obidzinski (2010) model given here. While I have simply assumed exogenous destination preferences, Bubb et al.'s non-refugees respond to international wage gaps and migration costs. The larger the wage gaps between potential destinations and refugee-generating countries and the lower the migration costs, the more economic migrants are tempted to seek asylum. To counter the incentive effects of increasing wage gaps and decreasing migration costs, safe countries increase their standards of proof. (Bubb et al. also assume that not all potential asylum seekers are fully aware of the strength of evidence they can produce, introducing uncertainty about the application outcome among applicants.)

Bubb et al. (2011) analyse a bilateral scheme by which wealthy safe countries counter the incentive effects and stop economic migrants from seeking asylum in them. In this scheme, originally proposed verbally by Hathaway and Neve (1997), safe-but-not-wealthy countries agree to provide asylum to people who have sought asylum in wealthy countries and have satisfied their standards of proof. The wealthy countries agree to pay the poor countries for hosting the successful applicants. In equilibrium, an economic migrant does not seek asylum because successful asylum-seeking results in migration from his/her country to another economically similar country. On the other hand, refugees continue to seek asylum, as the cost of remaining in their own countries is very high for them.

The scheme is likely to encourage refugees to seek asylum in poor safe countries because they know they will be sent to a poor country even if they meet the requirements in wealthy countries. By seeking asylum directly in poor safe countries, they are likely to minimise the costs involved in asylum-seeking, such as transport costs. An implication is that the scheme is incentive-incompatible for poor safe countries because wealthy countries financially compensate them for receiving people who have already been qualified in the wealthy countries, not for providing asylum to people who come directly to poor countries.

Conclusion

By applying the theory of private provisions of public goods to asylum provision by safe countries, the literature helps our understanding of the incentive problems involved. By incorporating asylum-seeking behaviour, we see how two different types of externality may work together to lower each country's provision: easy riding caused by positive externalities from public good provision by others and the use of strategically complementary policies to deflect asylum seekers to other safe countries. Studies of potential policy instruments – competitively tradable asylum quotas, harmonised standards of proof and bilateral contracts to pay to relocate qualified asylum seekers – reveal the weaknesses, as well as the strengths, associated with them as a solution to inefficiently low asylum provision. Hence they motivate us to examine how to deal with the weaknesses and also to come up with alternative schemes.

Researchers are likely to benefit from further extension of the existing framework and a search for a new framework. All existing studies pose asylum provision as a static game. (As we saw, Czaika (2009) and Monheim-Helstroffer and Obidzinski (2010) do present two-stage games,

but every country's asylum provision is simultaneously determined in one of the two stages.) However, in reality both applications for and provision of asylum take place over time. For example, a country's current provision of asylum may well influence the future applications that the country will receive. If so, forward-looking governments of safe countries must solve the game by anticipating future flows of humanitarian immigration. Foged and Peri (2016) present Danish evidence that municipalities with ethnic enclaves created by the refugee dispersal policy attracted further inflows of refugees in subsequent years, although not through asylum-seeking but via family reunification. It suggests that the destination preference of refugees depends at least partly on past asylum provisions.

As yet another refugee crisis has recently hit Europe, we realise that the problem of international coordination in asylum provision is a recurrent and unresolved one that demands further investigation.

International Coordination of Regulation

David Lazer

Abstract

Trade among states with diverse regulatory systems creates the possibility of taking advantage of the cost differentials in production that result. However, it is increasingly clear that

what happens in one jurisdiction affects policy in other jurisdictions. It is often argued that this creates a 'race to the bottom' effect, where the most lax regulation gains an advantage, but the evidence on this is mixed, at best, and there is a plausible argument too for a 'race to the top' effect, where states set high regulatory standards as a barrier to entry.

Regulation is a pervasive element of modern government. The regulatory state has its hand in everything from the food we eat to the couches we sit on. The regulations we live with are necessarily a collective affair – as a general proposition two people who live in the same jurisdiction cannot choose different regulatory regimes. However, it is increasingly clear that regulation is a collective affair more broadly – what happens in one jurisdiction affects other jurisdictions. This interdependence creates potential governance challenges, in part due to strategic dilemmas that these interdependencies may create, as well as accountability issues that occur when important policies affecting a polity originate outside of that polity.

Samuelson (1949) offered an evocative thought experiment that sheds some light on the potential dilemmas. Imagine, Samuelson asked, the integrated economy of a world with no boundaries, no transportation costs. Now assume angels come along and divide the world up into different nations, with different allocations of factors of production. The question Samuelson posed was how international trade might allow the world to recapture that lost paradise, where the trade of goods is a substitute of sorts for a homogeneous distribution of factors of production.

Interestingly, international trade creates an opportunity where none existed in Samuelson's integrated economy, if we assume that Samuelson's integrated economy had a single regulatory regime. Specifically, trade among states with diverse regulatory systems creates the possibility of taking advantage of the cost differentials in production resulting from that regulatory heterogeneity. For example, if we imagine that state A has strict regulation of public good 1 and relaxed regulation of public good 2, and state B has relaxed regulation of public good 1 and strict regulation of public good 2, then both states can benefit from trade. Those sectors that can produce more cheaply in A (because of its more relaxed regulation of public good 1) will naturally arise there (even in the absence of capital mobility), and similarly with respect to sectors that would produce more cheaply in B. Generally, the basis for trade (national and international) rests in significant part on the pillar of heterogeneity (that is, comparative advantage). Samuelson's angels create the possibility of exchange based on regulatory heterogeneity that did not exist in the integrated economy.

The preceding assumes that policy is exogenous and that all factors of production are immobile. What happens if we relax these assumptions? One possibility is that regulatory policies will diverge, because trade reduces the adverse economic effects of those policies. To take an extreme example, imagine a state with a preference for strong regulation of a particular sector that makes some good for which there is inelastic demand. In a closed economy the benefits of strict regulation need to be weighed against the fact that the costs of that regulation will be fully borne by consumers. In an open economy, it may be possible to regulate that sector out of existence, with fairly minimal welfare impacts on society – because that sector may locate in another jurisdiction where the demand for regulation in that sector is lower. That is, it is theoretically possible that trade will enable some jurisdictions to regulate more strictly, thus raising the average level of regulation in the international system.

Receiving far more attention, however, is the possibility of a 'race to the bottom' (RTB), where

the combination of trade and factor mobility yields uniform downward pressure on regulation across all jurisdictions. RTB has been asserted in many settings, although proven in few. The essential intuition is fairly simple. Consider the following simple model of the world, where there are two factors of production, say labour and capital. Labour is assumed to be immobile and capital mobile. If we assume that labour and capital are complements in production at the national level, this would yield a competition at the national level for division of the surplus produced through their combination. This intranational competition, in turn, has an international dimension because capital can flow to jurisdictions that offer the biggest share of that surplus. That is, effectively, labour from different jurisdictions will compete to attract capital. More capital will yield a larger surplus; however, the competition among jurisdictions means that most of that surplus will go to capital. We can see this type of dynamic, for example, in the competition among states in the United States to attract automobile factories, where, as Donahue (1997) documents, foreign manufacturers garnered enormous incentives from US state governments.

There is also clearly a RTB effect when there are physical externalities from one jurisdiction to another – for instance, when power plants are placed close to borders, and pollution spills over to the neighbouring jurisdiction. Except where noted, for this paper the case of physical externalities will be bracketed, because analytically it is uninteresting. In other words, it is clear that there is a potential for a collective failure when there are physical externalities (the most obvious contemporary example is carbon emissions).

When applied to the regulatory context, regulation may be seen, in part, as an effort by a jurisdiction to reallocate some of the surplus towards immobile actors. Environmental protection offers a nice illustration. Efforts to protect the local environment increase costs to capital. As a result, capital is less likely to locate in a highly regulated jurisdiction, lowering wages (relative to a more lax regulatory jurisdiction) to the point that capital is indifferent between locating in jurisdictions with different levels of regulatory stringency. The preceding discussion would suggest that given a large number of jurisdictions, and a lack of collusion among those jurisdictions, the net effect of dividing the world up will be to redistribute from immobile factors of production to mobile factors of production. In the example above, this redistribution would take place from the environment and from labour to capital.

The above discussion notwithstanding, RTB has had far more currency among politicians than economists. While analytic models, following from the studies of regulatory federalism by Tiebout (1956), sometimes find the possibility of an RTB, it is far from the typical finding (Oates 2002). It should be noted, however, that the federal context is an imperfect analogue for the international context. For example, these models assume strong sorting effects of citizens with respect to, for example, preferences for environmental protection. It is less likely that such significant sorting effects exist at the international level.

Similarly, empirically, there is relatively little support for RTB dynamics. For example, there is little evidence that firms locate based on relaxed regulatory regimes (Bartik 1988). There is also little evidence that increased capital mobility over the last few decades has created downward movement in regulation, and some evidence that supports the opposite proposition (such as Engel 1997; Fredriksson and Millimet 2002; Frankel and Rose 2005).

The lack of RTB effects may in part reflect that costs imposed by a regulatory system are a fairly small factor in the decision on location (Jaffe et al. 1995). Further, one likely and important reason for the lack of observation of RTB dynamics is the inability of researchers to capture the full range of reasons why firms decide to locate in particular jurisdictions. The decision to locate an oil rig in a particular location may be affected by environmental regulations, but first and foremost is certainly driven mostly by whether there is oil present at that location. An oil company, all else being equal, may prefer to drill in locations with less stringent environmental rules. However, those locations with the most desirable locations for drilling oil are also therefore in a position to seek a larger share of the income produced from that oil. This share, in those jurisdictions with preferences for a cleaner

environment, would likely in part be extracted through stronger environmental regulations. Empirically, this might yield the outcome that those locations with the most drilling will also have the strongest regulations. Such a snapshot might be misleading, since it might still be the case that regulatory competition results in more lax regulation than in a counterfactual world where capital were not mobile, or where policymakers colluded.

More generally, there are a variety of reasons why particular locations might offer particular advantages for capital. Some of these may be exogenous (such as those related to the location of particular natural resources). Others may be endogenous. For example locating particular physical capital (such as factories) in a specific location might facilitate the creation of human capital in that location, which might be relatively immobile. Closely related, there might be returns to scale at the industry-jurisdiction level. That is, the productivity of a firm might be positively related to the number of other firms in a jurisdiction or region. In fact, clustering of sectors in particular regions is quite common (Krugman 1996). If the emergence of such a cluster reflects external economies, this creates the possibility that a jurisdiction containing such a cluster can increase the stringency of its regulations without a worry that capital will flee (Baldwin and Krugman 2004).

The debate in the legal literature regarding the clustering of industry incorporations in Delaware offers an illuminating case study that illustrates this point. The starting point for this literature is the observation that Delaware towers over the rest of the United States in terms of number of incorporations. This was originally viewed as evidence of a lax regulatory regime in Delaware (Cary 1974). The essential argument was that corporations located in Delaware because doing so minimized the burdens placed on corporate management, often at the expense of shareholders. The hypothesized RTB was branded, as a result, as the 'Delaware effect'. This argument came under sharp criticism in the 1990s. The first critique was that there would be shareholder pressure (exerted in part through the stock price) against locating in a jurisdiction that did not preserve shareholder value (Revesz 1992). The dominance of Delaware thus reflects the capacity of Delaware to effectively manage corporate governance while still preserving shareholder value. That is, the dominance of Delaware reflects the benefits of regulatory competition, where Delaware simply provides superior governance to everyone else. A second critique (of both the benefits and the costs of regulatory competition) was that there are economies of scale in providing good corporate governance (Kahan and Kamar 2003). For example, good corporate governance requires predictability, and predictability is facilitated by ample case law. Delaware, by dint of historical accident, had garnered an insurmountable lead in effectively producing good corporate law. The implication of this, in turn, is that Delaware has a fair degree of slack in extracting some surpluses from the regulated parties, as long as it does so in a way that does not threaten its competitive advantage in corporate governance.

Note that there are RTB debates in other domains, such as welfare benefits (Dahlberg and Edmark 2008; Bailey and Rom 2004) and corporate tax rates (Basinger and Hallerberg 2004).

While these RTB debates rage on, with strong intuitions and political appeal ranged against modest analytic and empirical support from the economics literature, there is a stronger consensus about the potential capture of the regulatory system by domestic interests (Bartel and Thomas 1987) – which I will label 'regulation as protection' (RAP). To paraphrase Clausewitz, regulation may be viewed as market competition through other means. It is rare for regulation to be neutral in its impact on producers in a given sector. A more restrictive regulation has the potential to benefit some producers at the expense of others. For example, requirements for greater efficiency in cars benefit producers that already produce high-efficiency cars, at the expense of producers of low-efficiency cars. In the context of international trade, the alignment of interests will often be domestic producers opposed to international producers interested in entering the domestic markets and domestic consumers who might benefit from increased competition in the home market.

The potential scenario is for domestic producers to hijack the domestic regulatory apparatus as a means to block international competition.

It is also clear that in many sectors there are strong drivers for convergence in regulation. A simple example is the mandate in a jurisdiction to drive on one side or the other of the road. Given significant traffic between two jurisdictions, it is clear that there would be a strong benefit to a consistent standard for driving. Thus, for example, Canada, which had a patchwork of standards in the first half of the 20th century at the provincial level, with some provinces mandating left-hand traffic, and others right-hand traffic, gradually converged to right-hand traffic, with uniformity emerging by the middle of the century. This presumably was driven in part by the need for internal consistency, and in part because of the degree of traffic between the United States and Canada. In the regulatory context, such convergence may be seen fairly routinely across policy areas, for example in food safety (Lazer 2001), where small countries adopt the standards of their large export markets.

Regulatory convergence more generally may take place to guard export markets. As Vogel (1995) argues, this type of push for convergence often occurs in international trade when there are increasing returns to scale in production, combined with potential divergence in product standards. Thus, for example, Vogel documents the flow of environmental standards for automobiles around the world, which he labels the race to the top (RTT) 'California effect' in contrast to the RTB 'Delaware effect'. Vogel argues that there is potentially a systematic bias toward higher standards because of the efficiency imperatives of having consistent standards. Such an imperative should lead toward convergence on the strictest standard on the system (or at least a standard that would encompass the large majority of the system), so as to achieve efficiencies in scale of production. Such a diffusion pattern should follow the reverse direction of exports, for example, as Prakash and Potoski (2006) found with respect to the spread of ISO 14001 adoption.

Finally, even in the absence of trade or factor mobility, there is significant potential for regulatory interdependence due to policy information interdependence (PII). Policy is necessarily experimentation, and novel policies even more so. Regulation in jurisdiction A creates insights in jurisdiction B as to what would be good or bad policy, where this information spreads through various informational networks (Wolman and Page 2002; Lazer 2005). Emulation may reflect lesson drawing or serve the function of policy legitimation (Bennett 1997; Busch et al. 2005). There is a substantial literature on policy emulation (e.g. Rose 1993; Haas 1992), and it is clear that there is no reason to expect domestic regulatory policy to be exempt from emulation (e.g. Simmons and Elkins 2004).

This array of interdependencies offers an array of empirical challenges for the researcher and governance challenges for the policy maker. For the researcher, the potential presence of different processes (which, if validated, have very different normative implications) creates a difficult but not impossible nut to crack (for various recent efforts to deal with exactly this issue, see Braun and Gilardi 2006; Simmons et al. 2006; Levi-Faur 2005).

For the policy maker each of these kinds of regulatory interdependencies creates different types of collective strategic interaction problems (Lazer 2001, 2006), which in turn translate into a collective governance challenge (Scharpf 1997). RTB and RAP might be categorized as a prisoner's dilemma, where the potential dysfunctional equilibrium would be either suboptimally lax standards in the case of RTB, or suboptimally strict standards in the case of RAP. RTT may be viewed as a coordination game, where one potentially problematic outcome is the emergence of suboptimally strict standards (or perhaps worse would be the case where the RTT did not occur, where a critical mass of support did not emerge for any standard), with a handful of large jurisdictions driving the standards for the world. All of these issues might call for some type of negotiated standard. However, such centrally negotiated standards might eliminate some of the very benefits of trade in the first place. And the presence of PII would suggest a different kind of public goods issue than is usually associated with regulation – the public good of information.

This construction of regulatory interdependence suggests a dual conundrum. The first aspect of this is how to take advantage of the publicness of the information, and the second is how to support continued production of this public good (Lazer 2005).

International Economics, History of

M. June Flanders

Abstract

Starting with mercantilist theories, the article deals with laissez-faire rejections of mercantilism, the Ricardian justification of free trade and its extension to multiple countries and commodities. Heckscher–Ohlin trade theory, factor-price equalization and the 'Leontieff paradox' debate follow. Intra-industry trade is related to increasing returns, imperfect competition, and product differentiation. Trade and growth, economic geography, and tariffs and trade restrictions are summarized. Regarding macroeconomics, Hume and the monetary approach to the balance of payments are compared with income adjustment theories. International monetary regimes, exchange rate regimes, capital transfers, internal–external balance, and new international macroeconomics are discussed.

The Real Theory of International Trade

Contemporary international trade theory has its roots in classical economics, which developed in opposition to the widely accepted views, known (since Adam Smith's introduction of the term into British discourse) as mercantilism, held until the mid- 18th century by both policymakers and many analysts. This was a loose body of doctrine advocating extensive government control and interference in economic activity. In the context of international trade it refers to the imposition of

tariffs, quotas, and prohibitions, designed to maximize the balance of payments surplus and the net inflow of precious metals (specie). The justification for such policies took many forms. Since what we know as mercantilism lasted for about two centuries and arose in widely differing social and political contexts, there was room for substantial differences of opinion. In some cases it was apparently a fear of goods, in others an identification of specie with real wealth, and in still others, as Keynes (1937) suggested, a desire to stimulate employment. (Detailed critical surveys and analyses are to be found in Heckscher 1935; Viner 1937; Blaug 1985.)

Though he was not the first to oppose dirigisme and to see the advantages of trade and specialization, Smith, in his *Wealth of Nations* (1776), provided the starting point for classical theories of trade. He argued both that gold and silver are not real wealth and that generating a balance of trade surplus is not the only way to acquire them. His discussion of interference with trade in goods and services is the same as his treatment of other governmental interferences: he dealt with the interactions of markets for goods and factors, showing the effects of tariffs and subsidies on each. He recognized situations in which restrictions on trade might be justified: these included defence needs, retaliation and infant-industry arguments.

Smith did not develop a theory of comparative advantage, though he came close to it when he noted that Britain was more productive in manufactures relative to Poland than it was in agriculture (Smith 1776, pp. 6–7). But his main argument in favour of trade is indeed that which is now labelled the 'vent for surplus'. This is enunciated at several points, but a clear statement occurs when he says that, because of international trade, 'the narrowness of the home market does not hinder the division of labour in any particular branch of art or manufacture from being carried to the highest perfection. 'By opening a more extensive market for whatever part of the produce of their labour may exceed the home consumption' (1776, p. 415). Mill (1848) cites Smith as having viewed exports as an outlet for surplus, and Bastable (1897) takes Smith very literally on the surplus and attacks him vigorously for it, arguing that it implies the existence of unemployed resources. Schumpeter (1954, p. 374) accuses Smith of having 'believed that under free trade all goods would be produced where their absolute costs in terms of labor are lowest'. But Schumpeter notes that Viner indicates that Smith, and others before him, had formulated the more general proposition that, under free trade, commodities would be imported whenever they could be obtained most cheaply in this way. This includes the case where exports 'cost less to produce than it would cost to produce the corresponding imports at home and thus implies the theorem of comparative costs'. A contemporary evaluation of the several interpretations of Smith's trade theory is provided by Blecker (1997).

It was Ricardo, who, in his *Principles of Political Economy and Taxation* (1817), first articulated explicitly and emphasized and publicized the theory of comparative advantage (though Torrens, in 1815, had come very close to it), noting that absolutely lower costs in the production of all goods was not a sufficient reason for producing them all, and that it was generally to the advantage of a country to specialize in the production of that which it did best. Here, too, the objective was to influence policy. Ricardo, like Smith, developed his views on trade within the framework of his model of how an economy did or should operate. British manufacturers had no need of protection from imports, and his main concern was with duties on grain imports, the Corn Laws, which protected British agriculture. Ricardo attacked these because they raised food prices and hence real wages at the expense of profits, thus discouraging investment and growth. The equilibrium result would be zero saving and investment and a long-run stationary economy with wages at subsistence level. With free trade, national income would be maximized by keeping real wages in industry low and by concentrating output in the relatively low- cost sectors, regardless of absolute advantage or disadvantage. It was here that he inserted a brief monetary statement, that there was a natural distribution of specie, which depended on the economic size of each

country and the parameters of its monetary variables.

Ricardo's trade theory, like classical economics in general, is based on a model of supply: price is the long-run supply price. He implies that complete specialization is the norm, but he neither makes this explicit nor specifies how the gains from trade are divided between the trading countries. He considered the possibility of non-traded goods and the idea that a country could produce and export more than one good if country size or demand patterns were highly uneven.

Mill (1848, pp. 583–606) brought demand and, implicitly, its elasticity into the theory, thereby explaining how the terms of trade were established between the limits set by comparative advantage. He extended the analysis to include transport costs, more commodities (which limited the range of the terms of trade) and more countries. He also noted that, since the terms of trade must be the same for all countries, the gains from trade will be greater for those for which the opportunity cost of the exportable good is lower. These refinements were spelled out precisely in the 20th century by Graham (1923), who noted that the terms of trade and the probability of specialization depended on the relative size of the (two) trading countries and the relative importance of the (two) traded goods in total consumption. Furthermore, when more countries and/or more goods were brought into the picture, the final terms of trade were narrowed down even further, as was the exact number of goods traded by any given country.

Marshall (1879; 1923) generalized the theory into a two-country multi-commodity analysis (using the device of 'bales' of goods) and derived offer curves to depict graphically the general equilibrium in production and consumption that Mill had analysed only verbally. Edgeworth (1925) produced a similar analysis. The derivation of the offer (reciprocal demand) curves was not spelled out; all domestic markets were assumed to be equilibrium at each point on an offer curve. Marshall (1879) has a detailed analysis of equilibrium and stability conditions, but not, explicitly, elasticity.

A sizeable literature developed, well into the 20th century, both testing Ricardian comparative cost theories and justifying economists' generally free-trade position. In a fairly laboured list of possibilities, Samuelson (1939) showed that some trade is always better than no trade. This holds for various shapes of production possibilities curves, but its welfare implications depend on the welfare device of the ability of gainers to compensate the losers, or, as he put it, 'by Utopian co-operation everyone can be made better off as a result of trade' (1939, p. 204).

In the 1930s and 1940s, there was extensive discussion of arguments for and against tariffs, quotas, and other impediments, and the real gain – or loss – from imposing them. This included the debate on the relationship of trade structure to growth, which continues to the present.

A major paradigm shift came with the formal use of what are often called 'neoclassical' assumptions about technology and preferences in the analysis of comparative costs. In the entry in this dictionary on Haberler, Gottfried, it is claimed that, although Barone in 1908 (but not subsequently) had a (non-concave) production-possibility frontier and a community indifference curve, it was Haberler's independent discovery in 1930, and the use to which he put it, that transformed the theory of international trade. Haberler thereby broke with the labour theory of value, the production possibility frontier becoming standard in all economic theorizing and teaching. Lerner went on to draw a 'compound indifference curve' in 1932, and in 1934 developed the demand side fully. Both Lerner and Haberler (1936) dealt with the possibility of increasing returns, Haberler granting that this could justify tariffs.

In fact, Haberler was preceded by Bickerdike, and by Heckscher in 1918 and Ohlin in 1924, but the latter two published in Swedish, reducing the visibility of their work. They addressed the issue of factor prices under free trade. Ohlin published an enlarged version of his 1924 Ph.D. thesis in English in 1933; Heckscher's seminal paper was translated (partially) into English only in 1949.

Heckscher's general equilibrium analysis, in 1918, was wholly verbal. He examined the

reasons for, and results of, large-scale Swedish migration to America. In studying this, he showed that under certain circumstances trade in goods could substitute for movement of factors in equalizing factor prices. If factor endowments were not too different, factor prices would inevitably be equal throughout the world. Ohlin, his student, drew from this and, using Cassell's version of Walrasian general equilibrium analysis, developed a more formal approach (1924). Lerner demonstrated factor price equalization with arithmetic and geometry in a seminar paper in 1933, the Swedish work being unknown.

Ohlin himself rejected the conclusion of the equalization of factor prices. In his formal analysis he simply (inexplicably) assumed that each country was completely specialized; in verbal discussion, he always saw exceptions to any generalization. Among the obstacles to factor price equalization were insufficient geographical and occupational mobility of factors between industries within a country, increasing returns to scale, excessive imbalance in factor supplies, taxes, transport costs, and imperfect competition. All these had to be taken into account when explaining the actual patterns of trade. Furthermore, the verbal analysis is explicitly dynamic. One example is his discussion of the effects, almost year by year, of an increase in world demand for a country's exports. There is an increased demand for labour in that industry, so labour moves into it; individuals move, gradually, into the skill group required for those goods; labour moves, again gradually, geographically. All these take time: some years later, if demand remains as it was with no further increases, the supply of productive factors will have adjusted to the new demand levels. Ohlin's earlier work (his thesis) is replete with numerical examples of international and interregional differences in price levels, in expenditures for food and housing, and the like.

The factor price equalization aspect of the model was largely ignored until Stolper and Samuelson unearthed it in 1941. (When White reviewed Ohlin's book in 1934 and compared his model with the first German edition of Haberler's *International Trade*, he did not mention the factor price equalization issue at all.) The model was formalized subsequently by Samuelson (1948, 1949, 1951–2, 1953–4), and later elaborated, extended, and modified by Jones (2000, passim) and others. Originally these formalizations required very strict assumptions: two commodities, two countries, constant returns to scale, both goods being produced in both countries. The last requirement of the Heckscher–Ohlin–Samuelson model, as it became known, was very stringent. It meant that factor proportions had to be within what was called the cone of diversification, where both goods could be produced when prices were equalized across countries. Later models picked up some of the complications that Ohlin had enumerated earlier: Jones developed variations, and welfare implications, for the cases of specific factors (immobile between industries), increased numbers of goods and factors, trade in intermediate goods, and tariffs. A penetrating discussion of fundamental methodological issues in the development of the theory and the subsequent debate on the Leontief paradox is provided by De Marchi (1976).

The Heckscher–Ohlin paradigm remained untested and empirical work in trade proceeded along Ricardian lines until Leontief applied his input–output model to a test of United States trade and concluded that US exports were labour-intensive relative to imports. The implied paradox gave rise to an avalanche of theoretical and empirical work, ranging from multifactor models to specific explanations in terms of the period and the structure of world trade in the early post-Second World War period which was used in the study. One explanation offered was the possibility of reversals of relative factor intensities as relative factor prices changed, a proposition which led to a spate of ongoing debates in capital theory (Arrow et al. 1961.)

Baggott (1970) presents an exhaustive list and discussion of the various proffered explanations, including her own, that the United States in the relevant period was exporting capital directly through its balance of trade surplus, and also notes the possibility that some of the capital-intensive commodity imports were produced by branches of American firms, with American

capital. Caves and Jones (1977) give some of the highlights in the debate. Others sought to resolve the paradox in a wide variety of ways: for example, by claiming that there had been a conceptual misunderstanding, that labour needed to be augmented by considering human capital, and that during Leontief's sample period capital intensity was highly correlated with high natural-resource use. For an exhaustive treatment of the paradox and of the numerous attempts to resolve it, see Chipman (1965–66, 33 51–70).

Economic analysis and investigation move with events. Both output and trade became increasingly characterized by differentiated products, brand identifications, oligopolistic behaviour and the scale economies which these generated, strategic investment and marketing decisions, and expanding trade in intermediate products. Historically, the first phenomenon observed in the post-Second World War period was the large and growing intra-industry trade (see Grubel and Lloyd 1975). Helpman and Krugman (1985) treat such trade as a result of product differentiation, generally associated with monopolistic competition and increasing returns, and model it as coexisting with inter-industry trade based on factor endowments. A survey of trade theory based on imperfect competition due primarily to increasing returns can be found in Krugman (1987). The behaviour of multinational corporations and conglomerates, often producing and marketing a wide variety of products, demanded examination and explanation (see Caves 1982). Dixit and Norman (1980) include in their formal, general-equilibrium rewriting of trade theory the case of oligopolistic markets. Game-theoretic study of innovation strategies, outsourcing, and the political economy of trade restrictions policy followed. Refinements of these trends continue and are at the forefront of international trade theoretical and empirical work today (such as that of Grossman and Helpman 1991, 2002).

There has also developed a large literature on the mutual interaction of growth and international trade, which is a subject in and of itself, starting with Smith's vent for surplus theory, through issues of putative exploitation of developing countries, into contemporary empirical/historical studies of long-term growth, and the effects of differential increases in the several factors of production. The differential rates of technical progress, the diffusion (or lack of it) of technology, and the concomitant international differences in growth rates are some of the topics being analysed and explored. The existence of increasing returns, both to firms and to industries, first discussed by Haberler, has led to renewed interest in economic geography, a field being examined today both by economists and geographers and, perhaps, waiting for some real interdisciplinary exploration. A critical review of the field, and a plea for integration of new explorations in economic geography with industrial geography is offered by Martin and Sunley (1996).

Macro-Monetary Theory

Many of the mercantilists, with their concern for the accumulation of specie, evinced no sense of the impossibility of having a permanent balance of trade surplus. Some saw money as working capital that would drive an increasing volume of trade; others saw little problem in absorbing specie, perceiving trade as constrained by a shortage of coin. In the 16th and 17th centuries, there was increasing awareness of a link between money and the price level, culminating in Locke's formulation of the quantity theory (1696). Despite a partial anticipation of the result by Cantillon (1755; written c. 1730), it is Hume (1752) who is commonly credited with the price-specie- flow mechanism and the implied endogeneity of the money supply in an open economy. However, both were preceded by Isaac Gervaise, whose pamphlet of 1720 was almost totally ignored. Gervaise had an adjustment mechanism, essentially the monetary approach to the balance of payments (Gervaise 1720), which Ricardo 100 years later was to enunciate as the 'natural distribution of specie'. Beyond that, he had a model of financial adjustment through a money multiplier and real effects in the form of inter-industry shifts in production.

Hume argued that attempts to acquire precious metals, or prevent their export, would result in

price level changes, affecting the balance of trade and reversing the specie flows. The same line of reasoning (though under flexible exchange rates) informed the work of Ricardo (1811) and Henry Thornton (1802). Other highly sophisticated monetary writings of the time are discussed in Hollander (1910–11). The main point, that the money supply is endogenous, resurfaced almost 150 years later in the monetary approach to the balance of payments (see Frenkel and Johnson 1976).

In subsequent British writings, through much of the 19th century, the distinction between international and domestic monetary theory barely existed. The British economy was open; the London money market was the world's financial centre. The brilliant stream of monetary debate in 19th-century England (see Fetter 1965; Bagehot 1873), carried out largely by bankers and business people, concentrated on issues of monetary policy for an open economy, but with little attention to the effect of policy on the real sector or on long-term financial markets. The analysis focuses in general on the short run: international disturbances were both exogenous and temporary in that world, and the issue was really how to ride the storm – the underlying structure was always, implicitly, in equilibrium. This was a reasonably accurate picture of the England of the day, where long-term capital outflows were effected by changes in trade flows in the equilibrating direction, and much of any needed real adjustment was performed in the periphery (see Ford 1962). This literature had to do primarily with the reciprocal relationship between specie holdings and specie flows on the one hand and the domestic money supply on the other. Much of this involved differences in the definition of money, the role of the Bank of England, the vulnerability of the bank's gold stock, by law subject to drain by holders of Bank of England notes (paper money), and the appropriate measures which this very public, privately owned, institution could and should take to protect itself. (Evidence of the time, and subsequent histories, point to the uniqueness of the Bank of England; yet in the paradigm of the adjustment mechanism it is always treated as the prototype of central banks.)

Convertibility of Bank of England notes into gold was suspended during the Napoleonic Wars; when it was resumed, in 1819, the bank entered a period of more than half a century of recurrent crises and near crises, but managed to maintain the convertibility of its notes into gold. Discussion and debate in this environment was almost brought to an end when Walter Bagehot published his influential *Lombard Street* in 1873. Based on experience, and possibly as a result of his hectoring, the Bank of England learned in the subsequent decades how to handle its huge constituency of world and domestic finance on the basis of very small reserves of gold, developing, gradually, a number of highly sophisticated 'tricks' in the money markets to protect itself and forestall runs. Nothing about this management, meticulously documented by Sayers in his two separate studies, had to do with interactions between the real and financial sectors, certainly not in the context of long-run relationships. There was little if any discussion of the balance of trade, except when the original disturbance was a trade imbalance (usually temporary), such as a crop failure. And nothing remotely suggested automaticity of adjustment; the effects on the domestic money supply were to be avoided or at least mitigated. This relative neglect continued in discussion of British monetary policy and international adjustment until 1925, when it appeared in the debate on the resumption of gold convertibility. The previous examination, by the Cunliffe Committee in 1918, was noteworthy for its brevity. There was really nothing to discuss: specie outflow led to the Bank of England's changing bank rate, which reversed the outflow. Changes in expenditures play a secondary role in the process of adjustment to gold flows (see Flanders 1989).

Despite these objections, the automatic price-specie flow mechanism, stemming from Hume, lived on, until it was challenged in the 20th century by several analyses of what became known as the transfer problem. The origin of this is traced to Thornton, Ricardo, and others in the early 19th century who distinguished between money transfers and deficits caused by harvest failures. Bastable (1889) emphasized the impact of a monetary transfer, such as a tribute, on demand and the

possibility of effecting it with no change in the terms of trade. But this insight faded and reappeared only in the 20th century, when Taussig and his Harvard students, including Jacob Viner, John Williams and Harry Dexter White, examined the adjustments to the huge capital flows of the 19th and early 20th centuries. They found that income and expenditure changes played a much more critical role than had been thought. Adjustment was too smooth and too fast for it to have worked through Humean kinds of changes in price levels and thence in trade balances.

It was at this time, during the academic year 1922–23, that Ohlin, visiting Harvard, developed the approach first expressed in his 1929 debate with Keynes over German reparations, and then in great detail in his book (1933). He spelled out explicitly an expenditure-driven adjustment to international capital movements. (The irony is that Keynes could not see this.) Capital flows would lead to changes in total spending and hence directly in net exports. Price and wage changes might ensue but were not essential to the adjustment process.

The price-specie-flow story was challenged later, from a different flank, by Brown (1940), who demonstrated that the canonical view of the historical gold standard was mistaken and that in fact it had been a sterling standard, managed by the Bank of England. The system worked reasonably smoothly because trade and long-term capital movements were consistent with long-run equilibrium in the balance of payments. When this ceased to be true, England went off gold. Following the chaos of the inter-war period and the controls of the war and post-war years, the establishment of the International Monetary Fund constituted a recognition that the textbook adjustment mechanism of a metallic standard could not be relied upon. But what emerged in fact was a dollar standard rather than the intended multilateral system.

The textbooks continued to describe the international monetary system in terms of the price-specie flow mechanism and to treat capital movements as either factor flows (foreign investment) or short-term financial adjustments. In 1937, Hayek had taken the position that there had never been a true test of the price-specie flow mechanism in a multilateral world system in which domestic money supplies were endogenous and adjustments were automatic. In a neglected lecture at the London School of Economics he argued that the fixed exchange rate system, or gold standard, should not be abandoned on grounds of its failure, since it had never been operated correctly. There had never been a time, he said, when domestic money supplies were made to vary in response to specie flows as they would have had there been no sterilization or offsetting policies, that is, had the specie-flow mechanism functioned in the manner of the traditional paradigm.

Hayek's complaint, in the mid-1930s, was made in response to growing sentiment in favour of fluctuating or, more accurately, administratively pegged exchange rates. Given the willingness to consider changing the peg, the rate became a policy tool and a literature developed around what was called 'internal–external policy'. Beginning with Joan Robinson's attack on 'beggar-my-neighbour' devaluations (1937), there ensued a discussion of the effects of exchange rate changes on income and expenditure, as well as on the balance of payments; starting with the elasticities approach (elasticities of demand for and supply of exports, which proved to depend on general equilibrium in the domestic goods markets), moving on to the absorption approach to the balance of payments (introducing monetary effects as devaluation altered price levels) and culminating in Meade's massive multi-equation model of an open economy (1951). Meade rang the changes of the effects of various domestic monetary and fiscal policies directed at the level of employment and balance of payments equilibrium, under different conditions of price flexibility, capital mobility, wages policy, and various types of initial disturbance in regimes of (*a*) pegged and (*b*) flexible exchange rates (for a more detailed account, see Flanders 1989). Not dissimilar in aim and scope is a neglected attempt by Stuvel (1950) to formalize the effects of exchange rate changes; both he and Meade, by the way, confine themselves to comparative statics.

Discussions of optimal exchange rate regimes were based on the assumption that the large pre-war capital movements, characterized by political and economic speculative flights, were expected not to continue or, in any case, not be permitted. (As early as 1936 Williams outlined possible forms of international monetary and exchange arrangements.) In this light the recommendations for exchange rate flexibility of Friedman (1953), Meade (1955) and others were simple arguments in favour of permitting goods markets to clear by price variation.

The issue of the effects of internal financial policy on the foreign balance and hence on its success in achieving its domestic goals was explored with much simpler models, by Fleming (1962) and by Mundell (1960). These were initially designed to address the problem that domestic full employment policies, if successful, would worsen the trade balance. Some of their two-country models necessarily dealt with the impact on foreign countries as well. (Williams had raised this issue as early as 1934.) They produced models that dealt with the possibility of balance in external payments and attainment of a targeted level of domestic expenditure provided international financial capital flows were sufficiently elastic with respect to interest rate differentials. Metzler (1960) dealt with similar issues but concentrated primarily, in the spirit of Wicksell and Keynes, on the implications for domestic money markets and interest rates as the channel for influence on real absorption. His is a full employment model, so there is no government stabilization activity.

The question of whether monetary and fiscal authorities can maintain desired levels of inflation, real output and the real exchange rate continues to exercise the profession to the present day. Now, given the trend back into administered, if not fixed, exchange rates, the enormous stocks and flows of international financial assets, and the large current account imbalances that these permit, mirrored by the gaps between domestic savings and investment, the issue of the 'adjustment mechanism' takes the form of questions as to the sustainability of these imbalances and the consequences of diminishing or eliminating them. There is general agreement that the imbalances prevailing currently are not sustainable; the manner and consequence of their elimination is less obvious. See Clarida (2006) for an excellent summary of a National Bureau of Economic Research conference.

The overwhelming size and volatility of international financial flows (which, not by chance, coincided with the abandonment of the worldwide fixed exchange- rate system in 1973) have informed the reactivated discussions of optimum exchange rate regimes. Should rates be pegged (temporarily or in perpetuity, as in a model of dollarization) or allowed to float, freely or with some intervention? And if pegged, then to what? This leads to discussion of currency baskets, pegging to a weighted average of currencies; the question then is, what determines the weights (Flanders and Helpman 1979)? If the baskets are weighted by trade shares, international capital flows can prove highly disruptive. We are led, in turn, to the issue of whether capital movements can be controlled, and, if so, should they be, and which countries should be encouraged or permitted to attempt such controls. One line of discussion on this subject revolves around the proposed 'Tobin Tax' (Tobin 1978), designed to put a little 'sand in the wheels' of international monetary flows, which have become huge relative to commodity flows, and which can be highly erratic in response to short-run volatile shifts in expectations.

In Mundell's work the internal-external balance issue led naturally into a discussion of the requirements, in terms of both labour and capital mobility, for a group of countries to constitute an optimum currency area. (Abba Lerner had hinted at something like that in 1944.) At the time, the question was a theoretical curiosum. Twenty years later it led to substantive questions about the viability of the Eurozone as an optimum currency area, including analogies to studies of the United States as such (see Rockoff 2003), and whether a single currency and central bank can be sustained without a single fiscal authority which effects intra-area transfers.

At the same time, the recent neo-monetarism or new neoclassical trend in macroeconomics has

been paralleled by a 'new international macroeconomics'. An exhaustive and perceptive survey is provided in Lane (2001). Starting from the work of Obstfeld and Rogoff (1995), there have been numerous explorations of the impact of monetary shocks (and some consideration of technological shocks) on trade, prices, welfare, real exchange rates, real terms of trade in models of two countries, many countries, and a single small country. Some have sticky wages, all have administered prices, of various types. Different assumptions are made as to consumption elasticities, technology, non-traded goods, bias toward home goods, the inclusion of capital, financial structure and completeness of financial markets, *inter alia.* Some attempts at calibration of the models have been made, with varying success. While the spelling out of the microfoundations of international macroeconomics is intellectually satisfying, the results, as Lane, himself a contributor, avers, are 'highly sensitive to the precise denomination of price stickiness, the specification of preferences and financial market structure. For this reason, any policy recommendations emanating from this literature must be highly qualified' (Lane 2001, p. 262).

International Finance

Maurice Obstfeld

I

Abstract

Fundamental to international finance is the idea of 'external balance', whereby a country's external indebtedness does not threaten its ability to meet its international obligations. The requirements of external balance have varied with the nature of the linkages among economies across historical episodes. This article both reviews the major developments in the economic analysis of external balance and traces how nations have sought to achieve it from the era of the gold standard in 19th century through the Bretton Woods system to the era of floating exchange rates that began in 1973.

International finance is concerned with the determination of real income and the allocation of consumption over time in economies linked to world markets.

Fundamental to international finance is the somewhat elusive idea of 'external balance', which in practice entails a path of external indebtedness that does not threaten a country's ability to meet its international obligations. Because the nature of the linkages among economies has varied across historical episodes, the requirements of external balance have varied as well. International finance studies the policies and market forces which may lead to external balance under various conditions. The history of the subject illustrates how the nature of world market linkages has itself been changed by national efforts to cope with external constraints.

The national income identity is the necessary groundwork for any discussion of external balance. The national income of an open economy equals domestic product plus net factor payments from abroad plus net international transfer payments; the current account equals net exports of goods and services (including all net factor payments) plus net transfers. If national expenditure is defined as the sum of consumption and investment (by both the public and private sectors), the national income identity asserts that national income less national expenditure equals the current account. When in surplus, the current account therefore measures the growth of the economy's external assets; when in deficit, it measures the growth of external debt.

The Classical Paradigm

The classical Ricardo–Mill barter trade theory shows how the terms of trade and international production pattern are determined in a stationary world economy with balanced trade. The classical analysis of the transition to balanced trade may be viewed as an account of the convergence process to the long-run barter equilibrium. As Ricardo noted in the *Principles* (1817):

> Gold and silver having been chosen for the general medium of circulation, they are, by the competition of commerce, distributed in such proportions amongst the different countries of the world as to accommodate themselves to the natural traffic which would take place if no such metals existed, and the trade between countries were purely a trade of barter.

Historically, however, the classical paradigm of external adjustment preceded Ricardo. Major elements of the theory had been expounded quite clearly by the early 18th century, but the most coherent and effective exposition was given by Hume in 1752.

Hume assumed a world economy that settles trade imbalances exclusively through imports or exports of precious metals that also serve as money. Building on the quantity theory of money, he constructed a full dynamic model of the balance of payments and the terms of trade. The famous price–specie–flow mechanism was put forth as an automatic market process that always works to restore balanced trade.

Hume's goal was to refute mercantilist and protectionist arguments by showing that market forces would ensure in the long run a 'natural' distribution of specie among countries.

Hume invited his readers to imagine that four-fifths of Great Britain's money supply were 'annihilated in one night'. British prices would naturally fall, he argued, cheapening British exportables relative to foreign goods and creating a trade surplus. As a result of this surplus Britain would accumulate foreign wealth in the form of specie, seeing its money supply, and hence its prices, rise. Abroad, the drain of specie would lower prices. Britain's trade surplus would dwindle and eventually disappear once its terms of trade had improved sufficiently, and at this point, the natural distribution of specie would prevail. A hypothetical fivefold increase in Britain's money supply would set off the reverse process, involving an initial improvement in Britain's terms of trade and a trade balance deficit. Over time, specie would flow abroad as the terms of trade deteriorated and external equilibrium was restored.

There is little exaggeration in saying that issues raised by Hume's analysis dominated writing in international finance up until the inter-World War years. In a period that culminated in the classical gold standard, it was natural to take as the benchmark of external balance an absence of international specie movements. Hume had placed relative price movements at the centre of his account of how external balance would be attained, but subsequent writers asked whether direct income or wealth effects might also be operative, and whether external adjustment could take place in some cases without price changes. Such questions arose in the 1929 Keynes – Ohlin debate over the German transfer problem, but as Viner (1937) showed, the questions had been raised much earlier.

A simple model of a Humean world makes apparent some of the assumptions underlying the price–specie–flow mechanism. Such a model also serves as a springboard for understanding later developments in the analysis of external adjustment. (A more detailed exposition of a similar model is given by Dornbusch (1973), whose analytical approach is, however, somewhat different from that taken here).

Assume a world of two countries, each specialized in the production of a single commodity that is consumed in both countries. With given supplies of capital and labour within each country and perfect wage flexibility, home-country output is fixed at the full-employment level x and foreign-country output is fixed at y. Let q denote the price of y-goods in terms of x-goods (the terms of trade), z domestic expenditure measured in x-goods, and z^* foreign expenditure, also measured in x-goods. Then the domestic demands for the two goods are $c_x(q, z)$ and $c_y(q, z)$, while the foreign demands are $c_x^*(q, z^*)$ and $c_y^*(q, z^*)$.

Expenditure is determined by monetary conditions. The money supplies M and M^* are for simplicity taken to consist entirely of gold, and P and P^*denote the money prices of home and foreign goods, respectively. The exchange rate between domestic and foreign currency can be set at unity with no loss of generality, so the terms of trade, q, equal P^*/P. In each country there is a desired long-run (or 'natural') money supply: this is proportional to nominal output, and saving behaviour is governed by discrepancies between natural and actual money supplies. Because a country's net saving here equals its current account, which by assumption is settled in specie, saving behaviour determines the evolution of national money supplies.

These evolve according to the laws

$$\begin{aligned} \mathrm{d}M/\mathrm{d}t &= \theta(\chi Px - M)\mathrm{d}M^*/\mathrm{d}i \\ &= \theta^*(\chi^* P^* y - M^*), \end{aligned}$$

where $\chi(\chi^*)$ is the reciprocal of the home (foreign) country's long-run monetary velocity and $\theta(\theta^*)$ is the home (foreign) marginal propensity to dissave out of monetary wealth. Expenditure levels are therefore

$$\begin{aligned} z &= (1 - \theta\chi)x + \theta M/P, \quad z^* \\ &= (1 - \theta^*\chi^*)qy + \theta^* M^* P, \end{aligned}$$

where $\theta\chi$, $\theta^*\chi^* < 1$.

The model is closed by two equilibrium conditions. With a given world stock of monetary gold, M^w, home saving must equal foreign dissaving, that is, world expenditure must equal world output. In addition, the market for domestic goods must clear. By Walras's Law, these two

equilibrium conditions imply equilibrium in the market for foreign goods.

The condition of zero desired world saving is $(dM/dt) + (dM^*/dt) = 0$, or

$$P = \frac{\theta M + \theta^*(M^w - M)}{\theta\chi x + \theta^*\chi^* qy} \quad (1)$$

Equation 1 shows that, for given terms of trade and money supplies, the world price level adjusts to maintain consistency between the countries' saving plans. In equilibrium, this condition makes P a function of q and $M, P = P(q; M)$, with

$$\frac{q}{P}\frac{\partial P}{\partial q} = \frac{-\theta^*\chi^* qy}{\theta x^x + \theta^*\chi^* qy} > -1\,\frac{M}{P}\frac{\partial P}{\partial M} = \frac{(\theta - \theta^*)M}{\theta xPx + \theta^*\chi^* P^* y} \lesseqgtr 0.$$

The market for x-goods clears when

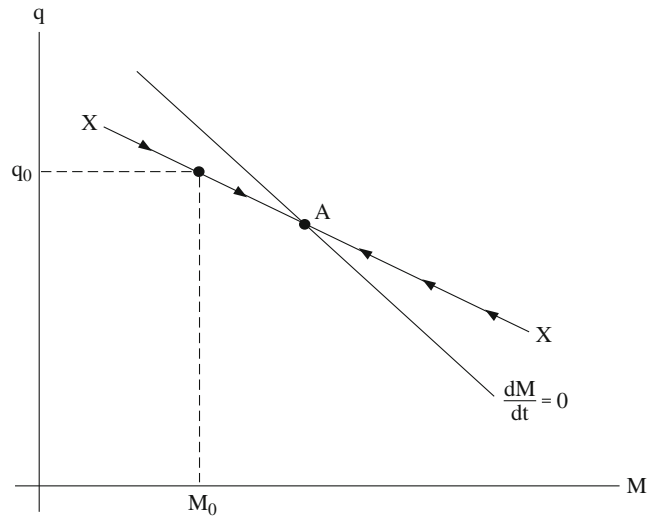
$$c_x[q, (1 - \theta\chi)x + \theta M/P] + c_x^*[q, (1 - \theta^*\chi^*)qy + \theta^* M^*/P] = x \quad (2)$$

Substitution of $P = P(q, M)$ and $M^* = M^w - M$ into (2) gives the curve describing combinations of M and q at which both goods markets clear and aggregate world saving is zero. The curve is labelled XX in Fig. 1 and is shown with a negative slope. The assumptions giving rise to this negative slope are crucial for analysing the Humean adjustment process. An increase in M (which necessarily implies an equal fall in M^*) causes an excess demand for x-goods equal to

$$\frac{\theta\theta^*(M + M^*)}{P(\theta M + \theta^* M^*)}\left[\partial c/\partial z - \partial c_x^*/\partial z^*\right]$$

near the system's long-run equilibrium (where $dM/dt = dM^*/dt = 0$). The term is the $\partial c_x/\partial z - \partial c_x^*/\partial z^*$ difference between the two countries' marginal propensities to spend on home-country goods; if the home-country marginal propensity is larger – the 'orthodox' presumption in transfer analysis (Samuelson 1971) – a redistribution of nominal balances in favour of the home country creates an incipient excess demand for its output. This excess demand is eliminated by a fall in q if the home- goods market is Walras stable, so XX slopes downward under standard assumptions concerning marginal spending propensities and Walrasian stability.

The curve in Fig. 1 labelled $dM|dt = 0$ describes points at which $M = {}_{\chi}p(q, M)x$. This locus has a negative slope algebraically smaller than that of XX. With goods markets continuously in equilibrium, the world economy travels along XX to its long-run equilibrium at point A, where



International Finance, Fig. 1

international prices and the distribution of specie give rise to balanced trade.

In most respects the model confirms Hume's account of the external adjustment process. A (small) fall in M to M_0, for example, leads to terms of trade q_0, which are worse for the home country. The terms-of-trade change is a direct result of the transfer of purchasing power to foreigners, which produces an excess supply of home goods at the initial prices. The home balance-of-payments surplus that simultaneously emerges causes a gradual redistribution of money in favour of the home country, so the home terms of trade improve during the transition to external balance.

If $\theta = \theta^*$, equilibrium P is a function of q alone, with a negative elasticity greater than -1. The rise in q caused by a fall in M is thus accompanied by a less- than-proportional fall in P and a rise in P^* that are reversed as the economy returns to point A. These results are in accord with Hume's predictions, but they need not hold if the expenditure responses to real balances differ sufficiently in the two countries. If $\theta > \theta^*$, a transfer of money abroad raises world saving for given terms of trade, so P^* may *fall* along with P and then rise during the subsequent adjustment. Likewise, if $\theta < \theta^*$, a money transfer abroad may reduce world saving sufficiently that P must *rise*, along with P^*, to restore goods-market equilibrium in the short run. In this case, the initial response to the disturbance is followed by price deflation in both countries.

This stylized version of Hume's paradigm may be used to analyse the transfer problem. Suppose that ownership of a portion of the foreign country's endowment is given to the home country. Does the home trade deficit necessarily increase by the amount of the transfer, or is the transfer undereffected, requiring a flow of specie to the home country to balance international accounts? A second focus of debate in the literature is the possibility that the transfer imposes a 'secondary burden' on the paying country by adding an equilibrium terms-of-trade deterioration to the primary income burden. Keynes and Ohlin clashed on this point in 1929, with Keynes arguing that the secondary burden is inevitable.

To simplify, suppose that $\theta = \theta^*$ and $\chi = \chi^*$. Since long-run money demand rises with income, the $dM/dt = 0$ locus shifts to the right, implying that the transfer at first is undereffected and that the world's gold stock is redistributed toward the home country. Under the standard assumption regarding marginal spending propensities, the transfer also creates an excess demand for x-goods at the initial terms of trade, so XX shifts downward. A secondary burden is thus imposed on the paying country, and this burden worsens over time as balanced trade is reestablished.

The Interwar Period

The years between the World Wars saw a partial and ultimately unsuccessful return to the gold standard, followed by extensive experimentation with floating exchange rates and direct controls on international payments as means of attaining external balance. Nurkse's (1944) account of the period is probably the most influential one. Writers on international finance continued to conceptualize external balance in terms of reserve movements. The spread of the gold-exchange standard, under which central banks held as foreign reserves currencies tied to gold as well as gold itself, broadened the class of assets through which balance-of-payments deficits were financed.

International capital movements were discussed increasingly in the theoretical literature, but they were viewed for the most part as an adjunct to the classical balance-of-payments adjustment mechanism. The theoretical discussions merely formalized a mechanism that had long been exploited by the Bank of England to regulate gold flows. A country that suddenly developed a trade deficit would face declining international reserves, a declining money supply, and rising interest rates. Rising interest rates would, however, attract foreign capital inflows and thus dampen the resulting deficit in the balance of payments. On this view, interest-sensitive capital flows had a potentially stabilizing role to play in discouraging protracted reserve flows. Given the turbulent conditions of the period, contemporary writers fully recognized that capital

flows motivated by fears of devaluation or political instability could just as well destabilize an already bad external payments problem.

Such 'short-term' or interest-sensitive capital movements were generally discussed separately from 'long-term' international capital movements which directly financed investment or government expenditures. Theoretical discussions of long- term capital movements focused mainly on the transfer mechanism, the balance-of- payments and terms-of-trade adjustments that would accompany an inter-country transfer of capital. Conspicuously absent from the literature were attempts to develop a normative intertemporal theory of international capital transfer. Such a theory naturally would have extended the prevailing external balance concept to comprise changes in nations' *overall* indebtedness rather than just changes in the central bank's foreign assets. It had been known, at least since Ricardo's *Principles*, that producers and consumers could gain if long-term foreign investment equalized profits internationally. The insight did not dominate thinking about the nature of external balance.

This gap in the literature is surprising in view of the developments in international capital markets over the previous century. Huge flows of long-term capital, primarily from Britain, had financed railroad construction and other investment in the Western Hemisphere. France and Germany also made significant foreign loans. In the early 1930s, widespread foreign debt default among the Latin American countries highlighted the need to analyse formality the sustainability of external debt paths. In the world assumed by Hume, specie flows had been the only means of settling current-account imbalances, and a concept of external balance based on balance-of-payments equilibrium had been defensible. Such a concept of external balance was outmoded, however, in a world where other types of asset trade could finance the current account.

The necessary change of perspective did not occur for several decades. Instead, the events and ideas of the interwar period led international financial theory to turn away sharply from the concern with the dynamics of international adjustment underlying the classical model. Emphasis shifted inward, to the interaction between the balance of payments and domestic economic conditions.

The Bretton Woods Period

The interwar experience had a profound influence on both the institutional framework of postwar international finance and the theoretical orientation of researchers. The international agreement reached at Bretton Woods in 1944 set up a world trading community linked by fixed dollar exchange rates, with a United States commitment to peg the dollar price of gold at $35 per ounce providing an anchor for the world price level. The agreement's provisions aimed to promote free trade in goods, but private capital movements were viewed as potentially disruptive and the widespread capital controls then in force were not discouraged. A prevailing view that flexible exchange rates had failed during the interwar period motivated the adoption of a fixed-rate system. Provision was made, however, for infrequent exchange-rate adjustment, after due consultation, in circumstances of 'fundamental disequilibrium' in the balance of payments.

Central to the design of the Bretton Woods system was a desire to avoid unemployment and ensure price-level stability. In the interwar years, many governments had resorted to competitive currency depreciations and trade restrictions aimed at reducing domestic unemployment. These 'beggar-thy-neighbour' moves made all countries worse off. Having recently experienced the hardships of the worldwide Great Depression, the Bretton Woods signatories recognized the goal of 'internal balance' – full employment with price stability – as a key aim of government policy. An International Monetary Fund was set up to reconcile the goals of internal and external balance. It was hoped that the availability of Fund credit would make it unnecessary for members to tolerate high unemployment in pursuing external balance, or to interfere with trade flows in pursuing internal balance.

In an environment of fixed exchange rates and extremely limited capital mobility, the overriding

external consideration for governments was the available stock of foreign, particularly dollar, reserves. The operative external target was therefore the acquisition of as many dollars as possible through balance-of-payments surpluses. As the reserve centre, the United States enjoyed the privilege of being able to finance its own balance-of-payments deficits by borrowing dollars from foreign central banks. In reality, however, the United States was not totally free of a reserve constraint. Foreign central banks could, and did, use their dollars to buy gold from the US authorities at the official price. The problem of gold losses became important as the postwar period of 'dollar shortage' ended in the late 1950s. In 1960, Triffin put the American external dilemma in its most sombre light: Once foreign official dollar holdings exceed the official value of the US gold stock, it would become impossible to satisfy all foreign claims to US gold without a rise in the dollar price of metal. The resulting confidence problem, Triffin predicted, would undermine the stability of the Bretton Woods system.

As it developed immediately after World War II, international financial theory reflected the new institutional arrangements, along with the economic assumptions underlying Keynes's (1936) diagnosis of the unemployment of the 1930s. The new paradigm, set forth very effectively by Metzler (1948, pp. 212–13), assumed sticky price levels and wages along with fixed exchange rates, thus precluding the relative- price adjustments at the heart of the classical paradigm while opening the door to employment fluctuations:

> The important feature of the classical mechanism ... is the central role which it attributes to the monetary system. The classical theory contains an explicit acceptance of the Quantity Theory of Money as well as an implied assumption that output and employment are unaffected by international monetary disturbances. In other words, the classical doctrine assumes that an increase or decrease in the quantity of money leads to an increase or decrease in the aggregate money demand for goods and services, and that a change in money demand affects prices and costs rather than output and employment ... . The essence of the new theory is that an external event which increases a country's exports will also increase imports *even without price changes*, since the change in exports affects the level of output and hence the demand for all goods. In other words, movements of output and employment play much the same role in the new doctrine that price movements played in the old.

An increase in external demand for a country's exports, for example, would raise the country's trade surplus in the first instance, but once the multiplier effect of the disturbance had raised income and hence import spending, the initial impact on the trade balance would be reduced. Metzler noted, however, that even if one assumed that investment spending responds positively to a rise in real income, it was unlikely that multiplier effects alone would ensure complete trade-balance adjustment in the short run.

The Keynesian account of external adjustment therefore contained an important gap. Private capital movements were largely ruled out in the Keynesian models, so incomplete trade-balance adjustment implied incomplete balance-of-payments adjustment and growing or shrinking central-bank foreign reserves. The models pushed monetary factors to the background, implicitly or explicitly assuming that central-bank sterilization operations were offsetting any monetary effects of the balance of payments. Only a few of the early postwar theorists, notably Meade (1951), assigned an important role to monetary factors.

Even if the sterilization assumption were granted, however, consideration of the system's inherent dynamics made clear the infeasibility of a *permanent* sterilization policy. Countries with persistent deficits would ultimately exhaust their available international reserves, including IMF credit; and even surplus countries might be unable to sterilize indefinitely if domestic financial markets were thin. How, then, could trade-balance equilibrium even be restored after a permanent external shock? Fiscal policy could be effective in situations where the needs of internal and external balance were both served by the same measure. In dilemma situations where fiscal measures could move the economy toward external balance only at the cost of increasing its distance from internal balance, the 'fundamental disequilibrium' clause of the IMF Articles of Agreement could be invoked and the currency devalued. But no

automatic market mechanism pushing the economy toward balance-of-payments equilibrium was featured in the early postwar writing.

In a series of remarkable papers published in the early 1960s, Mundell revived the explicit dynamic analysis of international adjustment. His models placed the monetary sector in the foreground, adopting a Keynesian liquidity-preference view of interest-rate determination. A prescient paper by Metzler (1960), written at about the same time, took a similar approach.

Mundell's paper on 'The International Disequilibrium System' (1961) criticized the Keynesian model's failure to account for the dynamic effects of payments imbalances. Even in a Keynesian world, Mundell argued, an income–specie–flow mechanism, analogous to Hume's price–specie–flow mechanism, ensures long-run balance-of-payments equilibrium. A 'fivefold increase' in a country's money supply, for example, depresses domestic interest rates, stimulates investment spending, and creates a deficit in the balance of payments. As the central bank loses reserves, however, the interest rate gradually rises and reduces investment, the process coming to an end (for a small country) only when the domestic money supply, the interest rate, investment, and output have returned to their original levels. The introduction of dynamic adjustment made it clear that sterilization could have only limited success as a policy response to permanent balance-of-payments disturbances. One source of dynamic effects, however, was not explicitly analysed in Mundell's work of the period. The omitted effect was the real-balance effect on expenditure, central to the classical account but possibly relevant (as Pigou had shown) under Keynesian conditions as well.

In line with the increasing international capital mobility that followed the European move toward currency convertibility in 1958, Mundell gave the capital account a prominent role in his models. The presence of capital mobility suggested a solution to the policy dilemmas that could arise under fixed exchange rates when the goals of internal and external balance appeared to conflict. Mundell showed that by gearing monetary policy to external balance and fiscal policy to internal balance, governments could simultaneously attain both goals. The key to the argument is the observation that monetary and fiscal expansion both raise output but have different effects on the capital account, monetary expansion causing capital outflows (by driving down the home interest rate) and fiscal expansion causing capital inflows (by raising the interest rate). With two independent instruments, both internal and external policy targets can be attained simultaneously.

While a major step forward, the Mundellian argument for a policy mix suffered from two drawbacks. First, the theoretical specification of the capital account as a function of international interest-rate levels was weak: it seemed unlikely that capital would flow at a uniform level forever even if the interest differential remained fixed. Missing was a discussion of stock equilibrium in international asset markets. The second problem with the policy mix was its definition of external balance. Would any policymaker view with satisfaction a permanently high interest rate that brought about balance-of-payments equilibrium by crowding out domestic investment and encouraging a build-up of external debt? Key considerations omitted from Mundell's model were the stock of net foreign claims and the associated flows of interest payments. Mundell himself (1968, p. 207) recognized that in many contexts, the definition of external balance as balance-of-payments equilibrium might be inadequate:

> Just as the composition of output is important (the division of output between investment and consumption affects additional growth targets), so an appropriate composition of the balance of payments is a legitimate target of policy.

Indeed, in spite of the continuing obligation to peg dollar exchange rates, the standard definition of external balance was becoming increasingly outmoded by the late 1960s. The balance of payments remained a legitimate concern, of course, in part because a large or persistent imbalance might look like 'fundamental disequilibrium' to the market and spark a speculative attack on the currency involved. But the increasing integration of national financial markets – a development epitomized by the growth of Eurocurrency trading – weakened

the bite of the balance-of-payments constraint. In a hypothetical world of *perfect* capital mobility, a central bank short on reserves can essentially borrow them from abroad at no net cost simply by contracting domestic credit. Such an action, by causing an incipient rise in the home interest rate, leads to an instantaneous private capital inflow and an official reserve gain equal to the fall in domestic credit. The home interest rate, the money supply, output, and the national external debt are unchanged in the final equilibrium: the central bank holds more foreign assets and fewer domestic assets, while the home private sector, having made the mirror-image adjustment, holds fewer foreign assets and more domestic assets.

The case of perfect capital mobility is an extreme one that does not fit the facts of the late Bretton Woods period. None the less, the opportunities for central banks to borrow dollar reserves in the international capital market had grown since the early 1960s. The situation facing the United States was quite different. As the primary international reserve issuer, its responsibility was to peg the dollar price of gold, a responsibility that would have required the gearing of US monetary policy to that external commitment. In spite of such expedients as the two-tier gold market established by central banks in 1968, the US did not succeed in preserving the dollar's link to gold. Triffin had been right. After a series of violent speculative attacks, the US severed the dollar's gold link in August 1971 and in December 1971 devalued the dollar against major foreign currencies. The patchwork system of fixed exchange rates proved unstable, and in the first months of 1973 the postwar period of floating exchange rates began.

Floating Exchange Rates

The industrialized countries adopted floating dollar exchange rates as an interim measure, but in fact a significant body of economists had come to advocate floating rates by 1973. Friedman's (1953) powerful case for flexible rates was the opening shot in a campaign to revise the then-prevailing view, expounded by Nurkse (1944), that the floating-rate experiments of the interwar years were disastrous. By the time Johnson wrote his well-known polemic of 1969, Friedman's views had gained many adherents.

The fundamental argument for floating rates was that they would free governments of the balance-of-payments constraint and allow them to use monetary policy to attain domestic economic goals. Equilibrium in the balance of payments would be automatic if central banks simply refrained from intervening in the foreign exchange market. At the same time, floating rates would permit central banks to target their nominal money supplies without being frustrated by offsetting interest- sensitive foreign reserve flows. Widespread restrictions on trade and capital movements, motivated in part by a desire to impede reserve flows under the fixed- rate regime, could be dismantled.

Subsequent experience was to provide only partial vindication to the advocates of floating. In the decade after 1973, barriers to capital movement were reduced to insignificant levels in many of the industrial countries. This development helped spark unprecedented growth in international financial intermediation. Under the new exchange-rate regime, however, policymakers became more acutely aware that the traditional definition of internal balance as full employment cum price stability really involved two, quite distinct, goals. Under a floating exchange rate, monetary expansion aimed at domestic unemployment translates immediately into currency depreciation, higher import prices, and heightened inflationary expectations.

Conversely, a rapidly adjusting exchange rate provides a powerful channel through which inflationary expectations can have a direct and immediate effect on inflation in an open economy. Any short-run tradeoff between inflation and unemployment would therefore be less favourable under a floating rate. Floating rates certainly allow countries to choose their own trend inflation rates. But it soon became evident that if disturbances to the economy originated predominantly outside the money market, the inflationary cost of using monetary policy to target employment could be quite high.

Sharp exchange-rate movements might also have adverse distributional effects in the economy, and these, together with a desire for price-level stability, led central banks to intervene, at times heavily, in the foreign exchange market.

Correspondingly, the predicted drop in central banks' demand for international reserves did not materialize (although the composition of reserves did change over time as the Deutschmark and yen became important reserve currencies and the pound sterling retreated). Central banks' use of foreign reserves to manage exchange rates did not necessarily imply an operative balance-of-payments constraint, however, since in many countries the same exchange-rate effects could have been achieved at an unchanged reserve level through domestic credit measures.

Under conditions of limited capital mobility, such as those existing in the early 1950s when Friedman wrote, the automatic balancing of international reserve movements by a floating exchange rate amounted essentially to the automatic balancing of the current account. With means other than reserve flows available to settle current-account imbalances, however, there is no theoretical necessity for a floating rate to balance the current account in the short run. A current-account deficit, say, can be financed entirely through domestic borrowing abroad with no decline in the central bank's foreign assets. Experience was to show that floating exchange rates themselves could not prevent the emergence of large and persistent current-account imbalances. These imbalances were problematic not only because they usually entailed costs of shifting productive resources between the economy's tradable and nontradable sectors, but also because they implied changes in foreign debt and thus in sustainable future consumption levels.

Attention therefore shifted to the mechanism of current-account adjustment under floating exchange rates and capital mobility, with researchers asking, as Hume had, if market forces would automatically push economies toward current-account balance. The new generation of dynamic open-economy models produced in the mid-1970s built on a number of antecedents in the literature. One of these was the neoclassical monetary approach to the balance of payments, which stressed the real balance effect and the transition to long-run payments equilibrium (see, for example, Frenkel and Johnson 1976). The second important antecedent was the closed- economy literature on money and growth, which had clarified the stock-flow distinction in multi-asset models with wealth accumulation. As suggested by the rational-expectations revolution in macroeconomics, many model builders endowed agents with forward-looking exchange-rate expectations that played a key role in clearing the asset markets.

The intrinsic dynamic mechanism in these models is fuelled by wealth, broadly defined to include not only real monetary balances, but also foreign assets and possibly capital, physical as well as human. (See Obstfeld and Stockman 1985, for a survey.) In line with the long-run nature of the inquiry, the 'classical' conditions of price flexibility and full employment were generally assumed, giving a productions structure similar to the Humean model set out above. Where the models differed essentially from Hume was in the wider spectrum of marketable assets, and in the resulting portfolio problem of private agents. Each given configuration of world asset stocks determines a short-run equilibrium defined by the requirements of market clearing in asset as well as goods markets. The resulting equilibrium wealth levels and real interest rates determine consumption levels at home and abroad, but there is no necessary requirement of current-account balance in the short run: goods-market equilibrium implies only that one country's planned current-account surplus equals the other's planned current-account deficit. The international adjustment process can now be visualized. All else equal, the deficit country is running down its wealth by borrowing from abroad, so its consumption is falling and foreign consumption is rising. Under the orthodox transfer criterion, this redistribution of wealth between the countries causes the deficit country's terms of trade to deteriorate over time; if anticipated, the evolution of the terms of trade has further repercussions on world real interest rates and expenditure levels. The process comes to an end once the deficit country's consumption has fallen into line with its income, which is lower than initially because of the increased interest

burden of the external debt. (A very similar adjustment process would take place with mobile capital and a fixed exchange rate, but reserve movements rather than exchange-rate movements would contribute to asset-market balance during the transition to long-run equilibrium.)

This simple picture of the adjustment process becomes more complicated once domestic capital accumulation is allowed. A current-account deficit may now finance an investment boom in which the deficit country's terms of trade improve over time. Eventually, however, the international wealth-flow mechanism restores a balanced current account. Further complications arise when the classical assumptions are dropped and Keynesian price stickiness in output markets is assumed. In such models, the approach to the long-run, full-employment equilibrium can be oscillatory.

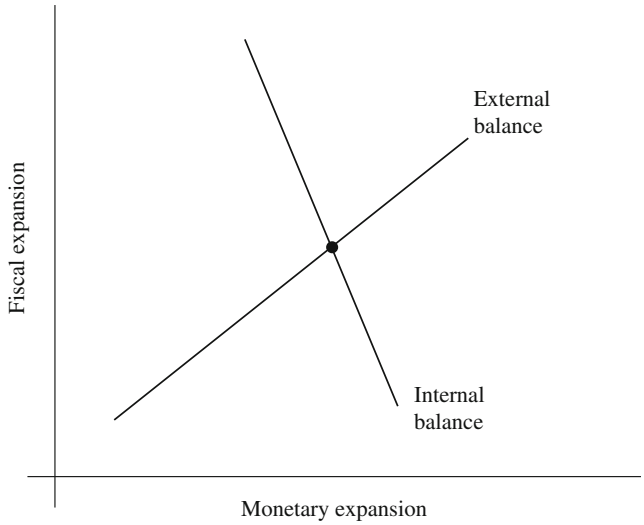
For a single economy with Keynesian features, there is an analogue to the Mundellian idea of using monetary and fiscal policy simultaneously to attain internal and external targets. Figure 2, which is developed more fully in Obstfeld (1985, pp. 408–10), illustrates this approach. The downward sloping internal-balance schedule shows combinations of monetary and fiscal ease consistent with full employment. On the assumption that monetary ease improves the current account by depreciating the currency, the external-balance schedule, which shows policy settings consistent with some current-account target, slopes upward. The intersection of the two schedules shows how policies should be set to achieve both of the government's goals in the short run.

Even if one leaves aside the complex game-theoretic problems surrounding interactions between expectations and policy, the usefulness of the above framework as a normative guide is limited by its failure to incorporate some key dynamic elements. If the government can hit its targets only by running a budget deficit, its fiscal stance must eventually be reversed if the government debt is to be serviced. In addition, the policy equilibrium shown in Fig. 2 may imply a domestic investment rate that is socially sub-optimal. Finally, the framework itself gives no guidance as to the appropriate external-balance criterion. The balanced current account reached in the hypothetical long-run equilibrium of a stationary world economy may be far off the mark in the short run in which policy decisions must be made. Recently, the theory of international finance has made partial progress in addressing these issues.

The Intertemporal Analysis of External Balance

In the 1980s, it became increasingly common to analyse the dynamic behaviour of open

International Finance, Fig. 2



economies in terms of the intertemporal maximization hypothesis applied by Fisher (1930) to the theory of saving and investment. As usual, this trend was the result of both new theoretical approaches in macroeconomics generally and of economic events that existing open-economy models seemed ill-equipped to analyse.

Lucas's (1976) influential critique of econometric policy evaluation was important in motivating the intertemporal approach. Lucas argued that the standard econometric models of the time would generally not be invariant to policy changes. Because the parameters estimated were not the 'deep' parameters describing preferences or technology, but instead reflected both deep structure and the policy environment prevailing over the estimation period, the models could not be used to analyse *changes* in the policy environment. Lucas's analysis suggested that more reliable policy conclusions might be drawn from open-economy models if demand and supply functions were derived from the optimal decision rules of maximizing households and firms.

Further impetus to develop an intertemporal approach came from events in the world capital market, particularly the international pattern of current accounts following the sharp oil-price increases of 1973–1974 and 1979–1980. The divergent patterns of a current-account adjustment by industrialized and developing countries raised the inherently intertemporal problem of characterizing the optimal response to external shocks. Neither classical nor Keynesian transfer analysis offered any reliable guidance on this question. Similarly, the explosion in bank lending to developing countries after the first oil shock sparked fears that some countries' external debt burdens would become unsustainable. The need to assess developing-country debt levels again led naturally to the notion of an intertemporally optimal current-account deficit.

Any intertemporal analysis of external balance must begin by specifying the economy's technological and market opportunities for shifting consumption over time. These opportunities are described by the economy's intertemporal budget constraint, which specifies the terms on which the economy can borrow or lend abroad, as well as the domestic investment technology. Separate analysis of the public and private sector's budget constraints illuminates the link between the public finances and external imbalances, as measured by the balance of payments or by the current account. The economy-wide budget constraint results from consolidation of the public- and private-sector constraints.

Assume for simplicity that a single good is consumed and produced on each date, and consider the position of a small open economy that can borrow or lend internationally at the real interest rate ρ. For each date t, the government of the economy chooses a level of real government consumption, $g(t)$, and a (possibly negative) level of real transfers to the private sector, $\tau(t)$. The government finances its outlays by issuing debt, by printing money, and by drawing on the interest paid by the central bank's foreign reserves. (For present purposes, the central bank's budget is best viewed as a component of the government's budget). Let $b^{G}(t)$ denote real government bond holdings (other than central-bank foreign reserves), $D(t)$ the money value of central-bank domestic credit, $P(t)$ the money price level, and $r(t)$ real foreign reserves. If the government pays the interest rate ρ on the public debt $[-b^{G}(t)]$, then the path of government bond holdings satisfies the equation:

$$\begin{aligned} \mathrm{d}b^{G}(t)/\mathrm{d}t = {} & \rho\left[b^{G}(t) + r(t)\right] \\ & + [1/P(t)]\mathrm{d}D(t)\mathrm{d}t - g(t) \\ & - \tau(t). \end{aligned} \tag{3}$$

Changes in the economy's money supply, $M^{s}(t)$, result from changes in the central bank's foreign or domestic assets. If the world price level P^{*} is constant (so that proportional changes in $P(t)$ equal proportional changes in the exchange rate), then the central-bank balance-sheet identity implies $\mathrm{d}M^{s}(t)/\mathrm{d}t = p(t)[\mathrm{d}r(t)/\mathrm{d}t] + \mathrm{d}D(t)/\mathrm{d}t$. Let $m(t)$ denote the private sector's desired real money balances and $\pi(t)$ the home inflation rate. On the assumption that the money market is continuously in equilibrium, $m(t) = M^{s}(t)/p(t)$ and Eq. 3 becomes

$$\mathrm{d}\left[b^{\mathrm{G}}(t)+r(t)\right]/\mathrm{d}t=\rho\left[b^{\mathrm{G}}(t)+r(t)\right]+\pi(t)m(t)+\left[\mathrm{d}m(t)/\mathrm{d}t\right]-g(t)-\tau(t). \quad (4)$$

Integrate (4) forward from $t = 0$ and impose the condition $\lim_{t\to\infty}\exp(-\rho t)[b^{G}(t) + r(t) \geq 0$, which restricts the government to borrowing paths such that the public debt is assymptotically paid off. The result is the intertemporal budget constraint of the government,

$$\int_0^\infty [g(t)+\tau(t)]\exp(-\rho t)dt \leq \int_0^\infty [\pi(t)m(t)+dm(t)/dt]\exp(-\rho t)dt + b^{G}(0)+r(0).$$

The inequality states that the present value of net government outlays must be less than the present value of the seigniorage from money creation plus the government's initial asset position. The latter quantity, in turn, equals central-bank foreign reserves less the public debt. For a world of perfect capital mobility, the constraint makes clear that it is the government's overall asset position that is relevant for assessing solvency. The level of foreign reserves $r(0)$ has little significance in itself. As noted earlier, the central bank can increase its reserves by selling other government assets (thus reducing $b^{\mathrm{G}}(0)$ by an amount equal to the rise in reserves). The transaction requires no change in the path of planned government outlays, $g(t) + \tau(t)$.

Consider next the private sector. Let $b(t)$ denote net private real bond holdings and $k(t)$ real capital holdings. (By assumption capital's real price equals unity). Foreigners do not hold domestic money or capital, although the analysis could easily be modified to account for these possibilities. Given an inelastic labour supply normalized at unity and a neoclassical production function $x[k(t), t]$, private-sector assets obey the equation

$$\mathrm{d}[\mathrm{b}(t)+k(t)+m(t)]/\mathrm{d}t = x[k(t),t]+\rho b(t)+\tau(t)-c(t)-\pi(t)m(t). \quad (5)$$

Define investment $i(t)$ as $\mathrm{d}k(t)/\mathrm{d}t$. The sum of (4) and (5) is

$$d\left[b(t)+b^{\mathrm{G}}(t)+r(t)\right]/dt = x[k(t),t]+\rho\left[b(t)+b^{\mathrm{G}}(t)+r(t)\right]-c(t)-i(t)-g(t).$$

The sum $b(t) + b^{\mathrm{G}}(t) + r(t)$ will be denoted by $f(t)$: $f(t)$ equals the economy's overall net claims on the rest of the world. Integrated forward and combined with the condition $\lim_{t\to\infty}\exp(-\rho t)f(t) \geq 0$ the above equation implies the economy's overall intertemporal budget constraint,

$$\int_0^\infty \{c(t)+i(t)+g(t)-x\left[k(t),t\right)\}\exp(-\rho t)\mathrm{d}t \leq f(0). \quad (6)$$

(The same constraint is relevant when the private sector is prohibited from transacting in the world capital market, but the paths of consumption, investment, and output would generally change if such a prohibition were imposed.)

Inequality (6) states that the present value of the economy's expenditures cannot exceed the present value of output plus initial net external assets. Alternatively, (6) constrains the present value of the economy's trade balance deficits to its initial foreign asset stock. The initial foreign asset stock thus limits the economy's ability to maintain absorption levels in excess of output.

An implication of the analysis is that the most appropriate indicator of flow disequilibrium in external transactions is the change in the economy's overall external assets – the current account. A surplus in the balance of payments may indicate low domestic credit expansion or growing domestic money demand; but when the government has unlimited access to the world capital market, a growing stock of foreign reserves is, in itself, neither a necessary nor a sufficient condition for a sound external position.

The important consequences of current-account flows do not imply that external balance and current-account balance are the same. In analogy with the idea of a high-employment government budget surplus, external balance could be defined roughly as a current account that

maintains the highest possible steady consumption level consistent with the economy's expected intertemporal budget constraint. (A more exact definition would require a more explicit treatment of the preferences of households and the government). Temporary unfavourable movements in output, world interest rates, or the terms of trade are appropriately offset by temporary current-account deficits, while temporary surpluses are an appropriate response to temporary favourable shocks. External balance in the face of a permanent shock, however, generally requires a rapid adjustment to current-account balance.

Similarly increases in the productivity of investment can justify a current- account deficit that is fully consistent with external balance in a long-run sense. In terms of Eq. 6, a technological innovation implying a gradual upward shift of the production function $x[k(t), t]$ generates higher levels of consumption and investment, and thus an initial current-account deficit. The ability to borrow abroad prevents the sharp rise in the interest rate that would occur initially in a closed economy; a higher investment level than under intertemporal autarky is supported by the foreign capital inflow. As productivity growth returns to normal, investment falls and current-account balance is restored with consumption and output at permanently higher levels.

These points can be made graphically in terms of a two-period Fisherian model (see Fig. 3). The axes measure amounts of the two goods available, present and future consumption, and the indifference curves show preferences over those goods. Investment opportunities are described by the production-possibilities frontier, which indicates the amount of future consumption obtained from a given input of present consumption. With the opportunity to borrow abroad at an interest rate ρ, the economy chooses to invest at point A and consume at point B, both of these points lying on the economy's budget line, which has slope $-(1 + \rho)$. Given preferences and technology, it is optimal for this economy to run a first-period current-account deficit equal to the horizontal distance between B and A; in period two, the country runs a surplus to repay its earlier borrowing. External balance thus entails an initial current-account deficit for the country shown, but surpluses for countries whose autarky interest rates are less than the equilibrium world rate ρ. The model is a parable of the development process.

When distortions in the economy cause the actual current account to diverge from its optimal level, governments may find it appropriate to adopt policies, such as taxes or subsidies on capital movement, that move the economy closer to the ideal external balance. Policies that operate directly on the distortions in question (if these can be identified) will, as usual, be best. Interesting problems arise when the countries being analysed are large enough that their governments can affect world real interest rates (and other world prices) through their actions. In this situation, the normative guidelines offered by the above approach are not directly applicable to policy analysis, and governments instead condition their actions on the conjectured responses of other governments. A Nash–Cournot equilibrium, in which each government maximizes over policy settings taking as *given* the policies of other governments, will in general be Pareto-inefficient from a global viewpoint. When governments recognize their policy interdependence, welfare in each country can be improved though policy cooperation. The practical difficulty lies in the negotiation process through which all parties agree to choose a particular point on the world contract curve.

Sovereign Borrowing and Credit Constraints

The intertemporal analysis of external balance sketched above assumes a world in which individuals, or at least governments, can borrow unlimited amounts in the world capital market, subject only to their intertemporal budget constraints.

Individual and sovereign borrowers alike, however, often appear to face binding credit constraints as a result of nonrepayment risk. After the early 1980s, the extreme difficulty for many industrializing countries of tapping world credit markets focused attention on how countries' borrowing possibilities are affected by the possibility of sovereign debt default. The problem is a central

one because most developing-country debts are either contracted directly by government agencies or are government-guaranteed.

Eaton and Gersovitz (1981) presented an early explicit analysis of the sovereign repudiation problem in an international setting. Claims on sovereign debtors are usually not legally enforceable, so the analysis of sovereign default cannot be conducted in terms of bankruptcy laws that govern cases of individual default. Eaton and Gersovitz hypothesized that a sovereign debtor defaults whenever the present discounted benefit of doing so exceeds the present discounted cost. Potential lenders, understanding the debtor's decision rule, will never lend so much that a sure incentive to default is created. Accordingly, sovereign borrowers may find themselves credit-rationed, unable to borrow as much as would normally be optimal at the interest rate quoted by lenders.

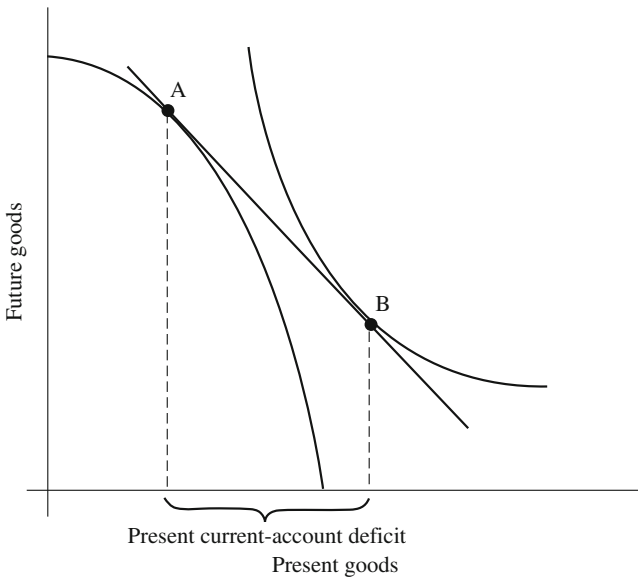
There are several potential costs of sovereign default. A defaulting country's external assets, such as foreign reserves or goods in transit, can be seized. The country could, in addition, find itself unable to borrow in the future in response to unexpected changes in its income or technology. Continued participation in the world trade and payments system might become infeasible altogether.

This 'willingness to pay' hypothesis has radical implications for the analysis of external balance. The borrowing country shown in Fig. 3, for example, would repudiate its foreign debt if that action were costless, thus avoiding the resource transfer it would otherwise have to make in the second period. As a result, period- one borrowing would take place at a country-specific interest rate reflecting the probability of default, with the extent of borrowing limited by the market's estimate of default costs. At interest rates so high that default was certain, no lending at all would occur.

The analysis of external balance becomes much more complex in such a setting.

Not only is the allowable current-account deficit more severely circumscribed; in addition, the policymaker must consider how various policy actions will affect the costs of default and hence the availability of foreign credit. Trade liberalization measures that move the economy away from an autarkic production allocation increase the cost of default by making the economy more vulnerable to disruption of its foreign trade. Such measures will therefore ease international credit constraints at the same time as they improve the static allocation of national resources. Conversely, trade restrictions aimed

International Finance, Fig. 3



at improving the current account may well reduce a country's creditworthiness.

The traditional balance-of-payments target has a rationale if the government believes that foreign credit lines may disappear unexpectedly. There is then a case for holding precautionary reserves to finance current-account deficits that may become necessary at times when credit happens to be tight or non-existent. The same purpose would be served, however, if foreign assets held by government agencies other than the central bank were run down at such times.

Internal and external balance may be irreconcilable for countries that seek to continue external debt service in the face of severe limitations on foreign borrowing. After the early 1980s, many developing countries were able to obtain private external finance only through 'forced' bank lending orchestrated by the IMF and central banks. Measures to reduce current-account deficits in line with the external funds available (and in line with IMF stabilization targets) pushed many economies into deep recession. As of this writing, it is unclear how long it will remain politically feasible for debtor governments to downplay internal-balance goals in order to continue avoiding default. There are increasingly frequent calls for some form of debt relief. Such proposals amount to the *ex post* indexation of debt contracts to adverse contingencies that were not entirely under the debtors' control.

The debt crisis of the 1980s has raised deep and consequential questions about the types of assets traded between developed and developing countries. Before the debt crisis, the typical loan contract between banks and developing-country borrowers was indexed only to the London Inter-Bank Offered Rate, and not to other factors that might alter the borrower's ability to repay. Trade between developed and developing countries in a wider spectrum of state-contingent assets would improve the international allocation of risk, and thus help to avoid future debt crises. A greater share for equity in settling current-account imbalances is one possible step in this direction. Such reforms would not eliminate the sovereign-default problem entirely, nor would they eliminate the moral-hazard problem emphasized by critics of debt-relief proposals. The possibility of a widespread and synchronized default could be sharply reduced, however, under innovative external financing arrangements.

The structure of international financial intermediation also has implications for the mutual adjustment process of industrialized countries. Current-account imbalances are only one avenue through which countries can maintain long-run consumption levels in the face of real income fluctuations or changes in investment productivity. Similar consumption-smoothing can be obtained with smaller current- account imbalances if there is a greater degree of international portfolio diversification. Lucas (1982), for example, models a world of two exchange economies with perfect international risk sharing in which consumption levels can be perfectly correlated internationally even though current-account imbalances never take place. The problem of external balance therefore never arises in Lucas's idealized setting. In reality, the extent of international portfolio diversification seem to be much smaller than plausible financial models of an integrated world capital market would predict. Why this should be so is a major empirical puzzle, and a problem for policy as well.

International Financial Institutions (IFIs)

John Toye

Abstract

The International Monetary Fund was established to manage international payments post-Second World War. The gold exchange standard re-established current account convertibility in the industrialized nations and oversaw rapid growth of international trade. After that standard collapsed in 1971 the IMF ran stabilization programmes for developing countries, with mixed success. The World Bank was set up to provide medium-term loans at concessional interest rates for (post-war) reconstruction and to develop capital-poor areas. In 1979 it initiated programme lending with conditions to promote economic adjustment. Conditionality has been under-enforced but increasingly loans go to countries that show commitment to liberal economic reforms.

The two major international financial institutions, the International Monetary Fund (IMF) and the World Bank, were designed on an Anglo-American plan, negotiated by John Maynard Keynes and Harry Dexter White. After gaining wider approval

at the Bretton Woods conference in July 1944, they were set up in order to introduce new elements of multilateral regulation into the working of the international economy (Skidelsky, 2000)

The International Monetary Fund

The IMF, established in 1947 to manage international payments in the economic chaos that followed the Second World War, had four Charter objectives: to restore a system of multilateral payments for current transactions between its members; to minimize disequilbrium in the members' international balances of payments; to promote exchange stability; and 'to facilitate the expansion and balanced growth of international trade, and to contribute thereby to the promotion and maintenance of high levels of employment and real income'. In promoting all of these objectives, the Fund originally acted as the umpire of a set of rules of international monetary behaviour.

Originally, the IMF managed a system of fixed, but adjustable, exchange rates against the US dollar, which itself was pegged to gold. In order to keep exchange rate fluctuations within set limits, each member country – and the membership then was much smaller than it was in 2005 (over 180) – paid into the Fund a capital sum, determined according to its importance in world trade, and was given a borrowing 'quota' related to its capital. Voting power in the organization is related to the size of this capital. In balance of payments difficulties, members were permitted to borrow from the Fund and repay over the following two or three years. Thus the Fund acted as a bank, but the scale of the 'banking' operation was initially small. Between 1947 and 1955, 14 out of 59 members made drawings, at an annual rate of $46 m. This equalled 0.06 per cent of world imports. In 1990–8, when 78 out of 182 members made drawings, the rate was $13.4bn, or 0.29 per cent of world imports.

The gold exchange standard succeeded in re-establishing current account convertibility in the industrialized nations, while permitting countries to maintain capital account controls. The IMF had less success in shortening and reducing the severity of balance of payments disequilibria (Killick, 1985). Nevertheless, under this system, international trade did grow rapidly, and employment and real income also grew faster than subsequently. Fear of liquidity shortage led the IMF in 1967 to create Special Drawing Rights (SDRs) – the First Amendment of the Fund's Articles of Agreement – but they came too late to save the anchor of the system, the $35 an ounce fixed parity of the official price of gold. The ratio of US gold reserves to its liquid liabilities had fallen from 2.73 in 1950 to 0.41 by 1968. Once the private market gold price rose above the official price, dollar-gold convertibility was suspended de facto, and officially abandoned in 1971. The collapse of the gold exchange system was thus due to an inherent design flaw, and not to any particular failures of the IMF.

The Fund soon ceased to be a banker to OECD countries, and began to cast around for a new role in the developing countries. However, this changed the Fund from an institution of collective action for industrial countries into their instrument for disciplining others. The Second Amendment to the IMF Articles in 1978 allowed all forms of national exchange-rate mechanism, except pegging to gold. Many larger economies chose to float their currency. Many smaller economies chose to peg their exchange rate to other currencies or baskets of currencies. Systemic international economic coordination was replaced by G7 meetings that tried to 'talk down' or 'talk up' particular key currencies.

Under the gold exchange standard, developing countries had been of little interest to the IMF. Many had never been properly integrated into the system, although in Peru and Paraguay the Fund did pioneer policy-conditioned lending. From the early 1960s, under UN pressure, the Fund developed additional 'banking' facilities relevant to the needs of developing countries – for example, the Compensatory Financing Facility in 1963 and the Extended Fund Facility (EFF) in 1974, which provided medium-term finance, beyond the limits of normal lending, to support agreed stabilization programmes requiring structural adjustment.

The Mexican debt crisis of 1982 was a turning point in the history of the Fund. Following the

Baker Plan of 1985, the US Administration recruited the Fund, along with the World Bank, to be its managers at one remove of the prolonged debt crisis that for some years threatened the survival of major Western banks. The capital available to both institutions was increased. Building on the EFF, new longer-term lending facilities were created to channel credit to indebted developing countries. In 1986 the Structural Adjustment Facility was set up, and in 1987 the Extended Structural Adjustment Facility (ESAF), to provide loans to low-income countries suffering protracted balance of payments problems at 0.5 per cent interest over five and a half to ten years. Policy conditionality is strong under ESAF loans, and is specified in the Poverty Reduction Strategy Papers of the borrowing country.

However, IMF stabilization programmes frequently broke down before completion. Between 1979 and 1993, 53 per cent of 305 Fund programmes were uncompleted, often because of inadequate financing (Killick, 1995, pp. 58–65). If sustained, they improved the current account and the overall balance of payments, and slowed inflation, but at the cost of a short-term reduction in growth. The Fund came under particularly fierce criticism for its handling of the Asian financial crisis of 1997–8 (Stiglitz, 2002). It has since introduced reforms to improve its own transparency and member countries' data reporting standards.

The World Bank Group

The International Bank for Reconstruction and Development (IBRD) was established in 1946 in order to provide medium-term loans at less than commercial interest rates to governments for (post-war) reconstruction and for the development of capital-poor areas. Since then other parts of what is now called the World Bank Group have been added – the International Finance Corporation (IFC), set up in 1956 for lending to the private sector, the International Centre for the Settlement of Investment Disputes (1966) and the Multilateral Investment Guarantee Agency (MIGA) (1988). However, the most significant addition was the International Development Agency (IDA) in 1960, to provide long-term, highly concessional loans to the poorest countries.

Having largely missed out on post-war reconstruction lending, the Bank focused on project lending for economic development. Its procedure was to borrow on the developed country capital markets and re-lend (plus a small margin) for specific investment projects in developing countries. In the early years, this was a slow process, originally concerned with large physical infrastructure schemes, such as dams and electricity generation. After IDA gave the Group a development agency function, the composition of Bank investments began to change, gradually including agricultural and urban redevelopment projects. The criterion of project success was the *ex post* rate of return on each project. In 1973, a semi-independent Operations Evaluation Department was established to calculate this. The Bank's participation almost certainly produced a better quality of project than would have occurred in its absence. However, if fungibility exists, the economic effect of the investment cannot be measured by its *ex post* rate of return. Although fungibility need not concern a development bank, whose chief aim is to recover its loans, it should worry a multilateral aid agency funded by public capital, whose main objective is to promote the sound development of the borrower's economy. To ensure that, projects need to be appraised as part of a comprehensive development plan.

In the 1970s, when the economies of developing countries were disturbed by substantial economic shocks, the World Bank decided that the success of their individual loan projects, as measured by their *ex post* rates of return, was being affected negatively by their broader economic environment (rising oil price, high inflation, fixed nominal exchange rates, import restrictions, and so on). In 1979, the Bank initiated programme lending, previously regarded as an unsound banking practice. The new types of loans, structural (SAL) and sectoral (SECAL) adjustment lending, provided rapidly disbursing foreign exchange on condition that the borrowing government undertook economic policy changes, either economy-wide or sectorally.

Programme lending with policy conditions attached provided the instrument that the Bank could bring to the task of co-managing the 1980s debt crisis with the Fund. A Fund–Bank 'concordat' in 1989 established effective (though not formal) cross-conditionality of Fund and Bank loans. Bank adjustment lending became conditional on a pre-existing Fund programme, and a statement of economic policy for the borrowing country had to be agreed by both institutions – entitled the Poverty Reduction Strategy Paper.

The evaluation of the effects of programme lending is more difficult and controversial. Governments of developing countries have been reluctant to comply with some of the conditions for policy change laid down in the loan agreements. This is often described as a result of their 'lack of ownership' of the economic reform process. The Bank itself faces incentives that make it unlikely that it will react to non-compliance consistently with a discontinuation of funding (Mosley, Harrigan and Toye, 1995). Thus the evidence suggests that the Bank's loan conditionality is a weak instrument for inducing policy change (see Ferreira and Keely, 2000). At the start of the 21st century, the Bank was moving towards a lending strategy of selectivity, in which future loans are directed increasingly to countries that have already demonstrated their zeal for neoliberal economic reform.

The Bank has been criticized on the grounds that private flows to developing countries can do the job instead (Krueger, 1998). In 1970, IBRD net lending was about ten per cent of net private flows. In 1996, this share had fallen to 0.7 per cent. In 25 years, private flows had increased 40-fold, while IBRD flows had increased threefold in nominal terms. The original justification of IBRD loans in terms of imperfect private capital markets seems weak in the light of these figures, although private finance is very concentrated geographically and the Asian crisis showed how short term and volatile private money can be.

Apart from lending, the Bank undertakes many other activities. It conducts what is probably the largest single publication programme on development issues in the world. This includes its own research across the field of development problems, published in two house journals, flagship reports like the annual *World Development Report*, a host of monographs and a multitude of Working Papers. The Bank has also become a major provider of statistical data, including regular published series and data from household and firm surveys. It regards itself as a 'knowledge agency'.

International Income Comparisons

Irving B. Kravis

Despite the accumulating evidence of systematic error, the most common means of making international comparisons still remains the conversion of incomes expressed in own-currencies to a numeraire currency, most often the US dollar, via the exchange rate. The procedure has long been held suspect by travellers who could observe that some countries were dear and others inexpensive – i.e. that exchange rates did not reflect the purchasing power of currencies. As will be shown, the purchasing power of the currencies of poor countries tends to be understated by exchange rates. Exchange-rate conversions thus tend to exaggerate the dispersion of the real per capita incomes of the different nations.

Hence the unique character of making valid *international* income comparisons arises from the existence of different currency units and the need to compare their purchasing powers. For the most part, the other conceptual and empirical problems of international income comparisons are similar to those of within-nation comparisons across time or between persons at a given period.

Ignoring index number problems, the basic approach in recent international comparisons may be simply described as involving the derivation of a quantity (real income) comparison by dividing a price ratio into an expenditure ratio:

$$\frac{Q_j}{Q_b} = \frac{E_j}{E_b} \div \frac{P_j}{P_b}$$

where j and b are countries; Q's are physical quantities, E's are expenditures (for GDP or its components), and the P's are prices, the E's and P's being in own currencies. (P_j/P_b is the purchasing power parity.) Why not, it may be asked, make direct quantity comparisons of the commodities and services that make up the real incomes being compared? The answer is that it is more difficult for most kinds of goods to get a representative sample of country-to-country quantity ratios for the same or equivalent goods than it is to get a representative sample of price ratios. Also, the quantity ratios are more likely to be subject to greater sampling variations than price ratios.

The Evolving System of Comparisons

The history of international income comparisons includes many ad hoc efforts based on exchange rate conversions and only a few careful attempts to compare the purchasing power of currencies (Kravis 1984). The system of international income comparisons that is emerging towards the end of the 20th century has its origins in the study of the Organization for European Economic Cooperation (OEEC) by Gilbert and Kravis (1954). The OEEC study laid down a pattern that has been followed in the UN International Comparison Project (ICP) and related studies carried out by regional groups. In particular, the use of the price-times-quantity-equals-expenditure relationship and the breakdown of GDP in terms of its final product components rather than in terms of producing industries were carried over into the ICP work.

As of early 1986 the system included official benchmark studies for 60 countries with a 1980 reference date, and for diminishing numbers, for earlier reference dates as well, as far back as 1967 (UN and EC 1986; Ward 1985; Kravis, Heston, and Summers [hereafter KHS] 1982). Unofficial estimates based on extrapolations, to be described presently, were available for most other countries (Beckerman 1966; KHS 1978b; Summers and Heston 1984).

The evolution of the system has been greatly influenced by two major developments that had pervasive effects on the statistical description of the world economy. One was the emergence of national income accounting beginning in the years preceding World War II. Under the aegis of the United Nations a standardized system of national accounts was developed that was adopted by most nations of the world. The standardized system provided a common statistical framework for

international comparisons with respect to such important matters as the definition of income (the gross domestic product concept) and the prices at which goods are to be valued (producers' market prices). Earlier international income comparisons tended to focus on the incomes of selected groups of wage earners or employees and to exclude incomes other than those arising from employment. The recent ones are therefore more comprehensive in scope, both with respect to the types of income and population coverage than the past wage-earner-oriented studies. The fact that the ICP studies offer separate estimates for personal consumption may offset the disadvantage that they are based on the inclusion of gross capital formation rather than on some net concept.

The other major development, the advent of the computer, has greatly expanded the availability of methods that meet the needs of comparisons involving many countries at once. In most studies preceding those of the ICP, small numbers of countries were involved and the method turned on a series of binary comparisons – i.e. comparisons between pairs of countries – sometimes, as in the OEEC studies, with all the other countries compared with a country selected as the centre country (star system). This approach has the advantages of simplicity and ease of understanding. An important disadvantage is that the quantitative relationships among the other countries, derived from the relation of each to the centre country, will vary with the choice of a country for the central role. Without the computer, it would have been infeasible to find and apply methods that were invariant to the selection of the base-country, and which at the same time had other desired properties. An important additional property for the real income comparisons that was sought and attained is matrix consistency. This property is akin to that afforded by a time-to-time national accounts table showing the income originating in different economic sectors in constant prices. That is, the figures in any one column (pertaining to a given country) may be added to yield aggregate GDP and subaggregates (e.g. consumption, food, etc.), and the figures on any row (each pertaining to a final expenditure category) show the correct quantity relationships between the different countries. (See, for example, KHS 1982, p. 19.)

The Actual Work of Preparing the Comparisons

The actual work of the international income comparisons consists mainly of making price comparisons. The tasks involved are:

(1) Subdividing GDP into categories for which expenditure data and price comparisons can be obtained.
(2) Selecting and pricing a sample of specifications for each expenditure category.
(3) Aggregating the price relatives at the category level.
(4) Aggregation of the categories to form price and quantity indexes for GDP and its subaggregates.

In the literature on international income comparisons, the most intellectual effort has gone into devising index number formulas for the aggregation of the categories, a problem that has long fascinated economic statisticians. The formula chosen in the ICP is one which in principle values the quantities of goods in each country's GDP at world average prices. These values when summed yield the desired real income comparisons or comparisons for components of real income (e.g. consumption, food, beef). The formula, which was suggested by Robert Geary and amplified by S. Khamis, involves deriving the price comparisons and the average world prices simultaneously in two subsets of equations. Some statistical experiments have suggested that radically different results would not be produced by alternative formulas which have equally plausible claims to consideration (KHS 1982, pp. 95ff).

It has been objected that the per capita quantity indexes for poor countries are inflated because the weights are dominated by the expenditure of the rich countries. However, some experimental work indicates that the results are not greatly changed when the weights of low income countries are

greatly increased in calculating the world average prices (Kravis 1984).

The quality of the income comparisons is, as a practical matter, more vulnerable to the care with which the price comparisons are carried out than to any other phase of the work. Not only must the sample of specifications of each detailed category be representative of price formation influences in each country but the items actually priced in the different countries must be equivalent in quality. Among the means used in the ICP to ensure such equivalents were international exchanges of samples, visits by price experts from one country to partner countries to consult with their counterparts and to examine goods in shops, and resort to informal and formal advice of merchants, manufacturers and engineers. Once specifications were identified, it was necessary to ensure that the price provided was the national average price; this was the responsibility of the country's statistical authorities to supply, sometimes from prices collected for other purposes and in other cases from special price surveys.

Certain services for which outputs are difficult to measure, including education, medical care and government, cannot always be treated in this standard specification approach. In some cases, as services of physicians, quality-adjusted inputs were used as proxies for measures for the international comparison of outputs. Some have claimed that the treatment of these services led to an overstatement of the real per capita GDP of low income countries in Phase III (Maddison 1983) but sensitivity analysis indicates the possible impacts on real GDP per capitas of different treatments are small (Kravis 1986).

Substantive Findings

Comparisons based both on PPP and exchange rate conversions are shown in Table 1 for a selected set of countries. The countries are arranged by region and within region by ascending order of real GDP per capita; the exchange rate deviation index, the ratio of the PPP to the exchange rate conversion, is shown in column 3. It can be seen from column 3 that the estimates based on the PPP conversions tend to be higher for lower income countries. That is, poor countries tend to have lower price levels; their exchange rates understate the purchasing power of their currency. A consequence is that the spreads between the average incomes of the countries greatly diminishes when PPP conversions are used. For example, the ratio of the highest to the lowest per capita on the exchange rate basis is nearly 100 to 1 (Germany to Ethiopia) whereas on a PPP basis it is a little over 40 to 1 (Canada to Ethiopia).

Two lines of explanation have been offered for the tendency towards low prices in poor countries. In the productivity differential model, the productivity of poor countries is held to be lower in both traded and nontraded goods but by smaller differentials in nontraded goods (e.g. teaching). Prices of

International Income Comparisons, Table 1 Real per capital GDP, selected countries, 1980

GDP per capita	Converted by PPP (1)	Exchange rate (2)	Exchange rate – deviation index (3) = (1) ÷ (2)

I

traded goods tend to be drawn to international levels; low productivity in a poor country thus means low wages. However, the same wage level will also prevail in the poor country's nontradables sector, but with productivity somewhat better, prices will be lower. An alternative explanation turns on the labour-abundant factor endowments of poor countries and assumes that nontraded goods (especially services) are labour-intensive and therefore cheap in poor countries. The average price level is pulled down not only by low prices for nontradables but because tradables too, are cheaper since they almost always are sold with nontradable components (e.g. distribution costs).

Aside from the light shed on real per capita income, the ICP studies illuminate two other important aspects of the world economy. One is that it provides a comparison of the general (GDP) price level of the different countries. The price level is the ratio of the PPP to the exchange rate; it is the reciprocal of the exchange rate deviation index. Wide variations in price levels can be seen to exist even between different members of the European Common Market. These measures add to the existing information on *relative* movements of price levels, a measure of the *absolute* gap. They indicate for example that the German price level was 130 per cent of that of the US in 1980 and only 76 per cent of the US level in 1984 (Ward 1985).

The other broad set of insights into the structure of the world economy arises from the price and quantity comparisons that are available for components of GDP. A host of questions, many arising in connection with basic economic analyses such as cross-country demand studies can be answered by these comparative price and quantity data. How do food prices differ in low and high income countries? The quantity of medical care? The extent of R&D in real terms? The amount of government services? and so on.

The Future of International Income Comparisons

Since it is clear that benchmark estimates will not soon be available for many more than 60 to 70 countries, some less costly even if more approximate method of estimating real per capita GDP will have to be employed for the remaining 50 or so non-benchmark countries. Several approaches have been tried (Kravis 1984, p. 18). One approach is based on an estimating equation that embodies the relationship between real GDP per capita of benchmark countries and certain physical indicators such as milk or steel consumption (Beckerman 1966). Another uses certain widely available macroeconomic variables for the extrapolating equation (KHS 1978a; Summers and Heston 1984). (For example, real GDP per capita is taken as a function of exchange-rate-converted GDP per capita and the propensity to trade as measured by the ratio of exports plus imports to GDP.) The statistical margins of error surrounding these 'shortcut' estimates for non-benchmark countries make explicit the degree of uncertainty, in contrast to the seemingly unambiguous estimates produced by the exchange rate conversions. However, the exchange rate conversions are not error free; they are known to be biased. In fact, the shortcut estimates come closer than the exchange rage conversions to what full benchmark studies would yield, much closer for low and middle income countries (Kravis 1986). Benchmark studies would be best, but given that they will not be available for all countries in the near future, a mixed set of benchmark and short cut PPP estimates should be used.

International Indebtedness

Vladimir Brailovsky

After World War II many less-developed economies started industrialization programmes which contributed to the achievement of rapid and sustained growth of income. Although industrialization meant a continuous reduction of the import propensity of their economies, growth also implied that the level of imports tended to exceed that of exports. This gap was covered by external indebtedness and, to a lesser extent, by direct foreign investment. During the 1950s and the early 1960s, credit was granted mainly by the governments of advanced economies and multilateral financial organizations. Starting from the mid-1960s, however, international indebtedness was increasingly dominated by private banking, reducing the element of aid implicit in previous arrangements. More importantly, this shift in the nature of credit flows was less conducive to the coordination of policies between industrial and developing countries, the consequences of which became apparent later on.

The remarkable expansion of the world economy achieved during the 1960s was suddenly interrupted at the beginning of the 1970s, due mainly to the policy responses of advanced Western economies to the increase in commodity prices, especially oil. The dramatic increase in oil prices in 1973–4 and again in 1979–80 would have implied, *ceteris paribus,* a situation in which -current-account surpluses of OPEC countries and other producers would have been mainly reflected in compensating deficits of the OECD economies – the major importers of oil – and to a lesser extent in deficits of non-oil producers in the Third World. In fact, however, the deficits of the latter swelled much more than what would have been expected on the basis of this assumption. The reason being that, in order to eliminate their own deficits, the advanced economies applied restrictive fiscal and monetary policies which reduced their growth rates (Llewellyn et al. 1985). This affected disproportionately the exports from developing economies, thereby increasing their need for foreign lending. Private banking was instrumental in 'recycling' large amounts of petro-dollars – indirectly, through financial intermediation – into the debit side of the balance-sheets of these economies.

Thus, between 1973 and 1980, the OECD economy was only required to shift real resources to oil producers in the form of extra exports – the only inevitable cost arising from oil price

increases – of the order of half a percentage point of GDP. The rest of the oil earnings was used to accumulate financial assests. However, in spite of the small magnitude of this real transfer, the annual growth rate of income in these economies dropped two percentage points below its long-term trend. By 1980 the loss accumulated to 15 per cent of GDP (CEPG 1980).

The maintenance of growth in many underdeveloped economies during the 1970s, plus the availability of international finance in great amounts created by the oil surpluses, increased enormously the level of their foreign debt. The dramatic rise in interest rates at the end of this period, which took place in creditor countries as a consequence of the application of monetarist policies, compounded the problems of debt servicing. Uncoordinated policies of the international banking community made this increase in debt possible, in spite of the heavy exposure of private institutions to sovereign borrowers in the Third World. Equally irrational was their reaction at the beginning of the 1980s, when general economic conditions deteriorated and a sudden awareness of the risks involved was regained. From lending in almost limitless quantities, abruptly the banks decided not to lend at all.

It is of some interest to analyse in more detail the costs of the adjustment process that this sudden change in the availability of finance implied for developing economies. Take the national accounts identity

$$Q \equiv D + X - M \tag{1}$$

where Q is gross domestic product, D is domestic demand, and X and M are respectively exports and imports of goods and non-factorial services. The balance-of-payments identity can be represented as

$$B \equiv M - X + N \tag{2}$$

where B is net foreign borrowing less capital movements abroad and N net interest payments. If m is the import propensity, then for simplicity one can assume that

$$M = m \cdot Q \tag{3}$$

Taken together, these formulations imply that if B, X and N are given either by external circumstances or by history, then necessarily

$$D = [(B - N)(1 + m) + X]/m \tag{4}$$

$$Q = (B - N + X)/m \tag{5}$$

Under these assumptions, different mechanisms will be in operation in order to ensure that domestic demand and output attain the above values. Finally, transfers abroad of real resources are

$$T \equiv Q - D \equiv X - M \equiv -(B - N) \tag{6}$$

Take now a typical situation before the debt crisis in which $B > N$; that is, in which transfers of resources were obtained by developing countries, say by $A = B - N > 0$. Then compare it with one where $B = 0$, prevailing after the crisis. This quantity can even be negative if capital flights increase, as is usually the case when doubts are cast about the creditworthiness of a country. Whereas before the economy was receiving A, now it is transferring resources abroad equivalent to the amount of N. The difference is $(A + N)$. More importantly, the difference in domestic demand is $(A + N)(1 + m)/m$ and $(A + N)/m$ for output. Since m is normally between 0.1 and 0.2, even if it is considerably reduced in the process of adjustment (through devaluation and other policies), this implies that the economy is not only transferring $(A + N)$, but that in order to be able to pay, domestic output and demand must drop by a large multiple of $(A + N)$. Whereas the former are resources obtained by creditor nations, the latter are simply wasted for the world economy as a whole. If this adjustment process takes place simultaneously in several economies, the wastage is even greater since X will also tend to fall.

Once this basic relationship between transfers abroad and the domestic levels of demand and output is grasped, it is straightforward to understand the nature of the policy recipes of international organizations such as the IMF. They are directed mainly towards the lowering of domestic

demand through cuts in both the public sector deficit and consumption, the latter via a reduction of the real value of wages in terms of the exchange rate (i.e. devaluations). It is therefore not surprising that this adjustment process is normally accompanied by accelerating inflation, as a reflection of competing demands for shares in income, the level of which is drastically reduced. The external vulnerability of these economies is further enhanced in the long-rung, and capacity to pay curtailed, since prolonged situations of depression are not conducive to capital formation and productivity growth. This makes it more difficult to reduce the import propensity and to stimulate exports. The import propensity is also likely to increase if the economy follows a trade liberalization policy, another element in the book of orthodox recipes.

The real resources which less-developed economies have been transferring abroad since 1982 is considerably greater in relative terms than the amounts involved for advanced countries following the oil crisis. For example, Argentina, Brazil and Mexico have had to expand in recent years their trade surpluses to around 6 per cent of GDP (ECLA 1985). As a point of reference, Japan's trade surplus was not, at the time, greater than 2.5 per cent of output. Under these circumstances it is worth asking whether a policy, such as that proposed by the IMF and the international banks – which requires relatively poor countries to transfer abroad, year after year, a large proportion of resources, with a widening gap between potential and actual output – can be described as a permanent solution to the debt problem.

More likely than not, this situation will at some stage lead to an outright default by major debtors unless there is a change in the rules of the game. Defaults such as these have occurred in the past, and with little consequences to the debtors (Winkler 1933; Wynne 1951; Wood 1980). They may become an attractive option given the magnitude of the resources which can be reclaimed for domestic uses. Due to their heavy exposure to sovereign nations, banks have a lot to lose in this event, and there is little they can do in terms of legal and other sanctions (Kaletsky 1985). The costs of default can be minimized only to the extent that governments in advanced countries – once again, as during the 1950s and 1960s – play an active role in this field and the debt burden is shared equitably among the different parties involved. The incentive to do this lies in the fact that, given the private origin of international indebtedness, their own financial stability may be jeopardized.

International Liquidity

A. D. Crockett

International liquidity may be defined as that stock of assets which is available to a country's monetary authorities to cover payments imbalances (when the exchange rate is fixed) or to

influence the exchange value of the currency (when the exchange rate is flexible). A distinction may be drawn between unconditional liquidity, which is generally owned by the country concerned and may be used at its sole discretion, and conditional liquidity, which comprises access to borrowing facilities and is generally available only on conditions set by the lenders. Because of the obvious practical difficulties in measuring conditional liquidity, the operational measure of international liquidity that is generally used in discussion of the subject is that of gross international reserves.

The definition of international reserves used by the International Monetary Fund in compiling *International Financial Statistics* includes: gold; short-term foreign exchange holdings in convertible currencies; special drawing rights (SDRs); and reserve positions in the International Monetary Fund; As of December 1984, total holdings of reserves reported by member countries of the IMF amounted to SDR 438 billion (with gold valued at SDR 35 per ounce). Of this total, 8 per cent was represented by gold holdings (at SDR 35 per ounce); 10 per cent was reserve positions in the Fund; 4 per cent was SDRs; and the remainder was in holdings of foreign currencies (about 70 per cent of which was US dollars).

From an economic point of view, the most significant aspect of the subject of international liquidity is the relationship between the stock of reserves (whether for a country or the world as a whole) and other economic variables, such as the level of real output, the price level, and the pattern of balance of payments positions. It has been recognized that this relationship depends on the nature of the demand function for reserves, and of the arrangements governing reserve supply. Much of the literature on international liquidity has thus focused on these two aspects.

Concerning demand, the demand for reserves by countries, like that for national money by individual economic agents, rests on a desire to enhance welfare by cushioning fluctuations in absorption that might otherwise be made necessary by the non-synchronous nature of payments and receipts. A stock of reserves represents purchasing power that can be used to moderate the domestic economic impact of declines in foreign exchange receipts. Even where official reserve holdings are not in fact used for this purpose, their existence may facilitate the activation of international credits that serve the same purpose. Standard utility theory teaches that the optimum stock of reserves for a country will be that quantity at which the benefits of an additional unit of reserves (in terms of the flexibility it affords the monetary authorities) just balances the cost of acquiring and holding it. Key factors determining the demand for reserves are the amplitude of fluctuations to which an economy is subject in its external position; and the availability of alternative means of financing, or adjusting to, these payments disturbances. For an individual economy, therefore, reserve demand will depend on the structure of its balance of payments. Heavy dependence on exports of primary products subject to volatile supply and demand conditions will tend, *ceteris paribus*, to lead to a greater need for reserves. On the other hand, access to borrowing facilities to cover payments imbalances, or a willingness to allow the exchange rate or domestic policies to adapt so as to encourage accommodating capital flows, will reduce the demand for owned reserves.

For the world as a whole, it has generally been thought that payments disturbances would tend to grow with the underlying volume of world trade; however, there is less agreement about whether the relevant elasticity should, for practical purposes, be regarded as unity. (This debate parallels that on the income elasticity of the transactions demand for cash within a national economy). A further important issue is the extent to which exchange rate flexibility alters (presumably reduces) the demand for reserves. While governments have always had alternatives to reserve use for financing payments disequilibria (e.g. official borrowing, or the manipulation of domestic policies to encourage capital inflows or outflows) the introduction of greater exchange rate variability has created much greater scope for economizing on reserves. The extent to which such scope has been used, has however, varied among countries and over time. As a result, economists have had much less success in estimating stable demand functions for international

reserves than in finding stable money-demand functions in individual economies.

Concerning reserve-supply arrangements, there have been two alternative views of the mechanism at work, partly reflecting changing institutional conditions in the world economy. The traditional view, which was widely accepted until the latter 1960s, was that the stock of international liquidity was to a significant extent exogenously determined. There was little dispute that this was true of gold, where the price was fixed and the available physical quantity was being augmented at a relatively slow and predictable rate. It was also thought to be broadly characteristic of US dollars, with the payments deficit of the United States supplying foreign exchange which, under the then existing institutional arrangements, other countries felt obliged to accept and hold. The newer view of reserve supply arrangements sees the stock of international liquidity as being essentially demand-determined. With international capital markets having greatly expanded in size and efficiency, countries may collectively increase their stocks of owned liquidity through operations in domestic and international financial markets. In this view, reserve stocks can increase quite independently of the balance of payments position of reserve currency countries. If a country wishes to increase its reserve holdings, and is creditworthy, it may bid for the desired funds in international financial markets and hold them in the form of short-term securities. The liabilities which are the counterpart to the reserves thus created may be liabilities of the public or private sector, and may be issued by residents of any country with the creditworthiness (and exchange control permission) to do so.

These different views of reserve-supply arrangements, coupled with differences of opinion about the stability of the underlying demand for reserves, have major implications for the role of international liquidity in influencing developments in the world economy. At one extreme, if the demand for reserves was a stable function of variables that were closely linked to world output and trade, and if the available stock of reserves was externally fixed, there would be a tight linkage between international liquidity and economic activity. If reserves fell below the desired stock for a given level of economic activity, countries would, on average, seek to augment their liquidity through trade restrictions, exchange rate depreciation, or other measures aimed at strengthening their overall balance of payments. With a fixed stock of reserves, a deflationary bias would be imparted to the world economy until nominal incomes had been reduced sufficiently to correspond with the given reserve stock.

While it was never believed that such a tight linkage existed, the fear of reserve inadequacy became important during the 1960s. Gold was fixed in price and increasing only slowly in volume, while dollars were thought to be created by a process that would eventually prove unsustainable because of the effects of continued US deficits on countries' willingness to hold dollars. For this reason, it was felt that some other mechanism was required to meet the growth in demand for reserves. Initially, devices were employed to augment the supply of credit facilities (central bank 'swap' arrangements, General Arrangements to Borrow, increased drawing rights in the IMF) but it was generally felt that the system required a secular increase in owned reserves as well. The outcome of this debate was the decision (reached in 1967) to create a new international asset, Special Drawing Rights in the International Monetary Fund (SDRs). Since SDRs would not be the liabilities of any individual country, and would have a value linked to gold (later, to a basket of currencies), they would not be subject to the confidence factors that affected US dollars. At the same time, the volume of SDRs could be augmented (or reduced) by conscious decision in the light of the long-term needs of the world economy. At the time of writing, SDRs are valued in terms of a basket of the five major industrial country currencies and bear an interest rate (paid by countries whose holdings are less than their allocation and received by those countries whose holdings exceed their allocation) related to short-term market interest rates.

Since the shift to floating exchange rates, and partly as a result of it, a somewhat different view has developed of the factors influencing the demand for and supply of reserves. It has been

recognized that the demand for reserves by major countries with flexible exchange rates cannot be easily identified, and may change over time. At the same time, the flexibility with which international capital markets have functioned has permitted changing reserve demand to be accommodated relatively easily. For these reasons, several major industrial countries have not thought it necessary for international liquidity to be deliberately augmented through allocations of SDRs.

On the other hand, most developing countries have continued to pursue some form of pegging arrangement, and many of them have experienced difficulty in preserving access to international capital markets. Their need for reserves has tended to increase in line with the volume of their international transactions, and their means of satisfying this need has relied heavily on action to improve the current account of their balance of payments. Many observers have therefore advocated continued creation of SDRs as a means of satisfying the reserve needs of these countries without requiring excessive adjustment on their part. At the same time, it has been pointed out that SDRs would preserve the 'seignorage' associated with reserve issuance for the international community at large. Proposals to 'link' liquidity creation to development assistance, by allocating SDRs in the first instance to developing countries or to development finance institutions, have enjoyed considerable popularity in the economic literature, but have not had the support of major countries.

International Migration

George J. Borjas

Abstract

The resurgence of large-scale immigration in many countries has stimulated a great deal of research on many aspects of the economics of immigration. A key insight of economic theory is that the impact of immigration depends on how the skills of immigrants compare with those of natives in the host country. This article examines the ideas and models that are typically used to analyse flows of persons across countries, and illustrates how this framework increased our understanding of the determinants of the direction, size, and skill composition of immigrant flows, and of the consequences of those flows on economic outcomes.

There was a significant resurgence in international migration in the last three decades of the twentieth century. By the end of the century, about 175 million persons – or almost three per cent of the world's population – resided in a country where they were not born. Nearly 9 per cent of the population in Germany, 11 per cent in France or Sweden, 12 per cent in the United States, 19 per cent in Canada, 23 per cent in New Zealand, and 25 per cent in Switzerland is foreign-born (United Nations 2002). These sizable labour flows altered economic opportunities for workers in both sending and receiving countries, and generated a great deal of debate over the economic impact of immigration and over the types of immigration policies that host countries should pursue.

Labour flows across labour markets –whether within or across countries – play a central role in any discussion of labour market equilibrium. These labour flows help markets attain a more efficient allocation of resources. This article surveys the economic analysis of immigration. In particular, it investigates the determinants of the immigration decision and the impact of that decision on economic conditions in the receiving country.

The discussion emphasizes the ideas and models that are used to analyse flows of persons across countries, and examines the implications of these models for empirical research and for our understanding of the labour market effects of immigration. A key insight of economic theory is that the economic impact of immigration depends on how the skills of immigrants compare with those of natives in the host country. As a result, much of the research effort in the immigration literature has been devoted to: (a) understanding the factors that determine the relative skills of the immigrant flow; (b) measuring the relative skills of immigrants in the host country; and (c) evaluating how the skill composition of the immigrant influx affects economic outcomes.

Because the discussion focuses on the impact of immigration on economic conditions in the host country, the analysis ignores a number of equally important issues, in terms of both their theoretical implications and their empirical significance. Immigration, after all, alters economic opportunities not only in the host country, but in the source country as well. Few studies, however, investigate what happens to economic opportunities in a source country when a selected subsample of its population moves elsewhere. Similarly, the discussion focuses on the economic impact of immigrants, and ignores the long-run impact of the children and grandchildren of immigrants on the host country.

The Impact of Immigration on a Host Country's Labour Market

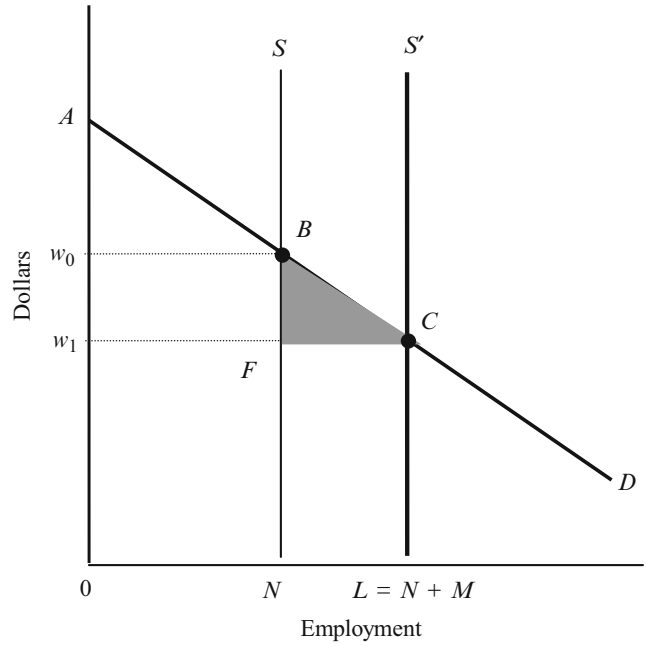
Consider initially the simplest theoretical framework that can be used to understand how immigration alters the economic rewards accruing to various factors of production in a host country. Suppose the linear homogeneous aggregate production function in the country is given by $Q = f(K, L)$, where Q is output, K is capital, and L is labour. The workforce contains N native and M immigrant workers, and all workers are perfect substitutes in production $(L = N + M)$. Natives own the entire capital stock in the host country and initially the supply of capital is perfectly inelastic. The supplies of both natives and immigrants are also perfectly inelastic. Finally, let the price of the output be the numeraire.

In a competitive equilibrium, each factor price equals the respective value of marginal product. The rental rate of capital in the pre-immigration equilibrium is $r_0 = f_K(K,\ N)$ and the price of labour is $w_0 = f_L(K,\ N)$. In the pre-immigration regime, national income accruing to natives, Q_N, is:

$$Q_N = r_0 K + w_0 N. \tag{1}$$

Figure 1 illustrates this initial equilibrium. Because the supply of capital is fixed, the area under the marginal product of labour curve (f_L) gives the value of the economy's total output. The national income accruing to natives Q_N is given by the trapezoid ABN0.

The entry of M immigrants shifts the supply curve and lowers the market wage to w_1. The area in the trapezoid ACL0 now gives national income.



International Migration, Fig. 1 The immigration surplus

Immigrants receive part of the increase in national income as labour earnings (w_1M). The area in the triangle BCF gives the increase in national income that accrues to natives, or the immigration surplus'. If we use the approximation that $(w_0 - w_1) \approx (\partial w/\partial L) \times M$, the immigration surplus as a fraction of national income equals:

$$\frac{\Delta Q_N}{Q} = -\frac{1}{2}\alpha_L \ \varepsilon_{LL} \ m^2, \tag{2}$$

where α_L is labour's share of national income $(\alpha_L = wL/Q)$; ε_{LL} is the elasticity of factor price for labour ($\varepsilon_{LL} = d \ log \ w/d \ log \ L$,with marginal cost held constant); and m is the fraction of the workforce that is foreign born $(m = M/L)$.

Equation (2) can be used to calculate how much a host country gains from immigration. In the United States, for example, the share of labour income is about 70 per cent, and the fraction of immigrants in the workforce was 13 per cent in 2000. Hamermesh's survey (1993, pp. 26–9) of the empirical evidence on labour demand suggests that the elasticity of factor price for labour may be around −.3. The US immigration surplus, therefore, is on the order of 0.2 per cent of GDP.

Immigration also redistributes income from labour to capital. As Fig. 1 shows, native workers lose the area in the rectangle w_0BFw_1, and this quantity plus the immigration surplus accrues to capitalists. The net changes in the incomes of native workers and capitalists are approximately given by:

$$\left.\frac{\text{Change in native labour earnings}}{Q}\right|_{dK=0} = \alpha_L \ \varepsilon_{LL} \ m \ (1-m), \tag{3}$$

$$\left.\frac{\text{Change in income of capitalists}}{Q}\right|_{dK=0} = -\alpha_L \ \varepsilon_{LL} m\left(1-\frac{m}{2}\right). \tag{4}$$

Consider again the back-of-an-envelope calculation for the United States. If the elasticity of factor price is −.3, native-born workers lose about 2.4 per cent of GDP, while native-owned capital gains about 2.6 per cent of GDP. A small immigration surplus may disguise a sizable income transfer from workers to the users of immigrant labour.

The derivation of the surplus in (2) assumed that the host country's capital stock is fixed. Alternatively, suppose that the supply of capital is perfectly elastic at the world price $(dr = 0)$, so that in the long run the capital stock adjusts completely to the increased labour supply. Differentiating the marginal productivity condition $r = f_K(K,L)$ implies that the immigration-induced change in the capital stock is:

$$\left.\frac{dK}{dM}\right|_{dr=0} = -\frac{f_{KL}}{f_{KK}} > 0. \tag{5}$$

The derivative in (5) is positive because $f_{KL} > 0$ when the production function is linear homogeneous.

The elasticity of complementarity for any input pair i and j is defined by $c_{ij} = f_{ij}f/f_i f_j$. (The elasticity of complementarity is the dual of the elasticity of substitution. Hamermesh 1993, Ch. 2, presents a detailed discussion of the properties of the elasticity of complementarity.) The immigration-induced wage change is then given by:

$$\left.\frac{d\log w}{d\log M}\right|_{dr=0} = \frac{\alpha_L}{c_{KK}}\left(c_{KK}\ c_{LL} - c_{LK}^2\right)m. \tag{6}$$

The linear homogeneity of the production function implies that $\left(c_{KK}\ c_{LL} - c_{LK}^2\right) = 0$, so that the host country's wage is independent of immigration. The immigration-induced capital flow re-establishes the pre-immigration capital–labour ratio in the host country. Immigration does not alter the price of labour or the returns to capital, and natives neither gain nor lose from immigration. The long-run immigration surplus is zero.

The conclusion that immigration does not alter labour market conditions in the long run depends critically on the assumption of a homogeneous labour force. Suppose there are two types of workers in the host country's labour market, skilled (L_S) and unskilled (L_U). The linear homogeneous aggregate production function is:

$$\begin{aligned} Q &= f(K,\ L_S L_U) \\ &= f[K,\ bN + \beta M,\ (1-b)N + (1-\beta)M], \end{aligned} \tag{7}$$

where b and β denote the fraction of skilled workers among natives and immigrants, respectively. The price of each factor of production, r for capital and $w_i (i = S,\ U)$ for labour, is determined by the respective marginal productivity condition. The assumption that r is fixed implies that the immigration-induced adjustment in the capital stock equals (see Borjas 1999, pp. 1703–5):

$$\left.\frac{dK}{dM}\right|_{dr=0} = -\frac{[f_{KS}\beta + f_{KU}(1-\beta)]}{f_{KK}}. \tag{8}$$

We can determine the impact of immigration on the wage of skilled and unskilled workers by differentiating the respective marginal productivity conditions and by imposing the restriction in Eq. (8). The wage effects of immigration are:

$$\begin{aligned} \frac{d\ log\ w_S}{d\ log\ M}|_{dr=0} &= \frac{\alpha_S}{c_{KK}}\left[c_{SS}c_{KK} - c_{SK}^2\right] \\ &\quad \times \frac{(\beta - b)}{p_S\, p_U}(1-m)m, \end{aligned} \tag{9}$$

$$\begin{aligned} \frac{d\log w_U}{d\log M}|_{dr=0} &= \frac{-\alpha_U}{c_{KK}}\left[c_{UU}c_{KK} - c_{UK}^2\right] \\ &\quad \times \frac{(\beta - b)}{psp_U}(1-m)\ m, \end{aligned} \tag{10}$$

where α_i is the share of national income accruing to factor i; and p_S and p_U are the shares of the workforce that are skilled and unskilled, respectively.

The assumption that the isoquants between any pair of inputs in the production function $f(K,\ L_S,\ L_U)$ have the typical convex shape implies that $c_{11}\ c_{22} - c_{12}^2 > 0$. Equations (9) and (10) then reveal that the impact of immigration on the wage structure depends on how the skill distribution of immigrants compares with that of natives. If the two skill distributions are equal $(\beta = b)$, immigration has no impact on the wage structure of the

host country. If immigrants are relatively unskilled $(\beta < b)$, the unskilled wage declines and the skilled wage rises. If immigrants are relatively skilled $(\beta > b)$, the skilled wage declines and the unskilled wage rises. In the long run, therefore, immigration lowers the wage of substitutes and raises the wage of complements.

It can be shown that the immigration surplus as a fraction of national income is given by:

$$\frac{\Delta Q_N}{Q}|_{dr=0} = \frac{-\alpha_S^2}{2c_{KK}}\left[c_{SS}c_{KK} - c_{SK}^2\right] \times \frac{(\beta - b)^2}{p_S^2 p_U^2}(1-m)^2 m^2. \quad (11)$$

The immigration surplus is zero if $\beta = b$, and positive if $\beta \neq b$. If immigrants had the same skill distribution as natives, the immigration-induced change in the capital stock implies that the wages of skilled and unskilled workers are unaffected by immigration. The gains arise only if immigrants differ from natives.

Some studies simulate this model to provide back-of-an-envelope calculations of the immigration surplus when there is heterogeneous labour (Borjas 1995; Johnson 1997). In the US context, the immigration surplus calculated in this more general setting is roughly of the same order of magnitude (less than 0.2 per cent of GDP) as that estimated from the simplest framework illustrated in Fig. 1. The available evidence, therefore, suggests that the net measurable gains from immigration to the United States tend to be small.

Finally, it is worth emphasizing that any credible estimate of the economic benefits from immigration must rely on a theoretical framework that fully captures the various effects which inevitably arise as the impact of immigration ripples through the economy. Inevitably, different models of the economy will lead to different estimates of the economic benefits. Recent theoretical work by trade economists, for example, suggests that if one takes the Ricardian perspective that the United States provides superior economic opportunities for all factors of production – so that both capital and labour would get higher returns by migrating to the United States – immigration would actually *lower* the GDP accruing to natives substantially, by around 1.0 per cent of GDP (Davis and Weinstein 2002). Therefore, the important point to draw from the existing evidence is that plausible models of the US economy indicate that, at best, the net gains from immigration for the native-born population are very small.

Estimating the Labour Market Impact of Immigration

As shown above, economic theory suggests that immigration into a particular labour market affects the wage structure by raising the wage of complementary workers and lowering the wage of substitutes. Almost all of the first-generation empirical studies in the literature define the labour market along a geographic dimension, such as metropolitan areas in the United States. Beginning with Grossman (1982), the typical study regresses a measure of native economic outcomes in the locality (or the change in that outcome) on the relative quantity of immigrants in that locality (or the change in the relative number). (Representative studies include Altonji and Card 1991; Card 1990; 2001; Pischke and Velling 1997.) The regression coefficient is then interpreted as the impact of immigration on the native wage structure.

This approach has two well-known problems. First, immigrants may not be randomly distributed across labour markets. If immigrants endogenously cluster in areas that have done well over some time periods, this would produce a positive spurious correlation between immigration and area outcomes either in the cross-section or in the time series. Second, natives may respond to the entry of immigrants in a local labour market by moving their labour or capital to other localities until native wages and returns to capital are again equalized across areas. For example, a large immigrant flow arriving in California might well result in fewer workers moving to California, as well as a reallocation of capital from other states into California. Interregional comparisons of the wage of native workers might show little or no

difference because the effects of immigration are diffused throughout the national economy.

In view of these potential problems it is not too surprising that the region-based empirical literature has produced a confusing array of results (see the survey in Friedberg and Hunt 1995). Nevertheless, there is a tendency for the estimated cross- region correlations to cluster around zero, creating the conventional wisdom that immigrants have little impact on the labour market opportunities of native workers. It would seem, therefore, that a fundamental implication of the competitive model of the labour market – that supply shocks alter the wage structure – is soundly rejected by the data.

Because local labour markets adjust to immigration, recent research emphasizes that the labour market impact of immigration may be measurable only at the national level. Borjas (2003) used this insight to derive an estimable framework that can be used to measure the national labour market effects of immigration by linking the evolution of the wage structure in the host country to changes in immigration. As an illustration, suppose that the national workforce in the host country is composed of skill groups defined in terms of both educational attainment and work experience. The aggregate production function at time t is:

$$Q_t = \left[\lambda_{Kt} K_t^{v} + \lambda_{Lt} L_t^{v}\right]^{1/v}, \tag{12}$$

where Q is output, K is capital, L denotes the aggregate labour input; and $v = 1 - 1/\sigma_{KL}$, with σ_{KL} being the elasticity of substitution between capital and labour $(-\infty < v \leq 1)$. The vector λ gives technology parameters that shift the production frontier, with $\lambda_{Kt} + \lambda_{Lt} = 1$. The aggregate L_t incorporates the contributions of workers who differ in both education and experience. Let:

$$L_t = \left[\sum_i \theta_{it} L_{it}^{\rho}\right]^{1/\rho} \tag{13}$$

where L_{it} gives the number of workers with education i at time t, and $\rho = 1 - 1/\sigma_E$, with σ_E being the elasticity of substitution across these education aggregates $(-\infty < \rho \leq 1)$. The θ_{it} give time-variant technology parameters that shift the relative productivity of education groups, with $\Sigma_j \theta_{it} = 1$. Finally, the supply of workers in each education group is itself given by an aggregation of the contribution of similarly educated workers with different experience. In particular,

$$L_{it} = \left[\sum_j \alpha_{ij} L_{ijt}^{\eta}\right]^{1/\eta}, \tag{14}$$

where L_{ijt} gives the number of workers in education group i and experience group j at time t (given by the sum of N_{ijt} native and M_{ijt} immigrant workers); and $\eta = 1 - 1/\sigma_X$, with σ_X being the elasticity of substitution across experience classes within an education group $(-\infty < \eta \leq 1)$. Equation (14) assumes that the technology coefficients α_{ij} are constant over time, with $\Sigma_j \alpha_{ij} = 1$.

The three elasticities of substitution that summarize all the economically relevant information in the production technology can be easily estimated using data on factor prices and quantities. The empirical application of this framework to US Census data from 1960 through 2000 in Borjas (2003) indicated that $\sigma_X = 3.5$, $\sigma_E = 1.3$, and $\sigma_{KL} = 1.0$. These elasticity estimates, combined with estimates of the size of the immigrant influx for each skill group, can be used to calculate the impact of immigration on the wage structure in a host country. Define the factor price elasticity giving the impact on the wage of factor y of an increase in the supply of factor z as:

$$\varepsilon_{yz} = \frac{d \log w_y}{d \log L_Z}, \tag{15}$$

It is easy to show that the factor price elasticities depend on the income shares accruing to the various factors and on the three elasticities of substitution in the three-level constant elasticity of substitution (CES) framework. The marginal productivity condition for the typical worker in education group s and experience group x can be written as $w_{sx} = D(K, L_{ij})$, where L_{ij} is a vector indicating the number of workers in each of the education–experience cells. Suppose that the

capital stock is constant. The short-run impact of immigration on the log wage of group $(s,\ x)$ is:

$$\Delta \log w_{sx} = \sum_i \sum_j \varepsilon_{sx,ij}\ m_{ij}, \qquad (16)$$

where m_{ij} gives the percentage change in labour supply due to immigration in skill cell (i, j). The available evidence suggests that the 1980–2000 immigrant influx into the United States, which represented an 11 per cent increase in labour supply, lowered the wage of the typical native worker by 3.7 per cent in the short run. As indicated in the earlier discussion, the adverse wage effects of immigration on the average worker are muted as the capital stock adjusts to the supply shock.

The Self-selection of Immigrants

As we have seen, the economic impact of immigration depends crucially on the differences in the skill distributions of immigrants and natives. Not surprisingly, a great deal of research effort has focused on the question of how immigrant skills compare with those of native workers. Perhaps the central finding of this literature is that immigrants are not a randomly selected sample of the population of the source countries.

It is instructive to consider a two-country model (Borjas 1987). Residents of the source country (country 0) consider migrating to the host country (country 1). Assume the migration decision to be irreversible. Residents of the source country face the earnings distribution:

$$\log w_0 = \mu_0 + v_0, \qquad (17)$$

where w_0 gives the wage in the source country; μ_0 gives the mean earnings in the source country; and the random variable v_0 measures deviations from mean earnings and is normally distributed with mean zero and variance σ_0^2. For simplicity, Eq. (17) omits the subscript that indexes a particular individual.

Suppose the potential earnings in the host country of emigrants from country 0 can be represented by:

$$\log w_1 = \mu_1 + v_1, \qquad (18)$$

where μ_1 gives the mean earnings in the host country *for this particular population*, and the random variable v_1 is normally distributed with mean zero and variance σ_1^2. The correlation coefficient between v_0 and v_1 equals ρ_{01}.

The mean μ_1 does not necessarily equal the mean earnings of native workers in the host country. After all, the average worker in the source country might be more or less skilled than the average worker in the host country. It is convenient to assume that the average person in both countries is equally skilled (or, equivalently, that any differences in average skills have been controlled for), so that μ_1 also gives the mean earnings of natives in the host country. This assumption helps isolate the impact of the selection process on the skill composition of the immigrant influx.

Equations (17) and (18) describe the earnings opportunities available to persons born in the source country. Assume that the migration decision is determined by a comparison of earnings opportunities across countries, net of migration costs. Define the index function:

$$I = \log\left(\frac{w_1}{w_0 + C}\right) \approx (\mu_1 - \mu_0 - \pi) + (v_1 - v_0), \qquad (19)$$

where C gives migration costs, and π gives a 'time-equivalent' measure of these costs $(\pi = C/w_0)$. A person emigrates if $I > 0$, and remains in the source country otherwise.

Migration is costly. Because the costs vary greatly among persons, and include direct costs, forgone earnings, and psychic costs, the sign of the correlation between costs and wages is unknowable. The distribution of the random variable π in the source country's population is:

$$\pi = \mu_\pi + v_\pi, \qquad (20)$$

where μ_π is the mean level of migration costs in the population, and v_π is a normally distributed random variable with mean zero and variance

σ_π^2. The correlation coefficients between v_π and $(v_0,\ v_1)$ are given by $(\rho_{\pi 0},\ \rho_{\pi 1})$. The probability that a person migrates to the host country can be written as:

$$P(z) = Pr[v > -(\mu_1 - \mu_0 - \mu_\pi)] = 1 - \Phi(z), \tag{21}$$

where $v = v_1 - v_0 - v_\pi,\ z = -(\mu_1 - \mu_0 - \mu_\pi)/\sigma_v$, and Φ is the standard normal distribution function.

It is easy to show that the emigration rate falls when the mean income in the source country rises, when the mean income in the host country falls, and when time-equivalent migration costs rise. Most studies in the literature on the internal migration of persons within a particular country focus on testing these theoretical predictions. The empirical evidence in these studies is generally supportive of the theory.

Although it is important to determine the size and direction of migration flows, it is equally important to determine *which* persons find it most worthwhile to migrate to the host country. This question lies at the heart of the Roy model (Roy 1951). Consider the conditional means $E(\log w_0|\mu_0,\ I > 0)$ and $E(\log w_1|\mu_1,\ I > 0)$. These means give the average earnings in both the source and host countries for persons who migrate. Note that the conditional means hold μ_0 and μ_1 constant. The calculation effectively assumes that the migration flow is sufficiently small so that there are no feedback effects on the performance of immigrants (or natives) in the host country or on the performance of the 'stayers' in the source country. Because the random variables $v_0,\ v_1$, and v_π are jointly normally distributed, these conditional means are given by:

$$E(\log w_0|\mu_0, I > 0) = \mu_0 + \left[\frac{\sigma_0\sigma_1}{\sigma_v}\left(\rho_{01} - \frac{\sigma_0}{\sigma_1}\right) - \rho_{\pi 0}\frac{\sigma_\pi}{\sigma_1}\right]\lambda, \tag{22}$$

$$E(\log w_1|\mu_1, I > 0) = \mu_1 + \left[\frac{\sigma_0\sigma_1}{\sigma_v}\left(\frac{\sigma_1}{\sigma_0} - \rho_{01}\right) - \rho_{\pi 1}\frac{\sigma_\pi}{\sigma_0}\right]\lambda, \tag{23}$$

where $\lambda = \varphi(z)/(1 - \Phi(z))$, and φ is the density of the standard normal. It is easier to interpret the results in Eqs. (22) and (23) by assuming that $\sigma_\pi = 0$, so that time-equivalent migration costs are constant. Let $Q_0 = E(v_0|\mu_0,\ I > 0)$ and $Q_1 = E(v_1|\mu_1,\ I > 0)$. The Roy model identifies three cases that summarize the skill differentials between immigrants and natives:

$$\begin{aligned} &Q_0 > 0 \text{ and } Q_1 > 0, \quad \text{if} \quad \rho_{01} > \frac{\sigma_0}{\sigma_1} \text{ and } \frac{\sigma_1}{\sigma_0} > 1,\\ &Q_0 < 0 \text{ and } Q_1 < 0, \quad \text{if} \quad \rho_{01} > \frac{\sigma_0}{\sigma_1} \text{ and } \frac{\sigma_1}{\sigma_0} > 1,\\ &Q_0 < 0 \text{ and } Q_1 > 0, \quad \text{if} \quad \rho_{01} < \min\left(\frac{\sigma_1}{\sigma_0}, \frac{\sigma_0}{\sigma_1}\right). \end{aligned} \tag{24}$$

Positive selection occurs when immigrants have above-average earnings in both the source and host countries ($Q_0 > 0$ and $Q_1 > 0$), and negative selection when immigrants have below-average earnings in both countries ($Q_0 < 0$ and $Q_1 < 0$). Equation (24) shows that either type of selection requires that skills be positively correlated across countries. The standard deviations σ_0 and σ_1 measure the 'price' of skills: the greater the rewards to skills, the larger the inequality in wages. Immigrants are then positively selected when the source country – *relative to the host country* – 'taxes' highly skilled workers and 'insures' less skilled workers from poor labour market outcomes, and immigrants are negatively selected when the host country taxes highly skilled workers and subsidizes less skilled workers.

There also exists the possibility that the host country draws persons who have below-average earnings in the source country but do well in the host country ($Q_0 < 0$ and $Q_1 > 0$). This sorting occurs when the correlation coefficient ρ_{01} is small or negative. This correlation may be negative when a source country experiences a structural political shift, such as a Communist takeover. In its initial stages, this political system often redistributes incomes by confiscating the assets of relatively successful persons. Immigrants from such systems will be in the lower tail of the post-revolution income distribution, but will perform well in a host country's market economy.

Equation (24) shows that neither differences in mean incomes across countries nor the level of migration costs determine the type of selection that characterizes immigrants. Mean incomes and migration costs affect the size of the flow (and the extent to which the skills of the average immigrant differ from the mean skills of the population), but they do not determine whether the immigrants are drawn mainly from the upper or lower tail of the skill distribution.

The discussion assumed that migration costs are constant in the population. Variable migration costs do not alter any of the selection rules if (a) time-equivalent migration costs are uncorrelated with skills, or (b) the variation in migration costs is 'small' relative to the variation in earnings. Otherwise, variable migration costs can change the nature of selection. Suppose that τ is negatively correlated with earnings, perhaps because less skilled persons find it more difficult to find jobs in the host country. This negative correlation increases the likelihood that the immigrant flow is positively selected.

Some of the implications of the Roy model have been tested empirically by estimating the correlation between the earnings of immigrants in a host country, typically the United States, and measures of the rate of return to skills in source countries. The evidence provides mixed support for the Roy model's prediction that immigrants originating in countries with higher rates of return to skills have lower earnings in the United States. Borjas (1987) reports that measures of income inequality in the source country, which are a very rough proxy for the rate of return to skills, are weakly negatively correlated with the earnings of immigrant men, while Cobb-Clark (1993) reports a similar finding for immigrant women. In contrast, Chiquiar and Hanson's study (2005) of Mexican emigration finds that the least skilled persons in the Mexican population tend to be under-represented in the Mexican-born workforce in the United States. Because the Mexican wage distribution has a larger variance than that of the United States, these low-skill workers would presumably be the persons most motivated to emigrate. This finding suggests that non-constant migration costs in the population of some source countries may play an important role in determining the selection of immigrants.

Measuring Trends in Immigrant Skills

Beginning with the work of Chiswick (1978), a large literature has developed that attempts to measure the skill differential between immigrants and natives at the time of entry and how this differential changes over time as immigrants adapt to the host country's labour market. A key result of this literature is that there exists a cross-sectional positive correlation between the earnings of immigrants and the number of years that have elapsed since immigration. As will be seen below, there has been a great deal of debate over the interpretation of this correlation.

The empirical analysis of the relative economic performance of immigrants was initially based on the cross-section regression model:

$$\log w_\ell = X_\ell \beta_0 + \beta_1 I_\ell + \beta_2 y_\ell + \in \ell, \qquad (25)$$

where w_ℓ is the wage rate of person ℓ in the host country; X_ℓ is a vector of socioeconomic characteristics (which includes age); I_ℓ is a dummy variable set to unity if person ℓ is foreign-born; and y_ℓ gives the number of years that the immigrant has resided in the United States and is set to zero if ℓ is a native. (The models used in empirical studies typically include higher-order polynomials in age and years-since-migration. These nonlinearities, however, do not play a role in the identification issue discussed below.) Because the vector X includes the worker's age, the coefficient β_2 measures the differential value that the host country's labour market attaches to time spent in the host country versus time spent in the source country.

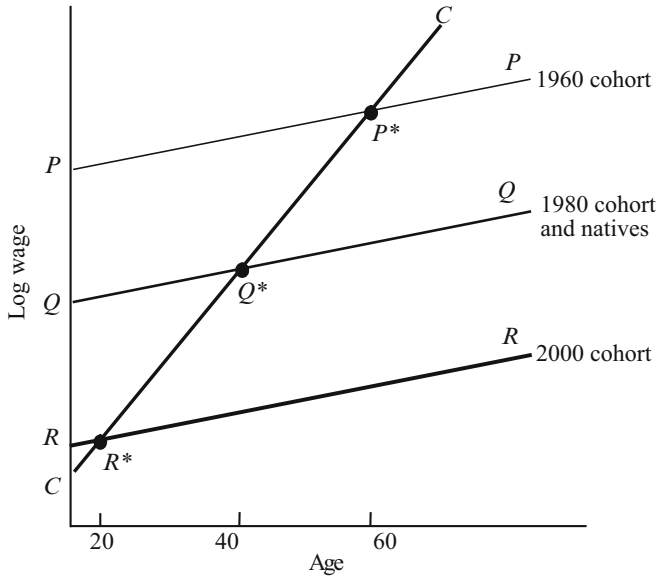
Cross-section studies of immigrant earnings in several host countries have typically found that β_1 is negative and β_2 is positive. (Although most of the empirical evidence focuses on the US experience, the literature finds a similar correlation in Canada – Baker and Benjamin 1994; Australia – Beggs and Chapman 1991; and Germany – Dustmann 1993.) Chiswick's (1978) analysis of

the 1970 US Census data indicates that immigrants earn about 17 per cent less than 'comparable' natives at the time of entry, and this gap narrows by slightly over one percentage point per year. As a result, immigrant earnings overtake those of their native counterparts after about 15 years in the United States. The steeper age-earnings profiles of immigrants was interpreted as meaning that immigrants accumulated more human capital than natives as the assimilation process took hold, closing the wage gap between the two groups. The overtaking phenomenon was then explained by assuming that immigrants were positively selected. As we have seen, this assumption about the selection process is not necessarily implied by income-maximizing behaviour on the part of immigrants.

Borjas (1985) suggested an alternative interpretation of the cross-section evidence. Instead of interpreting the positive β_2 as a measure of assimilation, he argued that the cross-section data might be revealing a decline in relative skills across successive immigrant cohorts. In the United States, the post-war era witnessed major changes in immigration policy and in the size and national origin mix of the immigrant flow. If these changes generated a less-skilled immigrant flow, the cross- section correlation indicating that more recent immigrants earn less may say little about the process of wage convergence, but may instead reflect innate differences in ability or skills across cohorts.

To illustrate the identification problem, consider a hypothetical situation where there are three separate immigrant waves, and these waves have distinct productivities. One wave arrived in 1960, the second arrived in 1980, and the last arrived in 2000. Suppose also that all immigrants enter the United States at age 20.

Assume that the earliest cohort has the highest productivity level of any group in the population, including US-born workers. If we could observe their earnings in every year after they arrive in the United States, their age-earnings profile would be given by the line *PP* in Fig. 2. For the sake of argument, let's assume that the last wave of immigrants (that is, the 2000 arrivals) is the least productive of any group in the population, including natives. If we could observe their earnings throughout their working lives, their age-earnings profile would be given by the line *RR* in the figure. Finally, suppose that the immigrants who arrived in 1980 have the same skills as natives. If we could observe their earnings at every age in their working lives, the age-earnings profiles of this cohort and of natives would overlap and be given by the line *QQ*. Note that the age-earnings profiles of each of the immigrant cohorts is



International Migration, Fig. 2 Cohort effects and the immigrant age-earnings profile

parallel to the age-earnings profile of the native population. There is no wage convergence between immigrants and natives in this hypothetical example.

Suppose we now have access to data drawn from the 2000 decennial census. This cross-section data-set, which provides a snapshot of the US workforce as of 1 April 2000, provides information on each worker's wage rate, age, whether native- or foreign-born, and on the year the worker arrived in the United States. As a result, we can observe the wage of immigrants who have just arrived as part of the 2000 cohort when they are 20 years old (see point R^* in Fig. 2). We can also observe the wage of immigrants who arrived in 1980 when they are 40 years old (point Q^*), and we observe the wage of immigrants who arrived in 1960 when they are 60 years old (point P^*). A cross-section data-set, therefore, allows us to observe only one point on each of the immigrant age-earnings profiles.

If we connect points P^*, Q^*, and R^*, we trace out the immigrant age-earnings profile that is generated by the cross-sectional data, or line CC in Fig. 2. This cross-section line has two important properties. First, it is substantially steeper than the native age-earnings profile. The tracing out of the age-earnings profile of immigrants using cross-section data makes it seem as if there is wage convergence between immigrants and natives, when in fact there is none. Second, the cross-section line CC crosses the native line at age 40. This gives the appearance that immigrant earnings overtake those of natives after they have been in the United States for 20 years. In fact, no immigrant group experienced such an overtaking.

The identification of aging and cohort effects raises difficult methodological problems in many demographic contexts. Identification requires the availability of longitudinal data where a particular worker is tracked over time, or, equivalently, the availability of a number of repeated cross-sections so that specific cohorts can be tracked across survey years. Suppose that a total of Ω cross-section surveys are available, with cross-section $\tau(\tau = 1, \ldots, \Omega)$ being obtained in calendar year T_τ. Pool the data for immigrants and natives across the cross-sections, and consider the regression model:

$$\begin{aligned}\text{Immigrant equation}: \log w_{\ell\tau} &= X_{l\tau}\varphi_{i\tau} + \alpha y_{\ell\tau} \\ &\quad + \beta C_{\ell\tau} \\ &\quad + \sum_{\tau=1}^{\Omega} \gamma_{i\tau}\pi_{\ell\tau} + \varepsilon_{\ell\tau}, \quad (26)\end{aligned}$$

$$\begin{aligned}\text{Native equation}: \log w_{\ell\tau} &= X_{\ell\tau}\varphi_{n\tau} + \sum_{\tau=1}^{\Omega}\gamma_{n\tau}\ \pi_{\ell\tau} \\ &\quad + \varepsilon_{\ell\tau}, \quad (27)\end{aligned}$$

where $w_{\ell\tau}$ gives the wage of person ℓ in cross-section τ, X gives a vector of socio-economic characteristics (including age); $C_{\ell\tau}$ gives the calendar year in which the immigrant arrived in the host country; $y_{\ell\tau}$ gives the number of years that the immigrant has resided in the host country $(y_{\ell\tau} = T_\tau - C_{\ell\tau})$; and $\pi_{\ell\tau}$ is a dummy variable indicating if person ℓ was drawn from cross-section τ.

The identification problem arises from the identity:

$$y_{l\tau} \equiv \sum_{\tau=1}^{\Omega}\ \pi_\tau(T_\tau - C_{\ell\tau}). \quad (28)$$

Equation (28) introduces perfect collinearity among the variables $y_{\ell\tau}$, $C_{\ell\tau}$ and $\pi_{\ell\tau}$ in the immigrant earnings function. As a result, the key parameters of interest – α, β, and the vector γ_j – are not identified. Some type of restriction must be imposed to separately identify the aging effect, the cohort effect, and the period effects. Borjas (1985) proposed the restriction that the period effects are the same for immigrants and natives:

$$\gamma_{i\tau} = \gamma_{n\tau}, \qquad \forall\tau. \quad (29)$$

Put differently, trends in aggregate economic conditions change immigrant and native wages by the same percentage amount. A useful way of

thinking about this restriction is that the period effects for immigrants are calculated from *outside* the immigrant wage determination system.

The measurement of cohort and assimilation effects has received a great deal of attention, particularly in the US, context where the data indicate that cross-section age-earnings profiles overestimate the rate of convergence between immigrant and native earnings due to the presence of cohort effects like those illustrated in Fig. 2.

Immigration and the Welfare State

In addition to the labour market consequences, immigration has fiscal impacts on host countries because there may be significant costs associated with providing social services to the immigrants, and these costs will depend both on the skill composition of the immigrant population and on the generosity of the host country's welfare state. In fact, the immigration debate in many receiving countries has often focused on the possibility that immigrants may become public charges. Since 1882, for example, the United States has banned the entry of 'any persons unable to take care of himself or herself without becoming a public charge'. Similarly, the US immigration statutes declare that 'any alien who, within five years after the date of entry, has become a public charge . . . is deportable'.

There has been a great deal of concern over the possibility that the relatively generous welfare programmes offered by industrialized Western economies have become a magnet for immigrants. It is possible, for example, that generous welfare programmes attract immigrants who otherwise would not have migrated, or that the safety net discourages immigrants who 'fail' in the host country from returning to their origin. These magnetic effects raise questions about both the political legitimacy and economic viability of the welfare state. Who is entitled to the safety net that the host country's taxpayers pay for? And can the richer host countries afford to extend that safety net to the population of poorer countries? Surprisingly, few studies attempt to determine whether such magnetic effects are empirically important.

Much of the empirical debate over the link between immigration and welfare in recent years has instead been dominated by the bottom line: do immigrants pay their way in the welfare state? There exist a large number of accounting exercises, each purporting to calculate the amount of taxes paid by immigrants and the amount of social expenditures that can be attributed to immigrants. The estimates provided by many of these studies are often unconvincing, with the conclusion typically dictated by the accounting assumptions employed in the exercise. For example, how does one allocate expenditures in various public goods between immigrants and natives? In 1996, the US National Academy of Sciences attempted to settle the issue by examining in detail this contentious issue (Smith and Edmonston 1997, Ch. 6).

The National Academy report measured the 'short-run' impact of immigration on the fiscal ledger sheet of states and local governments, that is, the fiscal impact during a particular fiscal year. For two major immigrant-receiving states, California and New Jersey, the National Academy conducted an item-by-item accounting of expenditures incurred and taxes collected, and calculated how immigration affected each of these entries.

California attracts a disproportionately large number of the welfare recipients in the immigrant population, and provides a wide array of expensive services, ranging from generous welfare assistance to a world-class system of public universities and a sophisticated and well-maintained system of roads and freeways. It turns out that immigration increased the state and local taxes paid by the typical native household in California in 1995 by almost $1,174 annually. The cost-benefit calculation for New Jersey is less dramatic. Because New Jersey provides fewer state and local services, and because New Jersey attracts a different type of immigrant (more skilled and less prone to use government services), immigration increased the annual tax bill of New Jersey's typical native household by only $229.

If one were to extrapolate these estimates nationwide, the National Academy concluded

that immigration increased the taxes of the typical native household in the United States by around $200 annually in the mid-1990s. There are approximately 90 million native households in the United States, so that the national fiscal burden is around $18 billion per year. Recall that the annual immigration surplus in the United States is estimated to be around 0.2 per cent of GDP, or roughly around $20 billion in 2000. In the short run, therefore, the available evidence suggests that the net gain (to the native population) from immigration is essentially zero.

It is important to note that this type of accounting exercise is myopic because it does not consider the long-run impact of immigration on government expenditures. For example, it has been argued that immigration may provide an important mechanism to alleviate the fiscal crisis that most industrialized countries will face as their populations age and the dependency ratio rises, putting much greater pressures on social insurance and the fiscal solvency of the welfare state. However, careful simulations of the fiscal consequences of this demographic transition –and of the costs and benefits from immigration in industrialized economies –suggest that immigration can play only a limited role in alleviating the fiscal stress.

Using an overlapping generations framework, these studies examine how the payroll tax rate must adjust to cover the expenses that will be inevitably incurred over the twenty-first century to provide social benefits to a relatively larger aging population (Fehr et al. 2004; Storesletten 2000). One can then simulate the impact of different immigration scenarios on the required payroll tax rate. These simulations typically suggest that the social insurance tax rate in industrialized economies will not fall drastically even if immigration were greatly expanded (such as doubling the size of the flow) over the next century.

The reason for the relative unimportance of immigration in this fiscal exercise is that immigrants themselves generate an increase in social expenditures, and this increase may reduce much of the perceived benefit from simply having a larger population over which to amortize the required expenses. In addition, social insurance programmes in many industrialized host countries tend to be progressive, so that the immigrant population, which is relatively low-skill, will generally contribute less to their funding and receive higher benefits. In short, immigration is not the panacea that can resolve the fiscal problems associated with an aging population in these societies.

International Monetary Fund

Brett House, David Vines and W. Max Corden

Abstract

The International Monetary Fund (IMF) was set up in 1944 and charged with supervising the post-war Bretton Woods system of pegged but adjustable exchange rates as a means of promoting international monetary cooperation. Since the Bretton Woods system broke down in 1971, the IMF's role has become more complicated. It has exercised surveillance over its members' policies, worked to ensure the stability of the international financial system, and assisted the world's poorest economies. This article reviews the history and achievements of the IMF as well as the challenges it faces in redefining its role at the beginning of the 21st century.

The International Monetary Fund (henceforth 'the IMF' or 'the Fund') was conceived at a conference at the Mount Washington Hotel in Bretton Woods, New Hampshire, in July 1944 and its Articles of Agreement entered into force in December 1945. The World Bank (henceforth 'the Bank') was set up at the same time. The IMF was established to promote international monetary cooperation and the elimination of exchange restrictions on current account

transactions; to facilitate trade, economic growth and high levels of employment; to foster exchange rate stability; and to provide temporary financial assistance to countries so as to ease balance of payments adjustment. More specifically, it was given the role of supervising a system of pegged but adjustable exchange rates, which became known as the Bretton Woods system. In the first two sections of this entry we explain how the Bretton Woods system worked, and why it broke down in 1971. In the following sections we consider the roles which the Fund now plays, which differ from its original activities. They are: surveillance, ensuring stability for the international financial system and for individual economies within this system, and assisting the world's poorest economies. As part of each of these three activities, the Fund also provides policy advice and technical assistance. This is a much less clear collection of responsibilities, and, as a result, the future direction of the Fund is somewhat uncertain. The aim of this article is to review the achievements of the Fund, and also the challenges that lie ahead. A related overview of some of the issues discussed here can be found in Gilbert and Vines (2004).

The Bretton Woods system

Intentions

As the Second World War drew to a close, the United Kingdom, the United States and their allies, inspired in part by the *General Theory* of John Maynard Keynes (Keynes 1936), established a policy framework in which countries would be able to promote high levels of employment and output, by means of demand management policies, focused mainly on fiscal measures. This would – it was hoped – avert slumps in growth and would thereby prevent the re-emergence of the kind of global depression that had occurred in the 1930s. (See Williamson 1983a; Moggridge 1986.)

From early on, Keynes had seen that such policies would need global support. This is because they would have to be reconciled with the need for each country to be sufficiently competitive; that is, each country would need to be able to export enough to pay for the imports that would be purchased at full employment. In 1942, Keynes put forward plans for a new post-war international monetary system designed to make this possible, which he called a 'Clearing Union'. (See Keynes 1971–88, vol. 25, pp. 41–67; van Dormael 1978; Gardner 1956.) His plan drew on the theoretical arguments in his *General Theory*, and also on the harsh practical example provided by the United Kingdom's return to the gold standard in 1925 (Eichengreen 1992). He argued that, for many countries, sufficient competitiveness would not be assured if the world returned to a gold standard after the war. Such a standard would require that any country with balance of payments difficulties, of the kind which Britain was likely to have, would need to rely on downward adjustment of its wages and prices in order to make its goods sufficiently attractive in world markets. Keynes judged that, in the political climate of the post-war world, such wage and price adjustments might not be possible. Nevertheless, because of the exchange rate instability of the early 1920s and the 1930s, he also showed no enthusiasm for floating exchange rates. The need for something different was discussed in much detail over the next two years with Harry Dexter White and others from the United States (Keynes 1971–88, vol. 25, pp. 338 ff.), including during a visit that Keynes made to Washington in 1943.

The analytical content of these immensely difficult negotiations is explained in Meade, James Edward, and is discussed in more detail in Vines (2003), which draws on the wonderful historical account by Skidelsky (2000). Skidelsky makes clear that Keynes was propelled in these discussions by the knowledge that the generous provision by the United States of wartime funding to the United Kingdom ('Lend Lease') had put the United States in a position in which it would be able to dismember the British Empire after the war. Keynes, who had been accustomed to Britain managing the global economy, wanted to create a new global order in which prospects for Britain remained acceptable, even although global economic hegemony would pass to the United States. He feared that difficulties in the balance-

of-payments adjustment process might impose, on deficit countries like Britain, an obligation to deflate demand below full employment, something which might not be matched by symmetrical over-expansion by surplus countries, and might thereby create pressures towards global deflation. This is why he wanted his Clearing Union to be able to create global liquidity. (Like a bank, it would 'clear' the overdrafts which countries could obtain from it.) He differed in this view from Harry Dexter White, who feared an outcome in which liquidity would be so freely available that there would be a great post-war worldwide inflation.

What emerged at Bretton Woods was a global system of pegged but adjustable exchange rates, to be overseen by an International Monetary Fund. The currency system was to have three major features. First, each country would establish a *par value* for its currency in terms of gold or dollars. Second, all exchange controls would be removed for current-account transactions and all currencies would be freely convertible into dollars, although controls on international capital flows would remain in place. Third, dollars would be freely convertible into gold. Thus, the system was to be a 'gold exchange standard'; it would differ from a gold standard in being a club rather than a unilateral pegging arrangement, and in allowing for occasional exchange rate changes.

The IMF would do two things in this system. First, exchange-rate pegs would only be adjusted if the approval of the IMF's Executive Board had been obtained. That approval would not be given unless there were deemed to be a 'fundamental disequilibrium'. This term was imprecisely defined, but it meant a situation in which an exchange rate was not at a level that would ensure that exports could equal imports at full employment. This kind of test was designed, with the 1930s in mind, to prevent countries pursuing a 'beggar-thy-neighbour' devaluation of their currencies so as to steer towards full employment by 'stealing' jobs from other countries rather than by expanding expenditure at home. A country with longer-term difficulties would be declared to be in 'fundamental disequilibrium' and would be expected to devalue its currency by an appropriate amount after consulting with the Fund and getting the required approval. Similarly, a country with an excessively large and sustained balance of payments surplus would be expected to revalue its currency.

Second, the Fund would be set up like a credit union, into which members would place deposits; a country in temporary balance of payments difficulty rather than 'fundamental disequilibrium' would be able to draw on a short-term basis from the Fund to help it address the problem. It was thought that these loans would be repaid quite rapidly (that is, within three to five years), since more fundamental difficulties would be addressed by exchange rate adjustments. Each country in this credit union was to be given a 'quota', based on a nonlinear equation that took account of a country's national income, its international trade, and its official reserves; services, other external current account transactions, and a measure of volatility were further added to the quota formula in the 1960s. The quotas would define each country's capital contribution, its borrowing entitlement, and, in aggregate, the Fund's lending capacity. The US quota was initially about 20 per cent of the total (less than would have been implied by a strict calculation based on the variables noted above), and originally the United Kingdom had, by design, the second largest quota. This was *not* like Keynes's Clearing Union, and Keynes was dismayed at how little the Fund would be able to lend (see Vines 2003). There have been a number of substantial increases in total quotas under regular quinquennial reviews, but they have not grown in such a way as to keep pace with the expansion of the world economy and international financial flows. In addition, as the relative size and importance of countries have changed, there has been a need to adjust both quota shares and the factors used in the calculation of these quotas. Both of these types of adjustment have been politically difficult; a (small and interim) adjustment for four emerging-market countries (China, Korea, Mexico, and Turkey) happened in September 2006.

The quota system partly determined the relative voting entitlements of countries on the

Executive Board of the Fund. It seemed obvious, for a credit union to which money had been contributed, to make voting power depend partly on the amount contributed, and on the amount which could be borrowed at a time of difficulty, rather than using a one-member, one-vote system of governance like that adopted at the United Nations. However, there were also a number of 'basic votes' allotted equally to all members, whose effect was to mitigate a little the voting power of large countries.

The Fund's Articles and their subsequent amendments established that a member is allowed to borrow up to a certain proportion of its quota as of right, without policy conditions. This amount was referred to as the 'reserve tranche'; it was equal to 25 per cent of quota and corresponded to the amount that a member had paid into the Fund in hard foreign currencies. Beyond the reserve tranche, a country had an option to borrow up to four 'credit tranches', each of which represented 25 per cent of quota. Access to the first credit tranche was relatively easy; borrowing under the subsequent or 'upper' credit tranches was normally made available through what were (and still are) described rather quaintly as 'stand-by arrangements'.

Consequences

The international monetary system followed only imperfectly the intentions underpinning the Bretton Woods system, and only until 1971. (See de Vries 1976.) Current-account convertibility, for most European currencies, was not achieved until 1958 (the year after a large US current account deficit). There was a reluctance to alter exchange rates even in the presence of 'fundamental disequilibrium'. And the Fund was unable to stop France from implementing a multiple currency system in 1948. One major currency, the Canadian dollar, floated from 1950 to 1962 and the Fund acquiesced in this. The Fund ratified British devaluations in 1949 and 1967 at short notice (though it was closely involved in discussions in the second case). It had little influence on US policies – and has had little influence ever since. It played virtually no role in the later US decision to end gold convertibility in August 1971, a decision which brought the Bretton Woods system crashing down. And it had limited influence on the policies of the principal surplus countries in the 1960s. On the other hand, the Fund did have a role in the exchange rate realignments of other currencies that took place in 1949, 1967 and 1971 as a result of the sterling and dollar devaluations, seeking to ensure 'orderly adjustment'. The most important point is that the IMF had an influence mainly through the conditions it could impose on those countries (such as the United Kingdom in 1976) which needed its funds.

When the Fund began providing stand-by arrangements in 1952 they were typically of short duration and did not feature any conditions. This may seem surprising now, given the close association in the popular imagination between conditional lending and the IMF. Policy conditions were first added to Fund- supported programmes in 1954, partially in light of the increase in the size of borrowing under stand-by arrangements, as compared with first-credit tranche financing. Quantitative targets or 'performance criteria' followed in 1957, in order to provide a clear baseline for policymaking under IMF-supported programmes, and an objective yardstick by which the effects of these policies – and the possible need for further adjustments – might be assessed. They were calibrated using the Fund's financial programming framework, developed by Polak (1957), and came to be a nearly universal feature of Fund-supported programmes by the mid-1960s. (See IMF 1987; 2004a; Mussa and Savastano 1999.) This combination of policy or 'structural' commitments and quantitative performance criteria came to characterize the 'conditionality' attached to IMF lending from the 1960s to the present. This was justified – then as now – not so much as a way of collateralizing IMF lending, and guaranteeing a turnover of the IMF's funds, but rather as a means of ensuring the viability of Fund-supported programmes and the quick adjustment of countries in crisis back to a balanced growth path.

The period from 1945 to 1971 was one of extraordinary dynamism (a 'golden age'): it was a time in which Europe and Japan were first rebuilt after the war and then proceeded to

catch up with the United States. The Bretton Woods system appears to have played a part in ensuring that this happened. In this system, the Fund was helped by the World Bank, whose role was to lend money for longer periods than the Fund, first for reconstruction after the war, and then, later on, to help finance development. (Keynes once helpfully remarked that in order to comprehend the Bretton Woods institutions one has to understand that the Fund is a bank, and the Bank is a fund.) The purpose of this World Bank lending was to enable these countries to borrow abroad (in a world in which there was little international mobility of private capital), to run balance of trade deficits, to invest, and to grow – with the expectation that the borrowing would then be repaid out of the increased export proceeds that investment and growth made possible. In addition, a conference in Geneva in 1947 established the General Agreement on Tariffs and Trade (or GATT) to supplement the Bretton Woods system by encouraging the growth of international trade. The GATT's role in promoting the liberalization of trade restrictions supplemented the Fund's role in promoting the liberalization of exchange restrictions on current account transactions. In due course, a series of GATT 'rounds' brought about tariff reductions, which helped to create markets for exports as countries expanded. With high employment, with balance-of-payments deficits dealt with as described above, and with many countries growing by exporting, there were clear incentives for most countries to support trade liberalization. That, in turn, made exports and imports more sensitive to exchange-rate levels and so made balance of payments adjustment easier to achieve by exchange-rate adjustments. Yet, these linkages between different aspects of the overall post-war policy framework are difficult to pin down empirically. This explains why economic historians still differ in their view as to how important the Bretton Woods system actually was in sustaining the golden age of growth observed in the 1950s and 1960s. (See Matthews et al. 1982; Matthews and Bowen 1988; Temin 2002; papers in Eichengreen 1995; and Eichengreen 2007.)

Breakdown and Reconfiguration

Up to the 1960s the growth of gold reserves had been slow, and the need for additional international liquidity was increasingly met by the use of the US dollar as a 'reserve currency'. This led to calls for the IMF to create a more multilateral way to augment official reserves. The IMF's Articles of Agreement were eventually amended in 1969 to allow the Fund to create 'special drawing rights' (SDRs) that would act as the Fund's unit of account and which could be used as a source of credit for member countries. (See Corden 1983a; Boughton 2001.)

In the 1960s, imbalances also began to emerge: by the latter part of the decade, the United States had a large balance of payments deficit. A belief emerged that the dollar price of gold might rise as economic growth in Europe and Japan weakened the US dollar's role as anchor of the Bretton Woods system. In 1968, central banks ceased their efforts to control the dollar price of gold in private markets, which meant that the prevailing fixed price of gold applied only to central bank dealings. The market price of gold rose: in August 1971, following a massive speculative attack on the dollar, the United States ended the gold convertibility of dollars held by central banks and, as a result, the entire gold exchange standard broke down. A reluctant movement from a pegged exchange-rate system to a system with floating exchange rates followed. This outcome can best be explained by three sets of factors. (See Corden 1993.)

First, many countries were unwilling to adjust the exchange rates for their currencies in the face of fundamental disequilibria. It was particularly problematic that the core country, the United States, behaved in this way. Because US productivity growth lagged behind that of the countries which were catching up with it, the trade position of the United States was at risk by the late 1960s. In addition, the United States fought the Vietnam War and launched its 'Great Society' programmes at the same time, without adequately raising taxes. The result was a large balance of payments deficit for the United States, the correction of which required both real exchange rate depreciation

and restraint of domestic expenditure. Neither of these actions was forthcoming.

Second, the growth of international capital flows – which was in part a result of the international stability associated with the golden age – helped to undermine the system. As first demonstrated by the 1967 sterling crisis, it was no longer possible for the IMF and national governments to set exchange rates without reference to the forward-looking perceptions of private markets about what sustainable exchange rates might be. With increasingly mobile capital, once a suspicion was generated that that there would be (or might need to be) a devaluation of a country's currency to preserve external balance, speculation could make it difficult or impossible for central banks to defend an existing rate. By 1971, the balance of payments deficit of the United States had caused a large build-up of mobile dollar holdings in offshore or 'Euro-dollar' accounts. These funds were used to finance the speculative attack on the dollar in 1971.

Third, the Keynesian macroeconomic policy framework established after the Second World War contained no clear responsibility for preventing inflation. Although there were periods of (generally unsuccessful) price controls or 'incomes policy', the seeds of incipient inflation were sown by this omission. Eventually, tensions generated by the oil price shock of 1973, and by the period of undisciplined inflation which followed it, led to more than the collapse of the Bretton Woods system. The entire structure of Keynesian, interventionist, high-employment policies, which had been at the centre of the post-war policy architecture, came tumbling down, both in the United States and in Europe. For the ten years after 1971, macroeconomic policy was in a state of worldwide disarray.

The great inflation of the 1970s led to significant movements in the real exchange rates between countries, which killed nearly all of the (many) attempts made at the time to reconstruct an international monetary system with pegged exchange rates. (See Williamson 1977.) There was only one lasting, partial, attempt to reconfigure such a system, in Europe, which led to the European Monetary Union.

For a period of time it appeared that the Keynesian approach to macroeconomic policy might be replaced by monetarist policies of a non-interventionist kind. But this alternative proved unsuccessful. Instead, with great difficulty, activist macroeconomic policies were reconstructed by the 1990s within inflation-targeting regimes, in which an inflation target was pursued through interest rate changes. This new system quickly came to be allied with a system of floating exchange rates in which there was a high degree of international capital mobility. In this new set-up, a floating exchange rate would help to stabilize demand, and movements in the exchange rate would become an important part of the process of inflation control. If a country suffered from a shock which raised prices, then its monetary policymakers would set higher interest rates, and the nominal exchange rate of the country would appreciate. This would reduce net exports and import costs, and so inflation.

As a result of this reconfiguration of policy assignments, a second revision of the Fund's Articles of Agreement was made in 1976 and came into effect in 1978. At Bretton Woods, the Fund had been set up to manage a pegged exchange rate system. But it came to be realized that a country cannot have, at the same time, an independent monetary policy, capital markets which are open to the rest of the world, and a pegged exchange rate. (These three things, taken together, have become known as an 'impossible trinity'. The reason that these things cannot occur together is to be found in the Mundell–Fleming macroeconomic model, which was developed by Fleming and Mundell, at the IMF, in the early 1960s.) As a result, the Fund's revised Articles ratified a new form of international monetary system in which a country did not have to establish a par value for its exchange rate, but could instead have exchange rate arrangements of its own choice.

Since 1978, the Fund has gradually been drawn into new roles, in support of this revised, and more flexible, system. As described in the introduction, its work now has three aspects. First, the Fund's Articles, as revised in 1976, require it to exercise surveillance and influence over macroeconomic policies, and to monitor and guard against the

development of unsustainable conditions that could lead to financial crisis. The Fund still lends to countries in balance of payments difficulty, and its second activity has been to do this for emerging-market economies and for 'transition economies' moving from central planning to market-based systems. More than this, the Fund helps such countries to deal with, and to prevent, the financial crises that have afflicted a number of them. Third, the Fund has lent money to the poorest developing countries, which generally do not have capital-market access. In these cases, Fund lending has often been indistinguishable from other long-term concessional development assistance, and the Fund's main distinctive contribution has been to work with central banks and finance ministries in crafting credible macroeconomic frameworks that can elicit further support from aid donors. We consider each of these three activities in turn.

The IMF and Policy Surveillance

Countries that are creditworthy, and which have access to highly mobile international capital under floating exchange rate regimes, no longer need to borrow from the Fund in the way they did when the Fund was first established. Such countries can adjust to balance of payments disequilibria through exchange rate movements, supported by foreign borrowing from sources other than the Fund. (See Corden 1983b, and Dam 1982). At the time of writing, no advanced country had agreed a borrowing arrangement with the Fund since the substantial stand-by arrangements with the United Kingdom and with Italy in 1976. Fund lending is only required at a time when a country ceases to be perceived as clearly creditworthy, something which, as of mid-2007, had not happened in industrial countries since 1976. This was true even at the time of the crisis of the Exchange Rate Mechanism of the European Monetary System in 1992. The Fund did not at that time provide financing to assist Sweden, Italy, the United Kingdom, or France in a defence of their currencies. When crisis struck, these countries (eventually) allowed their currencies to float downwards, rather than using lending from the IMF to defend further their exchange rates.

Nevertheless, a world with a high degree of international capital mobility is not without difficulties. In such a system, the spending decisions of nations can move away from permanently sustainable positions for very long periods of time, an outcome with an external current account deficit (or surplus) offset by an external capital account surplus (or deficit). The 'global imbalances' that can result have, as of mid-2007, been substantial at three points of time since the 1960s. In the late 1960s, as we have seen, the US ran a large current account deficit; current account surpluses of a number of European economies and of Japan, which, as noted above, were engaged in a process of export-led growth and 'catch-up', were the 'other side of the coin'. Nearly 20 years later, in the early to mid-1980s, President Reagan increased defence expenditures and cut taxes. Tight monetary policy was used to restrain demand in the United States, which caused the dollar to appreciate, and the result was a large current account deficit. Japanese current account surpluses were on the other side of this coin. Twenty years later, in 2007, the United States was again running a large fiscal deficit and an (unprecedentedly) large current account deficit; and again Japan was running the corresponding current account surpluses, along with China, other emerging-market economies in East Asia and elsewhere, and a number of oil-producing countries.

These global imbalances reflect decisions by countries to de-link income and spending over time. Of course, such 'intertemporal trade' can be welfare-improving. But such imbalances might instead reflect an urge by a deficit country to spend beyond its means. This was clearly the case for the United States in the late 1960s and the mid-1980s, and might also be the case from 2000 (and especially from 2005). Conversely, these imbalances might also partly reflect a desire by some countries to maintain their currencies at artificially devalued levels against the US dollar, in order to grow quickly through a process of export-led catch-up. This is something which, at one time, would have been called 'beggar-thy-

neighbour' behaviour of the kind which the IMF was established to prevent. As noted above, one can argue that this may have been what was done by western Europe and Japan in the late 1960s. Some commentators have argued that a number of emerging- market economies in East Asia, and elsewhere, were behaving the same way in the early 21st century (Dooley et al. 2003; Roubini and Setser 2005). These commentators, in recognition of the parallel, suggested that we were living under a 'Bretton Woods II' regime.

But global imbalances eventually unwind. They must do so if countries are eventually to repay what they owe. In 1971, global imbalances led to crisis, and to the collapse of the Bretton Woods financial system. By contrast, the imbalances of the mid-1980s were resolved in an orderly way. (See Eichengreen 2004; Eichengreen and Park 2006; Corden 2007; Joshi et al. 2006; Williamson 2006.) Such orderly adjustment requires the deficit country to cut expenditure, and its currency to depreciate significantly (unless it grows its way out of difficulty). It also requires, in addition, that expenditure in surplus countries expands so that global expenditure is maintained, or, if this does not happen, that global interest rates fall so that global expenditure is stimulated by other means. If all of this happens, as it did in the late 1980s, then the benefits of intertemporal separation between spending and income may not be diminished by the costs of an adjustment crisis.

There are four main ways in which the existence of the Fund helps global imbalances to unwind in an orderly manner.

First, ever since the second amendment of the Fund's Articles described above, the Fund has been required to exercise 'firm surveillance' over the exchange rate and macroeconomic policies of its members. As a result, the Fund regularly sends to each country an 'Article IV mission' whose purpose is to review the country's macroeconomic policies. This is done annually for most countries, and at interludes of up to 24 months in countries with active Fund-supported programmes. (For such countries the Article IV cycle is elongated since policies are reviewed frequently in the context of semi-annual or quarterly programme reviews.) All aspects of macroeconomic policy are considered on these occasions. Following the emerging- markets crises of the 1990s and early 2000s, the Article IV consultation process has been supplemented by detailed review of countries' financial sectors under the World Bank and IMF's joint Financial Sector Assessment Program (FSAP).

Second, the Fund provides a vast amount of published information and analysis, both about the world economy and financial system in general and about particular countries. The Fund's biannual *World Economic Outlook* provides a forecast for the world economy, and analyses multilateral and regional issues; this report is supplemented by *Regional Economic Outlooks*. These products are based in part on Article IV consultations and would not be possible without that process. The Fund also publishes a biannual *Global Financial Stability Report* which monitors markets, and several statistical publications that compile economic and financial data supplied by member countries, including *International Financial Statistics*.

Third, the Fund plays an important role in keeping the governments of all members in touch with developments in other countries and globally. The Article IV missions to the largest economies (and the related research, published in *Selected Economic Issues* papers that are companions to the Fund's Article IV staff reports) are particularly important in helping to keep governments informed of policies and developments that are likely to affect the world economy as a whole. Additionally, the Annual Meetings of the Boards of Governors of the IMF and the World Bank enable an informed exchange of ideas between countries, as do the Spring Meetings. The Fund thus provides a valuable global information network.

Finally, the Fund has also created a valuable global human network. Fund staff are of high quality, something which is necessary since they have to deal with senior officials in many countries. The offices of Executive Directors of the Fund in Washington act as valuable means of communication between the member nations of the Fund. And in many national capitals a large

number of public servants and elected officials have served on the Fund staff earlier in their careers, or have been located in Washington as Executive Directors at the Fund or as members of staff in Executive Directors' offices. This experience has made many decision-makers more internationally minded than they might otherwise have been.

Nevertheless, some have argued that the Fund's 'firm surveillance' is not firm enough. Arriazu et al. (1999) discuss the impact of Fund surveillance, country by county, in the Article IV consultation process. They note that, although these consultations have been 'taken seriously', it does not appear that these reviews by the Fund have had more than an occasional impact on national policy decisions in some countries. A more recent assessment of Article IV consultations by Meyer et al. (2004) reaches similar conclusions. When an Article IV mission goes to a country that does not borrow from the Fund (and which therefore does not require the Fund's *imprimatur* in order to obtain loans from other official creditors or from banks), the mission is usually relegated to a mainly advisory role, for which 'surveillance' may be too grand a label. But this *de facto* situation is not inevitable, since the *de jure* position of the Fund is that it should assess and appraise as well as advise. Goldstein (2006) asserts that there are gaps in the current practice of bilateral surveillance and argues, in particular, that the Fund's dealings with China in the early 21st century have not been satisfactory in addressing and effecting remedies for exchange rate misalignments. He further observes that the Fund's Managing Director has only rarely used the power granted to him by the 1977 and 1979 Board decisions on ad hoc and 'supplemental' consultations with members to address cases where a country's exchange rate policies appear inconsistent with the exchange rate principles of the Fund's Articles. (See Boughton 2001.)

It is important to note that these critics do *not* seek policy changes from countries, in the interests of the greater good, that such countries would find unattractive if left to make policy choices on their own. That is, it is not suggested that the Fund could enforce a 'cooperative' outcome in macroeconomic policymaking when countries would prefer a different selfish, or 'Nash,' outcome. (This difference between Nash and cooperative outcomes was much discussed in the 1980s literature on policy coordination, summarized by McKibbin 1997). Instead, it is argued that the Fund could enable cooperative outcomes, so that any adjustments in countries' policies that need to happen in the face of global imbalances might happen in the right sequence rather than in a disorganized manner. The capacity to enforce even this modest form of coordination might occasionally be important in the adjustment processes. (See Kumar 2006; Wolf 2005, 2006; Joshi et al. 2006.)

There was action of this kind under the Plaza Accord of September 1985, although it was not coordinated by the Fund. At this time, the finance ministers of the world's five largest national economies agreed that the value of the dollar needed to go down. They also arrived at some (rather general) agreements on the monetary and fiscal policies that would be needed in order for this fall in the dollar to be achievable, and announced coordinated intervention in foreign-exchange markets to help bring it about.

To act effectively in this way requires the Fund to come to terms with the difficult tension between its strengths as a universalist institution and the need, on occasion, to bring together a more limited group of players. But it is an objective of the Fund's current Medium-Term Strategy that it should provide such a forum (IMF 2005b). The Fund's Multilateral Consultation on global imbalances began by consulting with the United States, the European Union, Japan, China and Saudi Arabia, and it reported on its findings in April 2007. This work ran in parallel with similar discussions at summit meetings of Heads of Government of the Group of Eight Countries (or G8), and at meetings of the finance ministers and central bank governors of these countries. The G8 consists of the United States, Russia, Japan, Germany, Britain, France, Italy, and Canada. This is a powerful collection of countries, but it is not clear that these G8 meetings have had the right participants to deal with the global imbalances of the early 2000s. China and India have not been members

I

of this group (though they have been observers), nor have many of the major oil-producing economies; by contrast, Canada and Italy, while committed to the G8 process, have been perhaps too small to contribute substantially to coordinated efforts to unwind global imbalances. The Fund may therefore have more to offer than such G8 gatherings, since the Fund can act as a locus of coordination amongst subsets of its membership, convening small groups of countries to deal with particular problems.

Nevertheless there are three reasons why further progress may be slow on this front.

First, in the words of the IMF's Independent Evaluation Office (IEO) (IMF 2006a, p. 2), 'As a result of its ... [country-by-country] orientation, multilateral surveillance has not sufficiently explored options to deal with policy spillovers in a global context'. Pursuing this theme, Mervyn King, Governor of the Bank of England, made it clear (King 2006b) that more effective multilateral surveillance would require: (i) that countries made clearer commitments about their objectives for macroeconomic policies (that is, fiscal, monetary and financial); (ii) that the Fund's Article IV and the *World Economic Outlook* processes focused more transparently on cases when these policy commitments, and the countries' policy actions, are not globally consistent; and (iii) that this process also transparently demonstrated the negative spillover effects that come from such lack of consistency and proposed actions to reduce such negative spillovers. But, given the limits to the precision of what we know about the international economy at any given time, doing this would be difficult. And it should be noted that the Fund's management issued a rejoinder to the 2006 IEO report which explained this difficulty.

Second, there may well be governance limitations on such firm surveillance. As of 2007, Article IV consultations were not finalized by the Fund Staff sent on the Article IV mission, but by the Fund's Executive Board, whose views were conveyed to the authorities of the country concerned after discussion at the Board. It is possible that this has compromised the space for missions to assess and appraise frankly. If the process of IMF surveillance were made more independent of the IMF's Executive Board, then this might allow clearer messages to be delivered to the Fund's member countries. As against this, the messages might then lose political weight because they would no longer be seen as the views of the global community represented in the Executive Board.

Third, and fundamentally, the Fund is not an agent of a sovereign state in the way that central banks (except the European Central Bank) are, however 'independent' these central banks may be. As a result, the Fund has no actual instruments of its own with which its recommendations on global cooperation can be implemented. It must always rely on being able to persuade its members to act.

The IMF and Crises in Emerging Markets Since 1980

In the mid-to-late 1970s, after the rise in the price of oil in 1973, funds flooded from oil producers on to the international capital market and flowed to middle-income countries. The early to mid-1990s saw a further massive surge of private capital flows into emerging market economies, and this was repeated in the mid-2000s. The economic benefits of such international mobility are obvious: if capital flows from relatively rich to relatively poor countries, and if the rate of return is high in poor countries, the potential gains are high for both borrower and lender. But such funds are not always used well, the volatility of these flows can be very high, and they can create dangerous mismatches in the maturities and currencies of assets and liabilities. Indeed, these flows contributed to three major waves of financial crises, in Latin America, East Asia and Russia, something which called into question the stability of the entire international financial system. Across these regions of the world, the IMF has been required to help prevent such crises through surveillance. It has also been required to assist in the orderly workout of crises, through lending and through ongoing engagement in the development of macroeconomic policies in the countries which it assists. We explain how the Fund's activities

have evolved in these emerging-market economies, and how its role has broadened. We do this by examining the three generations of emerging-markets crises that occurred from the early 1980s onward.

The Latin American Debt Crisis: A 'First-Generation' Crisis

Oil money, facilitated by loans from international banks, financed a spending boom in Latin America and elsewhere during the 1970s. This led to a rapid increase in foreign debts (Little et al. 1993) in countries which were not in a position subsequently to adjust and service these debts. In due course, significant balance of payments problems emerged when, in 1980–82, real interest rates rose, driven by tight monetary policy in the United States and by a world recession which worsened the terms of trade for many emerging-market economies. These countries rediscovered the truth of what Keynes had maintained 40 years earlier: adjustment to external difficulties requires both good budgetary control and an appropriately competitive real exchange rate (Corden 1990; Little 1993). This turned out to be something which many policymakers in Latin America, and elsewhere, were unable to engineer, and monetized fiscal deficits led to reserve losses, uncontrolled devaluations of currencies and inflation, and difficulties in meeting foreign-currency-denominated debt obligations. Currency and debt crises were triggered more or less mechanically as macroeconomic fundamentals drove reserves down to critical levels, resulting in what has become known as a 'first-generation' crisis.

Although Latin America is most closely associated with the debt crisis of the early 1980s, other countries, including Morocco, were also involved. The crisis placed the IMF at the centre of the world stage in a way which made it more prominent than it had ever been under the Bretton Woods system. The Fund played four roles. First, it offered financial support with stand-by arrangements and other lending facilities. Second, the Fund came to define the broad envelope of resources that a country could be expected to devote to meeting its residual obligations under a debt rescheduling. In turn, the Fund, together with the United States and other bilateral creditors in the Paris Club, pressed creditor banks to reschedule debts and to engage in 'concerted lending' programmes, threatening to provide no support for indebted countries if banks did not cooperate, and, hence, making defaults more likely. Third, the Fund's advice and conditionality, together with that of the World Bank, had significant effects on indebted governments' policies: they were encouraged to undertake growth-oriented structural reforms to escape from their debt problems. Fourth, the Fund's reports and conditionality provided the 'seal of good housekeeping' on the basis of which banks and bilateral creditors could justify rescheduling existing debt and providing new funds.

This use of the Fund, and the broader strategy surrounding it, is usually associated with James Baker, then Secretary of the US Treasury. It was a success only to the extent that it made the financial crisis manageable. The strategy avoided explicit debt reduction and insisted that indebted countries meet their obligations, although over an extended period of time. (This lengthening of the repayment profile did, of course, lead to some reduction in the net present value of debt.) Such an approach was advocated by the governments of major industrialized countries, especially the United States, that were concerned about systemic risks to their own banking systems arising from widespread write-downs of debt. The Fund was criticized in some quarters for agreeing to this strategy and for acting as an 'enforcer' of debt service on behalf of private banks.

A policy shift took place in 1989. Under the Brady Plan, also initiated by the US administration, the Fund and the World Bank provided encouragement and some financial support for debt reduction programmes for those countries (notably Mexico) where major policy reforms were being undertaken. The shift from the Baker Plan to the Brady Plan represented a tilt in favour of debtor countries relative to creditor banks. But this came only after a long period in which these banks were able to rebuild their balance sheets, thereby putting them in a position to weather debt restructuring. The US Treasury induced creditors to grant write-downs to debtor countries by

collateralizing the debt that emerged from these restructurings. The Fund backed up this carrot by concluding financing packages with debtor countries before the terms of debt reschedulings had been determined: a practice that came to be known as 'lending into arrears'. This acted as a stick to weaken creditor leverage in the negotiation process, and it also greatly strengthened the role of the Fund in debt work-outs since, during the negotiations, Fund staff came to play a major role in influencing debtor countries' macroeconomic policies.

The Mexican 'Tequila' Crisis: A 'Second-Generation' Crisis

The Latin American debt crisis of the early 1980s had been caused by *public*-sector overspending. But in 1994 something new happened. A major financial crisis, caused by the outflow of *private* capital, of the kind which had brought down the Bretton Woods system in 1971 and the European Monetary System in 1992, happened in Mexico. The Mexican crisis was different from the Latin American turmoil of the 1980s in that it was set off not just by fundamental weaknesses, such as unsustainable fiscal and current account deficits, but also by currency mismatches on the public-sector balance sheet. (See Calvo and Mendoza 1996.) These caused a 'second-generation crisis' in the form of a self-fulfilling currency run. This crisis presented new challenges for the IMF since it marked the first of a series of crises in emerging markets that originated in the capital account, rather than the current account, of the external balance of payments. The IMF was called on to assist Mexico despite the fact that its Articles of Agreement provide it with only limited jurisdiction over capital account issues.

Mexico had implemented a comprehensive reform programme in the early 1990s, which included financial liberalization and the completion of the North American Free Trade Agreement (NAFTA) in 1993. This led to a surge in investment financed mainly by foreign capital flows. The result was a large (real) overvaluation of the peso and a very large current account deficit. Initially, the government maintained prudent fiscal policy. But during 1994 many began to question the sustainability of the exchange rate, the fiscal position and current account deficit. By December 1994 there was a massive reversal of capital flows, and the peso plummeted. The consequences for Mexico were severe: inflation rose from 7 per cent in 1994 to 35 per cent in 1995; and GDP fell by 6.2 per cent in 1995 compared with a growth rate of 4.4 per cent in the preceding year.

The pain inflicted on Mexico by private investors led to a view that pegged exchange-rate regimes are unviable everywhere, not just in advanced industrial countries. (Mexico had a 'crawling peg' at the time.) And in Mexico there was a new emerging-market feature. Much of the Mexican government's debt was denominated in US dollars (for example, the *'tesobonos')* because of the difficulty and high costs of borrowing in local currency; much of the government's revenue stream, by contrast, was peso-denominated (although oil revenue was denominated in dollars). This mismatch meant that the collapse of the peso led the government to the verge of default in early 1995.

The Fund played a critical role in stabilizing the crisis. In particular, drawing on financing from bilateral creditors, it coordinated assistance, mainly from the United States, that totalled more than five times Mexico's quota entitlements at the IMF. After a significant real devaluation of the peso and fiscal correction, exports rebounded, the economy grew, although only slowly, and Mexico earned enough foreign exchange to repay the exceptional financing that had been provided to it during the crisis.

Some subsequent analyses (see, for example, Calvo and Goldstein 1996) were critical of the IMF's role in both surveillance and in crisis management for Mexico. But the arguments cut both ways.

On surveillance, it was claimed that IMF reports prior to the crisis placed insufficient emphasis on the vulnerabilities of public-sector and financial-sector balance sheets to the possibility of a run on the currency. Some authors argued that the Fund should have been more frank in conveying its views on macroeconomic and exchange-rate policy to its members, and that it should publish these appraisals. But there may

well have been inadequate provision of information by Mexico to the Fund, as well as to the public. In particular, it appears that incomplete data may have been provided on official international reserves and liabilities (although the Mexican authorities disagreed with this claim when it was made). As a result, following the Mexican crisis, the Fund began a drive to get countries to sign on to transparency standards, such as the Fund's Special Data Dissemination Standards (which were established in 1996; see Fischer 2004, p. 127). Additionally, the Fund began the practice of publishing Board documents, except when the authorities of a country objected. But this heightened focus on transparency left the Fund unclear on whether it should assist countries confidentially to prevent crises or spur corrective action by bringing bad news to the market. Given the sometimes self-fulfilling mechanics of second-generation currency crises, solving this dilemma is critical in defining the future role of the Fund in crisis prevention.

On crisis management, no clear conclusions emerged, either. *Ex post* it appeared that the private sector should have been prepared to lend short term to the Mexican government in the way that the IMF and the United States did. Overcoming such a market failure is surely a role of the IMF and national governments, and giving the IMF the capacity to provide such big loans seemed important to many observers. From this experience, Sachs (1995) concluded that the Fund should be given an explicit international lender-of-last-resort capacity, well beyond that formally possible under its 'credit-union' status, so as to enable it to be ready to respond forcefully and quickly to emerging crises, as it had done in the Mexican crisis. (See also Fischer 1999.) With such firm IMF action, currency crises could be contained as liquidity crises rather than becoming solvency crises. Indeed, it appears that the combination of large-scale IMF financing, combined with significant adjustment by the authorities, prevented the development of a solvency crisis in Mexico. However, some authors began to warn that, if the IMF always acted as a lender of last resort in the face of crisis, then this might create moral hazard on the part of lenders to emerging markets, who might expect to be able to lend virtually risk-free with any possibility of default prevented by IMF action. (The Fund-led bailout of *tesobonos* holders strengthened these fears.) These critics suggested that efforts be made to make sovereign debt rescheduling easier and more orderly (Eichengreen and Portes 1995), thereby containing the threat of creditor moral hazard.

The Asian Financial Crisis of 1997–98: The 'Third Generation' of Crises

Two and a half years later these issues re-emerged in Asia, in a crisis which interrupted a long period of sustained economic growth financed by exports and foreign capital inflows. Unlike the earlier Latin American debt crisis, or even in Mexico, fiscal profligacy played no *explicit* part in the East Asian crisis. But there were two other main policy failings. (See Bluestein 2001; Corbett and Vines 1999a, b; Corbett et al. 1999.)

First, much more than in Mexico, an underdeveloped financial system and over-protected financial sector in some Asian economies meant that the private sector had to rely on borrowing, rather than equity issuance, to raise investment funds. As a result, firms became highly leveraged, but banks continued to lend because they were underpinned by *implicit* government guarantees. When growth slowed, as it first did in Thailand in 1996, and then in other East Asian economies, these banks were exposed to the inability of borrowers to repay loans.

Second, a further difficulty arose, as so many times before, from the existence of fixed exchange-rate systems in some East Asian economies, but with a new twist. Banks financed much of their domestic corporate lending by borrowing in foreign exchange from abroad, often at shorter maturities than those employed when they lent onwards in domestic currency. Very little of this borrowing was hedged as a result of the implicit guarantee on the exchange rate. As noted in the previous paragraph, the financial sector was already in difficulty after the initial slow down in growth in 1996. Currencies fell in mid- to late 1997 because of foreign investors' concerns about these difficulties; as a consequence,

widespread bankruptcies and potential bank failures loomed because of the unhedged foreign-currency obligations. Fear grew that fiscal systems would be unable to bear the cost of large-scale bank rescues (Irwin and Vines 2003).

The East Asian debacle marked the advent of 'third-generation' crises in which currency crises and banking crises are intimately intertwined – situations in which vulnerabilities in the private balance sheet can quickly translate into a public debt crisis.

As in Mexico, the Fund played a large part in resolving the crises. The IMF moved quickly to lend very large sums to Thailand, Korea and Indonesia. Nevertheless, there has been widespread criticism of the Fund's behaviour before and after the crisis. (See, for example, Stiglitz 2002.)

Two difficulties must be acknowledged in the Fund's *crisis prevention* work in East Asia. First, the Fund may have underestimated the risks associated with capital account liberalization. Second, the Fund may not have been firm enough in warning of the difficulties inherent in maintaining a fixed exchange-rate peg. Nevertheless, Thailand, for instance, was warned privately by the Fund several times in the year leading up to the 1997 currency crisis. The Fund, like some private-sector analysts, saw problems looming in Thailand, but its advice was not heeded.

Concerning the Fund's work on *crisis management*, there are three points to consider.

First, as the Fund has acknowledged in both its own reviews of the East Asian crisis and in the evaluations performed by its Independent Evaluation Office (IEO) (IMF 2003), its programmes may have placed too much emphasis on tightening budgets in countries that were already running prudent fiscal policies. Stanley Fischer, then the Fund's First Deputy Managing Director (FDMD), argues, however, that this approach was driven by a need to boost government savings to support the current account and provision for the impending cost of bank restructurings. (See Fischer 2004.) Furthermore, the credibility of an adjustment programme at a time of crisis may hinge on policy erring towards being too tight, in order to send a clear signal to markets. Once the scale of the economic downturn became apparent in East Asia and current account balances improved, Fischer argues that the Fund programmes shifted to addressing structural problems. (See also Corden 1999; Boorman et al. 2000.)

Second, monetary policy was also tightened in an attempt to defend currencies. There is an inevitable trade-off between raising interest rates in order to moderate exchange rate depreciations and lowering interest rates so as to ease the stress on both the banking system and on corporations that depended on domestic credit. Stiglitz (2002) argues that the tightening was too forceful. However, it does appear that this tightening was essential in order to stem capital flight. Nevertheless, this tightening was not followed by a concerted move to an inflation-targeting regime of a kind that might have allayed concerns of further depreciation. Hence, pressure on the region's currencies continued. And rather than stimulating recovery, these depreciations proved contractionary, at least initially, owing to their effects on external debt burdens. (See Krugman 1999.)

Third, the Fund did not have a mandate to declare 'standstills' on external debt payments during the crisis. In corporate bankruptcies, standstills force creditors to share in the burden of crisis and agree to reasonable debt reschedulings. In the context of a currency crisis, a standstill mechanism would similarly 'bail in' foreign private-sector creditors and then make reschedulings possible to reduce debt to sustainable levels. The fact that a standstill was not imposed in Thailand, Korea or Indonesia enabled creditors to race to get their assets out of these countries. Negotiations with foreign creditors to Korea and Indonesia did ensure some rollover of existing short-term lending, with effects similar to those that might have resulted from standstills. In both cases, however, negotiations were pursued too late and without sufficient coordination to maximize their impact (though they did stave off collapse in Korea). The only comprehensive brake on external payments was that imposed in Malaysia through the implementation of capital controls rather than a standstill by the government of Prime Minister Mahathir bin Mohamad in late 1998, a move that contravened the Fund's advice. But this was done

only after substantial capital outflows from Malaysia had already taken place.

Because the Fund lacked a mandate to impose standstills, it lent countries money in an attempt to allay the concerns of foreign creditors and to stem capital flight. Given the scale of the external capital-account movements in these countries, the size of IMF financing packages soared, especially after it became clear that smaller lending programmes would be unlikely to produce adequate results. In the case of Korea, the authorities of the IMF's large shareholder governments, notably the United States and Japan, also made a key decision to pursue a debt rollover plan and to exert moral suasion on creditor banks. These banks presumably realized that the alternative would have been partial default. The IMF played a useful role in facilitating communication among the different actors, in providing information, and in certifying that the policies to be pursued by the Korean authorities were appropriate. The IMF's Independent Evaluation Office writes, 'No single national government, nor any private sector institution, could have played this role as effectively' (IMF 2003, p. 115).

Although the Fund's work in Korea showed that the IMF could effectively manage a debt workout, its conduct elsewhere in the East Asia crisis had the effect of shifting the balance of power in debt workouts back toward creditors. IMF programmes did *not* reduce the debt overhang in Indonesia and Thailand. Instead, governments rescued banks and corporations by shifting their debt to the public balance sheet. Taxpayers in these countries still bear the burden of this debt. Rather than 'bailing in' private creditors, the Fund's handling of the crisis in these countries may have provided creditors with an even bigger bailout than they might have expected under the terms established in the 1990s' Brady Plan.

Partially out of dissatisfaction with this result, Anne Krueger, who followed Fischer as the Fund's FDMD in 2001, proposed a bankruptcy or standstill procedure for countries, the 'Sovereign Debt Restructuring Mechanism' (SDRM) (Krueger 2002). The US Treasury and financial markets both opposed this proposal out of a concern it would create unrestrained debtor moral hazard. Under what came to be known as the 'Taylor Doctrine' (after John Taylor, then US Treasury Under Secretary for International Affairs), the US government argued that countries should be left on their own to negotiate with their creditors. But this is only feasible when the number of external creditors is small, which for most countries has not been the case since the 1980s when external borrowing was provided mainly under loans from banks. To help remedy this problem, the US supported the introduction of 'collective action clauses' (CACs) in bond contracts with commercial creditors. These clauses prevent rogue creditors from holding out in restructuring negotiations in order to extract a premium from the bond issuer; they work by enforcing a restructuring if a pre-specified minimum proportion of creditors have agreed to its terms. CACs do not, however, provide a framework to guide the allocation of losses between borrowers and lenders, which is necessary in any restructuring. In the absence of a clear means of sharing these losses, it may prove impossible to renegotiate debt owed to commercial creditors. When faced with debt-servicing problems, debtor countries may then decide to borrow from official sources (including the IMF, whose debt is senior to other external liabilities and not reschedulable) in order to repay private sector creditors, as happened in Korea, Thailand and Indonesia. Since private-sector creditors are likely to believe that this will happen, the Taylor doctrine's approach, even when coupled with CACs, might promote creditor moral hazard, something which has been feared ever since the Mexican crisis. Thus, although the Taylor doctrine's approach has the virtue of minimizing debtor moral hazard, it appears to go in the opposite direction by promoting creditor moral hazard.

Default: The Russian and Argentine Crises

Russia. The fall of the Berlin wall in 1989 and the dissolution of the Soviet Union in 1991 enabled the IMF at last to become a (nearly) universal institution. In three years, membership increased from 152 countries to 172, the most rapid increase since the influx of African members in the 1960s. The IMF supported programmes in most former

Eastern Bloc countries and newly independent ex-Soviet Republics to help ease the transition to a market economy. The contribution the IMF made to the speed and relative smoothness of this transition is, perhaps, one of its most singular and least-heralded achievements.

Russia, however, got off to an inauspicious start under the first stand-by arrangement with the Fund in 1992. The IMF encountered intense difficulties in influencing the Russian leadership (Odling-Smee 2004). GDP fell for several years under the IMF-supported combination of macroeconomic stabilization and industrial restructuring. Although the IMF can claim credit for helping to instil some monetary discipline by the mid-1990s, the process took time, foreign direct investment remained low, tax collection was poor, and the fiscal deficit remained large. Growth in real GDP did re-emerge by 1997. But, following the onset of the East Asian crisis, the ruble came under speculative attack in November 1997. Pressure on the ruble was compounded by foreign investors' attempts to hedge their ruble holdings, as well as by a drop in the price of oil, which accounted for about one-third of Russia's foreign-exchange inflows.

Russia sought additional IMF financing in early 1998, but agreement on the terms of a new programme could not be reached owing, in part, to a failure by the Russian authorities to secure an increase in fiscal revenue. As a result, foreign investors began to unload Russian assets and about US$4 billion fled the country in the summer of 1998. By the time additional IMF financing was agreed in July 1998, fears of a devaluation led to such a pronounced sell-off of Russian securities that the authorities were forced to devalue the ruble and halt payments on both domestic and foreign debt.

Although the Fund is routinely criticized for providing cover for private capital flight from Russia in the first half of 1998, private investors who maintained faith that the Fund would rescue Russia sustained even greater losses when the ruble was devalued. This was perhaps the largest case to that point where the Fund stepped away from a floundering member, declared a solvency crisis, and let private creditors sustain substantial losses. It marked a different approach to the challenge of balancing creditor and debtor interests from that which the Fund had adopted in East Asia. And in some ways it set a precedent for the Fund's handling of the Argentine crisis in 2001.

Argentina. After a sustained period of hyperinflation in the 1980s, Argentina decided in 1991 to peg its currency, the peso, to the US dollar under a quasi currency-board regime at a one-to-one parity. Although the Fund cautioned that Argentina had neither the fiscal discipline nor the robust export sector needed to sustain such a system, it went along with the authorities' plans and supported their macroeconomic programme under a series of lending arrangements. By the late 1990s, Argentina was widely hailed as a model of successful economic reform as the rate of inflation fell to single digits and growth increased. In addition, the economy had successfully weathered the global turbulence caused by the East Asian crisis of 1997–8, and the Russian crisis of 1998.

But the seeds of the problems identified by the Fund back in the early 1990s were beginning to bear fruit by the end of the decade. Fiscal policy remained insufficiently tight owing to the lack of effective central government control on provincial borrowing, and this stimulated domestic demand for imports. Argentina's export sector remained too small to finance these imports, and its real exchange rate made its goods uncompetitive on regional and international markets. As a result, Argentina chose to borrow substantial amounts in US dollars to finance its imports. Brazil's decision to float the real in 1999 in response to pressure from the Russian crisis made it even harder for Argentina to compete under its quasi currency-board regime. The Argentine authorities allowed the peso to float in January 2002, and it quickly collapsed from parity with the US dollar to an exchange rate of nearly 3.9 to the dollar in June 2002. Output fell sharply, inflation reignited, the government defaulted on its debt, and the banking system was largely paralysed.

The Argentine debacle rightly cast several doubts on the Fund's conduct of both crisis prevention and crisis management in emerging markets. At the outset of the 1990s, the Fund proved incapable of resisting Argentina's arguably

doomed effort to impose its quasi currency board. Subsequently, the Fund endorsed Argentina's exchange rate peg in a series of programmes through the 1990s that coincided with an accumulation of macroeconomic vulnerabilities. When the regime became unsustainable in 2001 (or earlier), the Fund maintained lending until the end of that year in an attempt to save the peg. After the crisis, the Fund resumed lending to an insolvent Argentina in 2003 at the behest of the Executive Board, even although misgivings were expressed by the Fund staff. IMF lending ceased again later in 2003 and Argentina pursued an aggressive 'take it or leave it' strategy with private creditors. The Argentinean authorities achieved a roughly 75 per cent write-down on the country's defaulted foreign bonds, while leaving nearly US$20 billion in unexchanged bonds in default (IMF 2005a).

The Fund's experience with Argentina demonstrates at least four things. First, it can be very difficult for Fund staff to resist Executive Board pressure to support a country with IMF lending, either when inappropriate policies are being pursued (for example, the creation of the quasi currency board) or when a country is insolvent (as Argentina was by 2003). Second, the Fund has sometimes found it just as hard as its members to take a stand against an inappropriate fixed-exchange-rate regime. Third, the absence of any international standstill process or debt restructuring mechanism makes it difficult and time consuming to reconstruct a financial system and to reach a balanced solution with creditors once a crisis has occurred. The Taylor doctrine has not worked out wholly as planned. Fourth, once damaged, the quality of the policy dialogue between the Fund and its members is difficult to restore. Since the crisis, Argentina's policies have appeared unsustainable: Argentina has contrived to keep its exchange rate at a level at which its exports seem to be excessively competitive, while relying heavily on high international primary commodity prices to sustain its balance of payments. These policies do not seem consistent with the world envisaged in the second amendment of the Fund's Articles, a world in which the Fund exercises firm surveillance over member countries' policies in its role as steward of the international financial system.

Conclusions

The capital account crises of the 1990s and 2000s represent a new chapter in the Fund's history: they mark a distinct shift from the Fund's previous bread-and-butter work of dealing with current account crises. These capital account crises created new challenges and strains on the Fund – some of which it responded to well, some less so.

On *crisis prevention* the Fund has learned much. After the Mexican crisis it promoted regulatory reform, increased transparency, and better monitoring in emerging market economies. The Fund's Articles prevent it from pronouncing on countries' particular choice of exchange-rate regimes. But in its policy advice the Fund has made clear that the trilogy of floating exchange rates, carefully sequenced liberalization of capital accounts and financial systems, and inflation targeting can work well (Blejer et al. 2001; Corden 2002; Batini et al. 2005); by contrast, the Fund has given clear advice about the difficulties faced by fixed exchange-rate regimes. The Fund has also attempted to reinvent itself as a lender of 'first resort' through the creation of contingent or 'pre-approved' lending facilities aimed at crisis prevention. These lending windows would provide members with an added incentive to pursue sound policies and a signalling framework under which they could commit to these policies. But the Fund's first effort in this direction – 1999's Contingent Credit Lines (CCL) – expired in 2003 after four years without use, owing to somewhat stringent qualification criteria, less than full automaticity in disbursements, and concerns amongst members that a request for a CCL might send a negative signal to capital markets. New effort was invested in the design of such an instrument, initially called the Reserve Augmentation Line (RAL), during 2006–07.

On *crisis management*, much work has been done to understand better how to construct, balance and sequence macroeconomic policy

restraint at a time of crisis. The Fund has developed a detailed debt sustainability framework and complemented its traditional analysis of financial flows with a 'balance sheet approach' to analysing stock imbalances, so as to enable it to understand the financial vulnerabilities of countries. This tool was designed to help Fund staff draw a clearer distinction between liquidity crises and solvency cases. (On this see Irwin and Vines 2005; Cohen and Portes 2004; Portes 2004.) But from the early 1980s onward, the three generations of crises outlined above also threw into sharp relief the problem of moral hazard arising from IMF lending. The need to balance better debtor moral hazard and creditor moral hazard became one of the key challenges facing the Fund in the design of its lending facilities and its accompanying policy responses to crises. This article has highlighted the manner in which the Fund has occasionally oscillated between favouring creditor interests and favouring debtor interests, in an attempt to balance these interests in an acceptable way.

The Fund's experience with crisis management in the 1990s revealed difficulties with Fund conditionality. By then the conditions attached to Fund loans had grown far beyond what had earlier been thought necessary to ensure adequate macroeconomic adjustment, and came to include substantial structural conditionalities. Some of these concerned macroeconomic issues of proper concern to the Fund. But there was also an explicit concern with a range of microeconomic reform issues, and, even more broadly, with poverty-reduction questions. Many observers, including Arriazu et al. (1999), IFIAC (2000) and Williamson (2000), have questioned the wisdom of this policy creep, although it should be said that, in some cases (for example, poverty reduction), the spread of IMF conditionality reflected the concerns of member countries rather than an attempt by the Fund to expand its mandate. Following member country dissatisfaction with the comprehensive conditionalities included in their programmes (Indonesia's programmes in the late 1990s are particularly relevant cases), there has been much work at the IMF since 2000 on streamlining conditionality, and on pulling back from a range of concerns about structural issues that are not deemed 'macro critical'. This led to a careful restatement during 2002 of the principles governing the IMF's design and implementation of conditionality, with a view to ensuring that the conditions attached to IMF lending focus only on policies essential to the macroeconomic viability of Fund-supported programmes. (See IMF 2002a; Boughton and Mourmouras 2004.)

At the time of the preparation of this article (2007) there was a lull in the frequency of crises, and a significant decline in the volume of Fund lending. The Asian, Russian and Argentinean borrowings which originated in the crises described above had all been repaid. There is a striking parallel here with the end of the 1980s, when the Fund's stock of outstanding loans to emerging markets was also quite modest. At that time, the Latin American arrangements that had originated in the crisis years 1980–83 had been repaid. But, just as then, risks remain; the international community must remain engaged in the task of ensuring that the Fund is prepared to respond to and manage crises when they occur.

Dissatisfaction with the Fund's crisis management in the 1990s and early 2000s cast a long shadow over the Fund's relations with many emerging-market economies, which may have some consequences. A number of East Asian countries, over the ten years following the East Asian crisis, accumulated in excess of a trillion US dollars of reserves. This massive reserve accumulation reflected a persistent excess of saving over investment across these economies, which may, at least in part, represent a conscious choice to amass reserves as a form of self-insurance against future crises. These countries went about a pooling of some of these reserves into a common fund, a process which began in 2000 when ASEAN, Japan, China and the Republic of Korea agreed to set up a bilateral currency swap scheme known as the Chiang Mai Initiative. There were some suggestions that this might one day form the basis of an Asian regional alternative to the IMF that would be designed to help these countries to co-insure and spread risks. But taking this step would require difficult decisions by these countries in order to make surveillance between the pool's members effective and enforceable.

And such a common pool of reserves might also create its own form of moral hazard if it were to encourage countries to take excessive risks with foreign borrowing.

The IMF and Low-Income Countries

Until the mid-1970s, the Fund's work in its role as coordinator and monitor of the international monetary system was concerned mainly with monetary, exchange-rate and trade issues. To the extent that the IMF also functioned as a credit union for countries in balance of payments difficulties, its lending focused on the provision of short-term, self-liquidating loans to buttress central banks through temporary balance of payments difficulties. The Fund's cornerstone principle of equal treatment of member countries dictated that finance to low-income countries was provided largely under stand-by arrangements on the same terms as those approved for emerging markets and industrialized countries. The oil crises of the 1970s, however, made it increasingly clear that intractable structural issues in many low-income countries needed to be tackled if balance of payments difficulties were to be addressed. As a result, the 1970s saw a lengthening of the average maturity of stand-by arrangements in both emerging markets and low-income countries, accompanied by the advent of lending on concessional terms, with lower interest rates, to low-income countries. This created some tension between the Fund's essentially monetary character and its deepening role in the provision of longer-term resources in support of broad macroeconomic adjustment in developing countries.

In order to provide member countries with more breathing room to enact structural economic reforms, the Fund created a series of new lending instruments from the mid-1970s onward. The first amongst these, the Extended Financing Facility (EFF), provided greater financing and longer maturities than traditional stand-by arrangements, but its terms were not concessional. The Fund's Articles of Agreement did not provide for the use of IMF resources for concessional lending to a subset of the Fund's membership, and the EFF's market-linked interest rates were identical to those of other Fund arrangements. An EFF did, however, typically carry more stringent conditionality than a stand-by arrangement in response to concerns that the EFF's greater financing implied a need for greater adjustment.

The obstacle to financing concessional lending posed by the Fund's Articles was overcome in the 1970s by the solicitation of donor funds and the sale of a portion of the IMF's gold. Concessional IMF lending began under the 1975 Oil Facility Subsidy Account, in which contributions from 25 countries were used to reduce the interest cost of borrowing from a Fund facility set up to assist countries deemed to have been most severely affected by the sudden rise in oil prices. In the following year, the IMF created a Trust Fund for all low-income countries out of profits from the sale of a portion of the Fund's stock of gold. The Trust Fund offered long-term low-interest loans to low-income countries from 1976 until its resources were fully committed in 1981. Borrowing under the Trust Fund was similar to financing under the first credit tranche: in order to obtain financing, low-income countries had only to demonstrate a balance-of-payments need and explain the efforts they were taking to reduce it.

These new financing windows provided concessional loans to developing countries, but it was feared that the weak conditionality attached to these loans did not induce sufficient adjustment (Boughton 2001). In the early to mid-1980s prices for many primary commodities collapsed, and several developing countries faced new external balance of payments challenges. The Fund moved to reinvigorate its concessional lending by using the repayments of Trust Fund loans to finance a new round of concessional credit under what, in 1986, came to be known as the Structural Adjustment Facility (SAF). The SAF marked a determined attempt by the Fund to integrate concessionality with conditionality. In part, this twinning of concessionality with conditionality allowed the Fund to lobby for new donor loans and grants, which expanded the SAF some threefold into the Enhanced SAF (ESAF) in 1987.

Boughton (2001) contends that the ESAF became one of the IMF's great success stories, as

it allowed the Fund to send billions of dollars to the world's poorest counties on concessional terms with longer maturities than was possible under previous IMF facilities. (See also Tarp 1993.) The ESAF also had a catalytic effect on lending from other official creditors, and IMF collaboration with the World Bank and the regional development banks, as well as with, inter alia, the UN, UNICEF, UNDP and bilateral donors, all appeared to improve under the ESAF process (Boughton 2001). In addition, IMF technical assistance to many developing countries on monetary, fiscal, and trade policy, as well as debt management, also expanded substantially in order to help countries achieve their programme commitments. This increase in technical assistance has been very valuable.

Despite these gains, and even although the ESAF was technically distinct from the Fund's general resources, some critics have charged that the ESAF marked an unfortunate departure from the Fund's monetary focus. Others have questioned the strict conditionality on adjustment agreed under ESAF-supported programmes, especially because some of the structural conditions have appeared to intrude on the traditional territory of the World Bank. In reply it might be said that this has happened partly because the Bank has not proved capable of devising appropriate macroeconomic conditions for its own loans. (See Gilbert and Vines 2000.)

Despite the Fund's efforts – both to revive its concessional lending in 1986 and 1987 and to increase its accompanying technical assistance – it was clear by 1988 that many low-income countries would find it impossible to grow without debt relief. Under the auspices of the Paris Club of bilateral creditors, a series of progressively more concessional refinancing terms for bilateral debts were agreed from 1988 onward, for both emerging market, and relatively poor, indebted countries. Nevertheless, even with this bilateral debt relief, many low-income countries had trouble meeting the payment obligations on their standby arrangements and EFFs. But the absence of a serious lobby of private creditors (most low-income countries' external debt was owed to the Paris Club and other public creditors) may have delayed efforts to find a comprehensive solution to the debt problems of developing countries until the late-1990s.

By the 1990s, the Fund's engagement in low-income countries had become the target of a rising chorus of concern. Some civil society organizations and academics, as well as some low-income governments themselves, contended that IMF conditionality and programme design in low-income countries tended to prioritize adjustment over poverty reduction, growth, and income distribution concerns. This criticism is summarized by Easterly (2005). It arose despite the fact that the Fund has been helping to produce, in many low-income countries, a marked stabilization in macroeconomic indicators, and in some cases the beginning of sustained periods of growth. In response to critics' concerns, and in a further step in the evolution of Fund lending, IMF Managing Director Michel Camdessus advocated in the mid-1990s a fresh model of engagement with low-income countries in which there would be a renewed role for the Fund in reducing global poverty and in promoting high-quality growth in developing countries.

This new strategy featured three main elements. First, along with bilateral donors and other international financial institutions, the Fund recognized that catalysing growth in low-income countries would require more profound debt relief, including treatment of previously unrescheduled multilateral concessional debt. The 1996 Heavily Indebted Poor Countries' (HIPC) Initiative represented the concerted efforts of the international community to address the external debt overhang in poor countries; the Initiative was later enhanced in 1999 to provide deeper and faster debt reduction. The HIPC Initiative was novel, particularly in that debt relief was explicitly tied to plans to spend debt-service savings on poverty-alleviating social expenditure. From 1999, these plans were articulated in a country-based Poverty Reduction Strategy Paper (PRSP). This approach, initiated by the Fund in conjunction with the World Bank, formed the second prong of the Fund's renewed engagement with low-income countries. The PRSP approach aimed to provide a clear country-owned link between national policy frameworks, donor

support, and development outcomes. The PRSP approach also dovetailed neatly with the United Nations' Millennium Development Goals (MDGs). These goals were articulated at the UN Millennium Summit in 2000 and were centred on halving global poverty by 2015. The PRSPs were also intended to form the basis of the targets and policy conditions in programmes supported by the IMF's Poverty Reduction and Growth Facility (PRGF). This was the successor in 1999 to the ESAF and formed the third element of the Fund's new approach to low-income countries.

The results of these initiatives by the early 21st century were mixed. Reviews of the PRGF by IMF staff in 2002 (IMF 2002b) and by the IMF's IEO in 2004 (IMF 2004b) found that PRGF-supported programs had become more accommodating to higher public expenditure, in particular pro-poor spending. Nevertheless, a review of PRGF programme design by the IMF Executive Board in September 2005 (IMF 2005c) found that per capita income and growth rates remained low despite some improvements in a range of macroeconomic indicators. More recently, the IEO found in its evaluation of Fund engagement in sub-Saharan Africa (IMF 2007b) that the PRGF and PRSP approaches had not had a significant positive effect on catalysing new aid flows. This is despite the fact that commitments to increase such flows were made in 2002 under the 'Monterrey Consensus' and at the Gleneagles G8 summit in 2005. The IMF's Spring 2007 *Regional Economic Outlook* noted, however, that Sub- Saharan Africa's growth performance since 2004 had been the best in more than three decades (IMF 2007d). In sum, the impact of the PRGF and PRSP on aid and spending in low-income countries remained inconclusive, but their growth effects appeared increasingly positive by 2007.

The advent of the HIPC Initiative, the PRSP and the PRGF together intertwined the work of the IMF and World Bank in developing countries to an unprecedented extent. The Multilateral Debt Relief Initiative (MDRI) agreed at the Gleneagles G8 Summit in 2005, and which provided a framework for the write-off of nearly all remaining HIPC-country debts to the IMF, World Bank and African Development Bank, represented a major step forward in this collaboration. While the MDRI drew a welcome line under the multilateral debt relief process, it left several questions about the next phase of IMF and World Bank support for low-income countries unanswered. Having written off so much concessional debt, the MDRI implied that future multilateral support for low-income countries should be provided only as grants, not loans. The source of financing for such grants remained unclear. And in some cases, financing, whether by grants or loans, may not be the most crucial contribution that the international financial institutions could make to development. The Fund's 2005 Policy Support Instrument (PSI), essentially a 'no money' programme, acknowledged that Fund macroeconomic advice, rather than short-term balance of payments financing, might be a valuable channel of support for developing countries. These matters have been complicated by the growth of 'South–South' flows in development assistance from new donors such as China and Brazil. These flows have raised doubts about the future necessity of concessional financing from the Bretton Woods institutions. But they have also called into question the conditionality that comes attached to IMF and World Bank money. Such financing from non-traditional donors could also complicate future debt restructurings, should they prove necessary, since most new donors have not been members of the Paris Club.

Throughout this section we have noted the latent tension between the Fund's monetary character and its long-term support for low-income countries. This tension is heightened by the intertwining of the work of the Fund and the World Bank, which we have just reviewed. The report of the external review committee on Bank–Fund collaboration (IMF 2007c) provided some suggestions on strengthening Bank–Fund collaboration, while reducing overlap between the two institutions.

The Future of the IMF: Next Steps

In mid-2004 the Fund's Managing Director, Rodrigo de Rato, launched a review of the role of IMF in light of the challenges posed by a

changing and increasingly complex global economic system. Stemming from this review, De Rato presented the aforementioned Medium-Term Strategy for the Fund (IMF 2005b) to the World Bank–IMF Annual Meetings in September 2005, and shortly thereafter followed up with a plan for the Strategy's implementation (IMF 2006b). The plan focused on specific proposals to ensure that the Fund:

- Provides more effective surveillance and better monitoring of policies in advanced economies, with a renewed emphasis on exchange rates;
- Provides better monitoring of emerging markets economies, re-explores financing mechanisms to help prevent crises, and reconsiders issues regarding capital account liberalization;
- Enhances the role of IMF in low-income countries, and sharpens its focus;
- Reforms IMF governance, particularly country representation; and
- Restructures the IMF's own budget, including by broadening the Fund's income base, and its management practices.

The plan also expressed an intention to expand the role of the IMF as a provider of technical assistance and training, while improving Fund communications and transparency to ensure that the Fund would play a more central role in global policy debates.

The Fund's Medium-Term Strategy is a clear response to the three dominant tasks it has assumed following the collapse of the Bretton Woods system of fixed exchange rates in 1971, tasks which we have reviewed in Sections 3–5 of this article. But if the Fund is to be able to act effectively in relation to these tasks it will need to have: (i) a better system of governance; (ii) a more secure and robust source of income so that it can cover its operating expenses; and (iii) a larger stock of resources to lend for crisis prevention and resolution. We conclude this article by briefly discussing these three issues. (See also Lane 2006.)

Governance

The first subsection of the Fund's Articles of Agreement made clear that its founding purpose was 'to promote international monetary cooperation through a permanent institution which provides the machinery for consultation and collaboration on international monetary problems'. At the time of the Fund's creation, most countries stood a reasonable chance of alternating between being a creditor to and borrower from the Fund over time. Since then, the ranks of creditors and borrowers have diverged as industrial countries have stopped using IMF financing, a role which has instead been filled by emerging market economies and low-income countries. A number of reformers such as Woods (2006) argue that the Fund's capacity to facilitate solutions to international monetary problems depends on the Fund's decision-making structure being made more reflective of the interests and voices of the emerging markets and developing countries which borrow from it, and which see their public policy frameworks at least partly determined by Fund conditionality. The demand for such reform is bolstered by the fact that the relative distribution of quotas, which determine the voting power in the Fund, has become separated from the relative economic (and political) weights of many emerging markets in the global economy. In addition, the relative power of basic votes, which were intended to provide some measure of fairness to poorer countries, has been substantially eroded relative to the contribution of quotas to voting weights at the Executive Board. The ad hoc provision of increased quota shares to China, Korea, Mexico, and Turkey in 2006 under the Fund's Medium-Term Strategy was a first step toward realigning voting power in the Fund with emerging markets' growing share of the world economy; further steps will be more difficult since increased voting shares for some countries will inevitably mean painful decisions to reduce the shares of others. It may, however, be possible for countries to change the way in which the 24 chairs on the IMF's Executive Board are allocated in order to compensate partly for changes in relative voting shares.

Changing the Fund's voting structure would not in and of itself alter the way in which the Fund operates, suddenly making it better able to deliver on the objectives set out in its 2005

Medium-Term Strategy. De Gregorio et al. (1999); King (2006a, p. 12); Dodge (2006a, b) and Kenen (2006) have all argued, however, that parallel changes in the Fund's governance arrangements might help the Fund in its push towards these objectives.

One proposal would put the responsibility for the delivery of improved policies more firmly in the hands of the management of the IMF. Up to 2007, the Executive Board of the Fund had involved itself in day-to-day reviews of Article IV reports, approved all lending decisions, and reviewed the design of the Fund's lending programmes. Stepping back from this activity would enable Directors to pay proportionately more attention to strategic issues. That would move the governance structure of the Fund closer to the relationship between management and advisory boards that one sees in the private sector, where non-executive directors bring dispassionate external views to broad questions of corporate operations and strategy, and clearly delegate day-to-day operations to management.

Evolution in this direction could strengthen the accountability of the Managing Director and his Deputies. In one version of this type of arrangement, all of the Managing Director, the Deputy Managing Directors, and Department Directors would report on a regular basis to the Board, but Executive Directors would be more removed from many of the day-to-day decisions of the institution. Doing this could have an effect – even if only implicit or indirect – on the Fund's ability to function better in its pursuit of more dispassionate surveillance. It might also lead to more effective crisis prevention and resolution through a careful balancing of debtor moral hazard and creditor moral hazard in Fund lending; and also to a clearer focus in the Fund's work with low-income countries.

A move to a non-resident Executive Board would draw a clearer line between the work of Directors and management. Such a move would leave the Managing Director in control of the execution of the Fund's work since the Executive Directors would give only part-time oversight and direction. Making this change would take the governance of the Fund closer to Keynes' original vision. (See King 2006a.) Directors would be the senior public servants that steer policy in their national capitals, and not, as in 2007, their proxies resident in Washington. In contrast with 1946, the ease of modern travel makes a non-resident Board, with meetings some six to eight times a year, entirely feasible. Any move in this direction would, however, need to ensure that the nexus of communication between capitals, which the Board currently provides, is preserved in some other way.

Income

In May 2006, the Managing Director established a committee (the 'Crockett Committee'), chaired by a former General Manager of the Bank for International Settlements, Andrew Crockett, to study options for sustainable long-term financing of the IMF. The Committee's report, released on 31 January 2007 (IMF 2007a), argued that the IMF's current funding model was unsustainable and that a more diversified income stream needed to be developed in order to guarantee the institution's financial future.

The IMF's revenue stream had been primarily based on income derived from its lending for crisis resolution (IMF 2007a, Annex 2, p. 2). This financing mechanism was not entirely appropriate, because, as Crockett said during the press briefing to launch the Committee's report, 'it's a concentrated income source … It's volatile, because when the Fund is lending a lot. . .it generates large resources. When the Fund is not lending, it doesn't generate resources.' In a low-lending environment, as existed in the early 21st century, the Fund's income model appeared untenable over the longer term; in the shorter term, it could also be inconsistent with sound incentives to minimize moral hazard in Fund lending.

The Committee considered some alternative sources of income for the Fund. In assessing these possibilities, the committee observed that the Fund's activities could be broken down into three types of functions that cut across the full membership of industrialized countries, emerging markets, and low-income economies: financial intermediation, the provision of global public

goods (for example, data, standards and codes, and combating terrorist financing), and the provision of bilateral services, in the form of capacity building and technical assistance.

The Committee concluded that revenue from Fund lending should be sufficient to cover its ongoing costs arising from financial intermediation. The Committee also noted that this income should not be used to cross-subsidize the provision of global public goods because (i) this income was too volatile for this purpose and (ii) cross-subsidization could cause IMF lending to become too expensive compared with private financing.

In order to ensure that the Fund could continue to provide its key global public goods, the Committee noted that the Fund could, like the United Nations, assess a periodic levy on member countries. The Committee did not, however, favour this source of income, as it 'would risk politicising the activities of the Fund' by making its work subject to regular financing calls. Nevertheless, the Committee did note that charging fees for some services might generate a small amount of additional revenue.

The Committee's core proposal concerned the creation of an endowment for the IMF that would provide a reliable income stream without relying on annual requests to member countries. The Committee suggested a further sale of IMF gold as a possible source of endowment funds. Such sales had been mooted at various points in the past for a variety of purposes; this was done to finance the establishment of the trust funds that underwrote the 1996 HIPC Initiative. But other plans for such sales have usually failed to gain enough support in the face of opposition from the United States and from gold-producing countries. To allay these fears, the Committee report suggested a 'balanced' approach, in which the Fund would also invest some of its quota resources in highly rated securities so that the burden of creating an investment endowment would not fall exclusively on the sale of gold.

As this article was being drafted, discussion was continuing on the exact form an endowment for the Fund could take. In meantime, the Fund had begun to invest some of its retained earnings from lending in investment grade securities in an effort to supplement its income.

Resources

The relative size of the Fund shrank markedly from the 1970s ownard in comparison with, inter alia, global reserves, international trade, financial flows, stocks of financial assets and world output. This decline in pecuniary stature has distorted some of the debates about the Fund's work, most notably on creditor and debtor moral hazard. Much of the debate over the implications of jumbo or 'exceptional access' arrangements in the 1990s (arrangements in which lending was equivalent to 300 per cent of quota or more) would be moot if regular quota increases had maintained the Fund's relative size in the global economy. Indeed, had the Fund grown through regularly scheduled quota increases, very few of the arrangements of the 1990s and 2000s would have been deemed at all exceptional. This suggests a simple yardstick for an appropriately-sized IMF: at any given time, the sum of the Fund's quotas should enable a risk-adjusted subset of its membership to borrow from the Fund on non-exceptional terms to finance their adjustment needs.

Accepting the validity of such a yardstick depends critically, however, on one's ultimate view of the role the IMF should play in the international system: trusted macroeconomic advisor, catalyst for private capital inflows and foreign assistance, or potential lender of last resort at time of crisis? To some extent the Fund played all of these roles at the turn of the 21st century, though its reduced relative size meant that the lender-of-last-resort function was credible only for its smaller members. The Fund staff, its shareholders, and those who care about the future of the multilateral system will need to decide which of these roles the IMF should continue to play.

International Monetary Institutions

Stanley W. Black

Abstract

International monetary institutions are required to support payments arrangements between countries with different currencies and exchange rate arrangements. Reserve assets and adjustment and financing mechanisms are provided to assist markets in balancing conflicting objectives including economic growth and price stability, growing international trade and payments, and convertibility of currencies at reasonably stable exchange rates. The evolution of the Bretton Woods system has proceeded through floating exchange rates, increased capital mobility, financial crises, and various reform proposals. The development of regional monetary institutions has led to creation of the European Monetary Union and some steps towards increased Asian monetary cooperation.

Domestic money is conceived of by society as a device to facilitate transactions in the marketplace, as a temporary store of value, and as a unit of account for contracts. Given the possibilities of fraud and counterfeiting, domestic monetary authorities have been established to regulate

the quality of the domestic monetary unit in most countries. Such regulations attempt to guarantee the interchangeability of the different media, such as currency and the deposits of different banks, as well as stability in the value of the monetary unit, under conditions of prosperity.

International monetary arrangements are required under conditions of international trade when residents of different countries must make payments to each other, and yet wish to hold most of their assets in terms of domestic currency. Such arrangements are designed to guarantee *convertibility* of assets denominated in different currencies, so that payments may be made independent of country of residence, thus facilitating a free and open trading system. International monetary *institutions* such as the International Monetary Fund are designed to support international monetary arrangements by enforcing rules of behaviour, assisting countries in difficulties, and encouraging good practices.

Alternative Exchange Rate Mechanisms

Under a *gold standard,* domestic residents and foreign residents may freely convert domestic currency into gold at a fixed rate of exchange. This type of convertibility was eliminated in the 1930s in favour of a gold *exchange* standard, which allowed only foreign monetary authorities to exchange domestic currency for gold. Gold convertibility of both types was ended as part of the Smithsonian Agreement of 1971 (see below).

Under a system of *pegged* exchange rates between different currencies, as established by the Bretton Woods system (see below), convertibility implies that domestic residents are free to obtain foreign currency at a *fixed* rate of exchange for the purchase of foreign goods and services, inclusive of normal trade credit. Likewise, foreign residents are free to sell domestic currency obtained by sale of goods and services or to use it for purchase of domestic goods and services, at the same fixed rate of exchange. This definition does not require free convertibility for capital account transactions (those arising from exchanges of financial assets only).

Under a system of floating or flexible exchange rates, convertibility still implies that both domestic and foreign residents may freely convert domestic and foreign currency at the same rate of exchange for current account transactions, but the exchange rate at which this may be done is determined on a daily basis by market transactions, rather than being guaranteed by the domestic monetary authorities of the respective countries.

In 2005, only 20 out of the 184 member countries of the International Monetary Fund (IMF) declined to accept the obligations to current account convertibility. But in a large number of countries various types of restrictions limited convertibility in some way or created differences in the exchange rates applying to exports and imports. Non-unified exchange rates lead to inefficient allocation of resources, as previously documented by Bhagwati (1978). For example, 70 countries required repatriation and surrender of proceeds of exports or invisible transactions, 57 countries had payments arrears of one kind or another, and 11 countries maintained either dual or multiple exchange rates for different types of transactions. With respect to capital account transactions, the situation is much more restrictive: 126 countries had controls on international transactions in capital market securities, and 143 countries maintained controls on direct investment flows.

Reserve Assets

In order to guarantee convertibility of the domestic currency into other convertible currencies, monetary authorities hold stocks of *reserve assets*, which are liquid assets held in readily accepted international media of exchange, such as dollars, euros, and a few other currencies. In addition, IMF member countries have access to unconditional borrowing rights to obtain additional reserve assets in the form of their reserve positions in the Fund and Special Drawing Rights. These, together with reserve asset holdings, make up *international liquidity.*

Since most international payments are handled by inter-bank transactions, banks have sought to

minimize transactions costs by channelling their foreign exchange transactions through one or more *vehicle* currencies, the pound sterling in earlier days, but more recently the US dollar and to some extent the euro. Because the dollar is so widely used in private exchange transactions, monetary authorities also find it convenient to operate in dollars to ensure the convertibility of their currencies.

Adjustment Mechanisms

The existence of different national currencies and the need to maintain convertibility of the different currencies lead to the concept of balance of payments adjustment mechanism. At a given exchange rate, as long as the amount of foreign exchange earned through exports of goods and services and capital inflows just pays for imports and capital outflows, no external imbalance exists. If international capital markets were perfect and if investors were risk neutral so that assets denominated in different currencies were perfect substitutes for one another in private portfolios, there would in practice be a single world interest rate for short-term borrowing. Then imbalances between foreign exchange earnings and payments could simply be *financed* by borrowing in the international capital market. There would be no real distinction between the convertibility characteristics of the official liabilities of different borrowers.

But, in fact, countries face very real limits on the amount of foreign currency they can borrow abroad in exchange for domestic currency because of *exchange rate* risk, which limits the willingness of risk-averse foreign lenders to acquire domestic currency assets. According to the doctrine of *original sin,* countries with a history of convertibility problems are unable to issue foreign debt in their own currency (Eichengreen and Hausmann 2005). The ability to repay foreign currency debt is dependent on balance of payments adjustment. *Political* risk involves the possibility that exchange controls may be imposed in the future, preventing the repayment of foreign currency debt on the promised terms. Thus it is desirable for countries to have access to a variety of adjustment mechanisms to eliminate external imbalances, as well as a variety of sources of official financing in the form of international liquidity. The primary mechanisms of balance of payments adjustment are through movements in exchange rates and adjustments of income and price levels via monetary and fiscal policies. The need for adjustment can be postponed by imposition of tariffs and subsidies, quantitative restrictions on current account or capital account transactions, or controls over the allocation of foreign exchange. But tariffs, quantitative restrictions, and exchange controls generally involve inefficiencies in the allocation of resources, including in the latter case loss of convertibility of the domestic currency. Changes in monetary and fiscal policies or exchange rates have their own costs in terms of domestic policy objectives forgone.

Financing

Thus, a mixture of adjustment policies and financing mechanisms is provided in a system of international monetary arrangements. *Official* financing is provided either by drawing on holdings of official reserve assets or by borrowing from international institutions. *Private* financing can be arranged by a monetary authority borrowing from foreign banks or the international bond market. Either provides the ability to postpone adjustment. The optimum mix of adjustment and financing for an individual country depends on the costs of the various alternatives. By setting the costs of these alternatives, international monetary arrangements influence the behaviour of the world economy.

A Model of Adjustment Versus Financing

In the theory of adjustment versus financing, a country is faced with random balance of payments deficits and surpluses, which it may either finance by drawing on reserve assets or adjust by one of the adjustment mechanisms mentioned above. In one branch of the theory, due to Heller (1966) and others, the cost of adjustment is assumed to be a

linear function of the size of the adjustment, so that any adjustments are postponed to the last minute, at which time full adjustment takes place. Alternatively, one may assume a nonlinear cost of adjustment, leading to a theory of partial adjustment. Kelly (1970) and Clark (1970) assume that the country's welfare function depends on the mean and variance of income, so that gradual adjustments are preferred. The analysis determines both the optimum level of reserve holdings, R^*, and the optimum rate of adjustment α to that level, according to the equation

$$\Delta R = \alpha[R^* - R_{-1}] + u, \qquad (1)$$

where u is normally distributed with mean zero and variance σ^2 and $R_{-1}$is the stock of reserves at the end of the previous period. This equation assumes that changes in the stock of reserves arise from both the random shocks in the balance of payments and the desired rate of adjustment to the optimal level of reserves. From Eq. (1) we find that the variance of reserve holdings decreases as the speed of adjustment α increases from zero to one.

Tchebychev's inequality then enables one to show that, for a given probability of not exhausting reserves and given opportunity cost r of holding reserves, the optimum reserve holding R^* decreases with increasing α. As α increases, the need for more frequent adjustments raises the variance of income. Therefore the speed of adjustment should be chosen such that the welfare loss from increased variance in income due to a small increase in α is just counterbalanced by the welfare saving due to holding slightly smaller reserves.

According to this theory, international monetary institutions will strongly affect the behaviour of national policies concerning balance of payments adjustment and acquisition of reserves. Specifically, international money institutions will determine the opportunity cost of holding reserves, the penalty attached to running out of reserves, and the availability of different types of adjustment policies. By influencing countries' balance of payments adjustment policies, international institutions will also influence their domestic policies, since there is a trade-off between internal and external objectives of policy.

The Role of Markets and Institutions

An optimal design for the international monetary system depends on balancing among a group of conflicting objectives: growth of real income and employment, stable prices, efficient allocation of resources, maintenance of convertibility of currencies, improving the distribution of income, and growth of world trade. The relevant trade-offs can be understood in the context of an economic model. According to the model of adjustment and financing outlined above, reductions in the opportunity cost of holding reserves will lead to increased reserve holdings, a reduction in the speed of adjustment to imbalances, increased use of financing, and a decline in the variability of income. The slowdown in the speed of adjustment implies a change in the allocation of resources among countries. The increased use of financing may imply an increase in the rate of inflation. An optimal international system should balance these various considerations. For discussion of efforts to design such a system, see Solomon (1982) and the documents of the IMF's Committee of Twenty (IMF 1974).

In a purely laissez-faire system, market borrowing instead of official reserves would be the source of financing to postpone adjustment. Fluctuations in market interest rates would determine the terms of trade between adjustment and financing. As is usual in market solutions, the wealthy are in a better position to negotiate terms on loans. By contrast, a more institutionalized system provides access to financing at lower rates to those with a weaker market position, with more conditions on the use of the funds. Evaluating the difference between two such systems is a complex task. For an attempt, see Jones (1983).

The Evolution of International Monetary Institutions

Between the close of the Napoleonic Wars and 1880, the international monetary system gradually

moved onto the gold standard, which was fully achieved during the period 1880–1914. Under the leadership of Great Britain, sterling operated as a vehicle currency during this period, allowing an efficient international payments mechanism to develop. The increasing substitution of bank deposits for currency allowed an ever-larger volume of payments to be supported by a gradually rising supply of gold. Despite the best efforts of the Bank of England and other central banks, periodic crises interfered with the continued convertibility of individual currencies. And the system was characterized by substantial fluctuations in employment and prices, albeit about a rising trend of employment with no trend in prices.

Following the First World War, gold convertibility was resumed on a limited basis, until the Great Depression of 1929–33 brought it to an end. A period of fluctuating exchange rates, competitive devaluations, and increasing use of trade restrictions to promote domestic employment ensued. It is generally believed that the economic difficulties of the interwar period were major factors bringing on the Second World War.

The Bretton Woods System

The United States and Great Britain took the lead in constructing the post-war international monetary institutions, with Harry Dexter White and John Maynard Keynes drawing up rival designs for the new system agreed at the Bretton Woods Conference in 1944. The Articles of Agreement of the International Monetary Fund provided for a system based on pegged, but adjustable, exchange rates and an institution which would lend reserve assets to countries that were having temporary difficulties in maintaining convertibility. Resort to floating exchange rates, competitive devaluations, and trade restrictions to promote domestic employment were explicitly to be avoided, in the light of the problems of the 1930s. Convertibility for current account transactions was promoted, while capital account convertibility was required only for those transactions necessary for financing current payments.

The lending power of the IMF was based on *quotas* of gold and domestic currency contributed by each member country. Only the gold was to be paid in initially, but, if the Fund needed convertible currency to lend out, it would obtain it from any member whose currency was considered strong enough to be *usable.* Members could borrow automatically up to the amount of the gold portion or *tranche* of the quota, but only on demonstration of balance of payments need, and thereafter they could borrow more subject to meeting conditions on economic and financial policies. For further discussion of IMF policies, see Williamson (1983), Kenen (2001), and Truman (2006).

The initial post-war problem involved the establishment of a payments system that would promote economic recovery and the growth of trade among the former combatants. The International Monetary Fund limited itself to establishing a set of agreed par values for pegged exchange rates which could promote the growth of trade, leaving the provision of loans and grants for economic recovery to the United States, the strongest economy. Under this system, which was a form of gold exchange standard, countries declared their par values in terms of the US dollar, which in turn was convertible into gold at $35 an ounce. Thus the dollar became the key currency of the system, and most foreign exchange reserves came to be held in the form of dollars. Within Europe, convertibility remained limited until 1958, and the European Payments Union was established to facilitate intra-European payments. The re-establishment of convertibility led to fears that the IMF might have inadequate resources to deal with the problems of large member countries. In 1962 the General Arrangements to Borrow were created, to enable the Fund to mobilize additional resources from its largest members, the Group of Ten.

With the recovery of the European economies in the 1950s and the achievement of convertibility in 1958, the US dollar became gradually overvalued relative to gold and other currencies. As Robert Triffin (1960) pointed out, the key currency system required the United States to continue to run balance of payments deficits in order to supply other countries with increased foreign exchange reserves. As it did so, the gold reserve of the United States became increasingly inadequate

to guarantee gold convertibility of growing US official dollar liabilities at $35 an ounce.

A variety of solutions to this problem were proposed, including the creation of an artificial reserve asset to substitute for dollars, an increase in the dollar price of gold, and the adoption of floating exchange rates. In 1968 the First Amendment to the Articles of Agreement of the International Monetary Fund permitted the creation of Special Drawing Rights (SDRs), which have twice been allocated to member countries in proportion to their existing quotas in the Fund. SDRs, when utilized, permit the user to acquire convertible currencies from other members, upon the payment of interest. They represent a centralized mechanism for increasing the stock of reserves. By the early 1970s the gold convertibility of the dollar was under increasing pressure, for a variety of reasons. In August 1971 the dollar was unilaterally set loose from gold. The Smithsonian Agreement of December 1971 attempted to save the Bretton Woods system by multilateral realignment of exchange rates, including a devaluation of the dollar against gold and a widening of the narrow bands of fluctuation permitted around the newly fixed values. Some members of the European Communities (EC) agreed to maintain narrower margins of fluctuations versus each other's currency, in an arrangement that became known as the 'EC Snake'. Despite these efforts, the revised Bretton Woods system lasted only a little more than a year.

Floating Exchange Rates

In March 1973, exchange rates of most of the major industrial countries began floating. At the same time, most developing countries continued to peg their currencies to the dollar or another developed country currency, and the EC maintained the 'Snake'. About this time, a major effort to reconstruct international monetary institutions on the basis of pegged exchange rates began under the auspices of the IMF's Committee of Twenty. This effort collapsed in 1974, in part under the impact of the quadrupling of world oil prices by the Organization of Petroleum Exporting Countries.

In Jamaica in January 1976, the Interim Committee of the Board of Governors of the International Monetary Fund agreed on a Second Amendment to the Fund's Articles of Agreement, ratifying the system of floating exchange rates. First, stability of exchange rates was to be sought through stability of underlying monetary and fiscal policies rather than through pegging. Second, floating rates should be subject to a process of 'firm surveillance' by the IMF. Third, it was hoped that the SDR would 'become the principal reserve asset', with the role of gold and the dollar being reduced. Fourth, the fixed official price of gold was abolished and one-third of the IMF's gold was disposed of. Acceptance of the status quo was all that could be accomplished. The result, according to Corden (1983), was an international laissez-faire system.

In 2005 some 88 countries made use of floating exchange rates, while 51 had pegged exchange rates of one type or another and 48 operated within currency unions with other countries.

Increased Capital Mobility, the Asian Crisis and Reform Proposals

Beginning in the 1970s, international capital mobility increased significantly, as middle-income developing countries found new access to foreign borrowing and industrialized countries increasingly opened production facilities in each others' markets. In the early 1990s, the IMF began discussions of a possible amendment that would promote capital account convertibility as an additional goal of the international monetary system, on the argument that improved allocation of capital would lead to increased economic growth. But a series of crises in emerging market economies interfered with this project, most notably the Asian financial crisis of 1997, followed by the Russian crisis of 1998 and the Argentine crisis of 2001. Each of these events was preceded by substantial capital inflows seeking higher returns, which overwhelmed underregulated and underprepared domestic economies and financial systems. The convertibility of affected currencies was often temporarily impaired (Black et al. 2006). In some cases the IMF was seen as creating a permissive environment prior to the crisis, followed by harsh demands for domestic reforms subsequently, in

attempts to restore confidence and bring an end to capital outflow.

A substantial body of criticism on one side argued that, by its willingness to provide large amounts of financing to countries in crisis, the Fund had created 'moral hazard', encouragement to over-borrowing and over-lending in expectation of a bailout (International Financial Institution Advisory Commission 2000). On the other side, others claim that the Fund by its harsh requirements for reform was stifling economic recovery and growth (Stiglitz 2002). Both of these viewpoints may have had some validity, but in a sense they cancel each other out (see Kenen 2001). The Fund itself proposed creation of an international Sovereign Debt Restructuring Mechanism to assist defaulting countries in negotiations with creditors (Krueger 2003). This was rejected in favour of a more modest approach encouraging the use of collective action clauses in bond indentures requiring minority bondholders to accept terms of repayment agreed to by a majority.

Another criticism of the IMF is that its voting shares and representation appear outdated, as compared with the changing economic importance of different groups of countries (Truman 2006). In particular, large emerging market economies such as China, India, and Brazil are underrepresented, while the European Union countries with 32 per cent of the voting power are overrepresented. Obviously, changes in representation are extremely difficult to achieve, but will still be necessary to remedy a situation in which the rich creditor countries that do not utilize the Fund's resources have disproportionate voting power relative to the debtor nations that have greater need for use of its facilities.

The 'New' Bretton Woods and Asian Monetary Cooperation

Following recovery from the Asian crisis of 1997, countries such as Korea, China, Malaysia, Taiwan and India sharply increased their accumulations of international reserves, as developing Asian countries in total raised their reserves (minus gold) from SDR 414 billion to SDR 1,039 billion between the ends of 1998 and 2004. China, Hong Kong and Malaysia in particular sought to maintain exchange rates pegged to the US dollar, while the other countries managed their floating exchange rates so as to avoid undue appreciation against the US dollar, accumulating enormous reserves in the process. An influential paper by Dooley et al. (2004) argued that this relationship was a new version of the old Bretton Woods system, whereby other countries pegged their exchange rates to the US dollar, enabling the United States to run large current account deficits, while the creditor nations increased their exports to the United States. Alternatively, the vastly increased reserve holdings of Asian countries could be regarded as a precautionary response to insure the availability of financing to avoid the prospect of another sharp adjustment, following the unpleasant experiences of the 1997 Asian crisis.

The combination of increased regional reserve holdings and recent bad experience with internationally supervised adjustment has led Asian countries to embark on steps towards regional monetary cooperation, culminating in the so-called Chiang Mai Initiative for regional currency swaps among the Association of South East Asian Nations (ASEAN) plus China, Japan, and Korea (see Park and Wang 2005). ASEAN members realized that the industrial countries of the Group of Ten had previously used currency swaps among central banks to lend each other money in times of crisis and thus avoid the need for borrowing from the IMF with its conditionality. With growing availability of reserves in Asia, the ASEAN + 3 concluded that they might similarly help each other out in future. Under the leadership of the Asian Development Bank, further steps are contemplated, possibly including an Asian Monetary Fund and an Asian Currency Unit.

The European Monetary Union

The enlargement and strengthening of the EC 'Snake' in 1978, which was in the process renamed the European Monetary System (EMS), gradually led to the creation of the European Monetary Union with a unit of account, the European Currency Unit (ECU). The objectives of the enlarged EMS were to reduce intra-European exchange rate fluctuations, to promote convergence of macroeconomic policies within

Europe, and to reduce European dependence on US monetary policies. Over a period of 15 years, the EMS succeeded in these objectives, at the cost of a series of exchange rate realignment crises culminating in a major collapse of the system in 1992–3, when the narrow margins (plus or minus $2\frac{1}{4}$ per cent) were expanded (to plus or minus 15 per cent). The crisis was brought on by a combination of increasingly rigid exchange rates within the system, increased capital mobility as a component of the Single Market programme of the European Union, and stresses brought on by the unification of East and West Germany.

In response to these factors, and to further strengthen the integration of European markets and achieve a more symmetrical sharing of decision making in monetary policy, the Maastricht Treaty ratified in 1993 brought into being in 1999 the European Monetary Union, with a single currency, the *euro*, with monetary policy controlled by a European Central Bank (ECB) in Frankfurt, Germany, replacing the currencies of the 12 member countries of the eurozone. While the euro has been quickly accepted as an international currency, in both the member countries and their neighbours, the relatively conservative operations of the ECB together with the constraints on member countries' fiscal policy embodied in the Stability and Growth Pact have proven controversial in the light of slow economic growth in the eurozone.

The euro is gradually becoming more important in international transactions and in the foreign exchange market as a rival to the US dollar. In 2006 the IMF redefined the SDR currency basket reflecting the importance of currencies in international trade and finance to be composed of 44 per cent US dollars, 34 per cent euro, 11 per cent Japanese yen and 11 per cent pound sterling, as compared with the previous weights of 45 per cent US dollars, 29 per cent euro, 15 per cent yen and 11 per cent pound sterling.

I

International Monetary Policy

Paul De Grauwe

One of the main characteristics of the international monetary system is the absence of an international monetary authority (central bank) with policy making powers comparable to those central banks have at the national level. Whereas national central banks typically regulate domestic money markets in one way or another, there is no comparable authority to regulate international money markets. As a result, international monetary conditions will be the outcome of a decentralized decision-making process, in which market forces play a role together with the policies of a few important countries. Ultimately, therefore, international monetary relations will be influenced by the nature of the cooperation (or the lack of cooperation) among the central banks of the major countries.

There exist, of course, a number of international monetary institutions with important responsibilities. The most noteworthy are the Bank for International Settlements (BIS), and the International Monetary Fund (IMF). The latter has a major responsibility in providing credit to the countries with balance of payments and foreign debt problems. In addition, this role of the IMF has tended to increase during the last decade. Nevertheless it is fair to say that these institutions are far from having the powers and the responsibility a typical central bank has at the national level. It is also very unlikely that any of these institutions can be promoted to the position of a true world central bank in the foreseeable future.

The absence of a world central bank implies that the international monetary situation will be heavily influenced by the actions of the monetary authorities of the major countries. In fact, the nature of the domestic monetary policy regime in these countries is of crucial importance in the determination of the nature of the international monetary system. It is, therefore, useful to see how these domestic monetary policy regimes have changed over time, in particular in the United States which is the single most important country.

During the early postwar period the prevailing view in the US (and in other industrialized countries) was that the major responsibility of the central bank consisted in maintaining domestic price stability. This view, which originated in the writings of the classical economists, provided implicitly or explicitly the framework for monetary policy making in the major industrialized countries. The spillover of this view and of this policy attitude in the international sphere was a system of fixed exchange rates. The largest country, the US, was successful in stabilizing its price level. The other countries pegged their exchange rates to the US dollar, thereby also obtaining domestic price stability. As a result, during that period (which lasted roughly until the mid-sixties, and which is usually called the Bretton Woods System) the world experienced stable exchange rates and the absence of inflation. This arrangement, however, could only work satisfactorily if the countries pegging to the dollar were willing to subordinate their domestic monetary policies to the maintenance of a fixed dollar rate of their currencies. As the US policy was predicated on maintaining price stability, the willingness of the other countries to impose on themselves the discipline of a fixed exchange rate was great.

This situation began to change when views about the responsibilities of the central bank altered. Instead of being the guardian of a stable purchasing power value of money, the central bank was increasingly seen as an institution responsible for the stabilization of economic activity. This led to problems with the stabilization of the price level, and undercut the basis of the fixed exchange rate system. Inevitably, as countries used monetary policies to stabilize output, inflation rates became more variable and also more different across countries. In the end, fixed exchange rates had to be abandoned, and from the early Seventies on the industrialized countries allowed their exchange rates to float.

The responsibilities of the US in the fundamental change of the international monetary environment have been widely discussed (see e.g. Triffin

1968; Niehans 1974). By abandoning price stability as the major monetary policy objective, the US also transmitted inflationary shocks to those countries pegged to the dollar. As a result, these countries lost their willingness to maintain a fixed exchange rate with the dollar.

These changes in the domestic monetary policy regimes in the major industrialized countries have made exchange rates inevitably more variable than in the Bretton Woods period. This has also led to fundamental changes in the international monetary policy environment. Changes at three different levels can be identified.

A first change concerns the nature of the cooperation of the central banks. During the Bretton Woods period, the discipline of fixed exchange rates forced countries to coordinate their monetary policies closely. In fact, this coordination more or less automatically followed from these pegging arrangements. In addition, since pegging of the exchange rates occurred vis-à-vis the dollar, US monetary policies determined monetary conditions in the rest of the world. Thus, it can be said that the Bretton Woods system was a cooperative international monetary arrangement based on the leadership of the US.

The shift towards flexible exchange rates changed the nature of international monetary cooperation. First of all, as the movements of exchange rates tended to absorb monetary disturbances, the need to coordinate national monetary policies was generally felt to be less urgent. Second, when cooperation took place it tended to be of an ad hoc nature instead of automatic as in the Bretton Woods period.

It has been argued that this lack of explicit cooperative arrangements among the monetary authorities of the major industrialized countries is in itself a factor explaining the high volatility of the exchange rates observed since 1973 (see for example Williamson 1984). Certainly, this volatility of the exchange rates came as a surprise to most academic economists, who had been influenced by the conventional wisdom of the Sixties stressing that a flexible exchange rate system would make a smooth adjustment of external equilibrium possible (see Friedman 1953; Johnson 1967; Sohmen 1961). Those who read the old writers on the subject, however, knew better (see for example Bernholz 1982, for a survey of older views about flexible exchange rates.)

A second major change since the inception of flexible exchange rates concerns the nature of monetary interdependence between nations. Academic opinion prior to the Seventies was that a system of flexible exchange rates would make individual countries more independent in setting domestic monetary policies than a system of fixed exchange rates. In particular, it was thought that flexible exchange rates would allow countries to determine their own inflation rates, so that even when other countries followed inflationary policies, those countries that wanted it could insulate themselves from these foreign inflationary shocks.

These predictions of the merits of flexible exchange rates have been fulfilled only partially. It turned out to be true that countries can select their long-run inflation rates more or less independently if they allow their exchange rate to vary. Thus it was possible for countries such as Switzerland to have an inflation rate of only four per cent per annum during 1973–84 whereas the average in the industrialized countries was more than eight per cent per annum. On the other hand, it also appears that the short-term movements of inflation rates have been more correlated across countries during the floating rate period than during the period prior to 1973. Thus, although countries now have a higher degree of independence in selecting their long-run inflation rates, the yearly movements in these inflation rates turn out to be more dependent on outside price shocks than during the Bretton Woods period.

The reasons for this unexpected phenomenon are twofold. First, the occurrence of flexible exchange rates coincided with major supply shocks during the Seventies which tended to raise the rate of inflation in all countries. Second, the exchange rate regime experienced since 1973 was not a pure floating exchange rate system. Central banks continued to intervene heavily in the foreign exchange markets. They did this in (usually unsuccessful) attempts to mitigate the movements of the dollar. Thus, during the period 1973–78 the dollar declined substantially against

the other major currencies, and central banks bought massive amounts of dollars in order to stem its slide. This had the effect of expanding the money stocks in all these countries and tended to accelerate inflation. Exactly the opposite occurred during the period 1979–84 when the dollar experienced an unprecedented surge, and when central banks sold dollars and deflated their own money stocks.

This system of managed floating produced the curious result that monetary expansions and contractions which originated in the US were transmitted to the other industrialized countries as they would have been under a fixed exchange rate arrangement. And yet the dollar continued to be highly volatile, as these interventions in the dollar exchange markets failed to have much effect on the movements of the dollar. In a sense it can be said that the international monetary arrangement of the Seventies and the early Eighties combined the disadvantages of fixed and flexible exchange rates.

The shift to more flexible exchange rates produced a third major change in the international monetary policy environment. During the Bretton Woods period a major concern of monetary policy makers was control of the creation of international reserves. It was then widely felt that the mechanism of international reserve creation which was implicit in the gold-exchange standard was deficient. The rate of growth of the stock of international reserves (gold and dollars) did not correspond to the needs of an expanding world trade. In addition, the system had the disadvantage of leading to a disproportionate growth of the dollar stock relative to the stock of gold. As a result, a confidence problem arose concerning the ability of the US to maintain the gold convertibility of the dollar (a problem analysed by Triffin 1960, and Rueff 1961).

The 'liquidity problem' of the Bretton Woods system led to numerous schemes to manage the creation of international reserves (for a survey, see Grubel 1969, chapters 7 and 8). Without exaggeration it can be said that in those days the single most pressing issue of international monetary policy was thought to be this liquidity problem. Ultimately, this concern led to the creation of Special Drawing Rights, which were intended to substitute for gold, and which would enable the international community to regulate the creation of international reserves in a more rational way.

With the breakdown of the Bretton Woods system and of the gold exchange standard, these concerns about the creation of international reserves tended to fade away. Whereas in the Bretton Woods era the consensus was that the most important international monetary problem was how to create international reserves, there is now a growing consensus that the single most important issue faced by the international monetary system today is whether the degree of exchange rate variations has not become excessive. Concern that this may be the case has led some economists to propose schemes of coordination of monetary policies of the major industrialized countries, so as to stabilize exchange rates.

The need to come to such explicit cooperative agreements between central banks remains a controversial issue. There are essentially two schools of thought. The proponents of international monetary cooperation (e.g. McKinnon 1984; Williamson 1983) argue that the present flexible exchange rate regime leads to excessive movements of exchange rates, thereby making domestic macroeconomic management, and in particular the stabilization of the domestic price level, more difficult. In this view, cooperative agreements aimed at stabilizing the exchange rates must be given priority in order for countries to stabilize their economies in a more effective way.

A second school of thought turns the argument around and claims that domestic monetary stability comes first. In order to stabilize the exchange rate the monetary authorities of the major industrialized countries must follow more stable and predictable monetary policies. If this is done, the domestic price level can be stabilized so that the exchange rates can follow a more stable and predictable path. (Representative proponents of this view are Willett 1983; Haberler 1977.)

This debate has gone through many cycles in history. During the Twenties, after a period of strong fluctuations of the exchange rates, there was a widely held conviction that the paramount

task in the field of international monetary cooperation was stabilizing the exchange rates of the major currencies. This was seen as a first step towards the successful stabilization of domestic economies (see Clarke 1967, for a history of central bank cooperation during 1924–31). The whole cooperative effort underlying the Bretton Woods system was inspired by the same idea. During the 1960s, as major countries relaxed the monetary discipline needed to sustain a fixed exchange rate system, the view that domestic stability was a precondition for exchange rate stability gained respectability. In the early Seventies this view had become predominant among academic economists. Now, after many years of volatile exchange rate behaviour, the old view stressing the need to stabilize the exchange rates as a first step toward achieving domestic stability has regained some respectability.

The conflict between these two views, however, has not yet been settled. As a result, there is as yet no general agreement on how monetary policy should be conducted at the international level.

International Outsourcing

Deborah L. Swenson

Abstract

International outsourcing involves the import of intermediate inputs or services from unaffiliated foreign suppliers. While it implies that the production of a final product involves production activities in more than one country, this trade in intermediate inputs can be explained by traditional theories of international trade where countries have comparative advantage in different stages of production. However, since outsourcing relationships involve interaction with foreign partners, the choice of organizational form for these transactions is also influenced by industrial organization factors, such as search costs or contract incompleteness. This article discusses these

issues and the effects of outsourcing on the international economy.

In complex production processes firms face a classic make-or-buy question: should they purchase parts, assembly or services from an outside vendor, or perform those tasks themselves? In the domestic context, the benefits and costs of vertical integration are already well understood. However, declines in international transport costs, advances in remote management technologies and improved communications technologies have brought an international dimension to this question, as they have enabled an increasing number of firms to engage in international outsourcing, purchasing parts, assembly or services from unaffiliated international suppliers.

As with trade in final products, international trade in intermediate inputs is shaped by international differences in comparative advantage that reflect cross-country differences in factor costs, or relative productivities for different stages of production. Hence, when firms decide where to complete the production activities required for the creation of a final product – design, materials extraction, parts production, and assembly – comparative advantage influences the ideal country placement for each production stage. However, if there are international frictions, such as international transport costs or tariffs, outsourcing imports will emerge only when the international outsourcing benefits stemming from comparative advantage exceed the costs associated with these international frictions.

Broad examination of international trade data, such as that of Hummels et al. (2001), or Yeats (2001) indicates that international trade in intermediate inputs has grown even more rapidly than the generally large growth in international trade since 1960. This trade in intermediate inputs represents both outsourcing purchases from unrelated suppliers and 'offshoring', which is the import of parts or services from related overseas suppliers, such as foreign subsidiaries. Yi (2003) argues that two key economic factors explain why recent declines in international trading costs have generated such an exceptional increase in intermediates trade. First, trade in intermediates increases along an extensive margin as declines in trade costs enable products that were previously produced domestically to be more profitably produced through an internationally integrated production process. Second, the effects of declining frictional costs are magnified when intermediates trade involves multiple border crossings, since the benefits of falling tariff or transportation charges apply to each border crossing involved in the creation of the final product.

Nonetheless, while international differences in international factor costs provide an incentive for international outsourcing, differences in international factor costs are not sufficient in themselves to guarantee that outsourcing relationships will develop. Thus, there are two strands in the literature on international outsourcing that explain firm choices. The first emphasizes limits on outsourcing that relate to search costs and matching, while the second focuses on the firm's choice of organizational form when contracts are incomplete.

When the search for an appropriate outsourcing partner is costly, firms will search for a foreign partner if the expected increase in profit generated by the search exceeds the sunk costs of searching for an international partner. Thus, Grossman and Helpman (2005) demonstrate that, when the cost of foreign search is particularly high, firms may choose domestic outsourcing in the high-wage home country over foreign outsourcing in the lower-cost foreign country. In addition, if the appearance of potential outsourcing partners is endogenous, the increased demand for partners in a particular location generates a market thickness externality. Since the

entry of potential partners increases the likelihood that searches will be successful, the increase in expected profits in thick markets increases the equilibrium number of searches in the market that becomes more densely populated with suppliers. As a result, search cost frictions, and the market thickness externalities they generate support an international equilibrium in which firms may be indifferent between searching for partners at home and searching for them abroad, even though wages and factor costs are not equalized across countries. In support of these ideas, Swenson (2005) finds that, while costs matter for some US outsourcing decisions, the cost sensitivity is largest for industries that are less capital intense and for industries that have thicker international markets for suppliers. The quality of country institutions, such as the strength and efficacy of a country's legal system, also influence the strength of market thickness externalities, since favourable country institutions increase demand for international outsourcing partnerships, thus increasing entry by outsourcing suppliers.

Even when comparative advantage is sufficiently strong to favour the overseas purchase of intermediate inputs, problems caused by contract incompleteness present a second reason why firms may not choose to engage in international outsourcing. In this case, firms may alternatively choose to integrate vertically with their foreign suppliers, or to set up foreign subsidiaries to conduct and support their purchase of overseas inputs and supplies. Firms are particularly likely to choose such 'offshoring' arrangements when problems arising from contract incompleteness are present in an industry that requires significant relationship-specific investments (Head et al. 2004; Qui and Spencer 2002). Antras (2003) argues that contract incompleteness will be more problematic in capital-intense industries: an idea that finds empirical support in his observation that the fraction of US imports that are intra-firm is higher for capital-intense industries and for trade with more capital- abundant countries.

Since the set-up of a foreign affiliate often involves substantial foreign direct investment expenditure, not all firms will choose offshoring over outsourcing for their international purchases of intermediate inputs. In this vein, Antras and Helpman (2004) show that, when firms are heterogeneous in their productivity, different sourcing strategies will coexist in equilibrium, as each firm chooses the sourcing method that maximizes its profits. Feenstra and Hanson (2005) provide further evidence of heterogeneous organizational choices in the case of Chinese processing trade, where organizational variation across Chinese industries and Chinese provinces supports their model of firm organization which is based on a property- rights description of the firm. Finally, thick market externalities may generate multiple outsourcing equilibria, as McLaren (2000) describes in a setting where independent input suppliers face a hold-up problem when they develop special components for a specific foreign purchaser of intermediate inputs. Here, an increase in market thickness, due to an increase in the number of final goods firms who search for suppliers, reduces the hold-up problem, since the bid of the next-closest purchaser increases.

Cross-country cost differences influence firms' international outsourcing decisions. In turn, the growth of international outsourcing may lead to changes in the international equilibrium. First, if country endowments differ dramatically, ordinary trade in final goods may narrow cross-country differences in factor rewards, but fail to bring about factor price equalization. Using traditional trade models, Deardorff (2001) shows that outsourcing may facilitate factor price equalization. Deardorff also shows that outsourcing may reduce a country's welfare if changes in international prices cause a terms of trade loss which reduces a country's gains from trade, as compared with the gains it reaped from trade in final goods only. However, outsourcing will not harm, and may even help, country welfare when international prices are unaffected.

The effect of outsourcing on international factor rewards depends crucially on the nature of the production process. In a three factor world where production of intermediate inputs involves the combination of capital with skilled and unskilled labour, Feenstra and Hanson (1996) demonstrate how outsourcing may exacerbate income inequality in all countries, where income inequality is

measured by the compensation of high-skilled relative to low-skilled workers. Intermediate goods are ordered according to their relative use of skilled to unskilled labour, while all intermediate inputs have equal capital cost shares. The production of the final good involves the costless assembly of the full range of intermediate inputs. In this framework, outsourcing brought about by capital flows from the Northern country to the Southern country reduces the relative cost of capital in the south, thus lowering the relative cost of producing each intermediate input in the south. This causes the skill intensity of southern production to rise as the country begins to produce an expanded range of intermediate inputs, which were previously completed in the North. From the South's perspective, the activities are more skilled-labour intense than their previous set of activities, while the activities were the least skilled-labour intense activities of those that the North produced. Thus, the shift in intermediates production increases the compensation of high-skill relative to low-skill workers in both locations since the relative demand for skilled workers rises in both the North and the South. At a firm level, Head and Ries (2002) observe that the skill level of Japanese workers in Japanese multinationals rose especially rapidly when the Japanese firms imported an increasing portion of their products from low-income, presumably labour-abundant countries. In the end, the fact that international outsourcing provokes such strong political concern reflects the fact that outsourcing, like international trade, has the potential to influence relative factor rewards.

International Policy Coordination

Paul R. Bergin

Abstract

Coordination among national governments as they formulate macroeconomic policies has been proposed as a response to global integration among national markets. Policy coordination may be beneficial by preventing the externalities created by policy spillovers, as

well as by promoting international risk sharing. The usefulness of coordination depends upon numerous characteristics of an economy, including the degree of openness in goods and asset markets.

Coordination among national governments as they formulate macroeconomic policies has been proposed as a response to global integration among national markets.

Awareness has grown over time of how national macroeconomies are interconnected in a global marketplace. Rising trade volumes indicate international integration among goods markets, large international financial flows indicate integration in asset markets, and highly visible immigration flows reflect increasing integration in national labour markets. Progressive globalization in the private economic sphere has prompted the question of whether public policy likewise should be global. Should the policies that nations use to manage their national macroeconomies be coordinated jointly with other nations? This is not a new question, and economists have voiced a variety of opinions and theories. Most academic economists have tended to be sceptical about the need for explicit international policy coordination.

To date there is limited coordination of macroeconomic policies in practice. Under the Bretton Woods arrangement of fixed exchange rates following the Second World War II until 1973, the monetary policies of member countries were constrained by the need to maintain an exchange rate target. If a national central bank were to attempt to increase the domestic money supply or lower domestic interest rates as a means of stimulating domestic production, this would tend to lower the value of its national currency relative to others and violate the fixed exchange rate agreement. Since the dissolution of this system in the 1970s, many nations learned to appreciate the resulting freedom to use their monetary policy to pursue domestic objectives.

Nonetheless, over the decades since the end of the Bretton Woods system, economic officials of major industrial countries periodically have met to discuss exchange rate intervention and options for monetary and fiscal policies. Examples include the Plaza and Louvre accords in the 1980s. Without binding public agreements, it is not clear how much coordination takes place at such meetings, and the function served by them may simply be sharing information regarding policy intentions. In some regions of the world, a subset of countries have taken steps on their own to more formally coordinate their policies. The most dramatic form of international macroeconomic policy coordination of late has been the formation of the European Monetary Union in 1999. Eleven initial member countries ceded sovereignty over national monetary policy to a European Central Bank, where a single monetary policy must be agreed upon for the whole region.

The opinions of academic economists on the advisability of policy coordination have varied over time, largely in response to the introduction of new tools of economic analysis. Milton Friedman (1953) and others recommended against explicit coordination, suggesting that private market forces could be trusted to achieve a desirable outcome. In particular, exchange rate movements could serve a useful function of insulating countries against the macroeconomic shocks of their neighbours. In contrast, economists of the 1970s and 1980s were able to find theoretical rationales for policy coordination, using Keynesian models that featured frictions that prevented economic markets from operating efficiently on their own.

Finally a renewed interest in the subject since 2000, employing models with more microeconomic foundations, has produced new theoretical reasons to question the usefulness of policy coordination.

The rest of this article considers two primary motivations for policy coordination: preventing policy spillovers and promoting pooling of international risk. The article discusses each motivation in turn along with its limitations.

Policy Spillovers

One motivation for policy coordination is the possibility that the effects of policy spill over national borders to affect the macroeconomies of trading partners. For example, suppose there is a global shock that lowers global demand below some desirable level, such as a wave of pessimistic expectations that lowers investment expenditure. This might be undesirable, to the degree the excess inventories may lead to recession, with a scaling back of production and lower levels of employment. Keynesian theory indicates that one way policymakers can combat such a shortfall in demand is through expansionary fiscal policy, with a rise in government expenditure or a cut in taxes to stimulate private consumption demand. However, globalization affects this policy prescription. National policymakers may fail to respond if they fear that some of the benefit will leak abroad: a fiscal expansion may lead to a currency appreciation, making domestic goods less competitive than foreign goods. As a result, some of the increase in demand generated by domestic government debt will be used to purchase foreign goods and employ foreign workers.

Coordination of policymakers across countries may provide a way of eliminating the problem created by this externality. If a mechanism of coordination existed to make sure that all countries symmetrically expanded government spending, each government could be reassured that it would benefit from spillovers of demand from abroad, to compensate for the negative spillover of demand leaking abroad. A coordinated global fiscal expansion, the theory says, is an effective way of combating a global shortfall in demand.

Externalities also apply to monetary policy. Monetary expansions tend to cause currency depreciations that make domestic goods more competitive compared to foreign goods. The use of such policy to shift demand from foreign goods toward home goods to raise domestic production at the expense of lower foreign production is labelled ‘beggar-thy-neighbour’. One might imagine repeated rounds of such policies, with each country progressively increasing money supply to regain competitiveness. In the end competing policies will have no net effect on the exchange rate and competitiveness, but the net rise in the money supply of each country would produce the undesirable outcome of excessive inflation. Coordination agreements may commit countries to avoid such policy outcomes; they may agree to forswear beggar-thy-neighbour policies if there is a credible commitment from other countries to do the same. The end result is a better outcome for all.

The spillover argument in favour of coordination clearly depends on the degree to which the private economies are interdependent internationally. Consider goods market integration. If exports tend to be a small fraction of a country’s GDP, a currency depreciation raising exports a certain percentage will have a small effect on GDP in absolute terms. The international implications of any policy just wouldn’t matter very much. Asset market integration also has been found to be important. If asset markets do not view government debt issued by different countries as equivalent, then a fiscal expansion that raises the issue of debt in one currency could cause a currency depreciation rather than an appreciation, reversing the direction of the fiscal spillovers described above.

Policy spillovers and strategic interactions of policymakers are topics introduced in research by Hamada (1974), Oudiz and Sachs (1984), and Canzoneri and Gray (1985). When a Keynesian theoretical model embodying the spillover arguments above was quantified by Oudiz and Sachs (1984), it was found that the gains from coordination were too small to justify the effort. US merchandise exports to Europe at the time amounted

only to 1.6 per cent of US GNP. As a result, the gains from coordination were estimated at only about 0.5 percentage points of GDP for the United States. The lesson was that since international integration was actually quite low, there was little or no role for policy coordination. A question that is addressed later in this article is whether this conclusion continues to hold in a progressively more globalized and integrated world.

Policymaker Objectives

The relevance of policy spillovers has been qualified by recent research that studies the objectives of policymakers; see Obstfeld and Rogoff (2002), Corsetti and Pesenti (2005), and Canzoneri et al. (2005). This research features microeconomic foundations to describe the behaviour of consumers, workers, and producers. One benefit of deriving consumer behaviour from assuming they are trying to maximize a particular utility function is that this utility function provides a natural metric by which to evaluate the benefits of alternative policies. Further, it facilitates predictions about how policymakers will act, on the assumption that their behaviour is driven by the goal of improving the welfare of private consumers. For example, one might assume that the policymakers of each country act independently to maximize the utility of citizens in their own country. This 'Nash' solution can be contrasted with a coordinated solution, where an international coordinator chooses the policies of all the countries jointly to maximize the sum of utility of citizens across countries. Only if the outcome of the latter coordinated solution supersedes that of the independent Nash solution is there a clear motivation for international policy coordination.

Consider a simplified theoretical world of two countries populated by representative agents that consume and produce. Production involves labour supplied by these agents, combined with technology that is subject to uncertain shocks each year. Suppose these economies exhibit a market imperfection in the form of prices that must be set ahead of time and that cannot change in response to surprise fluctuations in productivity. Given this environment, imagine there is a negative productivity shock that lowers the level of output. In contrast to the argument of the previous section, it no longer is clear that a policymaker should respond by trying to restore output to its previous level by stimulating demand. This would make the welfare of the citizens even worse, because it would force them to work harder during periods where their labours are less rewarded. Instead, utility is made highest by using monetary policy to replicate the outcome of an economy that is free from the sticky-price market imperfection. In this flexible-price version of the world, citizens would choose to work and consume less during periods of low productivity, and choose to work more and acquire wealth during periods when productivity shocks are favourable.

Although it may seem counter-intuitive, a policymaker wishing to maximize the welfare of his or her citizens in such an economy often will contract the money supply when output falls due to the productivity shock. This has the effect of raising the relative price of home goods and reducing demand and hence production. The outcome of this Nash game differs from the outcome described in the previous section, and does not involve any beggar-thy-neighbour strategy. The domestic policymaker is perfectly capable of replicating the flexible price outcome by the appropriate application of domestic policy. Under certain conditions to be discussed below it turns out that the coordinated solution is identical to that for the Nash solution above. If policy in the two countries were dictated by a central coordinator trying to eliminate all externalities, the set of policies he would prescribe for each country would be identical to the policies that each country would have chosen independently. In this world the spillover argument fails to apply, and there is no benefit from international policy coordination.

International Risk Sharing

A second type of motivation offered for international policy coordination is the possibility that countries can benefit by mutually insuring each other against the effects of shocks. Ideally private

asset markets would include trade in securities contingent on the incidence of shocks, which households could use to insure themselves. For example, in the case of a fall in productivity and output in just one country, such securities would require a transfer of wealth from abroad to this country as a way of buffering the level of consumption despite the fall in domestic production. International trade in equities could serve this function. Suppose the residents of two countries each own half of the firms in the other country's stock market, and they thereby have claim to half of the output of each other's total production. If a productivity shock lowers the output of the home country but leaves the foreign country unaffected, when each country sends half of its respective production to the other country, this implies a net payoff from the foreign country to the home country. This transfer effectively spreads the impact of the productivity shock over the consumption levels of both countries and acts as a type of insurance. However, in the absence of a private market for such securities, there may be a role for policy coordination to replicate these insurance benefits.

For example, consider again the story above of a negative shock to productivity in one country. Another motivation for the policymaker to employ a contractionary monetary policy is to raise the value of the domestic currency, in order to raise the relative price of its exports to imports, the terms of trade. By making home goods more valuable, he or she raises the revenue from export sales abroad, transferring wealth to the affected country. The ability to manipulate the exchange rate to transfer wealth from the foreign to home country clearly could present a temptation to pursue beggar-thy-neighbour policies. But in the hands of a central policy coordinator, this becomes a means of making transfers between countries when useful for insurance purposes.

Note that a coordinated policy motivated by the objective of risk sharing might in principle conflict with the motivation for coordination laid out in previous sections. There is no reason to suppose that the degree of monetary contraction needed to transfer enough wealth to pool risk is also that degree needed to discourage production to the level consistent with flexible prices. That is, it may not be possible to use policy coordination to offset two economic distortions at the same time, the sticky-price and imperfect risk-sharing distortions. This is a point emphasized in the influential work of Obstfeld and Rogoff (2002).

Extensions to more Realistic Economies

While recent research has noted additional theoretical rationales for coordination, this may not change the conclusion that the gains are too small quantitatively to justify the effort. When Obstfeld and Rogoff (2002) calibrate with reasonable parameter values a model that combines imperfect risk sharing with nominal rigidities, it does find there is some positive gain from a coordinator choosing a policy as opposed to each country optimizing separately. But the additional benefit from coordination is small. As long as policymakers act wisely to replicate flexible price outcomes in their domestic economy, the benefit of coordinating with foreign countries is smaller by an order of magnitude. Several features of the theoretical economic environment are key to this result. Clearly key is the supposition that policymakers will act in a manner to maximize the welfare of their residents when given the freedom to do so. But also essential are assumptions about the behaviour of consumers, such as the willingness to substitute across home and foreign goods to maintain their level of utility, and a desire to smooth consumption levels over time.

As progressively more realistic economic environments are explored, the list is augmented of economic features that affect the decision to coordinate. One such feature is the nature of price stickiness. When exporting firms set their prices, many will set them in the currency of the buyer's market. If prices are sticky in the local currency, any fluctuations in the nominal exchange rate will have no effect on the price that consumers face in the market. So any attempt to use monetary policy to manipulate the terms of trade as an insurance device will fail. As demonstrated in Devereux and Engel (2003), local currency pricing kills off a primary motivation for policy coordination as

well as the temptation to pursue beggar-thy-neighbour policies in a sticky-price world.

On the other hand, some other realistic economic features tend to augment the benefits of coordination. These include the reliance on imported goods as intermediates in the domestic production process, in which case random fluctuations in the exchange rate can severely disrupt domestic production. Such issues are likely to be most important for small economies, especially those that specialize in assembly operations of imported components for final export. Another relevant feature is the presence of nontraded goods. If the productivity shocks hitting the nontraded sector differ from the traded sector, it can become difficult for international trade in asset markets to insure against them. Calibrating and simulating models with these more realistic features indicates that it is possible for some economies to benefit substantially from policy coordination (see Tchakarov 2004).

In sum, the size of benefits from coordination depends on a number of key characteristics of economies. These include how developed asset markets are, how responsive trade flows are to relative prices, how important it is to households to smooth their consumption levels over time, how imports are used, and how sticky prices are set. Whether policy coordination is worthwhile for a country depends largely on the individual characteristics of that country.

Openness Reconsidered

While the discussion above has offered two motivations for policy coordination, namely, risk sharing and price stickiness, a revealing distinction between the two is how they are affected by openness and globalization. Consider first openness in the form of international economic integration in goods markets. Goods trade itself may have built-in mechanisms that can help insure a country against country-specific output shocks. For example, if a country is hit by a fall in its production, the relative scarcity of home goods would induce a rise in their relative price. Depending on consumer preferences, such as a type implying constant expenditure shares over home and foreign goods, this terms-of-trade effect will be able to compensate home agents for the fact they have a smaller quantity of home goods. In particular, they will be able to import more foreign goods in exchange for the smaller quantity of home exports, and thereby enjoy a comparable level of overall consumption and utility as the foreign country. This means that goods markets potentially can do the job of pooling risk internationally without the need for an international policy coordinator.

This conclusion stands in sharp contrast to earlier literature. Recall that Oudiz and Sachs (1984) concluded that the need for coordination was small precisely because the degree of goods trade was small. But here we conclude that the need for coordination is small when goods market integration is high.

Consider also the implications of integration in asset markets. In the limiting case where asset markets were complete, with assets to insure against all shocks, private agents would be able to pool the risk of asymmetric shocks internationally on their own. Again, if private markets pool risk, there is no need for policy coordination to serve this function. Clearly the world remains far from complete asset markets, but international trade in equities is definitely on the rise, and international capital flows of various types have ballooned. One gets the impression that international integration has progressed faster in asset markets than in goods markets, so that this type of integration may be more important.

Nevertheless, integration in both markets works in the same direction here. A high level of integration, be it in either asset markets or goods markets, indicates there is less need for explicit international policy coordination to pool national risks. Contrary to the predictions of some analysts, as the age of globalism progresses we might see less pressure for international policy coordination rather than more.

International Real Business Cycles

Mario J. Crucini

Abstract

International business cycle research seeks to summarize the statistical properties of worldwide economic fluctuations and model them as the outcome of purposeful decisions by individuals, firms and policymakers who react to changes in their economic environment and an uncertain future. The focus is on identifying the sources of fluctuations and how interactions of economic actors play out in terms of cyclical movements in variables such as gross domestic product. The term 'real' indicates a sub-area of the research programme that focuses on non-monetary dimensions such as changes in productivity and fiscal policy rather than in the money supply and monetary policy.

International Real Business Cycles

Business cycles are the recurrent fluctuations of national output relative to its long-term growth trend. The qualitative features of these fluctuations are common to virtually all economies, with their quantitative properties differing somewhat across countries and time periods. Modern research seeks to summarize the statistical properties of business cycles and formally model them as the outcome of purposeful decisions by individuals and firms who react to changes in

their economic environment and an uncertain future. Whereas closed-economy analysis focuses on responses to domestic shocks and policy actions, open economy analysis *adds* to this international policy interaction and spillovers of foreign shocks to the domestic economy. The term 'real' indicates a sub-area of the business cycle research programme that focuses on non-monetary dimensions such as changes in productivity, taxes and government spending, rather than changes in the money supply and monetary policy.

Measuring International Business Cycles

What may be surprising to the uninitiated is the controversy surrounding business cycle measurement itself. Measures most often cited in the press are the calendar dates of business cycle peaks and troughs. In the United States, these dates are identified by the Business Cycle Dating Committee at National Bureau of Economic Research. A committee affiliated with the Center for Economic Policy Studies serves the same function for Europe. The logic of the methods used by both committees dates back to the classic contribution of Burns and Mitchell (1946), pioneers of formal business cycle measurement.

In academic work, economists favour econometric methods in which the logarithm of real gross domestic product, y_t, is decomposed into a growth trend, $y_{g,t}$, and a business cycle component, $y_{c,t}$:

$$y_t = y_{g,t} + y_{c,t}. \tag{1}$$

A large applied econometrics literature achieves trend and cycle decompositions by applying identifying assumptions on the innovations to the trend and cycle components of aggregate output. See, for example, Beveridge and Nelson 1981; Cochrane 1994; Crucini and Shintani 2006; Stock and Watson 2005. Here we employ the Hodrick and Prescott (1997) filter to achieve this decomposition since it is widely used in the literature. The Hodrick–Prescott filter provides a smooth estimate of the growth trend, $y_{g,t}$, and the cycle is computed as the difference between the growth trend and the original series.

Figure 1 displays the business cycle component of the logarithm of gross domestic product for eight industrialized countries: Australia, Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States. As is evident, business expansions and contractions are persistent. One also sees common features such as the emergence of a recession in the 1980s simultaneously in most countries.

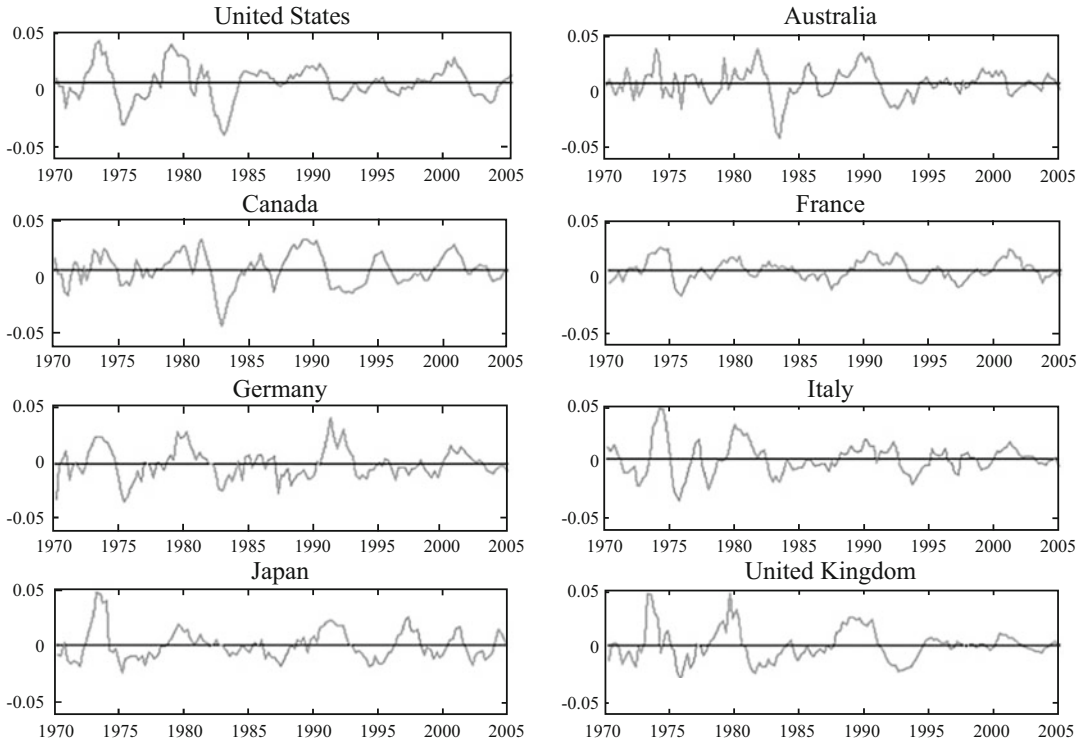
We organize our discussion of business cycle facts around two equations. The first is the national income and product accounts (NIPA) accounting identity. (The OECD data satisfy this identity when changes in inventories and a statistical discrepancy are included. We subtract these two items from output when we perform the variance decomposition of output from the expenditure side.)

$$Y_t = C_t + I_t + G_t + (X_t - M_t). \tag{2}$$

In words: the amount of output produced in the home country equals the sum of its uses in domestic private consumption and investment, C_t and I_t, government spending, G_t, and exports, X_t. Imports are deducted to avoid double counting since they are already counted in the other expenditure components.

The variables have been ordered in terms of the fraction of output accounted for by each component. Averaged across time periods and countries, consumption accounts for about 58 per cent of output and investment accounts for 23 per cent, while the percentages for government consumption, exports and imports are almost identical, at 18 per cent, 19 per cent, and 19 per cent, respectively. With the exception of exports and imports, the ratios differ modestly across industrialized countries when long-time averages are taken. We use Eq. (2) below to perform an *expenditure-side* decomposition of output variability.

The second relationship is a theoretical construct. The prototype model assumes that output is produced with two inputs, capital and labour. The production function relating inputs to outputs usually takes the form:



International Real Business Cycles, Fig. 1 Business cycle component of the logarithm of gross domestic product for eight industrialized countries, 1970–2005 (*Source*: OECD Quarterly National Accounts, CD-ROM and author's calculations)

$$Y_t = A_t K_t^{\alpha} N_t^{1-\alpha} \tag{3}$$

where A_t is total factor productivity, K_t is the stock of physical capital in place at time t, N_t is total hours of input at time t. The exponent $1 - \alpha$ measures the share of national income paid to labour (salaries and wages) since labour is paid its value marginal product in the model.

Taking logarithms of Eq. (3) provides the basis for the second variance decomposition:

$$y_t = a_t + k_t + (1 - \alpha)n_t. \tag{4}$$

We compute a_t as a residual, setting $\alpha = \frac{1}{3}$ (the share of capital income in national income) and using standard measures of physical capital and aggregate hours, as the inputs on the right-hand-side of the equation. We call this our *production-side* decomposition.

Table 1 contains business cycle statistics for each country using data from the first quarter of 1970 to the first quarter of 2005. Beginning with the variance of the cycle itself, we see that the United States has the most variable business cycle, with a standard deviation of 1.58 per cent per quarter, while France, at the other end of the scale, has a standard deviation of only 0.91 per cent. Australia, Canada, Germany, Italy, Japan and the UK have remarkably similar volatility, in the range of 1.32–1.48 per cent.

Turning to the details, we see that investment and trade flows are much more variable than output; consumption is less variable than output while government spending is the least variable. There are some quantitative differences across countries, but the rankings are robust.

The correlation of variables with output indicates the cyclicality of a variable. If the correlation is positive, the variable is said to be pro-cyclical: on average, it rises when the economy is in an expansionary phase and falls when the economy is in a contractionary phase. All

Correlation of savings and investment	0.63	0.44	0.67	0.58	0.44	0.80	0.47	0.83

Notes: All variables except the net export ratio are the Hodrick–Prescott cycle components. All nominal variables are deflated by the Gross Domestic Product Deflator (*Source*: OECD Quarterly National Accounts, CD-ROM)

variables except government spending and the net export ratio are strongly pro-cyclical, consumption and investment particularly so. In a statistical sense, government spending seems to provide some stabilization by virtue of its low variability and near-zero correlation with the cycle. Imports are consistently more highly correlated with domestic output than are exports. This makes economic sense since import demand is influenced by domestic income while export demand depends on potentially diverse income developments across a country's trading partners.

On the production side of the equation, capital is less cyclically variable than either productivity or labour input (a notable exception is France). The ranking of the variability of labour input relative to productivity is ambiguous.

Variance Decompositions

The variance decomposition of output from the expenditure side or production side is computed as:

$$std(y) = \sum_z s_z \cdot std(z) \cdot corr(z, y) \qquad (5)$$

where s_z is either the expenditure share or the production share for variable z (productivity gets a weight of one), $std(z)$ is the standard deviation of component z over the cycle and $corr(z, y)$ is the correlation between component z and income. The variance decomposition is exact in levels, but approximate in logs, because the NIPA identity involves levels. The variance decomposition is exact on the production side because of the log-linearity of the production function.

On the expenditure side consumption and investment account for about 95 per cent of the cyclical variation in aggregate demand. There is no consistent ordering of their relative importance. The reason for consumption's impact is that about two-thirds of aggregate demand is accounted for by this component. While investment is a paltry 23 per cent of aggregate demand, it is about twice as variable as consumption and therefore exerts an influence on the cycle larger than its expenditure share would suggest. Imports are often as important as consumption or investment, while the contribution of exports is not robust across countries. However, since imports and exports enter the national income and product identity with opposite signs, they tend to cancel out. Fluctuations in government spending contribute little to the cycle, for three reasons. First, government spending accounts for a relatively small amount of aggregate demand, close to the investment and trade shares and much lower than that of private consumption. Second, government spending is typically less variable than output. Third, the correlation between government spending and output is close to zero, on average. (In periods of war, such as the Second World War, the picture is very different since government spending is a much larger fraction of output and is strongly pro-cyclical.)

To turn to the *production side*, total factor productivity and changes in labour input account for virtually all of the cyclical variation in output (the cross-country average contribution of these two combined is 95 per cent). This is because each of these variables is highly variable and highly correlated with output, much more so than is true of the physical capital stock. Moreover, capital's share in income is exactly one-half that of labour's, reducing its influence relative to labour. While productivity and labour have a comparable influence, the source of the influence differs. Labour input is more variable than productivity, but gets a weight of two-thirds, less than the unit coefficient on total factor productivity (see Eq. (4)).

It should be stressed that, while these accounting-based decompositions are useful in framing the discussion, they do not tell us what the underlying sources of business cycles are. To see this, consider the distinction between choice variables and exogenous variables. In the prototype real business cycle model, productivity is the only exogenous source of economic change, all other variables are responding optimally to this variable. The model, then, tells us that productivity variation accounts for all of business cycle variation and the various facets of how this plays out across macroeconomic aggregates reflect the choices made by individuals, firms and governments, in response to these productivity changes.

Thus, in practice, there is a subtle link between exogenous impulses and endogenous responses to them. For example, Imbs (1994) introduces variable capital utilization into the model described above. Since capital utilization is not part of what we are measuring in our physical capital stock series, we incorrectly allocate variation in capital utilization to productivity. It is natural to think that this leads us to overestimate the role of productivity. Baxter and Farr (2005) show, however, that, when one moves from a model with constant utilization of capital to one with variable utilization, the response of the economy to a productivity change of a fixed size is larger when utilization is variable than when it is fixed. This moves the bias in the other direction. The lesson here is that theory and measurement work best in concert to achieve the most accurate possible attribution of economic variance.

International Dimensions of the Business Cycle

We turn, now, to key international facets of business cycles: (*a*) the current account balance, (*b*) international business cycle co-movement and (*c*) relative price determination.

The Current Account

An important goal of international business cycle research is to improve our understanding of the time path of the current-account balance or the trade balance. International trade focuses on the direction and composition of trade and often assumes balanced trade. International finance

focuses on the current account, modelling the dynamics of savings and investment over time. Since the business cycle involves time variation, it is natural to emphasize the international finance perspective.

The current account equals the difference between savings and investment. National savings is the sum of private savings and public savings. Private savings is the difference between disposable income and private consumption while public savings is the difference between tax revenue and government expenditure.

$$\begin{aligned} CA_t &= S_t - I_t S_t \\ &= \underbrace{(Y_t - T_t - C_t)}_{\text{private saving}} + \underbrace{(T_t - G_t)}_{\text{public saving}}. \end{aligned} \tag{6}$$

In a closed economy, of course, the current account is identically equal to zero – each dollar of savings must be allocated to domestic investment. An open economy, freed from this constraint, rarely finds itself with a current account balance; when current savings fall short of (or exceed) current investment levels, a current account deficit (or surplus) obtains. Feldstein and Horioka (1980) vividly demonstrated that, when the data are averaged over long periods of time, savings and investment rates are highly positively correlated – countries with higher than average savings rates tend to have higher than average investment rates. Business cycle correlations of saving and investment tend to be lower than the Feldstein–Horioka values, suggesting that large deviations in the current account are transitory. The correlation of national saving and national investment over the cycle ranges from a high of 0.80 in Italy to a low of 0.44 in both Australia and Germany (see Table 1).

International Business Cycle Co-Movement

International co-movement may be expressed in different ways. Kose et al. 2003, among others, use state space models in which there are world, country and idiosyncratic factors in the income process as well as in each component of aggregate demand. This method avoids an arbitrary choice of numeraire and helps to identify what economists refer to as the 'world business cycle'. Here we use the correlation of a foreign variable with its US counterpart. As is evident in Table 2, positive movements of foreign variables with their US counterparts are the rule rather than the exception. In terms of rankings, output tends to be more correlated than the components of aggregate demand; investment and government spending have particularly low international correlations. The rankings are more ambiguous in a statistical sense and for a broader range of countries than Table 2 suggests; see Ambler, Cardia and Zimmerman (2004).

International Real Business Cycles, Table 2 International business cycle co-movement correlation with US counterpart, 1970Q1–2005Q1

	Australia	Canada	France	Germany	Italy	Japan	UK
Output	0.46	0.71	0.36	0.42	0.32	0.43	0.64
Panel A. Demand side							
Consumption	− 0.09	0.53	0.37	0.37	0.01	0.35	0.50
Investment	0.29	0.16	0.25	0.47	0.15	0.42	0.40
Government	0.22	0.29	− 0.04	0.05	− 0.01	0.07	0.06
Exports	0.03	0.33	0.40	0.34	0.10	0.25	0.32
Imports	0.13	0.45	0.36	0.32	0.40	0.29	0.50
Savings	0.53	0.68	0.38	0.39	0.33	0.51	0.37
Net exports	− 0.18	− 0.50	− 0.08	0.23	− 0.29	− 0.16	0.07
Panel B. Supply side							
Productivity	0.42	0.53	− 0.07	0.21	0.04	0.27	0.36
Capital	0.33	0.18	0.08	0.17	0.09	0.31	0.55
Labour	0.42	0.59	0.36	0.39	− 0.17	0.42	0.60

(*Source*: Author's calculations)

To turn to the *production side*, we see that US labour input has the highest correlation with its counterpart abroad, ranging from 0.60 with the UK to a low of minus 0.17 with Italy. International productivity levels also tend to be positively correlated, though not to the extent of labour input. Changes in capital formation have a low international correlation, consistent with other facets of this input documented above. The highest international business cycle correlations are between Canada and the United States, geographic neighbours with similar institutions and extensive trade relations.

Real Exchange Rates and the Terms of Trade

The two key international relative prices are the real exchange rate and the terms of trade. The real exchange rate is:

$$Q_t^R = \ln\left(E_t P_t^* / P_t\right) \tag{7}$$

where E_t is the nominal exchange rate between the home and foreign country and P_t and P_t^* are home and foreign price indices (usually the consumer price index), respectively. In words: Q_t^R is the cost of the foreign consumption basket relative to the domestic consumption basket after converting to a common currency. According to the purchasing power parity proposition, the dollar goes just as far in foreign countries as it does in the United States in terms of purchasing power. This implies that $Q_t^R = 1$ at each point in time.

In practice, however, the real exchange rate is highly variable and very persistent. High variability suggests large absolute departures from parity, while high persistence implies that, when a price gap opens up internationally, it tends to remain open for many months rather than days or weeks. In terms of the time series measurement of this property, at business cycle frequencies, it appears that the real and nominal exchange rates have approximately the same variance while the price ratio term $\left(P_t^* / P_t\right)$ is very stable. For example, the standard deviation of the nominal exchange rate between the United States and France is about 8.52, close to the standard deviation of their bilateral real exchange rate at 7.95, while the price ratio has a standard deviation of only 1.17 (see Table 3). These numbers are typical of US bilateral real exchange rates with respect to other industrialized countries. One also finds that the real exchange rate is not highly correlated with quantity variables such as output or even net exports (not shown).

To turn to the terms of trade, it is defined as:

$$Q_t^T = P_t^m / P_t^x \tag{8}$$

where P_t^m and P_t^x are import and export price indices for a particular country. Since these price indices are domestic deflators, they are already expressed in the home currency terms, and the spot exchange rate is not needed to convert them

International Real Business Cycles, Table 3 Cyclical properties of real exchange rates and the terms of trade

	US	Australia	Canada	France	Germany	Italy	Japan	UK
Panel A. Standard deviations								
Price ratio				1.17	1.42	1.67		1.74
Nominal exchange rate				8.52	8.37	8.51		8.20
Real exchange rate				7.95	8.06	7.80		
Terms of trade	2.90	5.21	2.44	3.50	2.61		5.68	2.64
Trade ratio		9.94	4.60	3.66	3.90		7.29	3.94
Panel B. Contemporaneous cross correlations								
Output and net exports	− 0.30	− 0.19	− 0.43	− 0.30	− 0.05		− 0.23	− 0.25
Output and the terms of trade	− 0.08	− 0.30	− 0.11	− 0.14	− 0.09		− 0.09	0.22
Terms of trade and net exports	0.28	− 0.07	0.06	− 0.51	0.00		− 0.50	− 0.54

Sources: Terms of trade moments are from Table 1 in Backus and Crucini (2000). Sample periods are as follows: Canada, the United Kingdom and the United States, 1955Q1–1990Q3; Australia, 1960Q1–1990Q3; France, 1970Q1–1990Q3; Germany, 1968Q1–1990Q3; Italy, 1970Q1–1990Q2; Japan, 1955Q2–1990Q3. Real exchange rate moments are from Chari et al. (2002); sample period is 1973Q1–2000Q1

to common units. Unlike the real exchange rate, economic theory does not place strong restrictions on the time series or cross-country behaviour of the terms of trade. Given the presumption that countries import different goods from those they export, we expect the terms of trade to be different from unity, and it should fluctuate, too.

Australia and Japan have the highest terms-of-trade variability, about twice that of the other countries, with the exception of France, which experiences terms-of-trade variability between these extremes. The terms of trade does not have a robust correlation with either output or net exports.

Modelling International Business Cycles

Quantitative theoretical investigations of business cycles seek to account for business cycle facts using models in which consumers are thoughtful and informed, firms employ workers and utilize capital efficiently, and policymakers use a combination of rules and discretion to achieve various economic objectives. The key dimensions of study are those unique to international economics: matching the international character of the world business cycle and the business cycle properties of the current account, the real exchange rate and the terms of trade.

The Current Account

The most rudimentary model of current account behaviour is one in which a small open economy faces an exogenous world interest rate and income stream. To fix ideas, think of a small country that produces mostly oil with perfect access to international capital markets. If the country is always producing at capacity, all of its income variation is due to changes in the price of oil in world markets. What does the intertemporal approach to the current account predict in this circumstance?

The theory reduces the NIPA identity to: $S_t = Y_t - C_t$, so that consumption decisions effectively determine saving decisions. Investment is absent since we are abstracting from changes in production capacity and its utilization. While this model seems simplistic, the identity is deceptive since it suggests that only current income enters into the current consumption–savings decision. In fact, the most widely used set-up has its roots in the seminal contribution of Friedman (1957), with individuals assumed to be able to draw upon the entire present discounted value of their future labour income. Whereas current income is the traditional argument in the Keynesian consumption function, wealth plays this role in modern macroeconomics. Since wealth is the sum of the market value of financial assets and all future anticipated flows of income, expectations play a central role in the modern consumption function. (There are many extensions to this basic framework that prevent individuals from drawing upon their lifetime wealth for present consumption: collateral requirements, limits on debt-to-income ratios and credit histories. Discussion of these extensions is beyond the scope of this survey.)

Much of the intuition for the impact of a changing income profile on the current account of a small open economy is available from Quah's (1990) formulation of the permanent-income hypothesis. He assumes a constant interest rate, quadratic preferences and rational expectations. He allows income to contain both permanent and transitory shocks. If we assume income follows a first-order autoregressive process: $Y_{t+1} = \rho Y_t + \nu_{t+1}$, where ν_{t+1} is news about income (that is, under rational expectations, news about income is: $E_{t+1} Y_{t+1} - E_t Y_{t+1} = \nu_{t+1}$), the predicted change in consumption in response to this news is:

$$\Delta C_{t+1} = \frac{r}{1 + r - \rho} \nu_{t+1} \tag{3.1}$$

and the change in the current account on impact, on the assumption it was in balance initially, is:

$$\begin{aligned} \Delta CA_{t+1} &= \Delta Y_{t+1} - \Delta C_t \\ &= \nu_{t+1} - \frac{r}{1 + r - \rho} \nu_{t+1}. \end{aligned}$$

Since output deviations from trend (the business cycle) are persistent, it is safe to assume, $\rho > 0$. A plausible value for r is 0.05 (a five per cent real interest rate). Note that the consumption response depends positively on persistence since wealth effects are rising in the persistence of the income change. As persistence moves from zero toward

unity, the effect on the current account rises from close to unity toward zero. This algebra delivers a key prediction of the intertemporal approach, that consumption smoothing leads to current account surpluses during booms unless the income change is viewed as permanent (that is, $\rho = 1$) in which case the current account is predicted to remain unchanged.

While there is evidence to suggest an interest rate channel on consumption, it does not help to resolve the counterfactual prediction of a pro-cyclical current account from the consumption side, just established. There are two reasons for this. First, if interest rates are higher during a boom in the home country, individuals would tend to tilt consumption from current to future periods (that is, postpone durable goods purchases) – the intertemporal substitution effect. This would reinforce rather than overturn our prediction that the current account moves into surplus during a boom. If real interest rates actually fell during a boom, the intertemporal substitution effect would operate in the right direction, but the evidence on the cyclicality of the real interest is ambiguous. Second, when we move to a general equilibrium setting, incorporating home and foreign responses, the increase in the real interest rate is shared by the two countries and therefore incapable of delivering the asymmetric consumption responses necessary to move the current account balance. This leaves us with the need to look elsewhere for a channel that moves the current account in a countercylical direction.

To return to the algebra of the current account identity, it would appear that what is needed for a countercyclical current account is for domestic investment to rise more than domestic savings during a business cycle expansion:

$$\begin{aligned} \Delta CA_t &= \Delta S_t - \Delta I_t \\ &= (\Delta Y_t - \Delta C_t) - \Delta I_t. \end{aligned} \tag{3.3}$$

The identity reveals the tension between the consumption smoothing channel, whereby a transitory change in income is mostly saved, pushing the current account towards surplus and the investment channel, which pulls in the opposite direction, towards a deficit.

In a model with only one good, the consumption smoothing channel wins the contest unless the shocks are highly persistent (see, for example, Backus et al. 1992; Baxter and Crucini 1993; Mendoza 1991). Persistence, by increasing the impact response of consumption due to the larger wealth effect, helps to push the current account towards balance, leaving the investment channel to produce a deficit. Extensive empirical investigations of the intertemporal approach to the current account may be found in Glick and Rogoff (1995) and Nason and Rogers (2006). (Sachs (1981) provides early evidence on the investment channel.)

Extensions of the model to multiple goods helps avoid this unpleasant arithmetic because individuals want to increase consumption of both the domestic good and the foreign good, increasing import demand and reinforcing the tendency towards a deficit from a traditional trade channel. Demonstrations of this effect under complete and incomplete risk sharing are found in Backus et al. (1994) and Arvanitis and Mikkola (1996), respectively. (JoAnne Feeney (1994) provides an insightful exposition of this issue.)

To summarize, early developments of the intertemporal approach to the current account emphasized the consumption smoothing channel and predicted that current account surpluses would occur when output was temporarily above trend. Current account surpluses are often described as *good* based on the idea that surpluses flow from good economic times. The complete model of the current account adds investment dynamics and allows for the possibility that investment-led booms produce current account deficits. These theoretical developments and their empirical implications have led to a more balanced view of the current account: that we need to understand the sources of the changes in the current account before making value judgements about them. Kollman (1998), appears to be the first quantitative simulation of US and European current account dynamics using a modern real business cycle analysis that incorporates variation in productivity, government spending and national tax rates.

The World Business Cycle

Conceptually, the world business cycle is simple to define: the deviation of world output from its growth trend. The practical difficulty is the measurement of world output because national output is denominated in domestic currency. Converting nominal output into a common currency using spot nominal exchange rates greatly exaggerates fluctuations in output because nominal exchange rates are much more volatile than either real production or price levels. Moreover, prices vary considerably across nations even after conversion to a common currency, making it difficult to construct an appropriate deflator to convert nominal gross international product into real gross international product. Here we follow much of the existing literature and use real gross domestic product of each country, and compute correlations across them. If real output is highly correlated across countries, we have evidence of a world business cycle. As we documented earlier, most macroeconomic aggregates are positively correlated across countries, indicative of a world business cycle. How do business cycle researchers account for this fact?

There are two channels through which positive economic co-movement may arise: endogenous propagation and exogenous propagation. Positive endogenous propagation refers to a situation in which a disturbance originating in one country has a positive impact on both home and foreign output levels. For example, rapid development in China drives up demand for crude petroleum and fuels economic expansions in countries that are specialized in oil production. Positive exogenous propagation refers to the correlation of shocks across countries. For example, the Second World War witnessed dramatic increases in national output in most industrialized countries as government spending rapidly expanded during the conflict. In practice, endogenous propagation and exogenous propagation are difficult to distinguish, presenting one of the key challenges of business cycle research.

Real business cycle researchers have devoted most of their effort to measuring total factor productivity, which has been found to be highly persistent and positively correlated across countries. Correlations over the business cycle are typically lower than correlations over long periods of measurement, suggesting more commonality in the technological trend than in the productivity cycle. (When analysis extends to small developing countries the business cycle correlations sometimes exceed the growth correlations.) Given the lower correlation of fiscal variables with the cycle and their modest cyclical variation, it is not surprising that they have received less attention in empirical and theoretical analysis than productivity. Two key studies of the empirical behaviour of international taxes and their equilibrium implications using dynamic equilibrium theory are Mendoza et al. (1994), and Mendoza and Tesar (1998), respectively. Both studies suggest international taxation is more relevant for secular and long-run trends than it is for business-cycle fluctuations.

Apart from the obvious role of the correlation of the shocks that drive business cycles, three economic factors have proven critical in determining the ability of dynamic equilibrium models to generate international co-movements resembling those we see in the data. The first is the extent to which domestic and foreign goods are substitutes in demand. The second is the extent to which factors of production are internationally mobile. The third is the extent of international financial linkages.

The first generation of models by Backus et al. (1992) and Baxter and Crucini (1993) followed the analytical structure of the closed economy models by Kydland and Prescott (1982) and King et al. (1988) quite closely. Despite the similarity, however, international economists were immediately confronted with two key modelling issues. The first had to do with factor mobility across countries, which is obviously absent in the closed economy setting. The mobility of labour across countries seemed minor enough to ignore, physical capital mobility was not. Since physical capital takes real resources to reallocate, the standard approach has been to subject capital accumulation to adjustment costs (or time to build as in Backus et al. 1992). Without some cost of physical capital mobility, capital would be predicted to move rapidly and in large amounts

across national boundaries in response to persistent changes in productivity or taxes. Such factor movements generate strongly negative correlations of output from the supply side and unrealistically volatile investment over the business cycle.

The second issue model builders were confronted with was asset market structure. Much of aggregative economics is predicated on the basis that idiosyncratic shocks are irrelevant to macroeconomic fluctuations. In an economy with millions of individual agents and thousands of firms, the law of large numbers combined with not-too-objectionable restrictions of preferences and technology provided a compelling argument to abstract from idiosyncratic variation. At the aggregative international level, the number of shocks is small (in many models it equals the number of countries), and countries are large and few in number. Thus, it makes little sense to rely on the law of large numbers, so researchers adopted the assumption that agents pool nation-specific risks, avoiding the need to track the wealth distribution across countries.

Unfortunately, complete risk pooling in the one-sector model leads to a presumption that output is negatively correlated across countries while consumption is close to perfectly positively correlated. In the data, the reverse rankings of correlation tend to prevail, and the absolute level of consumption correlations is well below unity. The prediction of near-perfect consumption co-movement across countries derives from the risk-pooling assumption and the fact that agents face common prices and interest rates.

The negative correlation of income is driven by cost-minimizing production decisions where firms allocate plants and equipment to the most productive location. Thus, an increase in home productivity increases domestic output relative to foreign output directly, and this is reinforced by the flow of capital from the less productive country to the more productive country. Risk pooling also enhances the supply-side response by neutralizing the wealth redistribution effects on home and foreign labour supplies.

Debate continues as to what the appropriate asset market structure should be and how to incorporate changes in asset diversification in business cycle models. Baxter and Crucini (1995) and Kehoe and Perri (2002) show that, when risk pooling is limited, positive output co-movements are more likely to arise the more persistent are the deviations to relative international productivity. Also, consumption correlations may actually fall below output correlations if the shocks are close to permanent, a feature that is prevalent in the data and difficult to explain from a number of standard theoretical paradigms.

Researchers have had more success accounting for positive international output co-movement in models where countries depend on their trading partners for final goods or intermediate inputs they themselves do not produce. Examples of work along these lines include an extension of the multisector model with intermediate inputs of Long and Plosser (1983) to the open economy by Ambler et al. (2002), a model of the North–South business cycle by Michael Kouparitsas (1996) which emphasizes trade of manufactures for primary inputs across these two regions, and the introduction of home production by Canova and Ubide (1998). A contribution that extends the incomplete markets model developed by Baxter and Crucini (1995) to the two-good setting is Arvanitis and Mikkola (1996).

Real Exchange Rates and the Terms of Trade

Multiple sectors take centre stage when one considers the real exchange rate and the terms of trade. Approaches to international relative price determination may be usefully placed into two categories. One category focuses on the determination of international relative prices of different goods. A second category focuses on deviations from the law of one price, meaning identical goods trade at different prices in different countries.

A classic contribution in the former category is Backus et al. (1994) (BKK), who develop a two-country, two-good model. Each country specializes in the production of one of the two goods and the two goods are combined in production, via an Armington aggregator, to create a composite final good which is, in effect, the single final good in each economy.

The Armington aggregator is a function that describes how substitutable the two goods are in achieving a particular output level of the final good. To match low trade shares with the specialization-in-production assumption, home bias is assumed in the aggregator function. This means that the home country uses more of the home good when producing the composite good, and the foreign country behaves symmetrically.

This is an elegant model that ties in nicely with the one-sector two-country framework. The key difference between this model and the one-sector model is that specialization provides a motivation for keeping production levels more nearly equal across locations, since individuals have demands for each type of good. The model allows us to study the terms of trade, a key international relative price absent from the one-sector model, by construction. In the BKK model, the terms of trade and trade ratio are related as follows:

$$q_t = \ln\left(\frac{p_{bt}}{p_{at}}\right) = \omega + \frac{1}{\sigma}\ln(a_t/b_t). \qquad (3.4)$$

In words: an increase in production of the home good, a, drives down its relative price. The home terms of trade turn against the country experiencing the expansion, a pro-cyclical terms of trade, as BKK define it. In the data, the correlation varies substantially across countries in magnitude and sign. The model has difficulty matching both the observed volatility of the terms of trade and the quantity ratio; as the Euler equation makes clear, there is a trade-off between terms of trade and quantity ratio variability as the elasticity is altered. If we view a and b as the final consumption levels of each good, the quantity ratio is not nearly volatile enough, given a plausible degree of elasticity, to generate the terms of trade variation we see in the data. Backus and Crucini (2000) add an oil producing region (and sector) and find that the model does better in matching the cyclicality of the terms of trade and the trade balance than the original BKK model. Kose (2002) provides an extensive quantitative analysis of the variation of international relative prices and their role in the business cycles of small open economies.

Models that consider deviations from the law of one price differ in the source of the price deviations and their duration. Sticky-price models consider the deviations to be transitory, with nominal prices responding with a lag to changes in the economic environment. These models also assume trade in an infinite number of varieties, which allows individual firms to charge a markup of price over marginal cost. Key contributions in this area are Svennson and van Wijgenbergen (1989) and Obstfeld and Rogoff (1995).

Trade cost models treat price deviations as a consequence of a real resource cost of trading, or operating businesses, in different locations. The simplest version allows prices to vary across locations by a shipping cost, usually treated as proportional to the marginal cost of the producer/supplier. The seminal contribution is Samuelson (1952), with more recent contributions by Eaton and Kortum (2002) and Sercu et al. (1995). An alternative variant is to distinguish traded and non-traded goods with traded goods not subject to trade costs and non-traded goods assumed to be subject to prohibitive trade costs, as in the original Salter (1959) and Swan (1960) models. Stockman and Tesar (1995) conduct a quantitative investigation of the business cycle predictions of this class of model.

Recent efforts have focused on quantifying the role of sticky prices, imperfect competition and trade costs in accounting for international relative price deviations and their business cycle implications. Chari et al. (2002) conduct a quantitative evaluation of the sticky-price, imperfect-competition model and find that it can account for only a small part of the persistence and somewhat more of the volatility of the real exchange rate. (See also Betts and Devereux 2000; Bergin and Feenstra 2000.) Corsetti et al. (2005) and Ravn and Mazzenga (2004) show the promise of models that combine imperfect competition with real trading costs.

What is missing from existing models is a clear distinction between economic activities that take place at the dock and exchange in retail markets. Transportation costs alone cannot account for all of the retail price dispersion we observe. Presumably, this is because much of what the retail

market entails are local inputs of land, labour and infrastructure (some of it publicly provided). Models and empirical evidence are just now being developed to make these distinctions, such as Burstein et al. (2003) and Crucini et al. (2005), respectively.

International Reserves

Joshua Aizenman

I

Abstract

Developing countries, particularly in East Asia, account for most of the large increase in international reserves–GDP ratios in recent decades. Possible explanations include self-insurance against the output costs of sudden stops; precautionary fiscal demand by countries with inelastic fiscal outlays, sovereign risk, volatile and limited tax capacity; and a modern incarnation of mercantilism. Empirical studies reveal that the 1997–8 East Asian financial crisis triggered a sharp increase in hoarding international reserves. They suggest prominent roles for the precautionary demand and self-insurance motives and conclude that the financial integration of developing countries is associated with greater hoarding of international reserves.

International reserves are the liquid external assets under the control of the central bank. An intriguing development since the 1960s has been that, despite the proliferation of greater exchange rate flexibility, international reserves–GDP ratios increased substantially. Flood and Marion (2002) report that reserve holdings have trended upwards; at the end of 1999, reserves were about 6 per cent of global GDP, 3.5 times what they were at the end of 1960 and 50 per cent higher than in 1990. Practically all the increase in reserves-GDP holding has been by developing countries, mostly concentrated in East Asia.

These developments stirred lively debate among economists and financial observers. The earlier literature focused on using international reserves as a buffer stock, part of the management of an adjustable-peg or managed-floating exchange- rate regime. Accordingly, optimal reserves balance the macroeconomic adjustment costs incurred in the absence of reserves with the opportunity cost of holding reserves (see Frenkel and Jovanovic 1981). The buffer stock model predicts that average reserves depend negatively on adjustment costs, the opportunity cost of reserves, and exchange rate flexibility; and positively on GDP and on reserve volatility, driven frequently by the underlying volatility of international trade. Overall, the literature of the 1980s supported these predictions; see Frenkel (1983), Edwards (1983), and Flood and Marion (2002) for a recent review.

While useful, the buffer stock model has limited capacity to account for the recent development in hoarding international reserves – the greater flexibility of the exchange rates exhibited in recent decades should work in the direction of reducing reserve hoarding, in contrast to the trends reported above. As an indication of excess hoarding, observers noted that developing countries frequently borrow at much higher interest rates than the one paid on reserves.

The recent literature provided several interpretations for these puzzles, focusing on the observation that the deeper financial integration of developing countries has increased exposure to volatile short-term inflows of capital (dubbed 'hot money'), subject to frequent sudden stops and reversals (see Calvo 1998; Edwards 2004). Looking at the 1980s and 1990s, Aizenman and Marion (2003a) pointed out that the magnitude and speed of the reversal of capital flows throughout the 1997–8 crisis surprised most observers. Most viewed East Asian countries as being less vulnerable to the perils associated with hot money than Latin American countries. After all, East Asian countries were more open to international trade, had sounder fiscal policies, and much stronger growth performance. In retrospect, the 1997–8 crisis exposed hidden vulnerabilities of East Asian countries, forcing the market to update the probability of sudden stops affecting all countries.

The above observations suggest that hoarding international reserves can be viewed as a precautionary adjustment, reflecting the desire for self-insurance against exposure to future sudden stops. Self-insurance has several interpretations. The first focuses on precautionary hoarding of international reserves needed to stabilize fiscal expenditure in developing countries (see Aizenman and Marion 2003b). Specifically, a country characterized by volatile output, inelastic demand for fiscal outlays, high tax collection costs and sovereign risk may want to accumulate both international reserves and external debt. External debt allows the country to smooth consumption when output is volatile. International reserves that are beyond the reach of creditors would allow such a country to smooth consumption in the event that adverse shocks trigger a default on foreign debt. Political instability, by taxing the effective return on reserves, can reduce desired current reserve holdings. The tests reported by Aizenman and Marion (2003b) are consistent with this interpretation. Another version of self-insurance and precautionary demand for international reserves follows the earlier work of Ben-Bassat and Gottlieb (1992), viewing international reserves as output stabilizers (see Aizenman and Lee 2005; see Lee 2004, for insurance perspectives of international reserves applying the option pricing theory). Accordingly, international reserves can reduce the probability of an output drop induced by a

sudden stop and/or the depth of the output collapse when the sudden stop materializes (see Kaminsky and Reinhart 1999).

The views linking the large increase in hoarding reserves to deeper financial integration face a well-known contender in a modern incarnation of mercantilism: international reserves accumulations triggered by concerns about export competitiveness. This explanation has been advanced by Dooley et al. (2003), especially in the context of China. They interpret reserves accumulation as a by-product of promoting exports, which is needed to create better jobs, thereby absorbing abundant labour in traditional sectors, mostly in agriculture. While intellectually intriguing, this interpretation remains debatable. Some have pointed out that high export growth is not the new kid on the block – it is the story of East Asia since the 1950s. Yet the large increase in hoarding reserves happened mostly after 1997. This issue is of more than academic importance: the precautionary approach links reserves accumulation directly to exposure to sudden stops, capital flight and volatility, whereas the mercantilist approach views reserves accumulation as a residual of an industrial policy, a policy that may impose negative externalities on other trading partners.

Aizenman and Lee (2005) test the importance of precautionary and mercantilist motives in accounting for the hoarding of international reserves by developing countries. While variables associated with the mercantilist motive (like lagged export growth and deviation from purchasing power parity) are statistically significant, their economic importance in accounting for reserve hoarding is close to zero and is dwarfed by other variables. Overall, the empirical results are in line with the precautionary demand. The effects of financial crises have been localized, increasing reserve hoarding in the aftermath of crises mostly in countries located in the affected region, but not in other regions. A more liberal capital account regime is found to increase the amount of international reserves, in line with the precautionary view. These results, however, do not imply that the hoarding of reserves by countries is optimal or efficient. Making inferences regarding efficiency would require having a detailed model and much more information, including an assessment of the probability and output costs of sudden stops, and the opportunity cost of reserves. To conclude, greater exposure of developing countries to sudden stops and reversals of hot money as well as growing trade openness go a long way towards accounting for the observed increase in international reserves–GDP ratios by developing markets.

International Trade

John S. Chipman

Edgeworth (1894) opened his survey of the theory of international values with the provocative statement: 'International trade meaning in plain English trade between nations, it is not surprising that the term should mean something else in Political Economy'. This could equally well be said today. What distinguishes international from domestic trade is the greater prevalence of barriers (both natural and artificial) to trade and factor movements in the former; different currencies; and (perhaps most important) autonomous governments, leading to a pattern of shocks which impact different countries in different ways. Because of these differences, a different type of theoretical model is called for. For example, international immobility of factors results in greater disparity in relative factor endowments among countries than among regions of the same country; these disparities may make it reasonable, as a first approximation, to ignore variations in supplies of factor services that come about in response to changes in factor rentals and commodity prices, if these variations are small in comparison with the differences in endowments. Likewise, great differences among resource endowments and productive techniques may make it reasonable to disregard differences in consumers' tastes within and across countries, even though this might be a very inappropriate type of simplification for purposes of analysing domestic trade.

The fact that national governments act independently leads to the need to analyse the effects of country-specific shocks, which take the form of intensification or liberalization of restrictions on trade or capital movements, unilateral transfers such as reparation payments, gifts, or loans, and disparities in monetary and fiscal policies. For this reason the emphasis in international-trade theory has from the beginning (Mill 1848; Marshall 1879) been on comparative statics: one wants to ascertain the qualitative, if not the quantitative, effect of a tariff or quota or transfer on the various quantities involved. To obtain unambiguous qualitative results one needs fairly drastic simplifications and strong assumptions. On the other hand, the emphasis in general-equilibrium theory (Walras 1874; Pareto 1896–97; Debreu 1959) has been on proving the existence, stability, and Pareto-optimality of competitive equilibrium, for which much milder assumptions are required. A good definition of international-trade theory as it has evolved would therefore be: 'general-equilibrium theory with structure'.

The requirements of 'simplicity' in a theory are not absolute, but vary with the goals of the theory and the technical resources available to researchers at the time. There is not much virtue in simplicity if a result that holds in a model of two countries, two commodities, and two factors does not generalize in any meaningful way to higher dimensions. With the increasing possibilities of handling large-scale models and data sets and estimating their parameters numerically, it is natural to expect a movement of both general-equilibrium traditions towards each other.

Attention will be focused here on the neoclassical model developed by Haberler (1930, 1933), Lerner (1932, 1933, 1934), Ohlin (1928, 1933), Stolper and Samuelson (1941), Samuelson (1953), and Rybczynski (1955), which Baldwin (1982) has described as the 'Haberler–Lerner–Samuelson model' – an appellation which is more accurate than the usual 'Heckscher–Ohlin theory', since the model commonly employed makes the simplifying assumption – rejected by Ohlin (1933, ch. VII) except in his illustrative Appendix I – that factors of production are inelastic in supply and indifferent among alternative occupations, allowing one to define unambiguously a country's production-possibility frontier. This model has in recent years come to

lose some of its hold on the profession – just as the Ricardian theory had in the 1930s – in favour of models that stress imperfect competition (see, e.g. Helpman and Krugman 1985). However, these latter models have so far not been successfully formulated as general-equilibrium models, and are thus still in a formative stage. It goes without saying that, in the nature of the case, a partial-equilibrium model is incapable of explaining or predicting trade patterns or analysing the effect on prices and resource allocation of trade restrictions and transfers.

The material that follows is divided into two parts. Part 1 covers the mathematical foundations of the received theory, and deals with the duality between production functions and cost functions, the concept of a national-product function, the Stolper–Samuelson and Rybczynski relations between factor rentals and commodity prices and between commodity outputs and factor endowments, the concepts of trade-demand functions and trade-utility functions, world equilibrium and its dynamic stability. Part 2 covers the applications of these basic concepts to the most noteworthy problems that have been the object of attention in the theory of international trade since its beginnings: the explanation of trade flows, the effect of unilateral transfers on sectoral prices and resource allocation, and the effect of trade restrictions such as tariffs and quotas. The reader who is interested in substantive questions is advised to proceed directly to Part 2.

Part 1. The Mathematical Foundations

Duality of Cost Functions and Production Functions

Let an industry produce a positive amount y of output of a particular product, with the aid of non-negative amounts υ_j of m primary factors of production, determining the vector $\upsilon = (\upsilon_1, \upsilon_2, \ldots, \upsilon_m)$. A *production function* f is defined over the non-negative orthant E_m^+ of m-dimensional Euclidean space, with values $y = f(\upsilon)$ on the non-negative real line E_1^+. We assume that f has the following properties:

(a) *Upper semi-continuity*: for each y the set

$$A(y) = \{\upsilon : f(\upsilon) > \} \tag{1}$$

is closed;

(b) *Quasi-concavity*: for each y, the set $A(y)$ defined by (1) is convex;

(c) *Monotonicity*: if $\upsilon, \upsilon' \in E_m^+$ are such that $\upsilon' \geqq \upsilon$, then $f(\upsilon') \geqq f(\upsilon)$.

Further properties of f will be specified later on.

We shall denote by $w = (w_1, w_2, \ldots, w_m)$ a vector of *factor rentals*, i.e. prices of the services of the m factors of production. The following conventional notation will be adhered to:

$$w \geqq 0 \text{ means } w_i \geqq 0 \text{ for all } i = 1, 2, \ldots, m;$$
$$w \geqq 0 \text{ means } w_i \geqq 0 \text{ for all } i = 1, 2, \ldots, m;$$
$$\text{and } w_i > 0 \text{ for some } i;$$

For each $y > 0$ and all $w \geq 0$ we define the *minimum total cost function* G by

$$G(w, y) = \min_{\upsilon} \{w \cdot \upsilon : f(\upsilon) \geqq y\}, \tag{2}$$

where $w \cdot \upsilon$ denotes the inner product

$$\sum_{j=1}^{m} w_j \upsilon_j$$

Mathematically, for each fixed y the function $G(\cdot, y)$ is the *support function* of the convex set $A(y)$ (cf. Fenchel 1953). It has the following properties:

(a^*) *Continuity* in w: for each y, $G(w, y)$ is continuous;

(b^*) *Concavity* in w: if $0 < \theta < 1$ then

$$(1-\theta)G(w^o, y) + \theta G(W^1, y) \leqq G\left[(1-\theta)w^o + \theta w^1, y\right];$$

(c^*) *Monotonicity*: $y' \geqq y$ implies $G(w, y') \geqq G(w, y)$ and $w' \geqq w \geq 0$ implies $G(w', y) \geqq G(w, y)$;

(d^*) *positive homogeneity* in w : $G(\lambda w, y) = \lambda G(w, y)$ for all $\lambda > 0$.

Property (a*) follows from (a) and the definition of G; property (c*) follows the definition of G and the fact that $y' \geqq y$ implies $A(y') \subseteq A(y)$; property (d*) follows immediately from the definition of G. To prove (b*), let w^0, $w^1 \geq 0$ and denote $w^\theta = (1–\theta)w^0 + \theta w^1$; from the definitions of G and $A(y)$ in (2) and (1), we have

$$G(w^o, y) \leqq w^o \cdot \upsilon \text{ for all } v \in A(y);$$
$$G(w^1, y) \leqq w^1 \cdot y \text{ for all } v \in A(y);$$

consequently,

$$(1-\theta)G(w^o, y) + \theta G\left(W^1, y\right) \leqq w^o \cdot v$$
$$\text{for all } v \in A(y).$$

Hence, in particular,

$$(1-\theta)G(w^o, y) + \theta G(w^1 \cdot y)$$
$$\leqq \min\left\{w^\theta \cdot \upsilon : \upsilon \in A(y)\right\} \equiv G\left(W^\theta, y\right),$$

which is the result sought (cf. Uzawa 1964b).

Of fundamental importance in international trade theory is the following *duality* theorem first proved by Shephard (1953). The formulation and proof contained in Theorem 1 to follow are due to Uzawa (1964b).

Theorem 1 (*Duality Theorem*). Define the set

$$B(y) = \{\upsilon : (\forall w \geq 0) w \cdot \upsilon \geqq G(w, y)\}, \qquad (3)$$

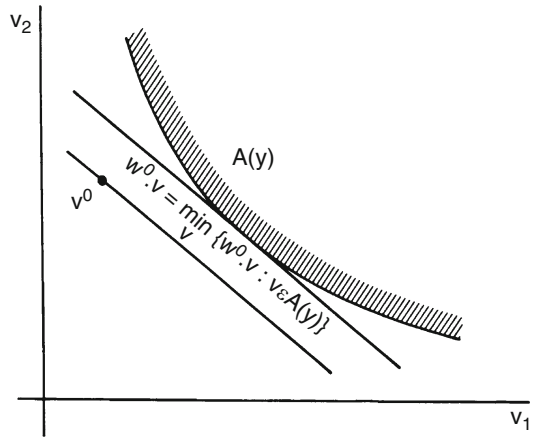
where G is defined by (2) and f satisfies properties (a), (b), (c). Then $B(y) = A(y)$, where $A(y)$ is defined by (1).

Proof: Let $\upsilon^0 \in A(y)$; then $f(\upsilon^0) \geqq y$, so for all $w \geq 0$,

$$w \cdot \upsilon^o \geqq \min_{\upsilon} \{w \cdot^u : f(\upsilon) \geqq y\} \equiv G(w, y)$$

that is, $\upsilon^0 \in B(y)$.

Conversely, suppose $\upsilon^0 \notin A(y)$. Since $A(y)$ is closed and convex by properties (a) and (b) of f, it follows from the separating hyperplane theorem of closed convex sets (cf. Fenchel 1953, p. 48) that there exists a vector $w^0 \neq 0$ such that



International Trade, Fig. 1

$$w^0 \cdot \upsilon^0 < \min_{\upsilon} \left\{w^0 . \upsilon : \upsilon \in A(y)\right\} \qquad (4)$$

(see Fig. 1). Now if w^0 has a negative component, it follows from property (c) that the corresponding component of $\upsilon \in A(y)$ may be chosen to be arbitrarily large, hence no minimum of $w^0 \cdot v$ over $A(y)$ exists; consequently, $w \geq 0$. But then the expression on the right of the inequality sign in (4) is just $G(w^0, y)$. From the definition of $B(y)$ in (3), it follows that $\upsilon^0 \notin$

$B(y)$. q.e.d.

The duality theorem may be stated in words as follows: given the function G, the set $A(y)$ may be identified with the set of all factor combinations υ which, at each constellation $w \geq 0$ of factor rentals, are at least as expensive as the minimal total cost of producing output y at factor rentals w.

Let us now explore the consequences of imposing a further condition on the production function f:

(d) *Positive homogeneity*: for all $\lambda > 0$, $f(\lambda\upsilon) = \lambda f(\upsilon)$.

From the definition of G in (2), we now have

$$G(w, y) = \min_{\upsilon} \left\{w \cdot \upsilon : f\left(\frac{\upsilon}{y}\right) \geqq 1\right\}$$
$$= \min_{b} \{yw \cdot b : f(b) \geqq 1\} \left(b = \frac{u}{y}\right)$$
$$= y \cdot \min_{b} \{w \cdot b : f(b) \geqq 1\}.$$

Thus, $G(w, y)$ factors into two terms, of which the second depends only on $w \geq 0$ and may be denoted

$$g(w) = \min_{v} \{w \cdot v : f(v) \geqq 1\}. \tag{5}$$

We therefore have

Theorem 2. If f satisfies properties (a), (b), (c), (d), then the function G of (3) factors into

$$G(w, y) = yg(w) \tag{6}$$

where g is defined by (5) and is continuous, concave, monotone, and positively homogeneous of first degree.

The properties of g specified in Theorem 2 follow directly from those of the function G.

We may now state a special form of the duality theorem for the case of homogeneous production functions.

Theorem 3. Let g be defined by (5) where f satisfies properties (a), (b), (c), (d), and let the function f^* be defined by

$$f^*(v) = \min_{v} \{w \cdot v : g(w) \geqq 1\}. \tag{7}$$

Then $f^* = f$.

Proof: Define the set

$$C(y) = \{v : [\forall w \in A^*(1)] w \cdot v \geqq y\} \tag{8}$$

where for convenience we define

$$A^*(p) = \{w : g(w) \geqq p\}. \tag{9}$$

(Since g is defined only for $w \geq 0$, $w \in A^*(p)$ implies $w \geq 0$). First we shall show that $C(y) = B(y)$, where $B(y)$ is defined by (3). From (3) and (6), if $v^0 \in B(y)$ then for all $w \in A^*(1)$, $w \cdot v^0 \geqq G(w, y) = yg(w) \geq y$, so $B(y) \subseteq C(y)$. Conversely suppose $v^0 \in C(y)$ and take any $w^0 \geq 0$. Then from the homogeneity of g we have $g[w^0/g(w^0)] = 1$, hence from the definition (8) of $C(y)$ it follows that

$$\frac{w^o}{g(w^o)} \cdot v^o \geqq y,$$

i.e., $w^0 \cdot v^0 \geqq yg(w^0)$; thus $v^0 \in B(y)$. Therefore $B(y) = C(y)$ and by Theorem 1, $C(y) = A(y)$.

Now denote $r = w/g(w)$ and consider the set

$$C'(y) = \left[v : \min_{r} \{r \cdot v : r \in A^*(1)\} \geqq y\right]. \tag{10}$$

If $r \cdot v \geqq y$ for all $r \in A^*(1)$, then a fortiori $r \cdot v \cdot \geqq y$ for the $r \in A^*(1)$ which minimizes $r \cdot v$; hence $C(y) \subseteq C'(y)$. Conversely, for all $r \in A^*(1)$ we have $r \cdot v \geqq \min_r \{r \cdot v : r \in A^*(1)\}$, so $C'(y) \subseteq C(y)$. Thus $C'(y) = C(y) = A(y)$. But from (7), (9) and (10) we have

$$C'(y) = \{v : f^*(v) \geqq y\}. \tag{11}$$

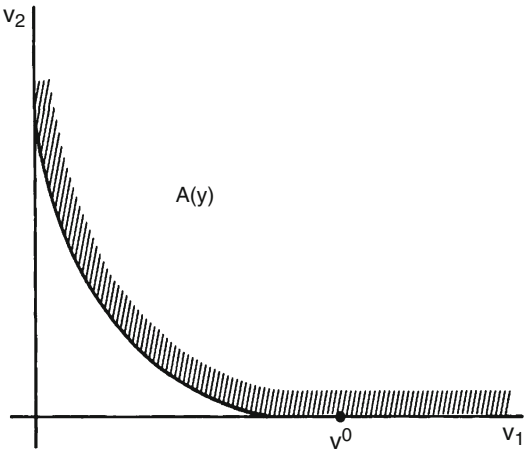
Since $A(y) = C'(y)$ for all y, therefore f and f^* coincide.

q.e.d.

Let us consider the consequences of adding to the properties (a), (b), (c) of f given in §1.1 the following further properties:

(b_1) *Strict quasi-concavity:* for each y, the set $A(y)$ defined by (1) is strictly convex;

(e) *Differentiability:* f has continuous first-order partial derivatives (Fig. 2).



International Trade, Fig. 2

For the time being, property (d) of §1.2 will not be used, but will be introduced again later on.

The problem of deriving the minimum total cost function $G(w, y)$ may be posed in terms of the following non-linear programming problem:

$$\text{minimize} \sum_{j=I}^{m} w_j \upsilon_j \text{ subject to } f(\upsilon) \geqq y, u \geqq 0 \quad (12)$$

Form the Lagrangean function

$$L(p^*, u; y, w) = \sum_{j=I}^{m} w_j \upsilon_j - p^*[f(\upsilon) - y] \quad (13)$$

where y, w are parameters and p^* is a Lagrangean multiplier. In accordance with the Kuhn–Tucker theorem (cf. Kuhn and Tucker 1951, p. 486) in order for $\upsilon^0 = (\upsilon_1^0, \upsilon_2^0, \ldots, \upsilon_m^0)$ to be a solution of the minimum problem (12), it is necessary and sufficient that υ^0 and some $p^* \geqq 0$ satisfy

$$\left.\frac{\partial L}{\partial \upsilon_j}\right|_{\upsilon=\upsilon^0} = wj - p^* \left.\frac{\partial f}{\partial v_j}\right|_{\upsilon=\upsilon^0} \geqq 0 : uj \frac{\partial L}{\partial \upsilon_j} = 0 \quad (14)$$

and

$$\sum_{j=1}^{m} \upsilon_j^0 \left.\frac{\partial L}{\partial \upsilon_j}\right|_{\upsilon j=\upsilon_j^0} = \sum_{j=1}^{m} \upsilon_j^0 \left(w_j - p^* \left.\frac{\partial L}{\partial \upsilon_j}\right|_{\upsilon j=\upsilon_j^0} \right) = 0 \quad (15)$$

as well as

$$\frac{\partial L}{\partial p^*} = -\left[f\left(\upsilon^0\right) - y\right] \geqq 0; p^* \frac{\partial L}{\partial p^*} = 0. \quad (16)$$

In the above we have used (e), but so far property (b_1) has not yet been used: Let us introduce the further properties:

(f) *indispensability*: $f(0) = 0$.
(f_1) *strict indispensability:* if υ has a component $\upsilon_j = 0$ then $f(\upsilon) = 0$.

Now suppose the solution υ^0 to (12) is such that $f(\upsilon)^0 > y$ (see Fig. 2). This violates (b_1), since strict quasi-concavity requires that if υ^0, $\upsilon^1 \in A(y)$ and $0 < \theta < 1$, the point $\upsilon^0 = (1 - \theta)\upsilon^0 + \theta\upsilon^1$ should be in the interior of $A(y)$. Suppose, however, that property (b_1) is not assumed, and that $f(\upsilon^0) > y > 0$; then $p^* = 0$ from (16) hence $w \cdot \upsilon^0 = 0$ from (15), and since $w \geq 0$ this implies that υ^0 has a zero component. Thus, if (f_1) is assumed, we have $0 = f(\upsilon^0) > y > 0$ – a contradiction. Thus, either (b_1) or (f_1) is sufficient – in conjunction with (a), (c), (e), to guarantee $f(\upsilon^0) = y$. If $w > 0$, a similar argument shows that (f) implies $f(\upsilon^0) = y$.

Now suppose that υ^0 is such that strict inequality holds in (14) for some j. Then $\upsilon^0_j = 0$ from (15) If (f_1) holds this would lead to a contradiction, since then $0 = f(\upsilon^0) \geqq y > 0$. If ($f_1$) is not assumed, but if (b_1) holds, then strict inequality in (14) implies that υ^0 has a zero component, so υ^0 is on the boundary of $A(y)$; but $2\upsilon^0$ is also on the boundary of $A(y)$, by property (c), and consequently the mid-point $1\frac{1}{2}\upsilon^0$ is as well, contradicting (b_1). Thus, if (a), (b), (c), (e) hold, then either (b_1) or (f_1) implies that equality holds in (14) for all $j = 1, 2, \ldots, m$.

Consider a solution υ^0 to (12) corresponding to a w^0 which has some zero components. Let $J = \{j: w^0_j = 0\}$. Then if $w^0 \cdot \upsilon^0 = C^0$, certainly $A(y) \subseteq \{\upsilon: w^0 \cdot \upsilon^0 \geqq C^0\}$. Let υ^1 be such that $\upsilon^1_j > \upsilon^0_j$ for $j \in J$ and $\upsilon^1_j = \upsilon^0_j$ for $j \notin J$. Then $w^0 \cdot \upsilon^1 = w^0 \cdot \upsilon^0$, hence $\upsilon^1 \in \{\upsilon: w^0 \cdot \upsilon = C^0\}$. But by condition (c), $\upsilon^1 \in A(y)$; thus υ^1 and υ^0 are both on the boundary of $A(y)$, as is $(1 - \theta)\upsilon^0 + \theta\upsilon^1$ for $0 < \theta < 1$ (see Fig. 3). This contradicts (b_1). Therefore under (b_1), a solution to (12) exists only if $w > 0$.

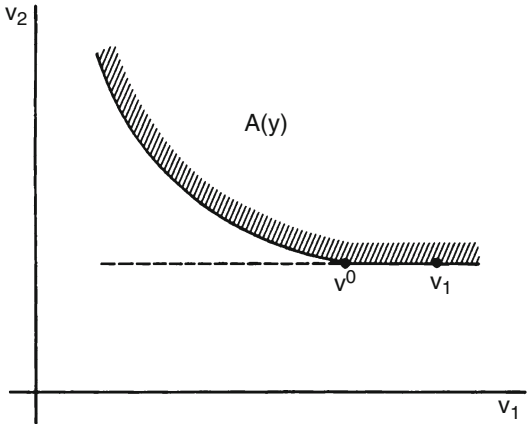
It should be noted that even if the function $G(w, y)$ of (2) is well defined in the sense

$$G(w, y) = \inf_{v} \{w \cdot \upsilon : f(\upsilon) \geqq y\}, \quad (17)$$

a solution of (12) need not exist. For example, if

$$f(\upsilon_1, \upsilon_2) = \frac{1}{\frac{1}{\upsilon_1} + \frac{1}{\upsilon_2}}$$

Then



International Trade, Fig. 3

$$G(0, w_2; y) = yw_2$$

but the *infimum* is achieved as $(\upsilon_1, \upsilon_2) \to (\infty, y)$. On the other hand a solution to (12) always exists if $w > 0$; for, choosing any $\upsilon^0 \in \text{int } A(y)$ and $w^0 > 0$, the set

$$A(y) \cap \left\{\upsilon : w^0 \cdot \upsilon \leqq w^0 \upsilon^0, \upsilon \geqq 0\right\}$$

is compact by virtue of condition (a), and from (b) and (c) the minimum of $w^0 \cdot \upsilon$ over this set is the minimum over $A(y)$.

An immediate consequence of (b_1) is that if (12) has a solution, it is *unique*. Since (12) need not have a solution unless $w > 0$, it is of some advantage to replace (b_1) by a weaker condition which still ensures uniqueness provided $w > 0$. Such a condition is

(b_2) if $\upsilon^0 \neq \upsilon^1$ and neither $\upsilon^0 \geq \upsilon^1$ nor $\upsilon^1 \geq \upsilon^0$, and if $0 < \theta < 1$, then $f[(1 - \theta)\upsilon^0 + \theta\upsilon^1] > \min[f(\upsilon^0), f(\upsilon^1)]$.

The above discussion may now be summarized in the following theorem.

Theorem 4. Let conditions (a), (b), (c), (e), (f) hold. Then if either (b_1) or (f_1) holds, any solution υ^0 to (12) has the property (Fig. 3)

$$w_j = p^* \frac{\partial f}{\partial \upsilon_j}\bigg|_{\upsilon=\upsilon^0} \quad (j = 1, 2, \ldots, m); \qquad f(\upsilon^0) = y. \tag{18}$$

If (b_1) holds, this solution is unique. If (b_2) holds and if $w > 0$, then a unique solution to (12) exists, and it satisfies (18).

We now proceed with an analysis of the solution υ of the programming problem (12) regarded as a function of the parameters $y > 0$, $w > 0$, when conditions (a), (b_2), (c), (e), (f) are assumed to hold.

In accordance with Theorem 4, the solution satisfies (18) and is unique, given y and w. Thus we have the functions

$$\upsilon_j = \upsilon(w, y) \qquad (j = 1, 2, \ldots, m). \tag{19}$$

It is shown in Fenchel (1953, pp. 102–4) that these functions are differentiable. Substituting (19) into (18) we obtain

$$p^* = w_j / \frac{\partial}{\partial \upsilon_j} f[\tilde{\upsilon}_1(w, y), \quad \tilde{\upsilon}_2(w, y), \ldots \tilde{\upsilon}_m(w, y)] = \tilde{p}^*(w, y).$$

The system of equations (18) defines a mapping $\mathscr{F}$ from the non-negative orthant of $(m + 1)$-dimensional space into itself:

$$\mathscr{F}^{-1}(\upsilon, p^*) = (w, y). \tag{20}$$

Equations (19) and (1.13b) define the inverse mapping:

$$\mathscr{F}^{-1}(w, y) = (\upsilon, p^*). \tag{21}$$

In accordance with (2) we define

$$G(w, y) = \sum_{k=1}^{m} w_k \tilde{\upsilon}_k(w, y). \tag{22}$$

We shall also define the *indirect production function f* by

$$\tilde{f}(w, y) = f[\tilde{\upsilon}_1(w, y), \tilde{\upsilon}_2(w, y)], \ldots, \tilde{\upsilon}_m(w, y)] \tag{23}$$

which satisfies the identity

$$\tilde{f}(w, y) = y \text{ for all } w, y. \tag{24}$$

Theorem 5. (*Fundamental Envelope Theorem of Production Theory*). The functions G, $\tilde{v}_l$, $\tilde{p}^*$ of (22), (19), (1.13b) are related by

$$\frac{\partial G(w, y)}{\partial w_j} = \tilde{v}_j(w, y) \quad j = 1, 2, \ldots, m \tag{25}$$

and

$$\frac{\partial G(w, y)}{\partial w_j} = \tilde{p}^*(w, y) \tag{26}$$

Proof: Differentiating (15) with respect to w_j, we obtain

$$\frac{\partial G(w, y)}{\partial w_j} = \tilde{v}_j(w, y) + \sum_{k=1}^{m} w_k \frac{\partial \tilde{v}_k(w, y)}{\partial w_j} \tag{27}$$

To prove (25) we must show that the second term on the right of (27) vanishes. Differentiating (23) with respect to w_j and making use of the identity (24) and the chain rule, we obtain upon substitution of (1.13b),

$$0 = \frac{\partial f(w, y)}{\partial w_j} = \sum_{k=1}^{m} \frac{\partial f}{\partial v_k}\bigg|_{v k = \tilde{v} k(w,\, y)} \cdot \frac{\partial \tilde{v}_k(w, y)}{\partial w_j}$$
$$= \frac{1}{\tilde{p}^*(w, y)} \sum_{k=1}^{m} w_k \frac{\partial \tilde{v}_k(w, y)}{\partial w_j}.$$

and (25) follows. Likewise, differentiating (23) with respect to y and using the identity (24) and the chain rule, we have upon making use once again of (1.13b),

$$1 = \frac{\partial \tilde{f}(w, y)}{\partial y} = \sum_{k=1}^{m} \left(\frac{\partial f}{\partial v_k}\right)_{v k = \tilde{v} k(w,\, y)} \cdot \frac{\partial \tilde{v}_k(w, y)}{\partial y}$$
$$= \frac{1}{\tilde{p}^*(w, y)} \sum_{k=1}^{m} w_k \frac{\partial \tilde{v}_k(w, y)}{\partial y}.$$

Thus, from this result and (22),

$$\frac{\partial G(w, y)}{\partial y} = \sum_{k=1}^{m} w_k \frac{\partial \tilde{v}_k(w, y)}{\partial y} = \tilde{p}^*(w, y),$$

establishing (26).

q.e.d.

It may be noted immediately from (22) and (25) that

$$G(w, y) = \sum_{k=1}^{m} w_k \frac{\partial G(w, y)}{\partial w_k},$$

providing the necessary and sufficient condition, by Euler's theorem, that G be homogeneous of degree 1 in w – a result already obtained in §1.1. Using (25) again it follows that $\tilde{v}_j$ is homogeneous of degree zero in w.

Now let us introduce condition (d): the positive homogeneity (of degree 1) of the production function f. Using (22) and (1.13b) we have, by Euler's theorem,

$$G(w, y) = \sum_{k=1}^{m} w_k \tilde{v}_k\,(w, y)$$
$$= \tilde{p}^*(w, y) \sum_{k=1}^{m} \left(\frac{\partial f}{\partial v_k}\right)_{v k = \tilde{v} k(w,\, y)} \cdot \tilde{v}_k(w, y)$$
$$= y \tilde{p}^*(w, y)$$

whence from (6)

$$\tilde{p}^*(w, y) = \frac{G(w, y)}{y} = g(w). \tag{28}$$

Defining

$$b_j(w) = \frac{\partial g(w)}{\partial w_j} \quad (j = 1, 2, \ldots, m) \tag{29}$$

we have from (25), (28), and (29),

$$\tilde{v}_j(w, y) = \frac{\partial G(w, y)}{\partial w_j} = y \frac{\partial g(w)}{\partial w_j} = y b_j(w) \tag{30}$$

hence the optimal factor-product ratios are given by

$$\frac{v_j}{y} = b_j(w). \tag{31}$$

From the differentiability assumption (e) imposed on the function f we can derive a strict quasi-concavity property of the function g. For suppose $w^0 > 0,\ w^1 > 0,\ and\ w^0 \neq \lambda w^1$; then from ($b_2$) and (e), we have $b(w^0) \neq b(w^1)$, where

$$b(w) = [b_1(w), b_2(w), \ldots, b_a(w)]. \tag{32}$$

Now by definition of g [see (5)]

$$\begin{aligned} g(w^0) &\leqq w^0 \cdot \upsilon \text{ for all } \upsilon \in A(1) \\ g(w^1) &\geqq w^1 \cdot \upsilon \text{ for all } \upsilon \in A(1) \end{aligned} \tag{33}$$

and moreover

$$\begin{aligned} g(w^0) &= w^0 \cdot \upsilon \text{ if and only if } \upsilon \in b(w^0) \\ g(w^1) &\geqq w^1 \cdot \upsilon \text{ if and only if } \upsilon \in b(w^0) \end{aligned} \tag{34}$$

Furthermore, $b(w^0) \neq b(w^1)$, so strict inequality must hold in one of the inequalities (33); thus if $0 < \theta < 1$,

$$(1-\theta)g(w^0) + \theta g(w^1) < \left[(1-\theta)w^0 + \theta w^1\right] \cdot v \text{ for all } v \in A(1)$$

and therefore in particular

$$\begin{aligned} &(1-\theta)g(w^0) + \theta g(w^1) \\ &< \min_v \left\{ \left[(1-\theta)w^0 + \theta w^1\right] \cdot v : v \in A(1) \right\} \\ &= g[(1-\theta)w^0 + \theta w^1]. \end{aligned}$$

So we have

(b^*) if $w^0 > 0,\ w^1 > 0$, and $w^0 \neq \lambda w^1$, and if $0 < \theta < 1$, then $g[(1-\theta)w^0 + \theta w^1] > (1-\theta)g(w^0) + \theta g(w^1)$.

If is not hard to see that a corresponding property (b_3) holds for f as well. Failure of $\left(b_3^*\right)$ when f is not differentiable, allowing $b(w^0) = b(w^1)$ for $w^0 \neq \lambda w^1$, is illustrated in Fig. 4.

In general, a flat segment on a production isoquant goes over into a kink on the dual cost isoquant, and vice versa. There is another still more subtle relationship, illustrated by the following function found in Katzner (1970, p. 54):

$$f(\upsilon_1, \upsilon_2) = \left(\upsilon_1^3 \upsilon_2 + \upsilon_1 \upsilon_2^3\right)^{1/4}$$

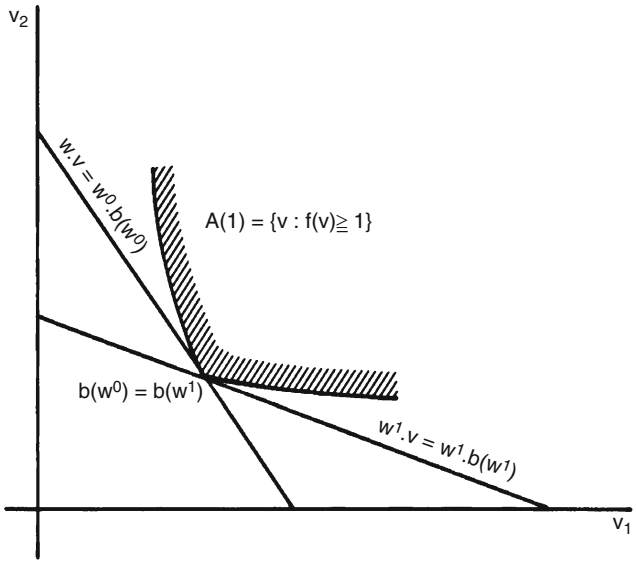
Its dual minimum-unit-cost function is found to be

$$g(w_1, w_2) = 2^{-1/4}\left[(w_1 + w_2)^{4/3} - (w_1\, w_2)^{4/3}\right]^{4/3}.$$

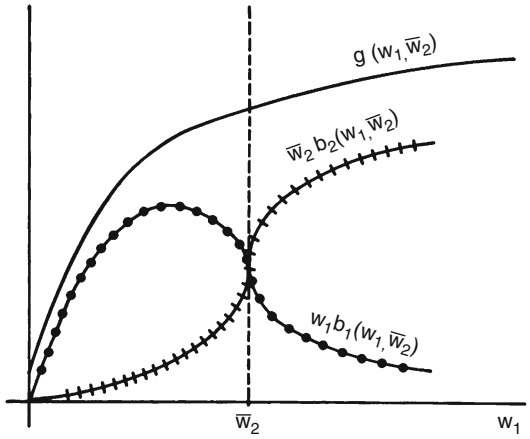
The isoquants of f are extremely flat at $\upsilon_1 = \upsilon_2$, and as a result g is once but not twice differentiable at $w_1 = w_2$. A graph of

$$g(w_1, w_2) = w_1 b_1(w_1,\ w_2) + w_2 b_2(w_1\ w_2)$$

for $w_2 = \overline{w}_2$ is shown in Fig. 5. At $w_1 = \overline{w}_2$, $\overline{w}_2$ $b_2(w_1,\ \overline{w}_2)$ has a slope of $+\infty$ and $w_1 b_1(w_1,\ \overline{w}_2)$ has a slope of $-\infty$, yet their sum is differentiable.



International Trade, Fig. 4



International Trade, Fig. 5

When the bordered Hessian of the production function f is invertible, its inverse is the bordered Hessian of the cost function g; in the above example, it is not invertible at $\upsilon_1 = \upsilon_2$.

A useful illustration of the duality of cost and production functions is given by the case of CES (constant-elasticity-of-substitution) production functions (cf. Arrow et al. 1961; Uzawa 1962):

$$f(\upsilon) = \left[\sum_{i=1}^{m} \alpha_i \upsilon_i^{1-1/\sigma}\right]^{\sigma/(\sigma-1)}$$

The corresponding cost functions have the form

$$f(w) = \left[\sum_{i=1}^{m} \alpha_i^{\sigma} w_i^{1-\sigma}\right]^{1/(1-\sigma)}$$

whose elasticity of substitution is $\sigma^* = 1/\sigma$.

The Production-Possibility Set

Suppose a country to be capable of producing n commodities with the aid of m primary factors of production. Denoting the output of commodity j by y_j, and the input of factor i into the production of commodity j by υ_{ij}, the production function may be written

$$\begin{aligned} y_j &= f_i(\upsilon_{1j}, \upsilon_{2j}, \ldots, v_{mj}) \\ &= f_j(\upsilon_j) \qquad (j = 1, 2, \ldots, n), \end{aligned} \tag{35}$$

where

$$\upsilon_{.j} = (\upsilon_{1j}, \upsilon_{2j}, \ldots, \upsilon_{mj}). \tag{36}$$

It will be assumed that f_j is:

(a) *Continuous*; i.e.,

$$\lim_{\upsilon_j \to \upsilon_j^0} f_j(\upsilon_j) = f_j\left(\upsilon_j^0\right);$$

(b) *Weakly monotone*; i.e., if $\upsilon^1{}_{.j} \geqq \upsilon^2{}_{.j}$ (meaning that $\upsilon^1{}_{ij} \geqq \upsilon^2{}_{ij}$ for $i = 1, 2, \ldots, m$) then $f_i(\upsilon^1{}_{.j}) \geqq f_j(\upsilon^2{}_{.j})$, and if $\upsilon^1{}_{.j} > \upsilon^2{}_{.j}$ (i.e., $\upsilon^1{}_{ij} > \upsilon^2{}_{ij}$ for $i = 1, 2, \ldots, m$) then $f_i(\upsilon^1{}_{.j}) > f_j(\upsilon^2{}_{.j})$;

(c) *Concave*; i.e., if $\upsilon^0{}_{.j}$ and $\upsilon^1{}_{.j}$ are any two vectors of primary inputs into the production of commodity j, then for any t in the interval $0 < t < 1$, (Fig. 5)

$$f_j\left[(1-t)\upsilon_j^0 + t\upsilon_j^1 \geqq (1-t) f_j\left(\upsilon_j^0\right) + t f_j\left(\upsilon_j^1\right)\right. \tag{37}$$

(d) *Positively homogeneous of degree* 1; i.e., for any $\lambda > 0$,

$$f_j(\lambda \upsilon_{.j}) = \lambda f_j(\upsilon_{.j}). \tag{38}$$

It will be convenient to introduce the $m \times n$ allocation matrix

$$V = \begin{bmatrix} \upsilon_{11} & \upsilon_{12} & \cdots & \upsilon_{1n} \\ \upsilon_{21} & \upsilon_{22} & \cdots & \upsilon_{2n} \\ \cdot & \cdot & \cdot & \cdot \\ \upsilon_{m1} & \upsilon_{m2} & \cdots & \upsilon_{mn} \end{bmatrix} \tag{39}$$

The element υ_{ij} is the input of factor i into the production of commodity j. The j the column of V will be donoted υ_j; according to this notation, υ_j is the transpose of $\upsilon_{.j}$, denoted $\upsilon_j = \mathrm{v}'_{.j}$.

Let l_i denote the country's total endowment of factor i. Then for each i the following resource constraint holds:

$$\sum_{j=1}^{m} v_{ij} \leqq l_j \quad (i = 1, 2, \ldots m). \tag{40}$$

Using (39) this can be written in matrix notation as

$$\begin{bmatrix} v_{11} & v_{12} & \cdots & v_{1n} \\ v_{21} & v_{22} & \cdots & v_{2n} \\ \cdot & \cdot & \cdots & \cdot \\ v_{m1} & v_{m2} & \cdots & v_{mn} \end{bmatrix} \begin{bmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix} \leqq \begin{bmatrix} l_1 \\ l_2 \\ \vdots \\ l_m \end{bmatrix}, \tag{41}$$

or simply

$$V_i \leqq l, \tag{42}$$

where l is the column vector of n ones and $l = (l_1, l_2, \ldots, l_m)'$ is the column vector of factor endowments.

In the absence of any additional restrictions, condition (40) expresses the *perfectly mobility* of factors among industries.

The country's *production–possibility set* is the set of all possible output combinations $y = (y_1, y_2, \ldots, y_n)$ that can be produced with the production functions (35) under the resource constraints (40). Formally, it may be denoted

$$\begin{aligned} \mathscr{Y}(l) = y : \text{there exist allocations } v_{ij} \geqq 0 \textit{ such that} \\ y_j = f_j(v_j)(j = 1, 2, \ldots n) \quad \text{and} \\ \sum_{j=1}^{n} v_{ij} \leqq l_j \quad (i = 1, 2, \ldots m). \end{aligned} \tag{43}$$

For notational convenience we may define the function $f(V)$ as the vector-valued function

$$f(V) = \left(f_1\left(v_1'\right), f_2\left(v_2'\right), \ldots, f_n\left(v_n'\right)\right)' \tag{44}$$

and write (43) in the more compact form

$$y(l) = \{y : (\exists V \geqq 0) y = f(V) \& V_l \geqq l\}. \tag{45}$$

Note that with this notation, condition (37) can be written (for $t = t_j$) in the form

$$\begin{aligned} f\left(V^0(I - T) + V^1 T\right) \geqq (I - T) f\left(V^0\right) \\ + T f\left(V^1\right) \end{aligned} \tag{46}$$

where $T = \text{diag}(t_1, t_2, \ldots, t_n)$ is an $n \times n$ diagonal matrix with $0 < t_j < 1$. Likewise, (38) may be written (for $\lambda = \lambda_j$) in the form

$$f(V\Lambda) = \Lambda f(V), \tag{47}$$

where $\Lambda = diag(\lambda_1, \lambda_2, \ldots, \lambda_n)$ is an $n \times n$ diagonal matrix with $\lambda_j > 0$.

Theorem 6. If assumptions (a), (b), and (c) hold, the production-possibility set $\mathscr{Y}(l)$ is convex.

Proof: Let y^0, y^1 both belong to $\mathscr{Y}(l)$; we are to show that for any t in the interval $0 < t < 1$, the output combination $y^t = (l - t)\, y^0 + ty^1$ also belongs to $\mathscr{Y}(l)$ (see Fig. 6).

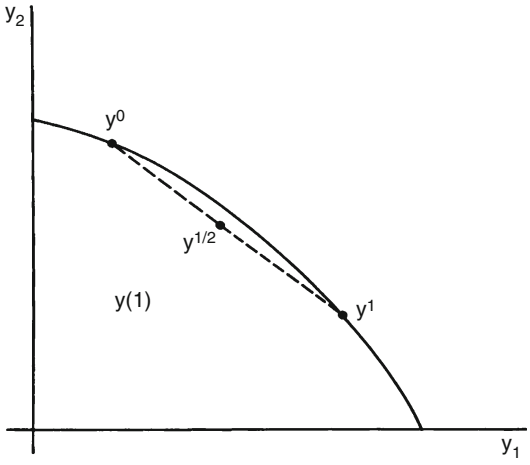
Since $y^0, y^{ty} \in \mathscr{Y}(l)$, this means that there exist two allocation matrices V^0, V^1 each satisfying (42), such that $y^0 = f(V^0)$ and $y^1 = f(V^1)$. Denote $V^t = (1 - t)V^0 + tV^0$. Then from (42),

$$V^t l = (1 - t)V^0 t + tV^1 l \leqq (1 - t)l + tl = l, \tag{48}$$

so V^t is a feasible allocation, and by concavity,

$$f(V^t) \geqq (1 - t) f\left(V^0\right) + tf\left(V^1\right) = y^t, \tag{49}$$

i.e., for each $j = 1, 2, \ldots, n$, denoting $v^t{}_{.j} = (1 - t)^{V}{}_{.j} + tv^1{}_{.j}$,



International Trade, Fig. 6

$$f_j\left(v^t{}_{\cdot j}\right) \geqq (1-t) f_j\left(v^0{}_{\cdot j}\right) + t f_j\left(v^1{}_{\cdot j}\right) = y^t{}_j. \quad (50)$$

By continuity and monotonicity of f_j, there exist $\lambda^t{}_j \leqq 1$ such that

$$f_j\left(\lambda^t_j v^t_j\right) = y^t_j \quad (j = 1, 2, \ldots, n). \quad (51)$$

(In particular, (51) follows if the stronger homogeneity condition (d) holds, by taking $\lambda^t{}_j = y^t_j / f_j\left(v^t_j\right)$ if $y^t{}_t > 0$, and 0 otherwise.) Equivalently,

$$f(V^t \Lambda^t) = y^t. \quad (52)$$

It remains only to verify that the matrix $V^t\Lambda$ of allocations $\lambda^t_j\, v^t_{ij}$ satisfies the constraint (42).

This is immediate from the fact that $0 \leqq \lambda^t_j \leqq 1$, whence from (48),

$$V^t \Lambda^t_l = V^t \lambda^t \leqq V^t_l \leqq l. \quad (53)$$

q.e.d.

Note that homogeneity of production functions is not needed for the above result (Fig. 7).

The National-Product Function

Let $p = (p_1, p_2, \ldots, p_n)'$ denote a vector of prices. The *national-product function* (cf. Samuelson 1953; Chipman 1972, 1974) is defined as the function

$$\Pi(p, l) = \max_{y \in \mathscr{Y}(l)} p \cdot y. \quad (54)$$

[See also Dixit and Norman (1980), who use the terminology 'revenue function'.]

For any fixed p, this has all the properties of a production function, but with some special peculiar features. These are illustrated in Fig. 7 to be explained shortly.

For each commodity, $j = 1, 2, \ldots, n$, define the uppercontour set

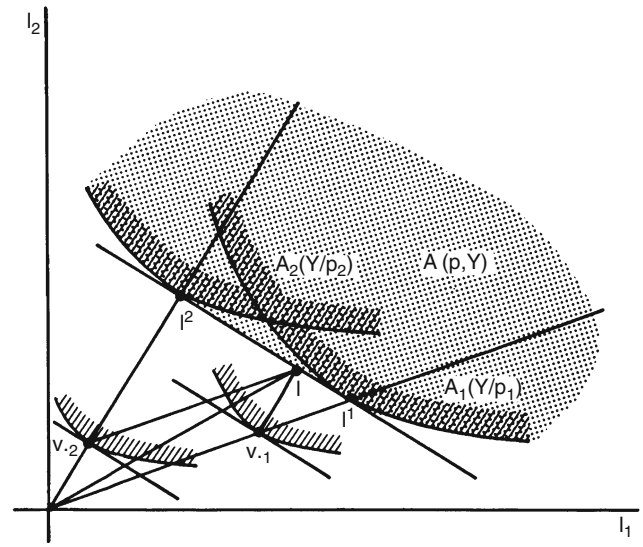
$$A_j\left(y_j\right) = \left\{l^j = \left\{l^j_1 = \left(l^j_1, l^j_2, \ldots l^j_m\right) : f_j\left(l^j\right) \geqq y_j\right\}\right. . \quad (55)$$

Then in particular,

$$A_j(Y/p_j) = \left\{l^j : p_j f_j\left(l^j\right) \geqq Y\right\} \quad (56)$$

is the set of factor-input combinations that will yield, at the given price p_j an amount of commodity j worth at least Y. Throughout this section it will be assumed that each f_j satisfies properties (a)–(d) of the preceding section.

Let us now introduce a stronger monotonicity condition that refers to the entire vector-valued function (63). It may be stated as follows: f is



International Trade, Fig. 7

(e) *Strictly monotone*, i.e., for each $V = [\upsilon_{ij}]$ and each $i = 1, 2, \ldots, m$, there is a $j = 1, 2, \ldots, n$ such that $\delta > 0$ implies

$$f_j(\upsilon_{1j}, \upsilon_{2j}, \ldots, \upsilon_{ij} + \delta, \ldots, \upsilon_{mj}) > f_j(\upsilon_{1j}, \upsilon_{2j}, \ldots, \upsilon_{ij}, \ldots, \upsilon_{mj}). \tag{57}$$

In words, if there is an increase in the amount of any one of the m endowments, it is possible to find an industry where this additional input will lead to increased output.

For any family of sets $S_1, S_2, \ldots, S_n$, each a subset of m-dimensional Euclidean space E^m, the *arithmetic mean* of this family (which is, for convex S_j, also the *convex hull* of $\cup^n{}_{j=1} S_j$) is defined and denoted

$$\mathop{\mathrm{M}}_{j=1}^{n} S_j = \left\{ s \in E^m : \left(\exists s^j \in S_j,\ \lambda_j \geqq 0, j = 1, 2, \ldots, n\right) \sum_{j=1}^{n} \lambda_j = 1 \text{ and } s = \sum_{j=1}^{n} \lambda_j s^j \right\} \tag{58}$$

Analogously to (55) we define the upper-contour set of the national-product function by

$$A(p, Y) = \left\{ l \in E_+^m : \prod(p, l) \geqq Y \right\}. \tag{59}$$

The following theorem characterizes the isoquants of the function $\Pi(p, \cdot)$ (see Fig. 7).

Theorem 7. Let all prices p_j, be positive, $j = 1,2,\ldots, n$, and let f satisfy conditions (a)–(d) of section "The Production-Possibility Set", as well as the strict montonicity condition (e). Then

$$A(p, Y) = \mathop{\mathrm{M}}_{j=1}^{n} A_j(Y/p_j), \tag{60}$$

i.e., the upper-contour set consisting of all factor combinations l that give rise to a national product of at least Y, is the arithmetic mean of the n upper-contour sets consisting, for each commodity j, of all factor combinations l^j that, when allocated entirely to industry j, give rise to a national product of at least Y.

Proof (a) let us first prove that

$$\mathop{\mathrm{M}}_{j=1}^{n} A_j(Y/p_j) \subseteq A(p, Y) \tag{61}$$

Let

$$l \in \mathop{\mathrm{M}}_{j=1}^{n} A_j(Y/p_j).$$

Then, by definition (58), there exist $l^j \in A(Y/p_j)$ and $\lambda_j \geqq 0$ such that

$$\sum_{j=1}^{n} \lambda_j = 1 \quad \text{and} \quad \sum_{j=1}^{n} \lambda_j l^j = l.$$

By definition (56), each l^j satisfies $p_j f_j(l^j) \geqq Y$, hence from the definition (54) of Π and the homogeneity of degree 1 of each f_j, we have

$$\Pi(p, l) \geqq \sum_{j=1}^{n} p_j f_j(\lambda_j l^j) = \sum_{j=1}^{n} p_j f_j(l^i) \geqq y \sum_{j=1}^{n} \lambda_j = Y.$$

From definition (59) it follows that $l \in A(p, Y)$, and (61) follows.

(b) We now show that

$$A(p, Y) \subseteq \mathop{\mathrm{M}}_{j=1}^{n} A_j(Y/p_j). \tag{62}$$

Let $l \in A(p, Y)$; then by definitions (59), (54) and (43), there exist allocations $\upsilon_j \in E^{m+}$ such that

$$\sum_{j=1}^{n} \upsilon_j \leqq l \quad \text{and} \quad \sum_{j=1}^{n} p_j f_j(\upsilon_j) = \Pi(p, l) \geqq Y. \tag{63}$$

By the strict monotonicity of f, the first inequality of (63) must be an equality; for, if for some $i = i'$ we have

$$\sum_{j=1}^{n} v_{i'j} < l_{i'}$$

then for some

$$j = j' \quad \text{and} \quad 0 < \delta \leqq l_{i'} - \sum_{j=1}^{n} v_{i'j}$$

the inequality (57) is satisfied, violating the definition (54) of $\Pi(p, l)$. Now define

$$\begin{aligned} \lambda_j &= p_j f_j(v_{\cdot j}) / \Pi(p, l), \\ l^j &= u_{\cdot j} / \lambda_j \quad (j = 1, 2, \ldots, n). \end{aligned} \tag{64}$$

Then

$$\sum_{j=1}^{n} \lambda_j l^j = 1 \quad \text{where} \quad \sum_{j=1}^{n} \lambda_j = 1 \tag{65}$$

By homogeneity we have

$$p_j f_j(l^j) = p_j f_j(v_{\cdot j}) / \lambda_j = \Pi(p, l) \geqq Y,$$

hence $l^j \in A_j(Y/p_j)$ from (56). Together with (63) this implies that (62) holds.

q.e.d.

Since for each fixed p the national-product function $\Pi(p, \ )$ has the properties of a production function (i.e. it is continuous, concave, monotone, and positively homogeneous of degree 1), we may associate with it a corresponding minimum-unit cost function $\Gamma(p, \ )$ defined by

$$\Gamma(p, w) = \min_{l} \left\{ w \cdot l : \prod(p, l) \geqq \right\}. \tag{66}$$

This will be called the *national-cost function*. Letting $g_j(w) = min_{v_{\cdot j}} \{w. v_{\cdot j} : f_j(v_{\cdot j}) \geqq 1\}$ denote the minimum-unit cost function dual to the production function $f_j(v_{\cdot j})\}$, we may define the upper-contour sets

$$A_j^*(p_j) = \left\{ w : g_j(w) \geqq p_j \right\} \tag{67}$$

And

$$A^*(p) = \{ w : \Gamma(w) \geqq 1 \} \tag{68}$$

The boundary of the intersection of all the sets (67) for $j = 1, 2, \ldots, n$ is known as the 'factor-rental frontier' (or 'factor-price frontier'-cf. Woodland 1982, pp. 49–52). The following theorem shows that it is also the contour of the corresponding national-cost function. Its shape will be similar to that depicted in Fig. 4.

Theorem 8. Let the prices p_j be positive, $j = 1, 2, \ldots, n$ and let f satisfy conditions (a) to (e) of section 1.2. Then

$$A*(p) = \bigcap_{j=1}^{n} A_j^*(p_j). \tag{69}$$

Proof Let $w \in A^*(p)$; then $\Gamma(p, w) \geqq 1$, i.e., $w \, l \geqq 1$, for all $l \in A(p, l)$. Choose such an l and let V be the optimal resource-allocation matrix: then

$$\Pi(p, l) = \sum_{j=1}^{n} p_j f_j(v_j) \geqq 1. \tag{70}$$

Defining λ_j and l^j as in (64), this gives (by homogeneity)

$$\sum_{j=1}^{n} p_j f_j(\lambda_j l^j) = \sum_{j=1}^{n} \lambda_j p_j f_j(l^j) \geqq 1, \tag{71}$$

and since

$$\lambda_j > 0 \text{ and } \sum_{j=1}^{n} \lambda_j = 1$$

this implies $p_j f_j(l^j) \geqq 1$, i.e., $l^j \in A_j(1/p_j)$, for each j. Now by hypothesis, (70) implies $w \geqq l \geqq 1$ hence

$$\sum_{j=1}^{n} \lambda_j w \cdot l^j \geqq 1, \tag{72}$$

and by the same reasoning as above this implies $w. l^j \geqq 1$ for all j, i.e.,

$$g_j(w)/p_j = \min_{l^j} \left\{ w \cdot l^j : l^j \in A_j(1/p_j) \right\} \geqq 1 \tag{73}$$

or $g_j(w) \geqq p_j$. From the definition (67) this shows that $w \in A_j^*(p_j)$ *for* $j = 1, 2, \ldots, n$.

Conversely, let $w \in \cap_{j=1}^{n} A_j^*(p_j)$; then $g_j(w) \geqq p_j$ for $j = 1, 2, \ldots, n$. From the definition of g_j, this implies $w\, l^j \geqq 1$ for all $l^j \in A_j(l/p_j), j = 1, 2, \ldots, n$. Choosing $l^j \in A_j\,(1/p_j)$ such that

$$\sum_{j=1}^{n} \lambda_j l^j = l, \Pi(p,l) \geqq \sum_{j=1}^{n} p_j f_j(\lambda_j l^j) = \sum_{j=1}^{n} \lambda_j p_j f_j(l^i) \geqq \sum_{j=1}^{n} \lambda_j = 1, \tag{74}$$

Hence

$$w \cdot l = w \cdot \sum_{j=1}^{n} \lambda_j l^j = \sum_{j=1}^{n} \lambda_j w \cdot l^j \geqq 1, \tag{75}$$

From the definition (66) this implies $\Gamma(p, w) \geqq 1$, and thus by (68) it follows that $w \in A^*(p)$. q.e.d.

Let us introduce a further assumption, that each f_j is

(f) *Differentiable.*

Then from Theorem 7 it follows that $\Pi(p, .)$ is differentiable. Its partial derivative with respect to l_i *is defined as the Stolper–Samuelson Function*

$$\widehat{w}_i(p,l) \equiv \frac{\partial}{\partial l_i} \Pi(p,l) (i = 1, 2, \ldots, m), \tag{76}$$

and the corresponding vector-valued function $\widehat{w}_i(p,l) \equiv \partial \prod(p,l)/\partial l$ is called the *Stolper-Samuelson mapping*. The values of this function are the shadow or implicit factor rentals of the respective factors.

Setting up the Lagrangean function

$$L(V, w; p, l) = \sum_{j=1}^{n} p_j f_j(\upsilon_j) - \sum_{i=1}^{m} w_i \left(\sum_{j=1}^{n} \upsilon_{ij} - l_i \right) \tag{77}$$

corresponding to the definition of the national-product function, we obtain the Kuhn-Tucker conditions

$$\frac{\partial L}{\partial \upsilon i_j} = p_j \frac{\partial f_i}{\partial \upsilon_{ij}} - w_i \leqq 0; \quad \left(p_j \frac{\partial f_i}{\partial \upsilon_{ij}} - w_i \right) \upsilon_{ij} = 0; \tag{78}$$

$$\frac{\partial L}{\partial w_i} = l_i - \sum_{j=1}^{n} \upsilon_{ij} \geqq 0, \quad \left(l_i - \sum_{j=1}^{n} \upsilon_{ij} \right) w_i = 0. \tag{79}$$

It will be observed that conditions (78) constitute, for each $j = 1,2,\ldots,n$, precisely the Kuhn–Tucker conditions for costminimization in industry j, where w_i, is the ith factor rental. The rentals defined by the Stolper–Samuelson mapping are therefore the market rentals that will obtain in competitive equilibrium.

Let us now explore the consequences of assuming that the function Π is differentiable with respect to p as well as l. Given p^0, l^0, let y^0 maximize $p^0\, y^0$. Define the function

$$H(p, l^0) = \Pi(p, l^0) - p \cdot y^0.$$

Then $H(p^0, l^0) = 0$ and $H(p, l^0) \geqq 0$ for $p \neq p^0$ (by the definition of Π), hence H reaches a minimum with respect to p at $p = p^0$. Since differentiability of Π implies differentiability of H, we have

$$\frac{\partial H(p^0, l^0)}{\partial p_j} = \frac{\partial \Pi(p^0, l^0)}{\partial p_j} - y_j^0 = 0.$$

This shows that y^0 is the *unique* y which maximizes $p^0.y$ subject to $y \in \mathscr{Y}\ (l^0)$. This is equivalent to saying that the *production-possibility frontier* $\widehat{\mathscr{Y}}$ (l) – i.e., the set of all $y \in \mathscr{Y}\ (l^0)$ which maximize $p.y$ for some $p > 0$ – is *strictly concave to the origin*. The apparently innocuous assumption that Π is differentiable with respect to p has thus led to an important substantive conclusion.

When Π is differentiable with respect to p, the function

$$\widehat{y}_j(p,l) = \frac{\partial}{\partial p_j} \Pi(p,l) \quad (j = 1, 2, \ldots, n) \tag{80}$$

is called the *Rybczynski function* for commodity j. The corresponding vector-valued function $\hat{y}(p, l)$ is called the *Rybczynski mapping*.

In general, we may define the *Rybczynski correspondence* by

$$\widehat{y}(p,l) = \left\{ y \in y(l) : p \cdot y = \prod(p,l) \right\}. \quad (81)$$

The above result shows that if Π is differentiable with respect to p, this correspondence is a singleton-valued mapping. We shall now obtain a necessary and sufficient condition for this single-valuedness, i.e., for the strict concavity to the origin of y (1).

Let the factor–output coefficients be denoted

$$b_{ij}(w) = \frac{\partial g_j(w)}{\partial w_i} (i = l,2,\ldots,m;\ \ j = 1,2,\ldots,n) \quad (82)$$

where g_j is the minimum-unit-cost function dual to the production function f_j. The following result was obtained by Khang (1971) and Chipman (1972).

Theorem 9. Let p^0, l^0 be such that there exists a $y^0 > 0$ which maximizes $p^0 \cdot y$ subject to $y \in \mathscr{Y}$ (l^0), and let $w^0 = \hat{w}\ (p^0, l^0) = \partial \Pi(\mathrm{p}^0, \mathrm{l}^0)/\partial l$. Let f satisfy the strict monotonicity condition (e).

Then in order that y^0 should be the unique maximizer of $p^0\ y$ subject to $y \in \mathscr{Y}\ (l^0)$, it is necessary and sufficient that the n columns of the factor-output matrix

$$B(w^0) = \begin{bmatrix} b_{11}(w^0) & b_{12}(w^0) & \cdots & b_{1n}(w^0) \\ b_{21}(w^0) & b_{22}(w^0) & \cdots & b_{2n}(w^0) \\ & & & \\ b_{m1}(w^0) & b_{m2}(w^0) & \cdots & b_{mn}(w^0) \end{bmatrix}$$

be linearly independent.

Proof: For convenience, denote $B^0 = B(w^0)$. Then from strict monotonicity of f we have

$$B^0 y^0 = l^0. \quad (83)$$

First we show that if rank $B^0 < n$ then y^0 is not unique. Since rank $B^0 < n$ there exists a vector $z^0 \neq 0$ such that

$$B^0 z^0 = 0. \quad (84)$$

Choose $\varepsilon^0 > 0$ such that

$$y^0 \pm \varepsilon^0 z^0 > 0;$$

then $y^0 \pm \varepsilon\ z^0 > 0$ for $0 < \varepsilon < \varepsilon^0$. From (83) and (84) we have $B^0(y^0 \pm \varepsilon^0 z^0) = l^0$ whence $y^0 \pm \varepsilon^0 z^0 \in \mathscr{Y}\ (l^0)$. Since y^0 maximizes $p^0 \cdot y$ over $\mathscr{Y}\ (l^0)$,

$$p^0 \cdot y^0 \geqq p^0 \cdot \left(y^0 \pm \varepsilon^0 z^0\right),$$

i.e., $0 \geqq \varepsilon^0 p^0 \cdot z^0 \geqq 0$. This implies $p^0 \cdot z^0 = 0$, hence $p^0 \cdot (y^0 \pm \varepsilon z^0) = p^0 y^0$ for $0 < \varepsilon < \varepsilon^0$, i.e.,

$$y^0 \pm \varepsilon z^0 \in y\left(l^0\right) \text{ for } 0 < \varepsilon < \varepsilon^0.$$

This shows that y^0 is not unique.

Conversely we show that if y^0 is not unique then rank $B^0 < n$. Suppose $y^0, y^1 > 0$ both maximize $p^0 \cdot y$ subject to $y \in = (l^0)$, where $y^1 \neq y^0$. Then $B^0 y^0 = B^0 y^1 = l$, hence $B^0(y^0 - y^1) = 0$; since $y^0 - y^1 \neq 0$, this implies that rank $B^0 < n$.

q.e.d.

From this result it follows that a necessary condition for the production-possibility frontier to be strictly concave to the origin is that $m \geqq n$. If $m < n$, it is ruled surface. However, the condition $m \geqq n$ is certainly not sufficient; one example is the case $m = n = 2$ when two isoquants for a dollar's worth of output are mutually tangent at a point along the endowment ray (cf. Lerner 1933, p. 13). For further discussion of these points see Kemp et al. (1978), and for an interesting characterization, see Inoue (1986) and Inoue and Wegge (1986).

To gain an intuitive understanding of the meaning of the differentiability of Π (.,l), let us assume that the f_j are differentiable and that the functions $\widehat{v}_{ij}\ (p, l)$, obtained with the $\hat{w}_i\ (p, 1)$ by solving the above constrained-maximum problem, are also single-valued and differentiable. Then from

$$\Pi(p, l) = \sum_{j=1}^{n} p_j f_j\left(\upsilon_j\right) \quad (85)$$

we have

$$\frac{\partial \Pi}{\partial p_k} = y_k + \sum_{j=1}^{n}\sum_{i=1}^{m}\left[p_j \frac{\partial f_j}{\partial v_{ij}} - w_i\right]\frac{\partial \hat{v}_{ij}}{\partial p_k} + \sum_{i-1}^{m} w_i \sum_{j=1}^{n}\frac{\partial \hat{v}_{ij}}{\partial p_k}. \tag{86}$$

If $w_i > 0$ then

$$\sum_{j=1}^{n} \hat{v}_{ij}(p, l) = l_i$$

$$\sum_{j=1}^{n} \partial \hat{v}_{ij}/\partial p_k = 0,$$

hence the last term of (86) must vanish. If $v_{ij} > 0$ then the bracketed term in (86) vanishes (by the Kuhn-Tucker conditions). If the bracketed term is negative then $\hat{v}_{ij}$ by the Kuhn-Tucker conditions, and thus $\partial \hat{v}_{ij}/\partial p_k = 0$. In either case, the second term on the right in (86) vanishes. The trouble occurs in the intermediate case in which factor i is on the verge of being employed in industry j, hence $p_j \partial f_j/\partial v_{ij} - w_i = 0$ and $v_{ij} = 0$; it is precisely in this case that $\hat{v}_{ij}(\cdot, l)$ will not be differentiable at that point. Formula (80) therefore fails at switching points where factors are on the verge of being employed in particular industries; a small price change in one direction will lead to their continued unemployment, but in the other direction to their being employed. Thus, $\Pi(\cdot,l)$ is non-differentiable at such switching points. Likewise, it is non-differentiable when the conditions of Theorem 9 fail, in which case a small price change may lead to a country's switching from specialization in one commodity to specialization in another. All this would become clearer if the theory were to be recast in terms of subdifferentials (cf. Rockafellar 1970).

Since $\Pi(p, \cdot)$ has the properties of a production function, from Theorem 7, it is concave; and since, as was seen above, $H(P,l^0) = \Pi(p, l^0) - p \cdot y^0$ is a minimum at $p = p^0$, where $\Pi(p^0, l^0) = p^0 \cdot y^0$, $H(\cdot, l)$ is convex, hence $\Pi(\cdot,l)$ is convex. That is, $\Pi(p, l)$ is convex in p and concave in l.

If it is twice continuously differentiable then Samuelson's (1953) 'reciprocity theorem' holds:

$$\frac{\delta \hat{y}_j}{\delta l_j} = \frac{\partial \prod}{\partial p_j \partial l_i} = \frac{\partial^2 \prod}{\partial l_i \partial p_j} = \frac{\partial \hat{w}_i}{\partial p_j}. \tag{87}$$

The Stolper–Samuelson And Rybczynski Mappings

When a country diversifies its production, by which we shall mean that it produces all n consumable commodities, as long as it is not on the verge of specializing, its factor-endowment vector will lie in the interior of a diversification cone – the convex cone whose extreme rays pass through the factor-input vectors in the n industries which minimize costs at the given factor rentals (cf. McKenzie 1955; Chipman 1966). As is clear from Fig. 7, the factor rentals will remain unchanged as the factor endowment vector varies within the interior of this cone; i.e. the function $\hat{w}(p, l)$ is independent of l for endowments l in this cone. Now if all n commodities are to be producted, costs cannot exceed prices; and competitive equilibrium requires that prices not exceed costs. Hence, from the homogeneity of degree 1 of the minimum-unit-cost functions, and by Theorem 5, we have

$$p_j = g_j(w) = \sum_{i=l}^{m} \frac{\partial g_j(w)}{\partial w_i} w_i = \sum_{i=l}^{m} b_{ij}(w) w_i, \tag{88}$$

or in matrix notation, where w and p denote column vectors of m factor rentals and n commodity prices respectively,

and thus

$$p = g(w) = B(w)' w \tag{89}$$

$$g[\hat{w}(p, l)] = p, \tag{90}$$

i.e., $\hat{w}(\cdot,l)$ is a local inverse of the mapping g. Since the Jacobian matrix of g,$B(w)'$, must have rank m if the diversification cone has a non-empty

interior (hence $n \geqq m$), the range of g is an m-dimensional manifold, hence (89) implies that the vector p of world prices cannot be varied arbitrarily (if the country is to continue to diversify) unless $n = m$.

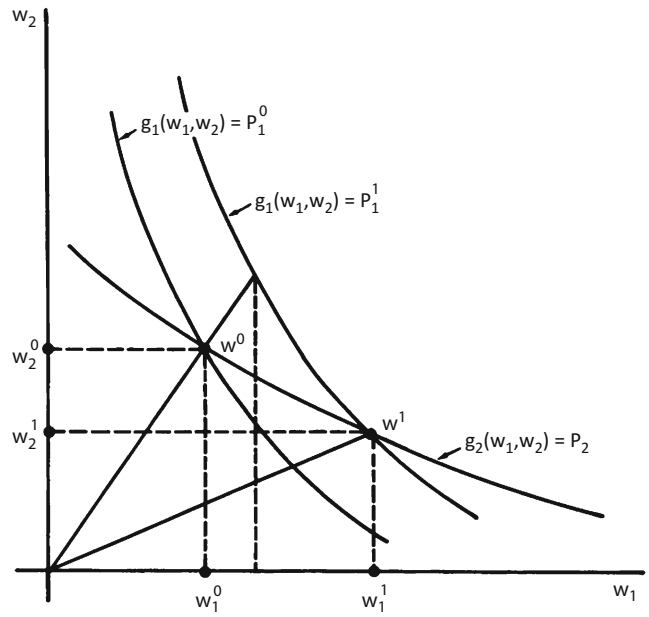
Even when $n = m$, the mapping g is in general not globally univalent. Gale and Nikaido (1965) obtained strong sufficient conditions for global univalence, namely that the principal minors of $B(w)$ be positive (this condition can be slightly weakened). Inada (1971) obtained some alternative conditions. In a controversy with Pearce (1967), McKenzie (1967) showed that it did not suffice to assume that $B(w)$ had a non-vanishing determinant for all positive w. The condition that $|B(w)| \neq 0$ for some $w = w^0$ is of course sufficient for local invertibility of g, but this inverse mapping depends on l. If two countries with identical technologies have their endowment vectors l in the same diversification cone, their factor rentals will be equalized even if g is not globally univalent. Nikaido (1972) showed that a modification of conditions originally suggested by Samuelson (1953) is sufficient for global univalence of g (Fig. 8).

Of particular interest is the nature of the Stolper-Samuelson mapping in regions where it is locally independent of l, i.e., the nature of the local inverses of g. For the reasons given above, discussion of this is effectively limited to the case $n = m$. Defining the diagonal matrices $W = \text{diag } w$ and $P = \text{diag } p$, and the matrix $\mathrm{B} = WBP^{-1}$, by dividing (88) through by p_j, one sees that B is column-stochastic (i.e., has unit column sums in addition to having non-negative elements); denoting its elements by $\beta_{ij} = w_i b_{ij}/p_j = \partial \log g_j/\partial \log w_i$, these satisfy

$$\sum_{i=l}^{m} \beta_{ij} = 1.$$

Denoting the elements of B^{-1} by b^{ij} and those of $B^{-1} = PB^{-1}W^{-1}$ by $\beta^{ij} = p_i b^{ij}/w_j$, these are equal to $\beta^{ij} = \partial \log \hat{w}_j/\partial \log p_i$. Denoting by l_m the column vector of m 1 s, from $l'_m \mathrm{B} = l'_m$ we have $l'_m \mathrm{B}^{-1} = l'_m \mathrm{B}\mathrm{B}^{-1} = l'_m$, hence B^{-1} also has unit column sums (cf. Chipman 1969, p. 402).

In the case $m = n = 2$, if we follow the convention of numbering commodities and factors in such a way that, at the initial equilibrium, $|B(w)| > 0$, i.e.,



International Trade, Fig. 8

$$\begin{vmatrix} b_{11}(w)\, b_{12}(w) \\ b_{21}(w)\, b_{22}(w) \end{vmatrix} = b_{11}(w) b_{12}(w) \left[\frac{b_{22}(w)}{b_{12}(w)} - \frac{b_{21}(w)}{b_{11}(w)} \right] > 0 \tag{91}$$

(which means that industry 2 uses a higher ratio of factor 2 to factor 1 than industry 1), then B^{-1}, which has non-positive diagonal elements and unit column sums, must have diagonal elements greater than or equal to unity. If B has its elements all positive, then the off-diagonal elements of B^{-1} are negative and the diagonal elements greater than unity. This, in substance, is the Stolper-Samuelson (1941) theorem. In words, for some association of commodities and factors, a rise in

one commodity price will lead to a more than proportionate rise in the corresponding factor rental (Fig. 9).

A simple proof is illustrated in Fig. 8, in the space of factor rentals. A rise in p_1 is shown by an upward shift in the isoquant $g_1(w_1, w_2) = p_1$ and a new intersection point with the isoquant $g_2(w_i, w_2) = p_2$ with lower w_2 and the rise in w_1 proportionately higher than that of p_1 (as long as the elasticities of substitution of the cost functions are positive, i.e., as long as the elasticities of substitution of the production functions are finite).

The Stolper-Samuelson theorem clearly does not generalize to higher dimensions. Either much stronger assumptions or much weaker conclusions are required. See Chipman (1969), Kuhn (1968), Inada (1971), Uekawa (1971), Ethier (1974), Jones and Scheinkinan (1977) and Neary (1985).

The Rybczynski functions $\hat{y}_j(p,l)$ exist as single-valued functions only for the case $m \geqq n$. If all n commodities are produced, and all m factors are fully employed, they satisfy the resource allocation equation

$$B[\hat{w}(p,l)]\hat{y}(p,i) = l. \tag{92}$$

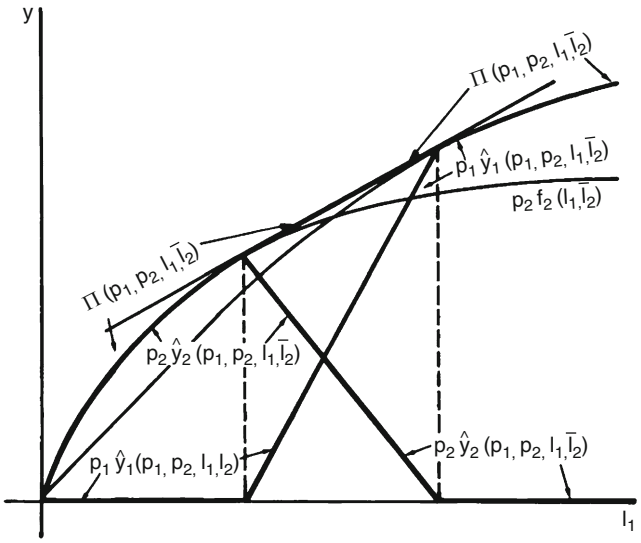
When $m = n$, since then w is locally independent of l, $\hat{y}(p,l)$ is locally linear in l for any fixed p and may be written as

$$\hat{y}(p,l) = B\left[g^{-1}(p)\right] l \tag{93}$$

(cf. Chipman 1971, p. 214, 1972, p. 216). The curious shapes of the Rybczynski functions are illustrated in Fig. 9.

As in the case of the Stolper-Samuelson mapping, one can consider the elasticities of outputs with respect to factor endowments when $m = n$. Denoting $L = \text{diag } l$ and $Y = \text{diag } y$ (not to be confused with the national-income variable Y of

International Trade, Fig. 9



section "The National-Product Function" above), we may define the matrix $\Lambda = L^{-1}BY$ with elements of $\lambda_{ij} = b_{ij}y_j/l_i = \partial \log l_i/\partial \log y_j$ (interpreting l_i in this relationship as requirements or demand for factor i, rather than supply). Its inverse $\Lambda^{-1} = Y^{-1}B^{-1}L$ has elements $\lambda^{ij} = b^{ij}l_j/y_i = \partial \log \hat{y}_i/\log l_j$. From the resource-allocation constraint

$$\sum_{j=1}^{n} b_{ij}y_j = l_i \tag{94}$$

it follows that

$$\sum_{j=1}^{n} \lambda_{ij} = 1,$$

i.e., Λ is row-stochastic (its elements are non-negative and its row sums are equal to unity). By the same reasoning as before, the row sums of Λ^{-1} are equal to unity. In the case $n = m = 2$, adhering to the convention (91) it follows that, when B has positive elements, the off-diagonal elements of Λ^{-1} are negative, and thus its diagonal elements are greater than unity. Thus, $\partial \log \hat{y}_i/\partial \log l_i > 1$ and $\partial \log \hat{y}_i/\partial \log l_i < 0$ for $j \neq i$; in words, a rise in the ith factor endowment will, at given world prices, lead to a more than proportionate rise in the output of the ith commodity, and a fall in the output of the jth commodity ($j \neq i$). As in the case of the Stolper-Samuelson theorem, this obviously does not generalize to higher dimensions unless stronger assumptions are made or weaker conclusions reached. A discussion of the nature of such generalized results will be found in Kemp and Wegge (1969), Wegge and Kemp (1969), Ethier (1974), Jones and Scheinkman (1977) and Neary (1985).

Interindustrial Relationships and other Refinements

The formal model treated so far assumes that production is completely integrated, contrary to fact. Indeed, a large part of international trade is in intermediate products. The main justification for not allowing for intermediate inputs at the very beginning is that it may obscure the logic of the analysis with inessential details. However, in view of the importance of the phenomenon it is desirable at this point to see how the formal framework needs to be modified (cf. McKinnon 1966; Melvin 1969a, 1969b; Khang and Uekawa 1973).

In place of (35) one needs to substitute the production function

$$\begin{aligned} q_j &= f_j(u_{1j}, u_{2j}, \ldots, u_{nj}, v_{1j}, v_{2j}, \ldots, v_{mj}) \\ &= f_j(u_j, v_j) \end{aligned} \tag{95}$$

(assumed homogeneous of degree 1) where q_j denotes gross output of commodity j, and u_{ij} denotes the amount of commodity i used as input to the production of commodity j. Its dual minimum-unit-cost function – equal to the price of commodity j when that commodity is produced – is denoted

$$\begin{aligned} p_j &= g_j(p_1, p_2, \ldots, p_j, w_1, w_2, \ldots, w_m) \\ &= g_j(p, w), \end{aligned} \tag{96}$$

and the input–output and factor–output coefficients are, in accordance with Theorem 5,

$$\begin{aligned} a_{ij}(p, w) &= \partial g_j(p, w)/\partial p_i; \quad b_{ij}(p, w) \\ &= \partial g_j(p, w)/\partial w_i. \end{aligned} \tag{97}$$

The production–possibility set (43) is now replaced by the *net-output-possibility set* defined by

$$y_j = f_i(u_j, v_j) - \sum_{k=1}^{n} u_{jk} \text{ and } \sum_{j=1}^{n} v_j \quad l \tag{98}$$

(cf. Khang and Uekawa 1973). This set is convex. Khang and Uekawa (1973) developed a generalization of Theorem 9 (section "The National-Product Function" above); see also Kemp et al. (1978) and Färe (1979). The concept of a national-product function can also be generalized to this case (cf. Chipman 1985a, pp. 405–6), allowing one to define net supply (Rybczynski) functions.

International Trade and Heterogeneous Firms

Marc J. Melitz

Abstract

Empirical studies of production units within sectors have reported a massive amount of heterogeneity in various performance measures (most notably, size and productivity). This heterogeneity, within sectors, matters for theoretical and empirical models of trade. Trade, or trade liberalization more generally, induces important reallocations between heterogeneous producers in a sector: the smallest, least productive producers are forced to exit, and market shares are further reallocated between less productive producers (who do not export) towards larger, more productive exporters. These reallocations generate a new channel for productivity and welfare gains from trade.

Census-wide 'micro' level studies of production units for a wide range of countries at all levels of development have documented substantial heterogeneity in virtually all relevant performance measures across these production units. For example, across all US manufacturing plants in 1992, a plant one standard deviation above the mean plant size is 167 per cent bigger, and a plant one standard deviation above the mean plant productivity level (value-added per worker) is 75 per cent more productive (Bernard et al. 2003). (More precisely, the standard deviation of log sales is 1.67 and that of labour productivity is 0.75.) These represent massive differences in performance outcomes, which are also reflected in differences in other key plant characteristics. Furthermore, the extent of this heterogeneity does not diminish much when looking within narrowly defined sectors. In the case of the US plants, the 75 per cent productivity difference mentioned above only drops to a 66 per cent difference when controlling for productivity differences across more than 400 different sectors.

These large differences in firm performance are also strongly correlated with the firm decision to engage in international transactions (such as exporting, importing intermediate goods from foreign suppliers, or investing in foreign subsidiaries): only a small proportion of firms report any such activities, even within narrowly defined sectors; and those firms are substantially larger and more productive than their counterparts with no international contacts in the same sector. (This pattern has been documented at both the firm and the plant level for a very wide range of countries. From here on out, I will mostly focus on differences between exporting and non-exporting firms, although similar differences have also been documented concerning multinational firms and firms that import intermediate goods from foreign suppliers.) For the United States, Bernard et al. (2006a, b, c) report that manufacturing plants are more than twice as large (value of shipments) as and 14 per cent more productive (value-added per worker) than their non-exporting counterparts in the same sector. (Bernard et al. 2006a, b, c, provide an extensive description of firm-level differences related to international trade based on US manufacturing data and also survey the related empirical and theoretical literatures.) Bernard et al. (2006a, b, c) also report how these exporting firms exhibit other different characteristics relative to non-exporters: they are more capital- and skill-intensive, and pay higher wages.

This strong correlation between export status and firm characteristics (notably higher productivity) naturally leads to the follow-up question of causality. A very large number of studies have examined this question, usually focusing on a firm's productivity trajectory over time relative to its export market entry decision. Virtually all these studies find a strong self-selection effect: firms are relatively more productive prior to their entry into export markets. (Two early influential papers in this area are Bernard and Jensen 1999, and Clerides et al. 1998). Several of these studies further reject the hypothesis of firm-level productivity growth following export market entry, although some studies, especially for developing countries, do report such a link. (See, for instance, Loecker 2007; Topalova 2004; Biesebroeck 2005; and the survey by Girma et al. 2004). However, this distinction – based on the timing of the export market entry – has been blurred given the evidence from some recent studies that firms make innovation/technology use decisions based on current or anticipated export market participation, as highlighted by Bustos (2006), Verhoogen (2007), and Trefler and Lileeva (2007). In such a case, productivity and exporting decisions are both endogenous with respect to one another, and the timing of the export market entry can no longer be used to identify causality. (Yeaple 2005, theoretically studies this joint technology adoption and export decision by firms, and explores the consequences for the return to skill – highlighting how skill-biased technological change may be induced by trade.)

Nonetheless, the results obtained clearly indicate that it is initially more successful firms that make the joint decisions concerning innovation (or 'higher' technology use) and export status. In other words, the least successful firms overwhelmingly tend to undertake neither activity.

Another part of the recent empirical literature using micro-level data has examined the consequences of this link between export status and productivity when the exposure to trade is changing (predominantly because trade costs are decreasing over time). In such a case, trade liberalization induces some reallocations between exporters and non-exporters competing in the same sectors (see Tybout 2003, for a survey of this literature). One influential such study by Pavcnik (2002) finds that most of the 25 per cent productivity increase in export-competing sectors in Chile between 1979 and 1986 is explained by reallocations between producers (generated by entry, exit, export market entry, and market share reallocations). However, since significant changes in trade regimes are also part of a larger set of substantial macroeconomic changes for the involved countries (as was the case for Chile), it nevertheless remains difficult to associate this type of reallocation-induced productivity growth to the direct effects of trade liberalization. One notable exception is Bernard et al. (2006c), who show that reductions in trade costs for US plants substantially increase both the probability of exit and that of exporting among non-exporters. Given the productivity advantage of exporters, this induces reallocations in favour of the more productive exporting plants and hence increases average industry productivity (which is also confirmed by Bernard et al. 2006a, b, c, as a result of the decrease in trade costs).

Clearly, these empirical patterns cannot be addressed by trade models based on representative firms. Such models, by construction, predict that trade affects all firms in a sector in similar ways. (Note that extensive firm-level heterogeneity per se is not necessarily problematic for a representative firm model of trade so long as firms, on average, respond in similar ways to trade. However, the evidence reviewed clearly shows that this is not the case.) In response to this empirical evidence, theoretical models of trade have been developed to incorporate firm-level productivity differences, and analyse the consequences for the effects of trade liberalization. One class of models, developed by Bernard et al. (2003) and Eaton and Kortum (2008), introduce stochastic firm productivity into the multi-country Ricardian model analysed in Eaton and Kortum (2002). In this class of models, there is a fixed number of products that can be produced by competing firms in all countries. All these firms (both in the same country but also across countries) use different technologies to produce the same good (based on a stochastic productivity

draw) – hence the Ricardian framework. Consumers in any given country buy each good from the lowest-cost producer across all countries. Due to trade costs, several firms producing the same good can survive if they are located in different countries (although each firm is the sole supplier to any given destination). This model thus emphasizes the resulting competition between firms to be this exclusive supplier. Bernard et al. (2003) show how such a model can be calibrated to fit both micro-level data on US producers and macro-level data on cross-country trade and aggregate production across countries. The calibrated model can then be used to analyse many counterfactual predictions involving the consequences of trade liberalization.

Another class of models developed in Melitz (2003) and Melitz and Ottaviano (2005) eschews the analysis of the direct competition between firms to produce the same good by using a monopolistic competition framework: each firm produces its own distinctive differentiated good. These models incorporate firm heterogeneity into the one-sector models of intra-industry trade (the 'new' trade theory) developed in Krugman (1979, 1980). In this type of model, the product variety available to consumers in any given country varies endogenously with the characteristics of the country and the trade costs linking it to its trading partners (these affect the endogenous number of varieties produced domestically, as well as the endogenous fraction of firms from all trading partners that export to that country). Firms face sunk costs of entry, along with uncertainty concerning their future productivity (or also possibly the quality of the differentiated good that is under development). Upon entry, each firm instantaneously learns about its productivity level, modelled as a draw from a known distribution. Due to the sunk nature of the entry costs, firms with heterogeneous productivity levels remain active and produce. The least productive firms face negative profits and therefore exit. As exporting is costly, only the relatively more productive firms (among those surviving) choose to export, while the remaining firms only serve their domestic market. Exporting is not profitable for these firms, either because it involves fixed or sunk costs, or because import demand is driven to zero at prices below the firms' delivered cost.

Both classes of models predict that trade liberalization induces the type of reallocations between firms that was previously described: the least productive firms are constrained to exit, new firms enter the export market, and market shares are reallocated towards more productive firms. These reallocations generate both aggregate productivity and welfare gains. Both classes of models also predict an important empirical regularity regarding bilateral trade flows: that differences in these trade flows reflect both differences in the amount of each good traded (the intensive margin of trade) as well as differences in the number of goods traded (the extensive margin of trade). (See Bernard et al. 2005; Broda and Weinstein 2006; Broda et al. 2006; Eaton et al. 2004; and Kehoe and Ruhl 2003, for some empirical applications). Helpman et al. (2007) and Chaney (2006) show how the framework of Melitz (2003) can be extended to derive a gravity specification for bilateral trade flows where trade costs affect both the extensive and intensive margins of trade. Both papers highlight the empirical importance of incorporating changes in trade at both margins.

Due to the absence of strategic interactions between firms, the monopolistic competition model of Melitz (2003) provides a convenient framework for the modelling of additional firm-level decisions in an open economy environment – where heterogeneous firms self-select into different types of activities. This framework can thus also explain why only a fraction of firms choose to become multinationals and operate foreign affiliates (horizontal foreign direct investment, FDI) as in Helpman et al. (2004) or integrate with their foreign suppliers (vertical FDI) as in Antras and Helpman (2004). (Helpman 2006, provides a much more extensive review of the related models.) Additionally, other firm-level decisions that are also affected by the exposure to international trade can be incorporated: the choice of technology as in Acemoglu et al. (2007), the level of investment in innovation as in Atkeson and Burstein (2006), or the range of products produced and exported

within multi-product firms as in Bernard et al. (2006b). Lastly, the structure from Melitz (2003) has also been fruitfully integrated into various other types of models that rely on the basic monopolistic competition of trade. This includes extension to two-sector models of trade with comparative advantage and factor proportion differences (Bernard et al. 2007), open economy models of growth (Baldwin and Robert-Nicoud 2006), and international macro-dynamics (Ghironi and Melitz 2005). In each case, the addition of firm-level heterogeneity allows the models to explore additional important features upon which a model with representative firms remains silent.

International Trade Theory

James E. Anderson

Abstract

International trade theory provides explanations for the pattern of international trade and the distribution of the gains from trade. The theory convinces most economists of the benefits of liberal trade. But many non-economists oppose liberal trade. Opponents include some who may have encountered trade theory but nevertheless fall prey to fallacious reasoning. This article attempts to convey why trade theory is so persuasive to economists and also to deal with why many non-economists are not persuaded.

Why do nations trade the products they do? Is trade a good thing? The theory of international trade provides answers. The answers are both convincing and elegant; hence, the vast majority of economists agree about the desirability of liberal trade. But the argument is also subtle and often misunderstood or distorted. Thus, a large proportion of the general population tends to oppose liberal trade from confusion. This article attempts to convey why the answers convince most economists and why their liberal trade position is so often misunderstood. The article's focus is theory, but theory convinces when it succeeds in fitting the data. Thus, passing reference will be made to empirical findings, a sensibility much more thoroughly developed in the graduate textbook of Feenstra (2003).

'Buy low, sell high' logic leads economists to comparative advantage theory. Comparative advantage means the comparison of *relative* price differences between nations to explain the pattern of trade. For example, compare the relative price of wheat in terms of cheese at home with the same relative price in the foreign economy in a hypothetical equilibrium with no trade (autarky) or with restricted trade. The country with the lower relative price of wheat is said to have a comparative advantage in wheat while the other country has, symmetrically, a comparative

advantage in cheese. Buy low, sell high logic predicts that a country will export the good in which it has a comparative advantage. (In the case of many goods, the prediction is that a country will on average export goods which are relatively cheap in the absence of trade and import goods which are relatively expensive in the absence of trade. The prediction is about correlation. Bernhofen and Brown 2004, show that Japan's opening to trade in the 1850s reveals data consistent with the prediction.)

Notice that the focus on relative prices tends to cancel out forces (exchange rate manipulations, environmental or labour standards) which cause national differences in levels of non-traded factor (or goods) prices. Note also that by this reasoning a country *must* have a comparative advantage in some good. Prices of non-traded factors of production adjust in general equilibrium so that each country ends up in the trade equilibrium with a competitive or absolute cost advantage in the good in which it has a comparative advantage. Partial equilibrium thinking takes factor prices as given and does not impose the external budget constraint that requires exports to pay for imports. Partial equilibrium reasoning leads to misunderstandings explored below as the absolute advantage fallacy.

Comparative advantage differences between nations are explained by exogenous differences in national characteristics. Labour differs in its productivity internationally and different goods have different labour requirements, so comparative labour productivity advantage was Ricardo's predictor of trade patterns. Ricardian trade theory is useful in its simplicity and even rather loosely confirmed by empirical evidence. The factor proportions theory added relative factor endowment differences to the exogenous explanation of comparative advantage (Jones 1987). More capital-abundant countries have higher labour productivity, but the advantage gained relative to the less abundant countries varies with the relative capital intensity of the good's technology. Combining technology and endowment differences appears to account well for actual trade patterns (Davis and Weinstein 2002).

Trade theory also encompasses endogenous differences between countries. One focus is on economies of scale. The wider market due to trade induces a cost advantage in an industry in one of the countries. Another theory is based on monopolistic competition, whereby the wider markets due to trade increase product variety as buyers seek the special characteristics of foreign brands. Differentiated products trade flows both ways within product categories.

Trade costs also shape the pattern of trade. The economic theory of gravity explains the complex bilateral trade patterns among countries. Actual trade is much lower than gravity predicts in a frictionless world, providing evidence of trade costs much larger than those due to policy or transportation. The costs are well explained by geography and a set of national differences. The stability of the relationships over time suggests that these costs change slowly.

There are gains from trade in all these models. But the division of the gains will be uneven and there will be losers. Distribution matters in two ways, between and within nations. Internationally, with only mild qualifications, gains are shared between nations: some trade is better than none. Each nation can act through trade policy to take more of the gain, however, leading to destructive trade wars with mutual losses. Within national economies, there are gains on average but there are ordinarily losers. National institutions act to redistribute some of the gains (US Trade Adjustment Assistance) or provide temporary relief from losses due to trade (escape clause protection), at the cost of lowering the overall gain from trade.

The topics of this outline are developed below in more detail. Section 1 examines the causes of comparative advantage. Section 2 exposes the absolute advantage fallacy. Section 3 reviews endogenous advantage. Section 4 sets out the economic theory of gravity and its implications. The concluding section examines the gains from trade.

Comparative Advantage

Ricardo explained comparative advantage as due to differences in labour productivity. Suppose that it takes two hours of labour to produce a bushel of

wheat in the home country, while it takes four hours of labour to produce a bushel of wheat in the foreign country. Also, it takes three hours of labour to produce a pound of cheese in the home country while it takes eight hours of labour to produce a pound of cheese in the foreign country.

Ricardo saw that the world trade equilibrium would result in the home country exporting cheese and the foreign country exporting wheat. This is because, in the absence of trade, a pound of cheese is worth 1.5 bushels of wheat (three hours per pound of cheese divided by two hours per bushel of wheat) in the home country while a pound of cheese is worth two bushels of wheat in the foreign country. The labour market equilibrium which accompanies such a trade equilibrium must have a foreign wage of at most one-half of the home wage (since, with a foreign wage equal to one-half the home wage, a bushel of wheat costs the same amount in each country, allowing production in both). If we consider a low-wage foreign economy, the labour market equilibrium accompanying the trade equilibrium could have a foreign wage no lower than three-eighths of the home wage (since in this case a pound of cheese costs the same amount in each country).

Notice that countries export the good in which they have the comparative labour productivity advantage, cheese for the home country and wheat for the foreign country. The numbers chosen make no difference to the logic; what is essential is that comparative labour productivities differ. One special aspect of the numbers deserves emphasis, however: the home country has an absolute labour productivity advantage in both goods yet trade occurs regardless.

Subsequent developments of trade theory generalized the production model. The essence of comparative advantage theory remains: trade is due to differences in relative prices that would obtain in the absence of trade, and an average of each country's citizens gain from such trade. The Heckscher–Ohlin analysis of the factor proportions model predicted that a country would have a comparative advantage in the good which made relatively intensive use of its relatively abundant factor. Thus, if the home country were relatively abundant in capital (which would explain why its labour was so much more productive in the preceding example), it would have a comparative advantage in the good which used capital relatively intensively (cheese in the preceding example). Conversely, the foreign country is relatively abundant in labour and has a comparative advantage in the good which uses labour relatively intensively (wheat in the example above).

Trade in goods compensates for the international immobility of factors. The factor content extension of Heckscher–Ohlin trade theory predicts that trade patterns permit each country to consume factor services as if it were in a completely integrated world, smoothing out differences in national factor endowments. Recent empirical work has met with striking success in combining factor endowment differences with technology differences as an explanation of observed trade patterns (Davis and Weinstein 2002).

Comparative advantage theory is much more general than the preceding discussion of special cases (Deardorff 1984), but predictions about the pattern of trade weaken with generality. On average a country will import goods that would be relatively expensive in the absence of trade. See the Appendix for a technical statement. See Bernhofen and Brown (2004) for confirming evidence based on Japan's opening to trade in the 1850s. The assumptions of the general model are that (*a*) price-taking consumers minimize the expenditure needed to realize any level of utility (real income), and (*b*) producers behave so as to maximize the national product given the resource endowments. Assumption (*a*) implies downward-sloping demand curves in the generalized form. Assumption (b) leads to upward-sloping supply curves in the generalized form. Scale economies and imperfect competition, treated below in the section on endogenous advantage, can lead to the violation of assumption (*b*).

The Absolute Advantage Fallacy

Businessmen naturally compare the money cost of the same good in different locations to draw inferences about the direction of trade. Absolute cost

advantage appears to imply that a nation imports goods that are cheaper abroad and exports goods that are more expensive abroad. The reasoning is insidious because it makes sense in many contexts. Absolute advantage appropriately addresses the householder's question of which good should be purchased, the businessman's question of how tough his competitors are. The individual businessman can appropriately take all other prices as given when contemplating his own actions, such as entering a new export market.

To see the difference between absolute and comparative advantage reasoning clearly, return to the Ricardian example above. If wages (measured in a common currency) were equal in the two countries prior to the opening of trade, the home country would have a 'competitive' or absolute advantage in both goods: it could undersell the foreign country in both wheat and cheese. Foreign businessmen would naturally be worried that they would all be driven from the market. This universal bankruptcy could not be an equilibrium, however, because the foreign workers would have no income to pay for home-produced goods. The imbalance between expenditure and income would also mirror the absence of exports to pay for imports. Market equilibrium would be reached through price changes, lowering the foreign wage or raising the home wage until the foreign workers could be employed in the industry in which the foreign economy has the comparative advantage. (Unless the two currencies were pegged, the exchange rate of the foreign economy could depreciate and create the same effect.) More general models of production lead to the same conclusion: *equilibrium costs will adjust to confer absolute advantage in the good in which each country has a comparative advantage.*

With many goods, comparative advantage applies to ranges of goods rather than to a single good, and the dividing line between comparative advantage and disadvantage is endogenous. The absolute advantage is weak in the mathematical sense in the case where both countries continue to produce the good.

Another illustration of the absolute advantage fallacy arises in popular concerns about the rapid productivity growth of China compared with that of the United States. A ten per cent improvement in productivity will indeed secure a ten per cent cost advantage for the businessman over his competitor. A ten per cent improvement in all Chinese productivity relative to the United States is unlikely to change comparative advantage (indeed, in the Ricardian example, comparative labour productivity advantage is unchanged) because Chinese wages will rise relative to US wages. Similarly, a ten per cent drop in all US productivity due to tighter environmental regulations will be unlikely to change comparative advantage because US factor returns will fall.

The widespread practice of making international comparisons of 'competitive advantage' is essentially misguided because it suggests the metaphor of a race. The race metaphor is extended in concerns about 'a race to the bottom', which supposedly expresses the dilemma of countries seeking to implement pollution or labour standards but being pressured to lower standards by their competition with foreign countries that have low standards. But nations do not 'compete' as firms do. A firm may well be unable to survive after implementing pollution reduction when its competitors abroad do not follow suit and no other prices change in the new equilibrium. Nations cannot similarly put themselves out of business because factor prices will change in the new equilibrium. Polluting industries may or may not survive at the new factor prices under the new regulations, but the nation's factors will be productively employed somewhere in the economy. Pollution reduction is costly with or without trade; nothing about the nature of a trading economy makes any essential difference to the nation's ability to implement desired standards. The desirability of trade is an *essentially* separate matter.

Endogenous Advantage

Many goods are traded because they are simply unavailable from local production. Some kinds of availability are exogenous to the interaction of nations – diamonds and oil are found only in a few locations. Endogenous availability is in

contrast driven by advantage arising from the economic interaction of nations. Endogenous advantage normally coexists with comparative advantage but it is simpler to consider special cases independent of comparative advantage. Theory focuses on endogenous advantage resulting from economies of scale. (In a formal but trivial sense, oil or diamond trade can be seen as comparative advantage trade – big oil deposits lead to a low relative price of oil where they are found. Moreover, comparative advantage trade is often associated with the disappearance of some industries in some countries. Neither of these associations of comparative advantage with availability is essential to the model, however.)

Trade based on scale economies features the possibility of multiple equilibria – one country will produce a good with scale economies but which nation ends up producing it can be a matter of chance. Since advantage is endogenous, it appears attractive in developing countries to attempt to reverse the historical head start of rich countries by starting up production behind protection and then later being able to compete on world markets. The record of success in such efforts is mixed.

Openness to trade will generally allow economies of scale to be more thoroughly exploited, so this is a new source of gains from trade. Moreover, wider markets may support a wider range of products, still another source of gains from trade. Each country shares in the gains from trade with scale economies under conditions that appear to be met in practice. (This claim is based on the results from numerous simulation models of trading economies that have been developed since the mid-1970s.) The theoretical possibility that a country can lose from trade based on scale economies has drawn a lot of attention from development economists in particular (Ethier 1982b). (Losses result when a trading equilibrium has a country importing the good with scale economies while still producing it. Since domestic scale is smaller, unit costs are higher, meaning that market forces perversely 'choose' to import a good with higher price than in autarky. Simulation models have not found such equilibria but they are possible.) Gains can be guaranteed if a country expands production in goods with scale economies, so it looks more attractive to use policy to promote production of such goods.

Scale economies come in two forms: external to the firm and internal to the firm. External scale economies are typified by specialized labour markets such as Silicon Valley, where the concentration of the market reduces search costs for computer engineers. External scale economies need not be location-specific, however. Increases in the scale of downstream final production can permit carrying on upstream input production with a specialized process that is cheaper at large enough scale. Such scale economies can operate at the level of the world economy and appear to be bound up with the recent phenomenon of outsourcing (Ethier 1982a). Global scale economies tend to guarantee mutual gains from trade among countries.

Internal scale economies are associated with imperfect competition when the size of the firm looms large relative to the market size. Trade tends to intensify competition and thus to reduce the inefficiency of monopoly, another gain from trade.

The most fruitful form of imperfect competition for trade theory has been monopolistic competition. Only Ford Motor Co. produces Ford autos (monopoly) but dozens of brands compete for auto buyers. Each design has a fixed cost of design (and marketing) which must be covered by sales net of variable cost. The total market size limits the number of designs which can profitably be produced. A signal accomplishment of trade theory in the 1980s was the embedding of monopolistic competition in a general equilibrium trade model (Helpman and Krugman 1985; Ethier 1982a). Progress was enabled by the simplifying assumption of symmetric firms: all brands were equally desirable and all firms' costs were the same.

Monopolistic competition provides an explanation of the two-way international trade that is found in many products such as autos, and of why two-way trade is more prevalent between similar countries. Trade between rich and poor countries, in contrast, is explained mainly by comparative advantage as autos exchange for agriculture.

Relative country size matters too, the home-market effect of Krugman (1980). Here the insight has been rigorously proved only for a two-country example. Start with two equally sized countries, then increase one relative to the other. Trade costs imply that the larger country will have a more than proportionally larger share of brands. Intuitively, with access to foreign markets being costly the home market, being larger, allows scale economies to be more readily exploited, increasing the larger country's share of differentiated goods production more than its share of world income.

Monopolistic competition theory has recently focused on the heterogeneity of firms. If the symmetry of firms on the demand side is retained, differences in firms' productivities imply differential responses to trade. The best firms export disproportionately while imports drive out the worst firms. Fixed trade costs add explanatory power; only the best firms choose to incur the cost of trade. A key element of the model is productivity shocks, firms discover their productivity after committing fixed costs. The distribution of surviving firms is related to the distribution of productivity shocks as well as economic determinants. The models of Bernard et al. (2003) and Melitz (2003) deserve special attention. The former focuses on competition within a variety while the latter focuses on competition across varieties. Both models imply new gains from trade in the form of overall productivity gains: opening trade causes the exit of weak firms and the expansion of strong ones.

Bilateral Trade Patterns

The trade theories presented above are focused on explaining the cross-commodity trade pattern of essentially two trading countries. The contemporary world of more than 100 countries (most of which are collections of distinct economic regions) has complex trade patterns.

The economic theory of gravity complements the preceding models by providing an explanation of bilateral trade (Anderson and van Wincoop 2004). Gravity fits the data well and reveals important information. The model is based on four assumptions: expenditure on goods from all sources is equal to income from sales to all sources, markets for all goods clear, (more restrictively) each country or region produces a unique good, and all countries have the same tastes for goods.

The third assumption – products differentiated by place of origin – appears to be the most restrictive. In practice, only models of this type do at all well in fitting bilateral trade patterns. Monopolistic competition provides one explanation for why products appear to be differentiated by place of origin. Eaton and Kortum (2002) show alternatively that productivity shocks in a Ricardian model will select producers within product lines, resulting at the aggregate level in what appears to be two-way trade. In either case, gravity ends up describing trade flows.

In a frictionless world, gravity theory predicts that the bilateral trade in a commodity as a share of world production of the commodity will be equal to the product of the source country's share of world production of the commodity times the consuming country's share of expenditure on the commodity. Alternatively, the model predicts that size-adjusted trade, the bilateral flow divided by the product of source country supply and consuming country expenditure, should be constant across country pairs in a frictionless world.

Actual trade flows are far smaller than the frictionless prediction (while shipments within regions are far larger, home bias). The deviations of actual bilateral trade from the frictionless prediction allows inference about bilateral trade costs. Distance appears to be more costly than can be accounted for by transport costs. Other costs are associated with non-contiguity, language barriers, exchange rate barriers, insecurity and other plausible bilateral characteristics. Just crossing a border imposes a cost which is larger than can be explained by policy variables.

Trade flows in the model are predicted to vary with relative resistance, equal to the ratio of the direct bilateral trade cost to the product of inward and outward multilateral resistance. Multilateral resistance is an index of bilateral trade costs, inward from every source to a particular destination or outward from a particular source to every destination. Multilateral resistance is linked to

country size and thus to explaining an important aspect of trade patterns. Since borders are costly, a big country tends to have lower multilateral resistance than does a small country because a smaller fraction of its shipments must cross borders. The size-adjusted internal trade of big countries will be smaller than that of small countries because big countries have higher relative resistance to their internal trade. These differences can be quite dramatic, as shown by studies of US and Canadian trade (Anderson and van Wincoop 2003), where the United States is about ten times larger than Canada.

Division of the Gains

Professional economists generally support liberal trade because theory and evidence persuade them that there are gains from trade in an average sense in all these models of the determinants of trade. But the division of the gains will be uneven and there can be losers. Most policy intervention with trade is explained by the policymakers' desire to alter the distribution of gains.

The gains from trade reasoning is illustrated with comparative advantage-based trade. Focus on a 'typical' household. Suppose that in autarky equilibrium, as in the Ricardian numerical example, the Home typical householder is willing to swap 1 unit of cheese for 1.5 units of wheat. That is, he would be indifferent to moving his consumption and production a small distance to offer the market 1 cheese for 1.5 wheat or 1.5 wheat for 1 cheese. Suppose that a typical foreign country household in the autarky equilibrium is willing to swap 2 wheat for 1 cheese. Now allow frictionless trade, and suppose for illustrative purposes that the new equilibrium price is equal to 1.75 wheat per unit of cheese. (Generally the price must lie between 1.5 and 2, always implying mutual gains.) Each Home household offers cheese to Foreign households in exchange for their wheat. Formerly it cost 2 wheat for 1 cheese in Foreign but now the 2 wheat will procure 1 cheese and leave 0.25 wheat left over, a gain from trade. Similarly, each Home household can obtain 1.75 wheat for 1 cheese where formerly this would procure only 1.5 wheat, a gain from trade of 0.25 wheat. Both households and hence both nations gain from trade. The numbers chosen illustrate a general principle: mutual gains result from trade when autarky relative prices differ. See the Appendix for a more formal discussion.

The mutual gains from trade claim may seem dubious because, with the numbers chosen, trade equilibrium requires that foreign wages must be lower than home wages. In effect, trade facilitates an exchange in which more than one unit of foreign labour exchanges for one unit of home labour – the home country is 'exploiting' foreign labour. Some anti-trade sentiment on the left in rich countries is based on this observation. (Marxism embeds the observation in a wider system of analysis, but it probably is no longer a basis for much sentiment on the left.) Nevertheless, foreign labour gains from trade, as does home labour. Prior to trade, a pound of cheese cost 1.5 bushels of wheat in the home country while it cost 2 bushels of wheat in the foreign country. By specializing in wheat production and exchanging it for cheese, foreign workers can obtain cheese more cheaply, at a price somewhere between 2 and 1.5 bushels of wheat. This exchange must make them better off. As for home workers, prior to trade, a pound of cheese obtained 1.5 bushels while with trade it obtains somewhere between 1.5 and 2 bushels. This must make home workers better off. Concern about the 'fairness' of the exchange in rich countries should lead to policies which might actually help the poor countries. Trade theory shows that anti-trade policies by rich countries will instead on average harm the poor countries.

Scale economies and imperfect competition models of trade suggest further gains. With scale economies, trade implies that the force of wider markets drives costs lower. With imperfect competition, trade stimulates competition and drives profit margins lower. Trade equilibrium with monopolistic competition suggests that consumers and intermediate input users gain from more variety of differentiated products (see Helpman and Krugman 1985).

The distribution of the gains matters, both between and within nations. Nationalist trade

policy can take more of the gains, leading to destructive trade wars with mutual losses. Negotiation of trade agreements and their enforcement through international institutions such as the World Trade Organization (WTO) help to restrain the destructive tendencies of unilateral action. Nations have an incentive to participate in negotiations and to join institutions such as the WTO because some trade is better than none for each nation. Theoretical qualifications to this statement must be entered in models of trade involving scale economies and imperfect competition, but in practice simulation of such models suggests that some trade remains better than none for each nation.

Within national economies the division of gains issue is much sharper: some members of a nation ordinarily lose from trade. Ricardo's one-factor trade model submerges income distribution. Multi-factor production models feature groups who must lose from trade. Loosely speaking, these groups are associated with import competing production (see Jones 1987).

In equilibrium the gains must ordinarily outweigh the losses within each nation, by the preceding national-gains-from-trade argument. For an economy with nonidentical households, this implies that there are gains from trade on average. Under special circumstances the gains can be redistributed so that all households gain. In practice, these circumstances are rarely met completely. Even so, most economists tend to favour efficiency-enhancing policies such as liberal trade on the pragmatic grounds that efficiency-reducing policies such as protection also cause gainers and losers, so it is better to go with the larger net gains and supplement them with feasible programmes to compensate the most obvious losers.

(A benevolent and very powerful government can in principle calculate and implement the lump-sum transfers – negative for gainers, positive for losers – that are required to achieve redistribution so that all gain. In practice, information is more limited and implementation more difficult – because households modify their behaviour to reduce their tax or increase their subsidy – than with the lump-sum story. Trade and public economic theory have relaxed the conditions somewhat. Income taxation can in some circumstances achieve redistribution with efficiency, but information limitations rule them out as a practical matter; see Guesnerie 2001. Dixit and Norman 1986, show that a system of consumption taxes – differentially taxing each commodity – that sacrifices some of the gains from trade is powerful in achieving gains for all. For a qualification of their argument, see Kemp and Wan 1986. Again, information limitations vitiate the applicability of this idea. Finally, a government that can discriminate powerfully between households is sure to be lobbied intensively by those able to organize politically, to the detriment of the unorganized.)

What if losers are not compensated? A person taking this question seriously must decide on liberal trade by weighting individual gains and losses. Ethical considerations give more weight to losses or gains to the poor than to the rich. The case for liberal trade is strengthened by ethical considerations because the illiberal trade policies of rich countries hurt the poor disproportionately, as documented by Gresser (2002). Poor countries have comparative advantage based on cheap low- skilled labour, hence discrimination against their exports harms the poor citizens of poor countries. At home in rich countries, protection makes food and clothing more expensive, a regressive tax on poor consumers. Among the poor, losers from protection appear almost surely to outweigh gainers.

On the way to equilibrium, it is theoretically possible that adjustment cost losses may temporarily exceed gains, justifying temporary relief measures. For example, workers displaced by import competition may be unemployed for a time. Extensive investigation of US cases suggests that such adjustment cost losses from trade are small, of short duration, and are swamped by the gains from trade. A typical investigation reports that the net cost to the economy of using protection to reemploy a worker far exceeds the wage the worker would receive in the job, usually several (up to ten) times the wage. In practice, therefore, temporary protection for workers cannot be justified on efficiency grounds, though it remains possible to justify it on equity grounds.

Economists in favour of liberal trade point out that protection can be replaced with much less inefficient methods of compensation to displaced workers.

A substantial part of the opposition to liberal trade is based on confusion and ignorance. Confusing absolute advantage with a valid theory of trade sows fear that a nation must protect itself from overwhelming competition. Greatly exaggerated notions of the size of adjustment costs leads to support for protection. Ignorance of the harm done to the world's poor by protection persuades many who support redistribution of income to support protection that harms the majority of those they seek to help. The combination of confusion and ignorance among the 'disinterested' with well-organized special interest groups explains the power of protectionism.

Appendix

The general statement of comparative advantage is that on average a country will import goods that are relatively expensive in autarky. Let m denote the vector of excess demands in equilibrium, positive for imports and negative for imports. Let p denote the vector of relative prices in autarky in the home country and let p^* denote the vector of relative prices in autarky in the foreign country. Then the vector inner product $(p - p^*)'m \geq 0$.

The key requirement for the proposition is 'as if' optimization by consumers and producers, leading downward-sloping demand and upward-sloping supply in the generalized sense (the substitution effects matrix of real income-compensated excess demands, m_p^c, is negative semi-definite). If the actual trade equilibrium involves trade distortions, the additional requirement is that trade not be on balance subsidized. Let t be the vector of trade taxes, positive for import taxes and negative for export taxes (and negative for import subsidies and positive for export subsidies). The requirement is $t'm \geq 0$.

The 'buy low, sell high' logic implies that a surplus is captured by trade, so comparative advantage trade is closely linked to the gains from trade. 'As if' optimization means that consumers lower the expenditure required to support given real income by reallocating consumption in trade equilibrium as compared with autarky, while optimization by producers means that income is raised by reallocating production in trade equilibrium as compared with autarky.

Similar comparative advantage statements can be made concerning the factor content of trade; countries tend to import (embodied in goods) the factors that are relatively expensive in autarky (see Neary and Schweinberger 1986).

International Trade, Empirical Approaches to

Stephen J. Redding

Abstract

This article reviews empirical research in international trade, which has undergone a resurgence since the mid-1980s. The article begins with traditional trade empirics, in which cross-country differences in opportunity costs of production (comparative advantage) are the basis for trade, before turning to new trade empirics, in which consumer love of variety and increasing returns to scale give rise to trade in similar goods between similar countries. More recent empirical research has emphasized heterogeneity across products within industries and across individual plants and firms, while other recent work has focused on the political economy of trade policy.

Traditional Trade Empirics

The idea that comparative advantage provides an explanation for 'inter-industry trade' (the international exchange of one set of goods for another) dates back to Ricardo (1817), who emphasized technology differences as the source of cross-country variation in opportunity costs of production. While some early empirical studies adopted a Ricardian perspective (for example, MacDougall 1951), much of the empirical analysis of traditional trade frameworks has been concerned with the Heckscher–Ohlin (HO) model (Heckscher 1919; Ohlin 1924). In contrast to its Ricardian counterpart, the HO model assumes that countries have identical technologies, and instead emphasizes variation in country factor endowments and industry factor intensities as the source of differences in opportunity costs of production.

The stylized version of the HO model assumes two factors of production (capital and labour), two

countries (one capital-abundant), and two goods (one capital-intensive at all factor prices). In this stylized case, the model yields four sharp predictions: (*a*) the HO theorem – the capital-abundant country exports the capital-intensive good; (*b*) the factor price equalization theorem – with diversified production, international trade equalizes factor prices; (*c*) the Stolper–Samuelson theorem – with diversified production, an increase in the relative price of the labour-intensive good raises the relative and real return to labour and reduces the relative and real return to capital; (*d*) the Rybczynski theorem – with diversified production, an increase in the endowment of labour leads to a more than proportionate increase in the output of the labour-intensive good and reduces output of the capital-intensive good.

Early empirical examinations of the HO model were loosely motivated by these four theorems. In seeking to test the HO theorem, Leontief (1953) found that US exports were less capital-intensive than US imports, which appeared paradoxical within the confines of the stylized HO model. The key to resolving this paradox in Leamer (1980) was in rigorously deriving the correct empirical predictions directly from the theory. Indeed, a distinguishing feature of recent empirical studies of the HO model has been the derivation of empirical specifications from general equilibrium trade theory and the explicit recognition of the complexity of the model's predictions with many goods and factors of production.

With many goods and factors of production, and in the absence of trade costs, the theorems of the HO model are considerably weaker than in the $2 \times 2 \times 2$ stylized version, and hold only as averages or correlations. We begin by examining predictions for international trade (the generalization of the HO theorem). The many-good, many-factor version of the model does not predict the pattern of trade in individual goods, but does predict the pattern of trade in individual factor services. A country that is abundant in a factor is predicted to be a net exporter of the factor, where factor abundance is defined as an endowment exceeding the country's share of world consumption times the world factor endowment. Therefore, many empirical studies of the HO model have focused on its predictions for net trade in factor services. Following Leamer's (1984) early and influential treatment, Bowen et al. (1987) were the first to observe that a full test of the model's predictions for factor service trade requires three sets of separate data on international trade, factor input requirements and factor endowments. Early empirical results were discouraging from the point of view of the explanatory power of the theory. Bowen et al. (1987) found that the HO model performed no better than a coin toss in predicting the direction of a country's net trade in factor services. In response, Trefler (1993) argued that factor-augmenting technology differences could both explain patterns of trade in factor services and account for cross-country variation in factor prices. Under this hypothesis, first mooted in Leontief (1953), the HO model's predictions for factor service trade and of factor price equalization hold only after one controls for cross-country differences in the efficiency of factors of production. In subsequent work, Trefler (1995) identified two systematic departures between predicted and measured net trade in factor services: (*a*) 'The Case of the Missing Trade', where measured factor services trade is close to zero and much smaller than predicted by the HO model; and (*b*) 'The Endowments Paradox', where rich countries are scarce in most factors and poor countries are abundant in most factors.

One strand of recent research has argued that the HO model's predictions for factor service trade are much closer to the measured values for trade between regions within countries, where the model's assumptions of identical technologies, factor price equalization and identical and homothetic preferences are more likely to be satisfied. Davis et al. (1997) provide evidence supporting the HO model's predictions using data for trade between Japanese regions. A second strand of research has argued that factor-augmenting technology differences are not enough to explain international trade in factor services, but that a reconciliation between theory and data is ultimately possible. Davis and Weinstein (2001) provide evidence that international trade in factor services can be successfully explained if the HO model's assumptions are relaxed to introduce

cross-country differences in technology that vary between industries ('non-neutral' technology differences), trade costs and non-factor price equalization. While predicted and measured net factor service trade has been brought into line, the model is radically transformed by relaxing these assumptions.

We now turn to the predictions of the many-good, many-factor HO model for the international location of production (the generalization of the Rybczynski theorem). With an equal number of goods and factors of production and factor price equalization, the HO model implies a linear relationship between production and factor endowments. Estimating this relationship using cross-country data, Harrigan (1995) finds statistically significant coefficients on factor endowments, but large within-sample prediction errors, suggesting that the model performs poorly in explaining the international location of production. Gandal, Hanson and Slaughter (2004) and Hanson and Slaughter (2002) examine the HO model's prediction that, in an equilibrium where factor prices are pinned down by goods prices, changes in factor endowments should be absorbed through changes in output mix. Using immigration data for Israel and US states, they find some evidence in support of the model's prediction. More recent research reinforces conclusions from the analysis of net factor services trade by suggesting that non-neutral technology differences across industries are important for explaining the international location of production. In an influential paper, Harrigan (1997) estimates an equation for the share of sector in GDP derived from the neoclassical model of trade, which relaxes the assumptions of the HO model to allow for cross-country differences in technology. Both differences in factor endowments and differences in technology that are non-neutral across industries are found to be important in explaining cross-country variation in production structure. Other research finds evidence consistent with multiple cones of diversification within the HO model, where countries or regions specialize in a distinct set of goods, and as a result have different relative factor prices (Schott 2003; Bernard et al. 2005).

We now turn to the relationship between international trade and factor prices, an issue which rose to prominence with the debate about whether the rise in wage inequality in OECD countries since the 1970s is explained by international trade or skill-biased technological change. While the labour economics literature has tended to emphasize the role of skill-biased technological change, the international trade literature has produced mixed findings, as illustrated by the collection of studies in Feenstra (2000). One approach has examined the net factor content of trade and has typically found a relatively minor role for international trade (see, for example, Krugman 2000). Another approach has examined the relationship between relative goods and relative factor prices within the many-good, many-factor version of HO model (the generalization of the Stolper–Samuelson theorem). Here the results have been more sanguine about the contribution of international trade. Leamer (1998) shows how zero-profit conditions and the shares of factors in unit costs for a cross-section of industries can be used to estimate the changes in factor prices mandated by observed changes in goods prices. Assumptions are made about the degree to which improvements in technology are passed through into lower goods prices, and some evidence is found that trade-induced changes in goods prices during the 1970s pushed towards increasing wage inequality in the United States. Feenstra and Hanson (1999) extend the analysis to estimate the contribution of measures of technological change and outsourcing to changes in relative goods and hence through the zero-profit conditions to relative factor prices. In their baseline specification, they estimate that computers explain around 35 per cent of the rise in the relative wages of US non-production workers over the period 1979 to 1990, and outsourcing explains around 15 per cent.

One important difference between international trade and other fields, such as development economics, is that general equilibrium is central to many of the field's theoretical predictions. As it result, it has proved hard to find natural experiments that provide plausible sources of exogenous variation to identify relationships of interest.

Relatedly, many of the predictions of traditional trade theory with many goods and many factors relate to movements from autarky to international trade, but autarky is rarely observed. In two creative papers, Bernhofen and Brown (2004, 2005) exploit the dramatic opening of the Japanese economy in the 19th century from a state of near-complete isolation to test some of the most fundamental predictions of general equilibrium trade theory. In their first paper, they find evidence, supporting the general law of comparative advantage, that an economy's net export vector evaluated at autarky prices is negative. In their second paper, they estimate that, during the final years of Japan's isolation during 1851–3, real income would have had to increase by around eight or nine per cent in order to afford the consumption bundle that the economy could have obtained if it were engaged in international trade during that period.

New Trade Empirics

Although traditional trade theory emphasizes the international exchange of one set of goods for another (inter-industry trade) due to comparative advantage (dissimilar countries), much of international trade involves the two-way exchange of goods within industries (intra-industry trade) between developed nations (similar countries). This apparent disconnect between theory and data was documented in a number of early empirical studies, which examined the extent of intra-industry trade (for example, Grubel and Lloyd 1975) and the volume of trade between similar countries (for example, Linder 1961). This empirical evidence was a key motivation for the 'new trade theory' literature following Krugman (1979, 1980) that explained these features of international trade in terms of consumer love of variety and increasing returns to scale. Firms manufacture differentiated products and concentrate production in a single location, while consumers spread their expenditure across all firms' varieties, giving rise to two-way trade even if countries are identical. Although not the only explanation for intra-industry trade between similar countries (see Davis 1997), the combination of consumer love of variety and increasing returns to scale provided an entirely new intellectual framework for thinking about the causes and consequences of international trade.

In the HO model, the volume of trade is increasing in the extent of dissimilarity in countries' factor endowments, whereas in new trade theory the volume of trade is increasing in the similarity of countries' sizes. Indeed, new trade theory provides rigorous theoretical foundations for the so-called 'gravity equation', in which the volume of trade between two countries is proportional to the product of their sizes and measures of extent of trade frictions. Although the gravity equation had been known for some time to provide an extremely successful empirical explanation for bilateral patterns of international trade (classic early treatments include Tinbergen 1962, and Linnemann 1966), it initially suffered from a lack of theoretical foundations.

New trade theory's prediction that the volume of trade should be proportional to the similarity of country sizes was examined empirically by Helpman (1987) in specifications derived directly from the theory. Using data from 14 OECD countries over the period 1956 to 1981, both bilateral trade and the share of inter-group trade in total trade were found to be strongly increasing in the similarity of country sizes. While this appeared to strongly confirm the predictions of new trade theory, Hummels and Levinsohn (1995) found that the same patterns existed for trade between non-OECD countries, for which new trade theory's assumptions of differentiated products and identical and homothetic preferences appeared less appropriate. One explanation of why the gravity equation appears to work for such diverse groups of countries is that a number of alternative theoretical frameworks, including the HO model, yield this relationship. As argued by Deardorff (1998), the gravity relationship is a basic implication of specialization combined with identical and homothetic preferences. Therefore, the problem is not a lack but rather a surfeit of theoretical foundations. Consistent with this insight, Evenett and Keller (2002) found that increasing returns and factor endowments both

played a role in explaining the empirical success of the gravity equation for a diverse cross-section of developed and developing countries.

The gravity equation has been widely used in empirical work to estimate the impact on trade of a host of frictions, policies and institutions including national borders, transport costs, tariffs, common currencies and the World Trade Organization (WTO). A notable example is McCallum (1995), who finds that trade between Canadian provinces was more than 20 times larger than trade between Canadian provinces and US states, suggesting a surprisingly large impact of national borders on trade. Anderson and Van Wincoop (2002) show, however, that theoretical derivations of the gravity equation imply that bilateral trade depends not only on trade costs between regions themselves ('bilateral resistance') but also on trade costs with all locations ('multilateral resistance'). An implication is that national borders have a larger impact on inter-regional trade than on international trade the smaller a country is and the larger its trade partner. When countries are small, international trade is a large share of overall economic activity. Therefore, the national border has a large effect on multilateral resistance, and so leads to a large reduction in the cost of inter-regional trade relative to international trade. Estimating the gravity equation in a theory-consistent way, Anderson and Van Wincoop (2002) obtain much smaller, though still large, estimates of the trade impact of the Canada–US border.

In the presence of trade costs, an important difference emerges between the predictions of new trade theory and those of traditional trade theory. The combination of consumer love of variety, increasing returns to scale and trade costs in new trade theory generates a 'home market effect', whereby an increase in expenditure leads to a more than proportionate increase in domestic production of a good. The intuition is that increasing returns to scale imply that firms have an incentive to concentrate production, while transport costs imply that they have an incentive to concentrate production close to large markets. In contrast, traditional trade models imply that an increase in expenditure leads at most to a proportionate increase in domestic production if foreign export supply is perfectly inelastic. Otherwise, if the foreign export supply curve is upward sloping, some of the increase in expenditure is satisfied through higher foreign exports and the increase in domestic production is less than proportionate. Using international and Japanese regional data, Davis and Weinstein (1999, 2003) find evidence of home market effects for a number of manufacturing industries, which together account for a substantial share of overall manufacturing activity. Additional evidence in support of home market effects emerges from international trade data in Feenstra et al. (2001) and Hanson and Xiang (2004).

One feature of international trade that appears at first sight hard to reconcile with new trade theory is the large number of zeros between country pairs. The constant elasticity of substitution (CES) preferences and iceberg trade costs in new trade models imply that all country pairs trade a positive quantity of each variety. However, in an analysis of bilateral trade between 161 countries over the period 1970 to 1997, Helpman et al. (2006) find that roughly one half of the country-partner-year observations involve zero trade. A natural explanation for zero bilateral trade flows can be created within new trade theory if firm heterogeneity and fixed trade costs are introduced following Melitz (2003). Depending on the distribution of productivity within countries, firms may or may not find it profitable to incur the fixed costs of exporting to a particular market. Helpman et al. (2006) develop a methodology for estimating the gravity equation that not only controls for multilateral resistance as suggested above, but also controls for the existence of zero bilateral flows and the non-random selection of firms into exporting according to their productivity.

Finally, one key stylized fact about international trade since the Second World War is that it has grown far more rapidly than income. Two potential explanations are reductions in trade barriers following multilateral liberalization or regional integration, and improvements in transportation and communication technologies. Yi (2003) argues that is hard to explain the magnitude of the trade growth using standard trade models, and observed declines in trade barriers

unless one assumes implausibly high elasticities of substitution. However, augmenting standard models to include intermediate inputs enables the growth in trade to be explained with a smaller elasticity of substitution. In the augmented model, tariff reductions decrease the cost of shipping both intermediate inputs and final goods, and so have a magnified impact on overall trade volumes. Indeed, the geographical separation of stages of the production process is one of the distinctive features of trade at the end of the 20th century compared with an earlier era of international integration at the end of the 19th century. This geographical separation of stages of production has been variously referred to as vertical specialization, vertical disintegration, the fragmentation of production, the slicing of the value-added chain, geographical production networks and offshoring. Hummels et al. (2001) define vertical specialization as occurring when the following conditions are satisfied: (*a*) goods are produced in multiple sequential stages; (*b*) two or more countries provide value-added in the good's production sequence; (*c*) at least one country uses imported inputs in its stage of the production process and some of the resulting output is exported. The authors provide empirical evidence of the rapid growth in vertical specialization in the closing decades of the 20th century alongside the rapid growth in overall trade.

The Empirics of Product Trade

The dissemination of highly disaggregated datasets on trade in thousands of individual products (Feenstra et al. 2002; Feenstra et al. 2005) has contributed towards a shift in focus in empirical trade research towards the micro level. For the United States, data are available for over 7,000 seven-digit products of the Tariff Schedule of the United States (TS7) from 1972 to 1988 and for over 10,000 ten-digit products of the Harmonized System (HS10) from 1989 onwards.

In contrast to the empirical research on the HO model discussed above, which emphasizes specialization across products or industries, Schott (2004) provides compelling evidence of specialization *within* products. With US manufacturing imports taken as a whole in 1994, and the unit value ratio (UVR) defined as the ratio of value to quantity, the maximum UVR within products across trade partners is a factor of 24 times greater than the minimum UVR. The UVRs are higher for varieties originating in capital-and skill-abundant countries than for those sourced from labour-abundant countries, consistent with HO-based specialization. Similarly, UVRs are positively associated with the capital intensity of the production techniques that exporters use to produce them. Taken together, these and other findings in the paper suggest that comparative advantage operates at a much finer level of detail than customarily considered.

Another insight that emerges from the product-level trade data is the importance of the 'extensive margin' of the set of goods traded. Hummels and Klenow (2005) decompose variation in countries' aggregate exports into the contributions of the following terms: (*a*) the quantity of each good exported (the 'intensive margin'); (*b*) the set of goods exported (the 'extensive margin'); (*c*) the quality of goods exported. They find that the extensive margin accounts for around 60 per cent of the greater exports of larger economies, while the remaining intensive margin contribution of 40 per cent consists of higher quantities being exported at modestly higher prices. Kehoe and Ruhl (2004) establish an important role for the extensive margin in explaining the growth of trade following trade liberalizations. The set of goods that accounted for only 10 per cent of trade prior to liberalization are found to account for as much as 40 per cent of trade after liberalization. Using micro data from the U.S. Commodity Flow Survey, Hillberry and Hummels (2005) show that trade frictions such as distance reduce the aggregate value of trade primarily through the number of commodities shipped and the number of establishments shipping commodities (the extensive margin) rather than through the average value of shipments (the intensive margin). Together these findings present a number of challenges to standard trade models. For example, in marked contrast to the data, new

trade theory models without firm heterogeneity and fixed costs of trading imply that all of the adjustment to trade frictions occurs through the intensive margin.

Although consumer love of variety is one of the defining features of new trade theory, Broda and Weinstein (2006) were the first to estimate the welfare gains from an increase in the number of varieties imported over time. In their analysis, the product-level trade data is used to measure varieties, defined as the versions of a product supplied by different exporters. The methodology of Feenstra (1994) is extended to estimate separate elasticities of substitution for thousands of products and to evaluate the contribution of new varieties to the US import price index. According to their baseline estimates, conventional price indices that do not correctly control for variety growth overstate the growth in US import prices by around 1.2 percentage points per annum. The estimated contribution to US welfare from an increase in the number of varieties imported over the period 1972 to 2001 is around 2.6 per cent of national income.

The Empirics of Plant and Firm Trade

The analysis of micro data-sets on plants and firms presents additional empirical challenges to traditional and new trade theory, and prompted a wave of subsequent theoretical research. The first set of empirical challenges relates to producer heterogeneity and persistent reallocation. Whereas traditional and new trade theories typically assume a representative firm, micro data-sets reveal vast heterogeneity across plants and firms within narrowly defined industries, in terms of productivity, capital intensity, skill intensity and other characteristics (see for example the survey by Bartelsman and Doms 2000). Similarly, whereas traditional trade theory emphasizes net reallocations of resources between industries in response to exogenous shocks such as trade liberalization, micro data-sets reveal persistent job creation and job destruction in all industries even in the apparent absence of exogenous shocks. Additionally, job creation and job destruction are positively correlated across industries, implying that rates of gross job creation and destruction are large relative to the net reallocation emphasized in traditional trade theory. An implication of these findings is that the changes in employment across plants and firms are greater than those required to achieve the observed between-industry reallocation of resources ('excess job reallocation'), implying substantial within-industry reallocations of resources (see in particular Davis et al. 1998).

The second set of empirical challenges relates to the export behaviour of plants and firms. Traditional trade theory predicts net exports in one set of industries and net imports in another set of industries. New trade theory implies that all firms export as a result of consumer love of variety and increasing returns to scale. Yet, in micro data-sets, all manufacturing industries display a mix of exporters and non-exporters (see Bernard and Jensen 1995). Moreover, exporters are systematically more productive, more capital-intensive and more skill-intensive than non-exporters (see again Bernard and Jensen 1995). These findings have led to considerable debate as to whether high-performing firms become exporters or whether exporting leads to improved firm performance. The current consensus favours causality running from good firm performance to exporting (selection into export markets): see, for example, Bernard and Jensen (1999), Clerides et al. (1998) and Roberts and Tybout (1997).

The third set of empirical challenges relates to evidence from trade liberalizations in both developed and developing countries. Despite traditional trade theory's emphasis on between-industry reallocations of resources, one of the central findings from empirical studies of trade liberalizations is the importance of within-industry reallocations of resources across plants and firms. In an influential paper, Pavcnik (2002) finds that between-plant reallocations of resources account for around two-thirds (12.4 percentage points) of the 19 per cent increase in aggregate productivity in the Chilean manufacturing sector following the trade liberalization of the late 1970s and early 1980s. Similarly, Trefler (2004) finds an important role for reallocation in accounting for

the improvement in aggregate productivity in Canadian manufacturing in the aftermath of the Canada–US free trade agreement.

Together these empirical challenges have led to the development of new theoretical frameworks incorporating firm heterogeneity into both traditional and new trade theory (see in particular Bernard et al. 2003; Melitz 2003). The interplay between the econometric analysis of micro datasets on plants and firms and the theoretical analysis of firm-based responses to international trade is one of the most exciting areas of ongoing research.

The Empirics of Trade Policy

A final area of rapid recent progress is the empirical analysis of trade policy. A number of alternative approaches to modelling the political economy of trade policy have been taken, including median-voter theories, models where the government trades off political support from industry against consumer dissatisfaction, theories of lobbying by special interest groups, and models of electoral contribution.

One of the most influential lines of research follows the seminal work of Grossman and Helpman (1994). In their model, campaign contributions are designed to influence policy choices. Interest groups move first and offer politicians campaign contributions that depend on their policy stance. Politicians next maximize a political objective function which depends on both campaign contributions and social welfare. The political objective function is derived from microeconomic foundations within a model of electoral competition. The model yields a structural equation in which the level of protection depends on the political organization of the industry, the ratio of domestic output in the industry to net trade, and the elasticity of import demand or export supply. Goldberg and Maggi (1999) estimate the structural relationship implied by the Grossman and Helpman model and find broad empirical support. In particular, the pattern of protection differs markedly between politically organized and non-organized industries, though the implied weight on social welfare relative to political contributions is larger than expected. One of the distinctive features of recent empirical work in this area is again the rigorous derivation of empirical specifications from theoretical predictions. Gawande and Krishna (2003) survey both the recent empirical evidence and the results of earlier and more ad hoc empirical specifications.

A related theoretical literature has sought to model the politics of international trade agreements (for example, Grossman and Helpman 1995; Krishna 1998; McLaren 2002). One issue that has attracted particular attention is the extent to which regional preferential trade agreements reinforce or retard multilateral trade liberalization. Theoretical research has also examined the microeconomic foundations for observed features of international trade institutions such as the General Agreement on Tariffs and Trade (GATT) and the World Trade Organization (WTO) (see in particular Bagwell and Staiger 1999, 2001). Two key features are reciprocity and non-discrimination (the Most Favored Nation, MFN, principle). Empirical work in this area remains in its infancy and offers an exciting prospect for the future. In an analysis of US trade policy, Limao (2006) finds evidence that preferential trading blocs have acted as stumbling blocks for multilateral liberalization.

Internet and the Offline World

Avi Goldfarb

Abstract

This article emphasises that a key to understanding the (net) benefits of the Internet is to remember that all online activity has an offline context. People live their lives offline. Therefore, the fall in communication costs and the fall in distribution costs associated with the diffusion of the Internet had a heterogeneous impact across locations.

Introduction

There is a large and growing literature in economics and management that studies the benefits and costs of the Internet to firms, consumers, academics, and workers. Researchers have studied online purchasing habits, online advertising, online communication, online work, and online business strategy; and this research has built our understanding of how people behave online. Importantly, however, much of it has focused on data and settings that include only online activities.

In this article, I summarise a literature that argues that a key to understanding the (net) benefits of the Internet is to remember that all online activity has an offline context. People live their lives offline and therefore an understanding of offline opportunities, desires, and positions provides a more complete picture of the impact of the online communications channel. (Related literature reviews include Scott Morton (2006) and Lieber and Syverson (2012)).

Cairncross (1997) was among the first to recognise how the Internet helped substitute for several offline activities, emphasising how the Internet would bring about the 'Death of Distance'. This argument to some degree echoed McLuhan's (1962) much earlier writing about the impact of electronic media (mainly television) on global culture. Friedman's (2005) discussion of the 'Flat World' also is motivated by the reduced importance of the local environment due to advances in information and communication technology.

Much of the academic literature on this topic has emphasised the heterogeneous effects of Internet technology across locations. The next two sections discuss how reductions in communications costs and distribution costs have such heterogeneous effects across locations. For example, digital distribution of movies has a much larger impact on the types of movies available to consumers in North Dakota than in Manhattan. The next section discusses how different local regulatory environments mean that the impact of the technology varies across locations. The penultimate section emphasises that even if the benefits from Internet technology were uniform across locations, the costs of adopting Internet technology (for businesses and consumers) are lowest in large urban areas. The article concludes by reemphasising the importance of heterogeneous offline environments to understanding the impact of Internet technology.

Communication Costs

The Internet is a communications technology. Specifically, it is a series of protocols that allow computers to communicate with each other. These protocols, in turn, enable people to communicate in new, often relatively inexpensive, ways. For example, the marginal cost of sending an email is effectively zero. In contrast, the marginal cost of sending a letter is much higher. Furthermore, while the cost of sending a letter increases as borders are crossed, and often as distance increases, the cost of sending an email does not change with distance. Thus Internet technology has meant a lowering of communications costs, whether the communication was local or distant.

However, the impact of this reduction in communications costs differs by location and by type of communication. In particular, in order to understand the impact of the reduction in communications costs, researchers have focused on relative impact across locations. While communications costs fall everywhere, the size of the reduction depends on the alternative communications technologies available.

One possibility is that the Internet substitutes for things that are available offline. Online

advertising can substitute for offline advertising, online news can substitute for offline news, and online communication can substitute for offline communication. For example, Goldfarb and Tucker (2011a, b) show that online advertising is both more expensive and more effective in locations where regulations make offline advertising difficult; Sinai and Waldfogel (2004) show that online news substitutes for offline news; and Forman and van Zeebroeck (2012) demonstrate the online communication can overcome barriers to offline communication. Even when there are barriers to using the Internet to substitute for an offline activity, new markets can arise to overcome these barriers. For example, Jin and Kato (2007) use evidence from the sports memorabilia industry to demonstrate that asymmetric information issues in the online market can be overcome by the establishment of new markets for information, thereby enabling the online market to provide a reasonable substitute for the offline market.

An alternative to substitution is that the Internet complements things that are available locally. Goldmanis et al. (2010) emphasise that the Internet reduces search costs, benefiting the highest quality offline businesses while hurting others. Thus the Internet complements high-quality local businesses.

Blum and Goldfarb (2006) demonstrate that Internet surfing is disproportionately local, likely because consumer tastes are spatially correlated. While the paper focuses on the foreign (international) websites visited by consumers, the idea is best summarised by recognising that the consumers most likely to visit web pages associated with the Boston Red Sox live disproportionately close to Boston. One implication is that websites may arise locally to serve the tastes of nearby consumers. Similarly, in examining reviews on Amazon, Forman et al. (2008) show that people trust local reviews most, again suggesting spatially correlated tastes.

Hampton and Wellman (2002) argue that social networks are disproportionately local. Thus, Internet technology led the relative price of long distance communication to fall relative to local communication, but Internet communication remains local. Email is often sent within offices and households and Facebook social networks are highly local.

Gaspar and Glaeser (1998) recognised early the potential for the Internet to either substitute for or complement local activities. They pointed out that the impact of such a fall in communications costs does not necessarily increase distant communication relative to local communication, and the impact depends on the particular characteristics of the situation. Glaeser and Ponzetto (2007) argue that complementarities may be more important to driving overall economic activity than substitutes, and Forman et al. (2012) provides some evidence in support of their hypothesis.

This tension between the potential for the Internet to substitute for and complement local activities may be best represented by two papers that examined the impact of electronic communication on collaboration between researchers. Forman and van Zeebroeck (2012) examine the impact of Internet technology on collaboration within a large company. Specifically, they combine information on the location of patent holders within a company with information on the adoption of Internet technology (in the 1990s) across the company's geographically dispersed establishments. Their evidence suggests that the Internet increased collaboration within the company, especially between distant establishments. Agrawal and Goldfarb (2008) examine the impact of an early type of Internet technology, Bitnet, on collaboration between academic researchers. Their evidence also suggests that electronic communication increased collaboration; however, the effect is strongest between co-located universities. Thus, in contrast to Forman and van Zeebroeck's results within a firm, the results across universities suggest that co-location matters. While there are several possible interpretations of the different conclusions of Agrawal and Goldfarb (2008) and Forman and van Zeebroeck (2012), the most likely explanations emphasise differences across the empirical settings. In particular, while both examine the impact of a reduction in communications costs on research collaboration, the marginal benefit to communicating over distances within a firm may exceed the benefits across universities.

For example, within a firm, the availability of local substitutes might be more limited.

Furthermore, the reduction in communications cost facilitated by Internet technology has enabled the development of platforms that reduce frictions that can inhibit transactions. These platforms can have a different impact depending on the availability of local substitutes and complements across locations. For example, online auction platforms provide a communication (and transaction) platform for buyers and sellers to meet. Hortaçsu et al. (2009) examine the geographic patterns of trade on two large online auction platforms: eBay and MercadoLibre. While they show that the distance between buyer and seller is an important deterrent to trade on these platforms, these effects are smaller than those observed in studies of offline transactions. Thus, the reduction in communication costs facilitated by Internet technology disproportionately enables distant transactions relative to the pre-existing geographic distribution of transactions. The online setting enables transactions that might otherwise not be feasible, though distance does still play a role.

Crowdfunding platforms, such as Kickstarter and Sellaband, are another type of Internet-enabled platform. These websites enable entrepreneurs and artists to match with investors in settings that facilitate small scale investments in very early stage projects. Similar to the findings in Hortaçsu et al. (2009), Agrawal et al (2012) document substantial geographic distance between artists and investors on the Sellaband music crowdfunding platform. Importantly, however, this does not mean that geographic distance is irrelevant on crowdfunding platforms. Agrawal et al. (2012) show that the first investors in an artist are typically co-located with the artists. It is only once the artist reaches prominence on the website (partly due to the earlier local investors) that distant investments accelerate. Agrawal et al. explain this difference between local and distant investors with evidence on the offline social networks of the artists: the artists tend to know the early investors personally and because social networks are disproportionately local, early investors are disproportionately local.

This section has discussed findings that the reduction in communication costs associated with the Internet had heterogeneous effects on interactions. Broadly, while it increased both local and distant interaction, the relative impact varied across empirical settings.

Distribution Costs

Internet technology can reduce distribution costs. First, digital distribution means that the cost of sending digitised goods to customers (such as music, news and movies) is close to zero. Second, complementarities between digital ordering and courier systems mean that the cost of sending some physical goods to customers can be lower on online platforms than offline platforms.

Balasubramanian's (1998) model of competition between direct sales channels and offline retail stores provides a useful way to think about the impact of the Internet on retailing. In his model, online (direct) retailers are equally attractive to all customers. In contrast, offline retailers are most attractive to people who live near them. This means that, even though online retailing is equally attractive to all customers, the competition from offline stores is fiercest for customers that live near offline stores. Therefore customers that live near offline stores buy from those stores and customers that do not live near offline stores buy online. Forman et al. (2009) provide empirical evidence supporting this model, demonstrating that offline store openings change the distribution of sales on Amazon away from the top sellers. This implies that while the online channel means that total (firm and customer) distribution costs fall for all locations, the impact of the arrival of the online channel will be largest for those who live far from major retail centers. Brynjolfsson et al. (2009) similarly show substitution between online and offline channels in the apparent industry. Choi and Bell (2011) also demonstrate substitution between online and offline purchases in the diaper category. More importantly, they show that online retail has the ability to provide niche services in places without rich variety in a specific category. In particular, they

show that the best online customers for specialty diapers live in places with few babies. The ability of the online channel to substitute for the offline channel is therefore particularly acute for products where distribution varies with local demand.

For digital products that do not need to be shipped to be consumed, the Internet reduces distribution costs to near zero. Blum and Goldfarb (2006) show that for such products, the effects of borders and distance may disappear. In particular, Blum and Goldfarb show that for digital products that are not taste-based, distance does not affect web browsing behaviour. Thus, low distribution costs do eliminate the role of distance. That said, as mentioned above, this is not true of taste-based products such as music or movies. For those products, distance matters because tastes are spatially correlated.

Regulation

Regulation matters to consumer and business choices. Importantly, regulations vary across countries, states, and even cities. These regulations change the marginal benefit to online activities relative to offline activities. The earliest and perhaps most prominent stream of this literature examines the role of local sales taxes on online purchasing. Goolsbee (2000) demonstrated that the tax-free status of most online purchases played an important role in the rise of electronic commerce. In doing so, he provided evidence that the places with the most online purchases were places with high local sales taxes. Anderson et al. (2010) provided evidence that search processes play an important role in explaining the high rate of online purchases in states with sales taxes. Ellison and Ellison (2009) also find high taxes to be an important motivator for online purchases.

Aside from taxes, advertising and privacy regulations affect the use of the Internet in other ways. Goldfarb and Tucker (2011a) show that regulations banning personal injury lawyers from contacting customers directly appear to raise the price of search engine advertising. In other words, the online channel appears to substitute for the offline channel, partially circumventing the regulation. In a different context, Goldfarb and Tucker (2011b) demonstrate that regulations banning alcohol companies from using billboards appear to increase the effectiveness of online display advertising. Again, the online channel overcomes the barriers to advertising presented by the regulation. Privacy regulations also impact online behaviour. Goldfarb and Tucker (2011c) demonstrate that strict privacy regulations in the European Union appeared to reduce the effectiveness of online advertising.

Costs of Internet Adoption

This last, and briefest, section summarises research that emphasises that the cost of adopting the Internet (to consumers and businesses) varies across locations. Greenstein (2000) demonstrated that competition between Internet Service Providers is highly variable around the USA. Some locations had fierce competition while others had very little competition. Recent research has shown that this result persisted for many years (Mack and Grubesic 2009; Grubesic 2012; Prieger and Hu 2008). This variation in competition appears to lead to different prices for Internet access across locations (Greenstein 2000). For businesses, the main costs of adoption of Internet services involve training workers to use the technology efficiently. Forman et al. (2005, 2008) demonstrated that these costs are heterogeneous across locations within the USA. In particular, cities have much lower costs of adoption than rural areas. Overall, for both consumers and firms, costs of Internet adoption are lowest in urban areas and can be much higher in suburban and especially rural areas.

Summary and Conclusion

This article has emphasised the important role of an individual's offline surroundings in understanding their online behaviour. While the Internet can reduce communications costs and distribution costs, the impact of this reduction is heterogeneous across locations. The Internet can substitute for offline

activities, or complement them. Regulation affects how online and offline interact, and the costs of the adopting the technology itself vary across locations.

Looking forward, there are many reasons to expect more of the same: that heterogeneity in the offline environment will continue to impact online behaviour. With the rise of the mobile Internet, the role of offline surroundings may become even more important to understanding online behaviour (Ghose et al. 2012). Generally, without understanding an individual's offline opportunities, needs and desires, it is difficult to comprehend their online activities.

Internet, Economics of the

Nicholas Economides

Abstract

We discuss salient economic aspects of the Internet, including the possible abolition of net neutrality by local broadband access networks as well as potential incompatibilities and degradation of connectivity in the Internet backbone.

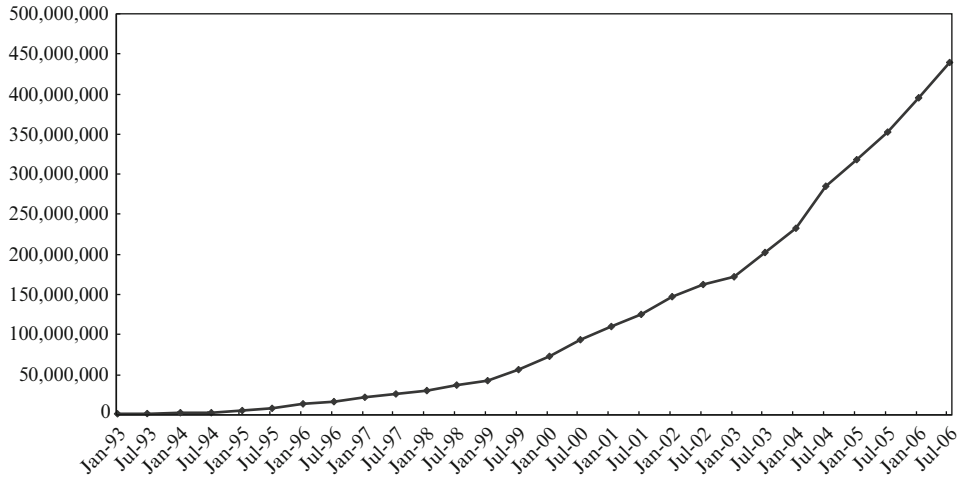
The Internet is a global network of interconnected networks that connect computers. The Internet allows data transfers as well as the provision of a variety of interactive real-time and time-delayed telecommunications services. Internet communication is based on common and public protocols. Hundreds of millions of computers are presently connected to the Internet. Figure 1 shows the expansion of the number of computers connected to the Internet.

The vast majority of computers owned by individuals or businesses connect to the Internet through commercial 'Internet service providers (ISPs). Educational institutions and government departments are also connected to the Internet but typically do not offer commercial ISP services. Users connect to the Internet either by dialing their ISP, connecting through cable modems, or residential 'digital subscriber line' (DSL), or through corporate networks. Typically, routers and switches owned by the ISP send the caller's packets to a local 'point of presence' (POP) of the Internet. Dial-up, cable modem, and DSL access POPs as well as corporate networks dedicated access circuits connect to high-speed hubs. High-speed circuits, leased from or owned by telephone companies, connect the high speed hubs forming an 'Internet backbone network'.

The Internet is based on three basic separate levels of functions of the network:

- the hardware/electronics level of the physical network;
- the (logical) network level where basic communication and interoperability is established; and
- the applications/services level.

Thus, the Internet separates the network interoperability level from the applications/services



Internet, Economics of the, Fig. 1 Internet survey host count, 1993–2006 (*Source*: Internet Systems Consortium). (Online) Available at http://www.isc.org. Accessed 29 January 2007

level. Unlike earlier centralized digital electronic communications networks, such as CompuServe, AT&T Mail, Prodigy, and early America On Line (AOL), the Internet allows a large variety of applications and services to be run 'at the edge' of the network and not centrally.

Residential Broadband Access Networks and Net Neutrality

Users pay ISPs for access to the whole Internet. Similarly, ISPs pay backbones for access to the whole Internet. ISPs pay per month for a pipe of a certain bandwidth, presumably according to their expected use. When digital content, for example, is downloaded by consumer A from provider B, both sides, that is, both A and B, pay. Consumer A pays to his ISP through his monthly subscription, and provider B pays similarly. In turn, ISPs pay to their respective backbones through their monthly subscriptions. The present regime on the Internet does not distinguish in terms of price (or in any other way) between bits or information packets depending on the services that these bits and packets are used for. This regime, called 'net neutrality', has prevailed on the Internet since its inception. Presently, a bit or information packet used for 'voice over Internet protocol' (VOIP), for search, email, for an image or for a video is priced equally as a part of the large number of packets that correspond to the subscription services of the originating and terminating ISP.

Taking advantage of a change in regulatory rules by the Federal Communications Commission that reclassified the Internet as an 'information service' rather than a 'telecommunications service', AT&T, Verizon and cable TV networks advocate price discrimination based on which application and on which provider the bits they transport come from. These local broadband access networks would like to abolish the regime of non-discrimination which has been called 'net neutrality' and substitute for it a complex price discrimination schedule where, besides the basic service for transmission of bits, there will be additional charges by the Internet access network levied to the originating party (such as Google, Yahoo or Microsoft Network, MSN) even when the application provider is not directly connected to the local access network.

The imposition of price discrimination on the provider side of the market and not on the subscriber is a version of two-sided pricing. It is uniquely possible for firms operating within a network structure. Besides traditional networks, such two-sided pricing is also possible for

intermediaries in exchange networks (such as the exchanges themselves). There is presently considerable debate on the legality as well as the efficiency properties of the implementation of such complex pricing strategies by broadband Internet access networks, mainly because of the very considerable market power of such firms.

Residential retail broadband Internet access customers may well have difficulty changing ISPs. Ninety-nine per cent of US households are offered Internet access by at most two firms – a telephone company through DSL and a cable TV company through a cable 'modem' – and many households are facing a monopoly of either cable or DSL. There are also switching costs to residential customers, such as changing equipment. Finally, residential customers are much more affected by contracts that bundle broadband Internet access with other services such as telecommunications and cable television.

As discussed earlier, the Internet under net neutrality separated the network layer from the applications/services layer. This allowed firms to innovate 'at the edge of the network' without seeking approval from network operator(s). The decentralization of the Internet based on net neutrality facilitated innovation resulting in big successes such as Google, MSN, Yahoo, and Skype. Net neutrality also increased competition among the applications and services 'at the edge of the network' which did not need to own a network to compete. Additionally, the existence of network effects on the Internet implies that efficient prices to users on both sides (consumers and applications) should be lower than in a market without network effects. Instead we see an attempt to increase prices that will reduce network effects and innovation.

Abolition of net neutrality raises both horizontal and vertical antitrust issues. To start with horizontal issues, last-mile carriers (who are selling as a duopoly or monopoly to residential consumers) may reduce capacity of 'plain' broadband Internet access service and/or degrade it so that they can establish a 'premium' service for which they intend to charge content/applications providers whose content or application is used by residential subscribers. Coordinated reduction of capacity in 'plain' service is reminiscent of cartel behaviour. In general, the coordinated introduction of price discrimination schemes may reduce output, which would reduce total surplus. Therefore, introduction of coordinated price discrimination may have anti-competitive consequences.

There is also a variety of potentially anti-competitive vertical effects. For example, a carrier may favour its own content or application over the content of a competing carrier or a company that does not have its own network. VOIP provided over broadband Internet competes with traditional circuit-switched service provided by AT&T and Verizon, and could be subject to discrimination. Additionally, both AT&T and Verizon are gearing to distribute video, and could favour their video services over those of others. But the anti-competitive concerns are hardly limited to products and services currently provided by the firms with market power in the access market. The carriers can also leverage market power in broadband access to the content or applications markets through contractual relationships. For example, a carrier can contract with an Internet search engine to put it in 'premium' service while searches using other search engines face considerable delays using 'plain' service. The question that confronts the US Congress in 2007 is whether it should intervene by imposing non-discrimination restrictions or wait instead for antitrust suits to filed and resolved. The crucial role of the Internet in US economic growth argues in favour of pre-emptive restrictions.

Backbone Issues

Backbone networks provide transport and routing services for information packets among high-speed hubs on the Internet. Backbone networks vary in terms of their geographic coverage. There is wide variance of ISPs in terms of their subscriber size and the networks they own. However, irrespective of its size, an ISP needs to interconnect with other ISPs so that its customers can reach all computers/nodes on the Internet. That is, interconnection is necessary to provide the universal connectivity on the Internet which is demanded by users. Internet networks interconnect in two ways: (*a*) private bilateral

interconnection, and (*b*) interconnection at public network access points (NAPs). Private interconnection points and public NAPs are facilities that provide collocation space and a switching platform so that networks are able to interconnect. Interconnection services are complementary to Internet transport. In a sense, the Internet backbone networks are like freeways and the NAPs are like the freeway interchanges.

Internet networks have contracts that govern the terms under which they pay each other for connectivity. Payment takes two distinct forms: (*a*) payment in dollars for 'transit', and (*b*) payment in kind, that is, barter, called 'peering'. Connectivity arrangements among ISPs encompass a seamless continuum, including ISPs that rely exclusively on transit to achieve connectivity, ISPs that use only peering to achieve connectivity, and everything in between. Although there are differences between transit and peering in the specifics of the payments method, and transit includes services to the ISP not provided by peering, these two are essentially alternative payment methods for connectivity. The transport and routing that backbone networks offer do not necessarily differ depending on whether cash (transit) or barter (peering) is used for payment.

Under transit, a network X connects to network Y with a pipeline of a certain size, and pays network Y for allowing X to reach all Internet destinations. Under transit, network X pays Y to reach not only Y and its peers, *but also any other network*, such as network Z by passing through Y, as in the diagram below.

X – – – – – – – – – – – – Y – = – = – = – = – = – Z

Under peering, two interconnecting networks agree not to pay each other for carrying the traffic exchanged between them as long as the traffic originates and terminates in the two networks. In the diagram above, if X and Y have a peering agreement, they exchange traffic without paying each other so long as such traffic terminating on X originates in Y, and traffic terminating on Y originates in X. If Y were to pass to X traffic originating from a network Z that was not a customer of Y, Y would have to pay a transit fee to X (or get paid a transit fee by X), that is, it would not be covered by the peering agreement between X and Y.

Although the networks do not exchange money in a peering arrangement, the price of the traffic exchange is not zero. If two networks X and Y enter into a peering agreement, it means that they agree that the cost of transporting traffic from X to Y and vice versa that is incurred within X is roughly the same as the cost of transporting traffic incurred within Y. These two costs have to be roughly equal if the networks peer, but they are not zero.

It is a commercial decision whether interconnection takes the form of peering or transit payment. Peering is preferred when the cost incurred by X for traffic from X to Y and Y to X is roughly the same as the cost incurred by Y for the same traffic. If not, the networks will use transit. As I explain below, the decision on whether to peer depends crucially on the geographic coverage of the candidate networks.

Generally, peering does not imply that the two networks should have the same size in terms of the numbers of ISPs connected to each network, or in terms of the traffic that the two networks generate. If two networks, X and Y, are similar in terms of the types of users to whom they sell services, the amount of traffic flowing across their interconnection point(s) will be roughly the same, irrespective of the relative size of the networks. For example, suppose that network X has ten ISPs and network has one ISP. If all ISPs have similar features, the traffic flow from X to Y is generally equal to the traffic flow from Y to X.

What determines whether a peering arrangement is efficient for both networks is the *cost* of carrying the mutual traffic within each network. This cost will depend crucially on a number of factors, including the geographic coverage of the two networks. Even if the types of ISPs of the two networks are the same as in the previous example (and therefore the traffic flowing in each direction is the same), the cost of carrying the traffic can be quite different in network X from network Y. For example, network X (with the ten ISPs) may cover a larger geographic area and have significantly higher costs per unit of traffic than network

Y. Then network X would not agree to peer with Y. These differences in costs ultimately would determine the decision to peer (barter) or receive a cash payment for transport.

Where higher costs are incurred by one of two interconnecting networks because of differences in the geographic coverage of the networks, peering would be undesirable from the perspective of the larger network. Similarly, one expects that networks that cover small geographic areas will peer only with each other. Under these assumptions, who peers with whom is a consequence of the extent of a network's geographic coverage, and may not have any particular strategic connotation. In a theoretical model, Milgrom et al. (2000) show how peering can emerge under some circumstances as an equilibrium in a bargaining model between backbones.

Structural conditions for Internet backbone services (ease of expansion and entry) ensure low barriers to entry and expansion, and easy conversion of other transport capacity to Internet backbone capacity. As discussed later, raw transport capacity as well as Internet transport capacity have grown dramatically. Transport capacity is almost a commodity because of its abundance. The business environment for Internet backbone services is competitive. Generally, ISPs buying transport services face flexible transit contracts of relatively short duration. This is reflected in competitive pricing. Economides (2006a) shows that AT&T and MCI had almost identical prices for transit in 1999 when AT&T's backbone business was significantly smaller than MCI's.

ISPs are not locked in by switching costs of any significant magnitude. Thus, ISPs are in good position to change providers in response to any increase in price, and it would be very difficult for a backbone profitably to increase price. Moreover, a large percentage of ISPs has formal agreements that allow them to route packets through several backbone networks and are able to control the way the traffic will be routed (multi-homing).

When an ISP reaches the Internet through multiple backbones, it has additional flexibility in routing its traffic through any particular backbone. A multi-homing ISP can easily reduce or increase the capacity with which it connects to any particular backbone in response to changes in prices of transit. Thus, multi-homing increases the firm-specific elasticity of demand of a backbone provider. Therefore, multi-homing severely limits the ability of any backbone services provider to profitably increase the price of transport. Any backbone increasing the price of transport will face a significant decrease in the capacity bought by multi-homing ISPs.

Large Internet customers also use multiple ISPs, which is called 'customer multi-homing'. They have chosen to avoid any limitation on their ability to switch traffic among suppliers even in the very shortest of runs. Customer multi-homing has similar effects as ISP multi-homing in increasing the firm-specific elasticity of demand of a backbone provider and limiting the ability of any backbone services provider to profitably increase the price of transport.

Like any network, the Internet exhibits network effects. Network effects are present when the value of a good or service to each consumer rises as more consumers use it, everything else being equal – see Economides (1996), Farrell and Saloner (1985), Katz and Shapiro (1985), and Liebowitz and Margolis (1994). In traditional telecommunications networks, an additional customer to the network increases the value of a network connection to all other customers, since each of them can now make an extra call. On the Internet, an additional user potentially

- adds to the information that all others can reach;
- adds to the goods available for sale on the Internet;
- adds one more customer for e-commerce sellers;
- adds to the number of people who can send and receive e-mail or otherwise interact in through the Internet.

Thus, the addition of an extra computer node increases the value of an Internet connection to each connection.

In networks of interconnected networks, there are large social benefits from the interconnection of the networks and the use of common

standards. A number of networks of various ownership structures have harnessed the power of network externalities by using common standards. Examples of interconnected networks of diverse ownership that use common standards include the telecommunications network, the network of fax machines, and the Internet. Despite the different ownership structures in these three networks, the adoption of common standards has allowed each of them to reap huge network-wide benefits.

As the variety and extent of the Internet's offerings expand, and as more customers and more sites join the Internet, the value of a connection to the Internet rises. Because of the high network externalities of the Internet, consumers on the Internet demand universal connectivity, that is, to be able to connect with every website on the Internet and to be able to send electronic mail to anyone. This implies that every network must connect with the rest of the Internet in order to be a part of it. The demand for universal connectivity on the Internet is stronger than the demand of a voice telecommunications customer to reach all customers everywhere in the world. In the case of voice, it may be possible but very unlikely that a customer might buy service from a long-distance company that does not include some remote country because the customer believes that it is very unlikely that he or she would be making calls to that country. On the Internet, however, one does not know where content is located. If company A did not allow its customers to reach region B or customers of a different company C, customers of A would never be able to know or anticipate what content they would be missing. Thus, consumers' desire for Internet universal connectivity is stronger than for voice telecommunications. Additionally, because connectivity on the Internet is two-way, a customer of company A would be losing exposure of his or her content (and the ability to send and receive e-mails) to region B and customers of company C. It would be difficult for customer A to calculate the extent of the losses accrued to him or her from such actions of company A. Thus, again, customers on the Internet require universal connectivity.

In markets with network externalities, firms may create bottleneck power by using proprietary standards. A firm controlling a standard needed by new entrants to interconnect their networks with the network of the incumbent may be in a position to exercise market power (see Economides 2006b). Often a new technology will enter the market with competing incompatible standards. Competition among standards may have the snowball characteristic attributed to network externalities.

Economics literature has established that using network externalities to affect market structure by creating a bottleneck requires three conditions (see Economides 1996; 1989; Farrell and Saloner 1985; Katz and Shapiro 1985):

- networks use proprietary standards;
- no customer needs to reach nodes of or to buy services from more than one proprietary network; and
- customers are captives of the network to which they subscribe and cannot change providers easily and cheaply.

First, without proprietary standards, a firm does not have the opportunity to create the bottleneck. Second, if proprietary standards are possible, the development of proprietary standards by one network isolates its competitors from network benefits, which then accrue to only one network. The value of each proprietary network is diminished when customers need to buy services from more than one network.

Third, the more consumers are captive and cannot easily and economically change providers, the more valuable is the installed base to any proprietary network. I show below that these conditions fail in the context of the Internet backbone.

For example, if universal connectivity were not offered by a backbone network, a customer or its ISP would have to connect with more than one backbone. This would be similar to the period 1895–1930 when a number of telephone companies run disconnected networks. Eventually most of the independent networks were bought by AT&T, which had a dominant long-distance network. The refusal of AT&T to deal and

interconnect with independents was effective for three key reasons: (*a*) AT&T controlled the standards and protocols under which its network ran; (*b*) long-distance service was provided exclusively by AT&T in most of the United States; and (*c*) the cost to a customer of connecting to both AT&T and an independent was high. None of these reasons applies to the Internet. The Internet is based on public protocols. No Internet backbone has exclusive network coverage of a large portion of the United States. Finally, connecting to more than one backbone (multi-homing) is a common practice by many ISPs and does not require big costs. And ISPs can interconnect with each other through secondary peering, as explained below. Thus, the economic factors that allowed AT&T to blackmail independents into submission in the first three decades of the 20th century are reversed in today's Internet backbone, and therefore would not support a profitable refusal to interconnect by any backbone.

The Internet fails to fulfill any of the three necessary conditions stated above under which a network may be able to leverage network externalities and create a bottleneck. First, there are no proprietary standards on the Internet, so the first condition fails. The scenario of standards wars is not at all applicable to Internet transport, where full compatibility, interconnection and inter-operability prevail. For Internet transport, there are no proprietary standards. There is no control of any technical standard by service providers and none is in prospect. Internet transport standards are firmly public property (Kahn and Cerf 1999; Bradner 1999). As a result, any seller can create a network complying with the Internet standards – thereby expanding the network of interconnected networks – and compete in the market.

In fact, the existence and expansion of the Internet and the relative decline of proprietary networks and services, such as CompuServe, can be attributed to the conditions of inter-operability and the tremendous network externalities of the Internet. AOL, CompuServe, Prodigy, MCI and AT&T folded their proprietary electronic mail and other services into the Internet. Microsoft, thought to be the master of exploiting network effects, made the error of developing and marketing the proprietary MSN. After that product failed to sell, Microsoft re-launched the Microsoft Network as an Internet service provider, adhering fully to the public Internet standard. This is telling evidence of the power of the Internet standard and demonstrates the low likelihood that any firm can take control of the Internet backbone by imposing its own proprietary standard.

Second, customers on the Internet demand *universal connectivity*, so the second condition above fails. Users of the Internet do not know in advance what Internet site they may want to contact or to whom they might want to send e-mail. Thus, Internet users demand from their ISPs, and expect to receive, universal connectivity. This is the same expectation that users of telephones, mail and fax machines have: that they can connect to any other user of the network without concern about compatibility, location, or, in the case of telephone or fax, any concern about the manufacturer of the appliance, the type of connection (wireline or wireless) or the owners of the networks over which the connection is made. Because of the users' demand for universal connectivity, ISPs providing services to end users or to websites must make arrangements with other networks so that they can exchange traffic with *any* Internet customer.

Third, there are no 'captive' ISPs on the Internet, so the third condition fails, for a number of reasons:

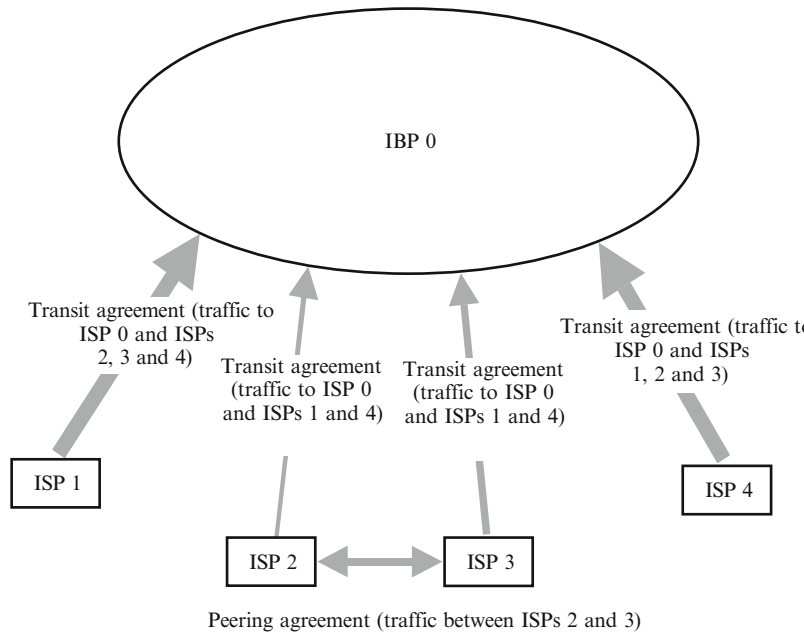
- ISPs can easily and with low cost migrate all or part of their transport traffic to other network providers;
- many ISPs already purchase transport from more than one backbone to guard against network failures and for competitive reasons (ISP 'multi-homing');
- many large websites/providers use more than one ISP for their sites ('customer multi-homing'); and
- competitive pressure from their customers makes ISPs agile and likely to respond quickly to changes in conditions in the backbone market.

Competitive conditions imply that significant price increase, raising rivals' costs or degrading interconnection are unlikely to be profitable on the Internet backbone.

If the large Internet backbone connectivity provider's strategy were to impose equal increases in transport costs on all customers, the response of other backbone providers and ISPs would be to reduce the traffic for which they buy transit from the large Internet backbone provider (IBP) and to instead re-route traffic and purchase more transit from each other. Thus, in response to a price increase by the large Internet backbone connectivity provider, other IBPs and ISPs would reduce the traffic for which they buy transit from the large IBP down to the minimum level necessary to reach ISPs that are *exclusively* connected to the large IBP. All other IBPs and ISPs would exchange all other traffic with each other bypassing the large IBP network.

Figure 2 shows the typical reaction of an increase in the price of a large IBP, and illustrates why the strategy of increasing price is unprofitable. Consider, for example, a situation where, prior to the price increase, four ISPs (1 to 4) purchase transit from IBP 0, which considers increasing its price. Two of these ISPs (ISP 2 and ISP 3) peer with each other. ISP 1 and ISP 4 buy transit capacity for all their traffic to IBP 0 and the other three ISPs. ISP 2 and ISP 3 buy transit capacity for all their traffic to IBP 0, ISP 1 and ISP 4.

Now suppose that IBP 0 increases its transit price. In response, ISP 1 and ISP 4 decide to reduce the traffic for which they buy transit from IBP 0, and instead to reroute some of their traffic and purchase more transit from ISP 2 and ISP 3 respectively. Because of the peering relationship between ISP 2 and ISP 3, all traffic from ISP 1 handed to ISP 2 will reach ISP 3 as well as ISP 4, which is a customer of ISP 3. Similarly, by purchasing transit from ISP 3, ISP 4 can reach all the customers of ISP 1, ISP 2 and ISP 3. Thus, in response to the price increase of IBP each of the ISPs 1, 2, 3 and 4 will reduce the amount of transit purchased from the IBP 0. Specifically, each of the ISPs buys from IBP 0 only capacity sufficient to handle traffic to the customers of network 0. This may lead to a considerable loss in revenues for IBP 0, rendering the price increase unprofitable. The big beneficiaries of the price increase of IBP 0 are peering ISPs 2 and 3, which now start selling transit to ISPs 1 and 4 respectively and become larger networks.



Internet, Economics of the, Fig. 2 Traffic flows between ISPs and a backbone

In response to a price increase by the large IBP, rivals would be able to offer their customers universal connectivity at profitable prices below the large IBP's prices. In the scenario described in the example above, market forces, responding to a price increase by a large network, re-route network traffic so that it is served by rival networks, except for the traffic to and from the ISPs connected exclusively with the large network. The rivals purchase the remaining share from the large IBP in order to provide universal connectivity. Thus, the rivals' blended cost would permit them to profitably offer all transport at prices lower than the large IBP's prices, but above cost.

A direct effect of the increase in price by the large network is that (*a*) ISPs that were originally exclusive customers of the large IBP would shift a substantial portion of their transit business to competitors, and (*b*) ISPs that were not exclusive customers of the large IBP would also shift a significant share of their transit business to competitors' networks, keeping the connection with the large IBP only for traffic for which alternative routes do not exist or for cases of temporary failure of the rivals' networks.

Similarly, degradation of interconnection to all backbones or sequentially one at a time is likely to be unprofitable. Degradation of interconnection to all backbones is clearly dominated by a price increase (since a price increase directly produces additional revenue to the firm, while interconnection degradation does not directly increase revenue), and, as we have shown above, competitive conditions severely limit price increases. Targeted degradation is also unprofitable for a large network that would initiate it for several reasons.

1. ISP clients of the targeted network are likely to switch to third IBP networks that are unaffected by the degradation; it is very unlikely that any will switch to the degrading IBP network because it is itself degraded and cannot offer universal connectivity; there is no demand reward to the large IBP network.
2. Degradation of interconnection hurts all the ISP customers of the targeting IBP network as well, since they lose universal connectivity; these customers of the large network would now be willing to pay less to the large network; this leads to significant revenue and profit loss.
3. After losing universal connectivity, customers of the large IBP network are likely to switch to other networks that are unaffected by degradation and can provide universal connectivity; this leads to even further revenue and profit loss for the degrading network.
4. Multi-homing ISPs would purchase less capacity from the large IBP network, or even terminate their relationship with the large network, which through its own actions sabotages their demand for universal connectivity; this further reduces demand and profits for the degrading network; the same argument applies to multi-homing customers of ISPs.
5. As the large IBP network pursues target after target, its customers face continuous quality degradation while the target's customers face only temporary degradation; this would result in further customer and profit losses for the large IBP network.
6. Prospective victims would seek alternative suppliers in advance of being targeted by the large IBP network; the scheme cannot play out the way it is proposed.
7. The degradation scheme is implausible in its implementation. How large do networks need to be to become serial killers? Why have we not observed this behaviour at all?
8. There is no enduring change to the number of competitors in a market caused by serial degradation in a market with negligible entry barriers; the eliminated rival is likely to be replaced by another.

In conclusion, competition on the Internet backbone is strong, with many carriers and easy entry, and thus presently there are no significant competition concerns for Internet backbone services. However, local broadband access is typically a duopoly or monopoly depending on location. As of 2007, local broadband access networks were proposing to abolish the regime of net neutrality and impose fees on content and applications providers. The legality of this proposed

change is questionable, and imposition of such price discrimination may have adverse consequences for consumers' total surplus.

Interpersonal Utility Comparisons

John C. Harsanyi

Abstract

Although we all make interpersonal utility comparisons, many economists and philosophers argue that our limited information about other people's minds renders them meaningless. If they are possible, interpersonal comparisons of utility *differences* must be distinguished from interpersonal comparisons of utility *levels*. Utilitarianism must assume the interpersonal comparability of utility differences to maximize a social welfare function, while Rawls's maximin principle requires interpersonal comparability of utility levels. Adopting an ordinalist or a cardinalist view of utility functions restricts the positions one can consistently take as to interpersonal comparability of utilities.

Suppose I am left with a ticket to a Mozart concert I am unable to attend and decide to give it to one of my closest friends. Which friend should I actually give it to? One thing I will surely consider in deciding this is which friend of mine would enjoy the concert *most*. More generally, when we decide as private individuals whom to help, or decide as voters or as public officials who are to receive government help, *one* natural criterion we use is who would derive the greatest benefit, that is, who would derive the *highest utility*, from this help. But to answer this last question we must

make, or at least attempt to make, *interpersonal utility comparisons*.

At the common-sense level, all of us make such interpersonal comparisons. But philosophical reflection might make us uneasy about their meaning and validity. We have direct introspective access only to our *own* mental processes (such as our preferences and our feelings of satisfaction and dissatisfaction) defining our *own* utility function, but have only very indirect information about other people's mental processes. Many economists and philosophers take the view that our limited information about other people's minds renders it impossible for us to make meaningful interpersonal comparisons of utility.

Comparisons of Utility Levels vs. Comparisons of Utility Differences

In any case, if such comparisons are possible at all, then we must distinguish between interpersonal comparisons of utility levels and interpersonal comparisons of utility differences (i.e. utility increments or decrements).

It is one thing to compare the utility level $U_i(A)$ that individual i enjoys (or would enjoy) in situation A, with utility level $U_j(B)$ that another individual j enjoys (or would enjoy) in situation B (where A and B may not refer to the same situation). It is a very different thing to make interpersonal comparisons between utility differences, such as comparing the utility increment

$$\Delta U_i\left(A, A'\right) = U_i\left(A'\right) - U_i(A) \qquad (1)$$

that individual i would enjoy in moving from situation A to situation A', with the utility increment

$$\Delta U_j\left(B, B'\right) = U_j\left(B'\right) - U_j(B) \qquad (2)$$

that individual j would enjoy in moving from B to B'. Either kind of interpersonal comparison might be possible without the other kind being possible (Sen 1970).

Some ethical theories would require one kind of interpersonal comparisons; others would require the other. Thus, *utilitarianism* must assume the interpersonal comparability of utility *differences* because it asks us to maximize a social utility function (social welfare function) defined as the *sum* of all individual utilities. (There are arguments for defining social utility as the *arithmetic mean*, rather than the *sum*, of individual utilities (Harsanyi 1955). But for most purposes – other than analysing population policies – the two definitions are equivalent because if the number of individuals can be taken for a *constant*, then maximizing the sum of utilities is mathematically equivalent to maximizing their arithmetic mean.) Yet, we cannot add different people's utilities unless all of them are expressed in the same utility units; and in order to decide whether this is the case, we must engage in interpersonal comparisons of utility differences. (On the other hand, utilitarianism does not require comparisons of different people's utility levels because it does not matter whether their utilities are measured from comparable zero points or not.)

Likewise, the interpersonal utility comparisons we make in everyday life are most of the time comparisons of utility *differences*. For instance, the comparisons made in our example between the utilities that different people would derive from a concert obviously involve comparing utility differences.

In contrast, the utility-based version of Rawls's *Theory of Justice* (1971) does require interpersonal comparisons of utility *levels*, but does not require comparisons of utility *differences*. This is so because his theory uses the *maximin principle* (he calls it the *difference principle*) in evaluating the economic performance of each society, in the sense of using the well-being of the *worst-off* individual (or the worst-off social group) as its principal criterion. But to decide which individuals (or social groups) are worse off than others he must compare different people's utility levels. (In earlier publications, Rawls seemed to define the worst-off individual as one with the lowest utility level. But in later publications, he defined him as one with the smallest amount of 'primary

goods'. For a critique of Rawls's theory, see Harsanyi 1975).

Ordinalism, Cardinalism and Interpersonal Comparisons

In studying comparisons between the utilities enjoyed by *one* particular individual i, we again have to distinguish between comparisons of utility *levels* and comparisons of utility *differences*. The former would involve comparing the utility levels $U_i(A)$ and $U_i(B)$ that i assigns to two different situations A and B. The latter would involve comparing the utility increment

$$\Delta U_i\left(A, A'\right) = U_i\left(A'\right) - U_i(A) \qquad (3)$$

that i would enjoy in moving from situation A to situation A', with the utility increment

$$\Delta U_i\left(B, B'\right) = U_i\left(B'\right) - U_i(B) \qquad (4)$$

that he would enjoy in moving from B to B'.

If i has a well-defined utility function U_i at all, then he certainly must be able to compare the utility *levels* he assigns to various situations; and such comparisons will have a clear behavioural meaning because they will correspond to the preference and indifference relations expressed by his choice behaviour. In contrast, it is immediately less obvious whether comparing utility differences as defined under (3) and (4) has any economic meaning (but see below).

A utility function U_i permitting meaningful comparisons only between i's utility levels, but not permitting such comparisons between his utility differences, is called ordinal; whereas a utility function permitting meaningful comparisons both between his utility levels and his utility differences is called cardinal.

As is well known, most branches of economic theory use only ordinal utilities. But, as von Neumann and Morgenstern (1947) have shown, cardinal utility functions can play a very useful role in the theory of risk taking. In fact, utility-difference comparisons based on von Neumann–Morgenstern utility functions turn out to have a direct behavioural meaning. For example, suppose that U_i is such a utility function, and let Δ_i^* and Δ_i^{**} be utility differences defined by (3) and by (4). Then, the inequality $\Delta_i^* > \Delta_i^{**}$ will be algebraically equivalent to the inequality

$$\frac{1}{2}U_i\left(A'\right) + \frac{1}{2}U_i(B) > \frac{1}{2}U_i\left(B'\right) + \frac{1}{2}U_i(A). \qquad (5)$$

This inequality in turn will have the behavioural interpretation that i *prefers* an equi-probability mixture of A' and of B to an equi-probability mixture of B' and of A. Of course, once von Neumann–Morgenstern utility functions are used in the theory of risk taking, they become available for possible use also in other branches of economic theory, including welfare economics as well as in ethical investigations. (It has been argued that von Neumann–Morgenstern utility functions have no place in ethics (or in welfare economics) because they merely express people's attitudes toward *gambling*, which has no moral significance (Arrow 1951, p. 10; Rawls 1971, pp. 172 and 323). But see Harsanyi 1984.)

Note that by taking an ordinalist or a cardinalist position, one restricts the positions one can consistently take as to interpersonal comparability of utilities:

(1) An *ordinalist* is logically free to *reject* both types of interpersonal comparisons. Or he may *admit* comparisons of different people's utility *levels*. But he *cannot* admit the interpersonal comparability of utility differences without becoming a cardinalist. (The reason is this. If the utility differences experienced by one individual i are comparable with those experienced by *another* individual j, this will make the utility differences experienced by *one* individual (say) i likewise indirectly comparable with one another, which will enable us to construct a *cardinal* utility function for each individual.)

(2) A *cardinalist* is likewise logically free to *reject* both types of interpersonal

comparisons. Or he may *admit* both. Or else he may admit interpersonal comparisons only for utility *differences*. (Though it is hard to see why anybody might want to reject interpersonal comparisons for utility levels if he admitted them for utility differences.) But he *cannot* consistently admit interpersonal comparisons for utility *levels* while rejecting them for utility *differences*. (This can be verified as follows. If utility levels are interpersonally comparable, then we can find four situations A, A', B, and B' such that $U_i(A) = U_j(B)$ and $U_j(A') = U_j(B')$. But then we can conclude that

$$\Delta_i^* = U_i(A') - U_i(A) = \Delta_j^* = U_i(B') - U_i(B')$$

which means that at least the utility differences Δ_i^* and Δ_j^* are interpersonally comparable. But since U_i and U_j are *cardinal* utility functions, any utility difference Δ_i^{**} experienced by i is comparable with Δ_i^*, and any utility difference Δ_j^{**} experienced by j is comparable with Δ_j^*. Yet this means that *all* utility differences Δ_i^{**} experienced by i are comparable with *all* utility differences Δ_j^{**} experienced by j. Thus, cardinalism together with interpersonal comparability of utility levels *entails* that of utility differences.)

Extended Utility Functions

In what follows, I will use the symbols A_i, B_i, ... to denote the economic and non-economic resources available to individual i in situations A, B, ... Moreover, I will use the symbol A_j to denote an arrangement under which j has the same resources available to him as were available to individual i under arrangement A_i. These entities A_i, B_i, ..., A_j, B_j, ... I will call positions.

Interpersonal utility comparisons would pose no problem if all individuals had the same utility function. For in this case, any individual j could assume that the utility level $U_i(A_i)$ that another individual i would derive from a given position A_i should be the *same* as he himself would derive from a similar position. Thus, j could write simply.

$$U_i(A_i) = U_j(A_j). \tag{6}$$

Of course, in actual fact, the utility of different people are rather *different* because people have different *tastes*, that is, they have different abilities to derive satisfactions from given resource endowments. I will use the symbols R_i, R_j, ... to denote the vectors listing the personal psychological characteristics of each individual i, j, ... that *explain* the differences among their utility functions U_i, U_j, ... Presumably, these vectors summarize the effects that the genetic make-up, the education and the life experience of each individual have on his utility function. This means that any individual j can attempt to assess the utility level $U_i(A_i)$ that another individual j would enjoy in position A_i as

$$U_i(A) = V(A_i, R_i), \tag{7}$$

where the function V represents the psychological laws determining the utility functions U_i, U_j, ... of the various individuals i, j, ... in accordance with their psychological parameters specified by the vectors R_i, R_j, ... Since, by assumption, all differences among the various individuals' utility functions U_i, U_j, ... are fully explained by the vectors R_j, R_j, ..., the function V itself will be the same for all individuals. We will call V an *extended utility function*. (See Arrow 1978; Harsanyi 1977, pp. 51–60; though the basic ideas are contained already in Arrow 1951, pp. 114–15.)

To be sure, we know very little about the psychological laws determining people's utility functions and, therefore, know very little about the true mathematical form of the extended utility function V. This means that, when we try to use Eq. (7), the best we can do is to use our – surely very imperfect – personal *estimate* of V, rather than V itself. As a result, in trying to make interpersonal utility comparisons, we must expect

to make significant errors from time to time – in particular when we are trying to assess the utility functions of people with a very different cultural and social background from our own. But even if our judgements of interpersonal comparisons can easily be mistaken, this does not imply that they are meaningless.

Ordinalists will interpret both the functions U_i and the function V as ordinal utility functions and will interpret (7) merely as a warrant for interpersonal comparisons of utility levels (cf. Arrow 1978). In contrast, cardinalists will interpret all these as *cardinal* utility functions and will interpret (7) as a warrant for *both* kinds of interpersonal comparison (cf. Harsanyi 1977).

Limits to Interpersonal Comparisons

It seems to me that economists and philosophers influenced by *logical positivism* have greatly exaggerated the difficulties we face in making interpersonal utility comparisons with respect to the utilities and the disutilities that people derive from ordinary commodities and, more generally, from the ordinary pleasures and calamities of human life. (A very influential opponent of the possibility of meaningful interpersonal utility comparisons has been Robbins 1932.) But when we face the problem of judging the utilities and the disutilities that other people derive from various *cultural* activities, we do seem to run into very real, and sometimes perhaps even unsurmountable, difficulties. For example, suppose I observe a group of people who claim to derive great aesthetic enjoyment from a very esoteric form of abstract art, which does not have the slightest appeal to me in spite of my best efforts to understand it. Then, there may be no way for me to decide whether the admirers of this art form *really* derive very great and genuine enjoyment from it, or merely *deceive themselves* by claiming that they do.

Maybe in such cases interpersonal comparisons of utility do reach unsurmountable obstacles. But, fortunately, very few of our personal moral decisions and of our public political decisions depend on such exceptionally difficult interpersonal comparisons of utility. (References additional to those listed below will be found in Hammond 1977 and in Suppes and Winet 1955).

Interpersonal Utility Comparisons (New Developments)

Claude d'Aspremont

Abstract

Recent developments on interpersonal utility comparisons rely on various interpretations of 'utility' indicators and combine in various degrees the 'subjective' appreciation of the social states by each individual and their 'objective' evaluation by the ethical observer. In a formal welfarist approach, interpersonal comparisons are specified by invariance conditions on social welfare functionals or on social welfare orderings. Interpersonal comparisons have also been introduced through scoring methods.

Distributive justice, whether in normative economics or in collective choice theory, can hardly be treated without introducing some interpersonal comparisons. But does this mean considering interpersonal *utility* comparisons? The term 'utility' has received so many different interpretations that the distinguishing mark of the utility approach to the evaluation of *social states* by an ethical observer is simply that it assigns to each member of the collectivity a *unidimensional individual indicator*. These indicators combine in various ways the 'subjective' appreciation of the social states by each individual and their 'objective' evaluation by the observer.

Bentham introduced an interpersonally summable notion of utility based on the objective property of things to procure either pain or pleasure, but it is the subjective reinterpretation given by J.S. Mill, for whom utility means 'pleasure itself' and 'exemption of pain', which has prevailed (Mongin and d'Aspremont 1998). In Harsanyi's (1977) reformulation of utilitarianism, the ethical observer is, with equal chance, any one of the individuals and obeys the rationality conditions of decision-making under risk. The criterion is expected utility computed from the individual von Neumann −Morgenstern (NM) utility functions, but 'corrected' for factual errors and 'censored' for anti-social attitudes.

Pareto has clearly distinguished between the objective notion of *utilité* (in the Bentham sense) and the subjective notion of *ophélimité*, as an ordinal measure of actual preference satisfaction. The latter has become the dominant concept in economics (the only concept in the new welfare economics), forbidding interpersonal utility comparisons and, ultimately, reducing preferences to observable individual choices (revealed preference theory). But Samuelson (1947) insisted that welfare economics cannot avoid ethical and interpersonal assumptions, and Arrow (1951) derived an 'impossibility theorem'. For a set $N = \{1, 2, ..., n\}$ of individuals and a set $X = \{x, y, ...\}$ of (more than two) social states, there is no acceptable *social welfare function*, associating every profile of individual preference orderings with one 'collective' preference ordering of X, and satisfying *weak Pareto* (if all strictly prefer one state to another, so should society) and *independence of irrelevant alternatives* (if individual preferences are modified

except for a subset of several alternatives, then the collective preference should not be modified on this subset). Such a social welfare function can only be *dictatorial*: one individual imposes his strict preference. Since all Arrow's assumptions concern 'preference satisfaction', modifying them and reinterpreting 'utility' involve ethical considerations.

Rawls's (1971) principles of justice are agreed upon in some original negotiation where all irrelevant personal features (including personal conceptions of the good) are ignored. Also chosen behind this 'veil of ignorance' is an 'index of primary goods' defined as an objective indicator of the fundamental resources (except for liberties and access to occupations, preliminarily and equally divided) allocated to each person to promote his own conception of the good. If such an indicator can be called 'utility', it is not in the sense of 'happiness' or 'preference satisfaction'. Desires (however intense) and tastes (however inexpensive) are not relevant per se. A similar view is represented by Sen's (1992) notion of capabilities, that is, the set of doings or 'functionings' available to a person, leading to an 'index of functionings'. What is at stake here, as in other theories concerned by opportunities (for example, Roemer (1996)), are the objectively defined conditions allowing individuals to exercise their freedom.

Extended Sympathy, Social Welfare Functionals and Welfarism

To formally examine the role of interpersonal utility comparisons in social choice, it is usual to start within the framework introduced by Sen (1970), in which the basic ingredient is a utility profile given by a real-valued function U defined on elements (x,i) of the Cartesian product $X \times N$. The function U can be seen as a vector of individual indicators $U_i(x) \equiv U(x, i)$, or as the *extended utility function* of an individual, evaluating from a moral viewpoint what it is to be anyone in any social state (exercising 'extended sympathy' or 'empathy'). Moreover, if for individual i one interprets the name i as designating all the characteristics of i, then one could look at the function U as a *fundamental utility function* (Harsanyi 1977), itself a representation of 'human nature' (Kolm 1972), which would then justify why every individual, when adopting the viewpoint of an ethical observer, should have the same extended utility function (or at least the same fundamental preference). Lack of identity could lead to a dictatorial ethical observer (see Suzumura (1996)).

The fundamental utility approach is also used in econometric estimations to define 'adult-equivalent scales' and different forms of exact aggregation (Blackorby and Donaldson 1991; Christensen et al. 1975; Deaton and Muellbauer 1980). Other measurement techniques, such as that which uses the number of 'just-noticeable-differences' between two alternatives (discussed in (Arrow 1951)) or the 'social indicators' approach using questionnaires about degree of happiness (discussed in (Fleurbaey and Hammond 2004; Hammond 1991)) are differently founded.

The U function is a very flexible informational basis to start with. For every x, we can denote U_x the *utility vector* $(U(x, 1), ..., U(x, n))$ in $\mathbb{R}^N$. Taking all functions U in some domain D determines the set of all admissible utility vectors. Sen's (1970) concept of *social welfare functional* (SWFL) associates every admissible extended utility function U in D with one (collective) preference ordering R_U. We denote I_U and P_U the corresponding indifference and strict preference relations. Using this notation, *Pareto indifference* means '$U_x = U_y$ implies xI_Uy' and *strong Pareto* requires in addition that '$U_x \geq U_y$ and $U_x \neq U_y$ implies $x\ P_Uy$'. Also, Arrow's independence of irrelevant alternatives can be weakened to *binary independence*, whereby for any two functions U and V with equal values on two social states x and y we have $xR_Vy \Leftrightarrow xR_Uy$.

An alternative framework is to define directly a *social welfare ordering* (SWO) denoted R^* on the set of admissible utility vectors. If the set of admissible utility vectors is large enough (for example, equal to $\mathbb{R}^N$), then, under Pareto indifference and binary independence, the two

frameworks coincide: $u = U_x$ and $v = U_y$ implies $uR^*v \Leftrightarrow xR_Uy$. This is called *welfarism* and is an extreme form of consequentialism. All the information required for social evaluation is contained in the final utility values. Under welfarism, strong Pareto (SP) reduces to the condition that $u \geq v$, and $u \neq v$ implies uP^*v (P^* denoting strict collective preference).

Invariance Axioms

Measurement theory (Krantz et al. 1971; Roberts 1980) associates with different measurement scales the associated meaningful statements. We are interested in meaningful statements about intrapersonal and interpersonal comparisons of utility. For instance, the Arrowian informational basis for SWFLs requires that only *intrapersonal level comparisons* are meaningful: $R_U = R_V$ whenever, for every i and all x, y, $U(x, i) \geq U(y, i)$ if and only if $V(x, i) \geq V(y, i)$. Another example (for this and others see Bossert and Weymark (2004)) is to consider meaningful *interpersonal comparisons of utility differences*: $R_U = R_V$ whenever, for all w, x, y, z and all i, j, $U(w, i) - U(x, i) \geq U(y, j) - U(z, j)$ if and only if $V(w, i) - V(x, i) \geq V(y, j) - V(z, j)$.

The more standard way (for example, Sen (1977)) to specify the measurability and comparability properties of 'utility' is to introduce invariance transformations $\phi = (\phi_1, \phi_2, \ldots, \phi_n)$, each ϕ_i being a real-valued function on $\mathbb{R}$. In the Arrowian framework, we get the invariance axiom of *ordinality and non-comparability* (ON): if each ϕ_i is increasing and if for every x, $V(x, i) = \phi_i(U(x, i))$, then $R_U = R_V$. Corresponding to interpersonal comparisons of utility differences, we get *cardinality and unit-comparability* (CU): if each ϕ_i is a positive affine transformation ($\phi_i(u_i) = a_i + bu_i$, with $b > 0$) and if, for all (x,i), $V(x,i) = a_i + bU(x,i)$, then $R_U = R_V$.

But there is a third way of specifying such conditions. We have stated these two axioms as restrictions on SWFLs. Under welfarism, they can be translated into axioms on SWOs, as

$$\begin{aligned}&\text{ON}: \text{for any increasing } \phi_i\text{'s},\\ &\quad uR^*v \Leftrightarrow (\phi_1(u_1), \ldots, \phi_n(u_n))\\ &\times R^*(\phi_1(v_1), \ldots, \phi_n(v_n));\\ &\text{CU}: \text{for any } a_i\text{'s}, b > 0,\\ &\quad uR^*v \Leftrightarrow (a_1 + bu_1, \ldots, a_n + bu_n)\\ &\times R^*(a_1 + bv_1, \ldots, a_n + bv_n).\end{aligned}$$

Invariance axioms determine the informational basis for social evaluation. They should not be considered as purely factual. By specifying the kind of information that a social evaluation can or cannot use, these axioms are taking an ethical stance. But their strong ethical implications are better measured when combined with other axioms. To illustrate, the following axiom allows for (and only for) comparisons of utility differences that are intrapersonal. It is *cardinality and non-comparability* (CN): for any a_i's and positive b_i's, if $V(x, i) = a_i + b_iU(x, i)$, for all (x, i), then $R_U = R_V$. Such a SWFL version of this axiom does not exclude interpersonal utility comparisons. It does allow us to compare *ratios of utility differences* of the sort $(U(w, i) - U(x, i))/(U(y, i) - U(z, i))$ between different individuals, and hence to compare measures of risk aversion in case X is specified as a set of lotteries and each $U_i(x)$ as an NM utility function. But the possibility of such comparisons is erased under welfarism, under which cardinal non-comparability reduces to ordinal non-comparability and, with strong Pareto, implies dictatorship (by Arrow's theorem). Under welfarism, ON becomes equivalent to CN: for any a_i's, positive b_i's,

$$\begin{aligned}&uR^*v \Leftrightarrow (a_1 + b_1u_1, \ldots, a_n + b_nu_n)\\ &\times R^*(a_1 + b_1v_1, \ldots, a_n + b_1v_n).\end{aligned}$$

If CN is replaced by CU and dictatorship is excluded by *anonymity* (any utility vector is socially indifferent to any of its permutations), then the only possibility is the *pure utilitarian* SWO: uR^*v if and only if $\sum_{i \in N} u_i \geq \sum_{i \in N} v_i$ (d'Aspremont and Gevers 1977).

This characterization of utilitarianism is directly related to Harsanyi's aggregation theorem since, under welfarism (and NM preferences), cardinality and unit-comparability become equivalent to NM-independence of the

collective preference ordering (Mongin and d'Aspremont 1998).

By giving priority to liberties and access to occupations, Rawls clearly departs from welfarism, even in a formal sense. However, to allocate other primary goods, a common index $V(x_i)$ is fixed, where x_i is the vector of primary goods to be allocated to individual i. Letting, for an allocation $x = (x_1, \ldots, x_n)$, $U(x, i) = V(x_i)$, we can fall again into the welfarist formal framework. Since the index is common to all, the associated invariance axiom is *ordinality and comparability*

$$OC: \quad \text{for any increasing } \hat{\phi}, \quad uR^*v \Leftrightarrow \left(\hat{\phi}, (u_1), \ldots, \hat{\phi}(u_n)\right) \times R^*\left(\hat{\phi}(v_1), \ldots, \hat{\phi}(v_n)\right).$$

Two other axioms are clearly required by Rawls: *anonymity* and *strong Pareto*, the latter being the reason why equal distribution of all primary goods is not the agreed-upon solution. To any u in $\mathbb{R}^N$, one can associate a (re)ordered vector $u_i(\cdot)$ with same components in $\{v \in \mathbb{R}^N : v_1 \leq v_2 \leq \ldots \leq v_n\}$, the set of ordered utility vectors. *Minimal equity* requires that one should never give priority to the best-off individual over the worst-off. Then, under *separability* (in choosing between two utility vectors the indifferent individuals should not be taken into account), the solution is the 'lexicographic maximin' (*leximin*) SWO : for any u, v in $\mathbb{R}^N$, uP^*v if and only if, for some k, $1 \leq k \leq n$, $u_{i(k)} > v_{i(k)}$, and, $\forall j < k$, $1 \leq j \leq n$, $u_{i(j)} = v_{i(j)}$. Leximin formalizes Rawls's 'difference principle'. Other concepts of opportunity equalizations can be so translated into welfarist terms (see Maniquet (2004)).

From a formal viewpoint, in the preceding result only utility levels are both intrapersonally and interpersonally comparable. If we add the same possibility for utility differences we have *full comparability*, that is

$$FC: \quad \text{for any } a, \ b > 0, \quad uR^*v \Leftrightarrow (a + bu_1, \ldots, a + bu_n) \times R^*(a + bv_1, \ldots, a + bv_n).$$

With this type of invariance and the same other assumptions (Deschamps and Gevers 1978), the SWO R^* can be either leximin or utilitarianism, but in a weak sense (that is $\sum_{i \in N} u_i > \sum_{i \in N} v_i$ implies uP^*v).

Many other invariance axioms can be introduced (for example, (d'Aspremont 1985)). Let us give only two more, *ratio-scale measurability*, *without* or *with interpersonal comparisons* of utility:

$$\text{RN}: \quad \text{for any positive } b_i\text{'s}, \quad \text{and } u, \ v \in \mathbb{R}^N, \quad uR^*v \Leftrightarrow (b_1u_1, \ldots, b_nu_n) \times R^*(b_1v_1, \ldots, b_nv_n);$$

$$\text{RC}: \quad \text{for any positive } b, \quad \text{and } u, \ v \in \mathbb{R}^N, \quad uR^*v \Leftrightarrow b_uR^*bv.$$

With ratio-scale measurability the origin is fixed, so that, under *RN*, utility levels are interpersonally comparable if they are of opposite sign (below or above the zero line). Moreover, under RC, all utility levels and differences are comparable. These axioms are most often applied on a positive domain (denoted $\mathbb{R}^N_{++}$). Under RN, ratios of utilities or percentage changes in utility are interpersonally comparable. If we add SP, then a continuous SWO on $\mathbb{R}^N_{++}$ can only be the Nash bargaining solution with status quo point normalized to zero: for some positive θ_i's, uR^*v if and only if $\prod_{i=1}^n u_i^{\lambda_i} \geq \prod_{i=1}^n v_i^{\lambda_i}$. Under *RC* and *SP* the set of continuous and anonymous SWOs is characterized by all homothetic, increasing, continuous and symmetric functions on $\mathbb{R}^N_{++}$ (for these and other results, see Bossert and Weymark (2004)).

Beyond Welfarism: Scoring and Fair Allocation Rules

Even when 'utility' simply represents actual preference satisfaction, it can be severely adjusted by the ethical observer (or rule designer). This is the case for various voting rules or more generally for *scoring rules*. These rules violate binary independence in one way or another, so that welfarism is excluded. Voting methods, such as Borda's, are

generally not acceptable for social evaluation, but some related rules are better candidates (Moulin 1988). Another 'scoring' method is *relative utilitarianism* (axiomatized by Dhillon and Mertens (1999)). Each $U_i(.)$ is supposed to have both a maximum $U_i^{\max}$ and a minimum $U_i^{\min}$ and to represent a NM preference ordering on X and the observer associates to it a NM utility function $V_i(.)$ ordinally equivalent to $U_i(.)$, and then, through individual affine transformations, defines the scoring function $S_i(x) = \left(V_i(x) - V_i^{\min}\right) / \left(V_i^{\max} - V_i^{\min}\right)$. The score $S_i(x)$ is the same whatever the arbitrarily chosen NM utility function $V_i(.)$ representing the preference ordering underlying the initial utility function $U_i(.)$, and measures of curvatures are preserved. The SWFL F is taken to be pure utilitarianism applied to the scores. It satisfies *ordinality and non-comparability* with respect to the utility functions $U_i(x)$ representing the individual preferences. Since the scores are defined as ratios of utility differences, they could be interpersonally compared, but, because their aggregation is utilitarian, it relies only on interpersonal comparisons of differences of scores.

Other concepts have been proposed in the literature on fair allocations, excluding welfarism in terms of the initial utility functions, but ending up applying some SWFL to some recalibrated utility. An example is the Pareto efficient egalitarian-equivalent allocation concept (Pazner and Schmeidler 1978). To illustrate, let $\overline{\omega}$ in $\mathbb{R}_+^L$ be the vector of total quantities of L goods and X be the set of feasible allocations $(x_1, \ldots x_n)$: each x_i is in $\mathbb{R}_+^L$ and $\sum_{i=1}^n x_i \leq \overline{\omega}$. If $U(x, i) = U_i(x_i)$ is increasing in each argument and continuous then one can define an ordinally equivalent function $V_i(x_i)$ such that $U_i(x_i) = U_i(V_i(x_i)\overline{\omega})$. A Pareto efficient allocation $\hat{x}$ in X is *egalitarian-equivalent* if $U_i(\hat{x}_i) = U_i(V_i(\hat{x}_i)\overline{\omega})$ and $V_i(\hat{x}_i) = V_j(\hat{x}_j)$ for all i,j. As observed in Fleurbaey and Hammond (2004), if individual preferences are convex, $\hat{x}$ can be obtained by applying the leximin SWFL on the $V_i(x_i)$'s. Again, starting with a concept defined in terms of purely ordinal and non-comparable utilities (the U_i's), we end up comparing and equalizing utility levels in terms of the V_i's.

Intertemporal Choice

Christopher F. Chabris, David I. Laibson and Jonathon P. Schuldt

Abstract

Decisions that have consequences in multiple time periods are intertemporal choices. Individuals typically discount delayed rewards much more than can be explained by mortality effects. The most common discount function is exponential in form, but hyperbolic and quasi-hyperbolic functions seem to explain empirical data better. Individual discount rates may be measured in a variety of ways, subject to important methodological caveats. Higher discount rates are empirically associated with a variety of substance abuse and impulsive conditions, including smoking, alcoholism, cocaine and heroin use, gambling, and risky health behaviours. By contrast, low discount rates may be associated with high cognitive ability.

Models of Intertemporal Choice

Most choices require decision-makers to trade-off costs and benefits at different points in time. Decisions with consequences in multiple time periods are referred to as intertemporal choices. Decisions about savings, work effort, education, nutrition, exercise, and health care are all intertemporal choices.

The theory of discounted utility is the most widely used framework for analysing intertemporal choices. This framework has been used to *describe* actual behaviour (positive economics) and it has been used to *prescribe* socially optimal behaviour (normative economics).

Descriptive discounting models capture the property that most economic agents prefer current rewards to delayed rewards of similar magnitude. Such time preferences have been ascribed to a

combination of mortality effects, impatience effects, and salience effects. However, mortality effects alone cannot explain time preferences, since mortality rates for young and middle-aged adults are at least 100 times too small to generate observed discounting patterns.

Normative intertemporal choice models divide into two approaches. The first approach accepts discounting as a valid normative construct, using revealed preference as a guiding principle. The second approach asserts that discounting is a normative mistake (except for a minor adjustment for mortality discounting). The second approach adopts zero discounting (or near-zero discounting) as the normative benchmark.

The most widely used discounting model assumes that total utility can be decomposed into a weighted sum – or weighted integral – of utility flows in each period of time (Ramsey 1928):

$$U_t = \sum_{\tau=0}^{T-t} D(\tau) \cdot u_{t+\tau}.$$

In this representation: U_t is total utility from the perspective of the current period, t; T is the last period of life (which could be infinity for an intergenerational model); $u_{t+\tau}$ is flow utility in period $t + \tau$ ($u_{t+\tau}$ is sometimes referred to as felicity or as instantaneous utility); and $D(\tau)$ is the discount function. If delaying a reward reduces its value, then the discount function weakly *declines* as the delay, τ, *increases*:

$$D'(\tau) \leq 0.$$

Economists normalize $D(0)$ to 1. Economists assume that increasing felicity, $u_{t+\tau}$, weakly increases total utility, U_t. Combining all of these assumptions implies,

$$1 = D(0) \geq D(\tau) \geq D(\tau') \geq 0,$$

where $0 < \tau < \tau'$.

Time preferences are often summarized by the rate at which the discount function declines, $\rho(\tau)$. For differentiable discount functions, the discount rate is defined as

$$\rho(\tau) \equiv -\frac{D'(\tau)}{D(\tau)}.$$

(See Laibson 2003, for the formulae for non-differentiable discount functions.) The higher the discount rate the greater the preference for immediate rewards over delayed rewards.

The discount factor is the inverse of the continuously compounded discount rate.

$\rho(\tau)$. So the discount factor is defined as

$$f(\tau) = \lim_{\Delta \to 0} \left(\frac{1}{1 + \rho(\tau)\Delta} \right)^{1/\Delta} = e^{-\rho}(\tau).$$

The lower the discount factor the greater the preference for immediate rewards over delayed rewards.

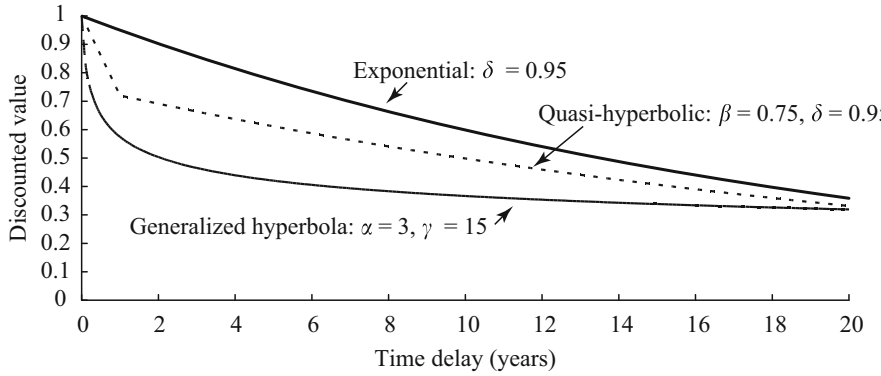
The most commonly used discount function is the exponential discount function:

$$D(\tau) = \delta^{\tau},$$

with $0 < \delta < 1$. For the exponential discount function, the discount rate is independent of the horizon, τ. Specifically, the discount rate is $-\ln(\delta)$ and the discount factor is δ. Figure 1.

The exponential discount function also has the property of dynamic consistency: preferences held at one point in time do not change with the passage of time (unless new information arrives). For example, consider the following investment opportunity: pay a utility cost of C at date $t = 2$ to reap a utility benefit of B at date $t = 3$. Suppose that this project is viewed from date $t = 1$ and judged to be worth pursuing. Hence, $-\delta C + \delta^2 B > 0$. Imagine that a period of time passes, and the agent reconsiders the project from the perspective of date $t = 2$. Now the project is still worth pursuing, since $-C + \delta B > 0$. To prove that this is true, note that the new expression is equal to the old expression multiplied by $1/\delta$. Hence, the $t = 1$ preference to complete the project is preserved at date $t = 2$. The exponential discount function is the *only* discount function that generates dynamically consistent preferences.

Despite its many appealing properties, the exponential discount function fails to match



Intertemporal Choice, Fig. 1 Three calibrated discount functions

several empirical regularities. Most importantly, a large body of research has found that measured discount functions decline at a higher rate in the short run than in the long run. In other words, people appear to be more impatient when they make short-run trade-offs – today vs. tomorrow – than when they make long-run trade-offs – day 100 vs. day 101. This property has led psychologists (Herrnstein 1961; Ainslie 1992; Loewenstein and Prelec 1992) to adopt discount functions in the family of generalized hyperbolas:

$$D(\tau) = (1 + \alpha\tau)^{-\gamma/\alpha}.$$

Such discount functions have the property that the discount rate is higher in the short run than in the long run. Particular attention has been paid to the case in which $\gamma = \alpha$, implying that $D(\tau) = (1 + \alpha\tau)^{-1}$.

Starting with Strotz (1956), economists have also studied alternatives to exponential discount functions. The majority of economic research has studied the quasi-hyperbolic discount function, which is usually defined in discrete time:

$$D(\tau) = \left\{ \begin{array}{ll} 1 & \text{if } \tau = 0 \\ \beta \cdot \delta^{\tau} & \text{if } \tau = 1, 2, 3, \ldots \end{array} \right\}.$$

This discount function was first used by Phelps and Pollak (1968) to study intergenerational discounting. Laibson (1997) subsequently applied this discount function to intra-personal decision problems. When $0 < \beta < 1$ and $0 < \delta < 1$ the quasi-hyperbolic discount function has a high short-run discount rate and a relatively low long-run discount rate. The quasi-hyperbolic discount function nests the exponential discount function as a special case ($\beta = 1$). Quasi-hyperbolic time preferences are also referred to as 'present-biased' and 'quasi-geometric'.

Like other non-exponential discount functions, the quasi-hyperbolic discount function implies that intertemporal preferences are not dynamically consistent. In other words, the passage of time may change an agent's preferences, implying that preferences are dynamically inconsistent. To illustrate this phenomenon, consider an investment project with a cost of 6 at date $t = 2$ and a delayed benefit of 8 at date $t = 3$. If $\beta = 1/2$ and $\delta = 1$ (see Akerlof 1991), this investment is desirable from the perspective of date $t = 1$. The discounted value is positive:

$$\beta(-6 + 8) = \frac{1}{2}(-6 + 8) = 1.$$

However, the project is undesirable from the perspective of date 2. Judging the project from the $t = 2$ perspective, the discounted value is negative:

$$-6 + \beta(8) = -6 + \frac{1}{2}(8) = -2.$$

This is an example of a preference reversal. At date $t = 1$ the agent prefers to do the project at $t = 2$.

At date $t = 2$ the agent prefers not to do the project. If economic agents foresee such preference reversals they are said to be sophisticated and if they do not foresee such preference reversals they are said to be naive (Strotz 1956). O'Donoghue and Rabin (2001) propose a generalized formulation in which agents are partially naive: the agents have an imperfect ability to anticipate their preference reversals.

Many different microfoundations have been proposed to explain the preference patterns captured by the hyperbolic and quasi-hyperbolic discount functions. The most prominent examples include temptation models and dual-brain neuroeconomic models (Bernheim and Rangel 2004; Gul and Pesendorfer 2001; McClure et al. 2004; Thaler and Shefrin 1981). However, both the properties and mechanisms of time preferences remain in dispute.

Individual Differences in Measured Discount Rates

Numerous methods have been used to measure discount functions. The most common technique poses a series of questions, each of which asks the subject to choose between a sooner, smaller reward and a later, larger reward. Usually the sooner, smaller reward is an *immediate* reward. The sooner and later rewards are denominated in the same goods, typically amounts of money or other items of value. For example: 'Would you rather have $69 today, or $85 in 91 days?' The subject's discount rate is inferred by fitting one or more of the discount functions described in the previous section to the subject choices. Most studies assume that the utility function is linear in consumption. Most studies also assume no intertemporal fungibility – the reward is assumed to be consumed the moment it is received. Many factors may confound the analysis in such studies, leading numerous researchers to express scepticism about the conclusions generated by laboratory studies. Table 1 provides a summary of such critiques.

Discount functions may also be inferred from field behaviour, such as consumption, savings, asset allocation, and voluntary adoption of forced-savings technologies (Angeletos et al. 2001; Shapiro 2005; Ashraf et al. 2006). However, field studies are also vulnerable to methodological critiques. There is currently no methodological gold standard for measuring discount functions.

Existing attempts to measure discount functions have reached seemingly conflicting conclusions (Frederick, Lowenstein and O'Donoghue, Frederick et al. 2003). However, the fact that different methods and samples yield different estimates does not rule out consistent individual differences. Dozens of empirical studies have explored the relationship between individuals' estimated discount rates and a variety of behaviours and traits. A significant subset of this literature has focused on delay discounting and behaviour in clinical populations, most notably drug users, gamblers, and those with other impulsivity-linked psychiatric disorders (see Reynolds 2006, for a review). Other work has explored the relationship between discounting and traits such as age and cognitive ability. Table 2 summarizes representative studies.

Smoking A number of investigations have explored the relationship between cigarette smoking and discounting, together providing strong evidence that cigarette smoking is associated with higher discount rates (Baker et al. 2003; Bickel et al. 1999; Kirby and Petry 2004; Mitchell 1999; Ohmura et al. 2005; Reynolds et al. 2004).

Excessive Alcohol Consumption While the association with alcoholism has received relatively little attention, the available data suggest that problematic drinking is associated with higher discount rates. Heavy drinkers have higher discount rates than controls (Vuchinich and Simpson 1998), active alcoholics discount rewards more than abstinent alcoholics, who in turn discount at higher rates than controls (Petry 2001a), and detoxified alcohol-dependents have higher discount rates than controls (Bjork et al. 2004).

Illicit Drug Use Recent studies document a positive association between discount rates and drug

Intertemporal Choice, Table 1 Potential confounds that may arise in attempts to measure discount rates in laboratory studies

Factor	Description
Unreliability of future rewards	A subject may prefer an earlier reward because the subject thinks she is unlikely to actually receive the later reward. For example, the subject may perceive an experimenter as unreliable.
Transaction costs	A subject may prefer an immediate reward because it is paid in cash, whereas the delayed reward is paid in a form that generates additional transaction costs. For example, a delayed reward may need to be collected, or it may arrive in the form of a cheque that needs to be cashed.
Hypothetical rewards	A subject may not reveal her true preferences if she is asked hypothetical questions instead of being asked to make choices with real consequences. However, researchers who have directly compared real and hypothetical rewards have concluded that this difference does not arise in practice (Johnson and Bickel 2002).
Investment versus consumption	Some subjects may interpret a choice in a discounting experiment as an *investment* decision and not a decision about the timing of consumption. For example, a subject might reason that a later, larger reward is superior to a sooner, smaller reward as long as the return for waiting is higher than the return available in financial markets.
Consumption versus receipt	Rewards, especially large ones, may not be consumed at the time they are received. For example, a $500 reward is likely to produce a stream of higher consumption, not a lump of consumption at the date of receipt. Such effects may explain why large-stake experiments are associated with less measured discounting than small-stake experiments
Curvature of utility function	A subject may prefer a sooner, smaller reward to a later, larger reward if the subject expects to receive other sources of income at that later date. In general, a reward may be worth less if it is received during a period of relative prosperity.
Framing effects	The menu of choices or the set of questions may influence the subject's choices. For example, if choices between $1.00 now and delayed amounts ranging between $1.01 and $1.50 were offered, subjects may switch preference from early to later rewards at an interior threshold – for example $1.30. However, if choices between $1.00 and delayed amounts ranging between $1.51 and $2.00 were offered, the switch might happen at a much higher threshold – for example $1.70 – implying a much higher discount rate.
Demand characteristics	Procedures for estimating discount rates may bias subject responses by implicitly guiding their choices. For example, the phrasing of an experimental question can imply that a particular choice is the right or desired answer (from the perspective of the experimenter).

use for a variety of illicit drugs, most notably cocaine, crack-cocaine, heroin and amphetamines (Petry 2003; Coffey et al. 2003; Bretteville-Jensen 1999; Kirby and Petry 2004).

Gambling Pathological gamblers have higher discount rates than controls, both in the laboratory (Petry 2001b) and in a more natural setting (Dixon et al. 2003), and among a population of gambling and non-gambling substance abusers (Petry and Casarella 1999). Moreover, Alessi and Petry (2003) report a significant, positive relationship between a gambling severity measure and the discount rate within a sample of problem gamblers. Petry (2001b) finds that gambling frequency during the previous 3 months correlates positively with discount rate.

Age Patience appears to increase across the lifespan, with the young showing markedly less patience than middle-aged and older adults (Green et al. 1994; Green et al. 1996; Green et al. 1999). Read and Read (2004) report that older adults (mean age = 75) are the most patient age group when delay horizons are only 1 year. However, this study also finds that older adults are the *least* patient group when delay horizons are from three to ten years. This reversal probably reflects the fact that 75-year-olds face significant mortality/disability risk at horizons of three to ten years.

Cognitive Ability Kirby et al. (2005) report that discount rates are correlated negatively with grade point average in two college samples. Benjamin et al. (2006) find an inverse relationship between

Intertemporal Choice, Table 2 Representative empirical studies linking estimated discount rates for monetary rewards to various individual behaviours and traits

Variable	Study	*N*	Discount rate findings
Nicotine	Bickel et al. (1999)*	66	Current smokers > never-smokers and ex-smokers
Alcohol	Bjork et al. (2004)	160	Abstinent alcohol-dependent subjects > controls
Cocaine	Coffey et al. (2003)*	25	Crack-dependent subjects > matched controls[a]
Heroin	Kirby et al. (1999)	116	Heroin addicts > age-matched controls
Gambling	Petry (2001b)*	86	Pathological gamblers[b] > controls
Risky Behaviour	Odum et al. (2000)*	32	Heroin addicts agreeing to share needle in a hypothetical scenario > non-agreeing
Age	Green et al. (1994)*	36	Children > young adults > older adults
Psychiatric disorders	Crean et al. (2000)	24	'High risk' patients [c] > 'low risk' patients
Cognitive ability	Benjamin et al. (2006)	92	Low scorers on standardized mathematics test > high scorers

Notes: N = total number of participants in study
*These studies used hypothetical rewards; others used real rewards
[a]Results based on those choices falling within the delay range of 1 week to 25 years. Overall analyses including shorter delays (5 min to 5 days) also revealed the same effect, but with smaller magnitude
[b]Gamblers with comorbid substance abuse disorders showed a greater effect than gamblers without such disorders
[c]'High risk' patients were those diagnosed with disorders carrying high risk for impulsive behaviour, according to *DSM-IV* criteria, such as patients with borderline personality disorder, bipolar disorder, and substance abuse disorders

individual discount rates and standardized (mathematics) test scores for Chilean high school students. Silva and Gross (2004) show that students scoring in the top third of their introductory psychology course have lower discount rates than those scoring in the middle and lower thirds. Frederick (2005) shows that participants scoring high on a 'cognitive reflection' problem-solving task demonstrate more patient intertemporal choices (for a variety of rewards) than those scoring low. Finally, in a sample of smokers, Jaroni et al. (2004) report that participants who did not attend college had higher discount rates than those attending at least some college.

All of these empirical regularities are consistent with the neuroeconomic hypothesis that prefrontal cortex is essential for patient (forward-looking) decision-making (McClure et al. 2004). This area of the brain is slow to mature, is critical for general cognitive ability (Chabris 2007), and is often found to be dysfunctional in addictive and other psychiatric disorders.

More research is required to clarify the cognitive and neurobiological bases of intertemporal preferences. Future research should evaluate the usefulness of measured discount functions in predicting real-world economic decisions (Ashraf et al. 2006). Finally, ongoing research should improve the available methods for measuring intertemporal preferences.

Intertemporal Equilibrium and Efficiency

E. Malinvaud

Abstract

A clear formalization of intertemporal equilibrium not only aids the fundamental conceptualization of economic activity but should also lead to comparative statics properties, which, dealing with intertemporal equilibria, have also been called 'comparative dynamics properties'. Particular importance has been given to the question of knowing how the interest rate changes from one stationary equilibrium to another when some specific change is being brought to its exogenous determinants. The theory of the optimum allocation of resources can likewise be transposed to the intertemporal framework. Applications of these properties may give insights on the evolution of prices through time.

People, corporations and governments take decisions for the future. What kind of consistency exists between these decisions? What role does the price system play in this respect? Is the resulting evolution efficient? How can economic organization be improved in order to permit a more satisfactory growth?

Confronted with such huge questions, economists have often answered quickly. Even when attention is limited to formal theory, which this article exclusively considers, many statements can be found which, taken as valid for a time, were later disproved. They had been obtained on special models and too easily given a broad validity. Indeed, the preliminary step should have been to find a general formal representation of economic activity through time, but this step was not given sufficient attention until the late 19th century (Böhm-Bawerk 1888; Fisher 1907). The central model with reference to which the whole theory can be built and developed clearly emerged only in the 1950s.

A survey on the subject must then start from first principles and note which major features of reality are still today neglected in main-stream theory. The significance of the most far-reaching results and the importance of some big question marks will then have to be assessed.

Intertemporal Decisions

Households save for future consumption, employees work overtime so as to have enough to enjoy their vacation, students strive to get a diploma so as to hold good jobs later, parents want to leave bequest to their children. Firms produce to inventories in the expectation of future sales, recruit and train staff that will later improve their competitiveness, install equipment to be used for many years, build new factories.

The main theories dealing with intertemporal economic problems see such decisions as parts of plans that the relevant agents make for all their future activities. Any household, for instance, is assumed not only to decide its present supply of labour and demand for goods, but also simultaneously to choose its plan for the labour to be later supplied and the goods to be later consumed, and this up to the end of its existence.

The notion of this plan can in principle be made richer by taking *uncertainties* into account; the future decisions are then conditional on events to be later observed, but they are already specified for all conceivable combinations of events. In principle again the structure of the plan must then depend on the structure of the *information* that the agent will receive. In the main intertemporal theories these complications coming from uncertainties and information are, however, neglected, so that the concept of a plan does not appear to be unduly abstract. When the relevance of these theories is assessed, one has to wonder about the consequences of the simplification, as will be seen in the sequel.

Analysis of intertemporal behaviour can adopt the familiar approach: the constraints to which the plan is subject and the objectives that it strives to achieve must be identified; then the optimization problem is solved. The purest of all theories simply transpose the classical analysis of consumer and producer behaviour (Debreu 1959). They assume the existence of a full system of discounted prices, with one such price for each commodity at each present or future date, a price at which agents will be able to buy or sell as much of this commodity as they may wish. They then directly reinterpret as follows the constraints and objectives that static atemporal theories made familiar.

As between the many plans that he can think of, a consumer is assumed to have a system of preferences that is often conveniently represented by a utility function, whose argument is a consumption vector with as many components as there are commodities and dates. A budget

constraint requires that the discounted value of the consumption vector does not exceed a given amount, the consumer initial wealth.

The chosen plan maximizes the utility function subject to the budget constraint. It then follows that the consumption of the various commodities (and the supply of labour) depend on what are the discounted prices and the initial wealth. The present saving of the consumer may be said to be equal to the interest income earned on his initial wealth *minus* the value of his present consumption (labour income appears negatively in this value). It is immaterial in this theory to know how saving is invested. Hence, the consumption plan and the resulting saving plan are seen as involving the whole future *life cycle* of the consumer (Modigliani and Brumberg 1954).

The plan of a producer is subject only to the constraints that technology imposes. The producer acts as a price taker. His objective is to maximize the discounted value of the plan. It follows that demand for inputs and supply of outputs are functions of the discounted prices. The balance between the value of present outputs and present inputs gives the financial surplus if positive or requirement if negative; this is subject to no direct constraint.

Such a theory of consumer and producer behaviour does not claim to apply to all problems concerning this behaviour. Clearly, analysis of the firm in particular must usually go far beyond the stylized description given above, even simply when investment behaviour is being studied (Nickell 1978). But the theory is supposed to be appropriate for fitting into the discussion of the broad questions raised by intertemporal equilibrium and efficiency.

Even when it is so circumscribed, the intent cannot be considered as fully achieved. Significant limitations must be kept in mind, since they may forbid application of the theory to some of the problems raised by equilibrium and efficiency over time; indeed, some of these limitations have been the motivation for theoretical developments that will not be discussed at length here, but must be mentioned.

Full knowledge of the system of discounted prices for purchases of sales at all relevant future dates is of course an abstraction. Forward prices exist for only a few basic commodities and a limited horizon. Whereas the interest rates at which one can borrow or lend for more or less long durations are fairly well defined, with non-negligible transaction costs and fiscal interference, however, prices that will apply to future transactions have to be forecast by the agents. The uncertainties that their forecast necessarily contains are neglected. Among the many consequences of this major simplification, one particularly notes that it rules out fundamental problems concerning the characterization of decision criteria of business firms (Drèze 1982).

Constraints on individual choices are also reduced to a minimum. No consideration is given to quantitative constraints, such as those following from mass unemployment on individuals looking for jobs or from business depression on firms looking for customers. When such constraints are binding, not only must the plans meet them, but also spillover effects from one period to others occur, according to laws that follow from the theory of individual behaviour under rationing (Samuelson 1947). In particular, consumers willing but unable to borrow are constrained by their current resources, a phenomenon that gives some justification to the Keynesian consumption function relating current consumption to current income.

Neglect of financial constraints may be considered as following from other theoretical simplifications, lack of uncertainty and full knowledge of discounted prices, which rule out insolvency; but it is often particularly restrictive. The role of financial constraints on investment behaviour indeed play a major part in the development of trade cycle theories (Haberler 1937).

Another notable feature of the theory is the simplicity of the trading relations that it assumes. Consumers and producers buy from ‘the market’ or sell to ‘the market’. A worker need not establish ties with a particular employer, nor a manufacturing firm to a particular supplier of raw material. Actually, intertemporal decisions are often subject to quite significant irreversibilities. Long-term commitments are frequent for easily understandable reasons, some of which have to do with the

specificities that characterize many production processes (for instance, most equipment, once bought, cannot be resold). Long-term contracts are also predominant on the labour market, even though many of their clauses often remain implicit. This feature motivates significant research nowadays, under the heading of 'implicit contracts' (Rosen 1985).

Limited as it is, the classical theory of individual intertemporal decisions is, however, indispensable as a starting point, from which the study of the many complexities of real life can proceed. It has moreover brought to light some quite relevant results, such as the fact that, contrary to common belief, the saving of a household need not be an increasing function of interest rates or that individual choice is bound to exhibit some degree of impatience (Koopmans 1960).

An Intertemporal Economy

The theory of general intertemporal equilibrium can also transpose the more familiar static theory. But clearly when so doing it does not go very far; new complications, specific to intertemporal problems, must be faced.

The simple transposition of the general competitive equilibrium assumes the existence of a terminal date, 'the horizon', a given set of consumers and producers whose activities end at this date, if not before. They all decide their plans at the initial date, on the basis of a full system of discounted prices, and acting as price takers. Perfect competition is assumed to imply that discounted prices are such that all markets clear; more precisely for a given date and a given commodity, aggregate supply and demand are defined by addition of corresponding individual supplies and demands contained in individual plans, which may then be considered as fully announced; at equilibrium the aggregate supply is precisely equal to aggregate demand, and this applies for any date and commodity. Hence, all individual plans are, from the initial date, mutually consistent for all future dates.

The usefulness of such an abstract equilibrium concept cannot be judged independently of its application, in particularly for the discussion of properties linking discounted prices to the agents' individual characteristics. Before facing this discussion, it is enlightening to consider how the model can be revised; this was done in three ways.

First, the hypothesis of a full system of markets, one for each date and commodity, has been relaxed and the notion of a *temporary equilibrium* made explicit (Hicks 1939; Arrow and Hahn 1971; Grandmont 1977). Markets then exist only for the exchange of commodities at the (initial) present date, as well as for the loans of one numeraire commodity from the present to the next future date. Thus, present prices and the interest rate of the first period are assumed to be determined by the law of supply and demand, individual plans being made mutually consistent for the initial data. But, in deciding their plans, individual agents have to form anticipations about future prices. Nothing guarantees that these anticipations are correct, so that individual plans will be revised with the passage of time, as actual prices are found to differ from what was expected.

Formal properties of this more realistic model will not be discussed here. Cases can be defined in which anticipations are later realized. It is then possible, but not always necessary when the future is unbounded, that the sequence of temporary equilibria coincides with the equilibrium defined from the hypothesis of a full system of markets. Thus, two sources of difficulty can arise: false anticipations and on the other hand instability following from the myopic functioning of the market system (Hahn 1968).

Second, coming back to the case of a full system of markets, one has relaxed the assumption of a finite horizon with a fixed set of agents. The problem of knowing which firms exist has not been considered as specific to the intertemporal models, and has not been discussed thus far in the framework of these models, given that infinitely lived firms have been assumed. But since the initial proposals of Allais (1947) and Samuelson (1958), consumers are more and more assumed to belong to overlapping generations, each generation living only for a finite time. Such a representation of the consumption sector is clearly more appropriate for long-term analysis than the

assumption of a given set of consumers living for ever, but it raises new difficulties (Balasko and Shell 1980–81).

Third, since long-term phenomena are often involved, it has been found natural and convenient to concentrate attention on specifications in which the exogenous conditions of economic activity, such as technology, tastes, size of the population, natural resources, remain the same through time or change in a simple way; for instance, population increasing at a constant rate while technology exhibits constant returns to scale and natural resources are unbounded. Within such specifications one has dealt with the particular case of a stationary equilibrium, or else with equilibria in which production and consumption all increase at the same constant rate, that is, the case of 'proportional growth'. The analytical usefulness of this assumption of stationarity was at the centre of an important debate on the building of the theory of capital during the 1930s (Knight 1935; Hayek 1936). It follows from the simple form that has the price system of a stationary equilibrium: all discounted prices can be computed from the prices of the present commodities using a single interest rate that applies to all future periods of unit duration. 'The interest rate' is then unambiguously defined (Malinvaud 1953).

Any General Law?

A clear formalization of intertemporal equilibrium not only serves to aid progress in the fundamental conceptualization of economic activity (hence indirectly in the rigour of the discussions concerning many particular questions) but should also lead to comparative statics properties, which, dealing with intertemporal equilibria, have also been called 'comparative dynamics properties'. Particular importance has been given to the question of knowing how the interest rate changes from one stationary equilibrium to another when some specific change is being brought to its exogenous determinants.

The study of this question concentrated on a number of conjectures, which turned out to be about as many disappointments for whose who had expected to find rigorous proofs of their general validity. It is now realized that the rate of interest is related in a very complex way to the many exogenous determinants of equilibrium and that changes of relative prices, which are associated with changes of interest, may be responsible for paradoxical effects. A brief survey of this theoretical search, that extended over many years, nevertheless reveals some basic issues.

Does a high preference of individuals for present consumption necessarily imply a high interest rate? The property was often asserted. When first publishing his *Theory of Interest* in 1907, Irving Fisher called it an impatience theory. Only later when he revised the book for the 1930 edition did he add the subtitle 'as determined by impatience to spend income and opportunity to invest it', which recognizes the role of the productivity of investment (Samuelson 1967). Quite significant cases have indeed been found in the overlapping generation model for which changes of impatience leave the interest rate unchanged (Samuelson 1958).

Does a decrease of the rate of interest mean a lengthening of the production process? The positive answer was taken for granted, at least as long as technology was given, by many economists and was at the head of the 'Austrian Theory' as developed mainly by Böhm-Bawerk (1889) and Hayek (1941). Actually, description of the production process was usually organized in such a way as to focus on the conjectured property, this being true also with such non-Austrian authors as Wicksell (1901). Final output, available for consumption at some date, was seen as resulting from a number of well-identified primary inputs made at previous dates and having 'matured' since then. The notion of an average period of production looked natural; an inverse relationship between this period and the rate of interest was expected. However, it turned out that, even restricting attention to the case of one primary input and one final output, one could not prove the relationship unless a special definition was given to the production period and a special phrasing to the property (Hicks 1939, 1973). Generalization to many primary inputs, many final outputs and many interdependent production processes raises the

fundamental difficulty resulting from induced variations in relative prices; it is quite unlikely that a generalized property could be proved (Sargan 1955).

A somewhat similar property was expected with another formalization that seems to be much more appropriate for describing technology in modern industry. The property concerns the choice of techniques and the notion that different techniques should be selected at various stages of development, as relative scarcity of the two main factors, labour and capital, changes and the interest rate moves accordingly. Its formal specification actually requires a particular model. The production possibility set is seen as resulting from combination of a number of elementary processes, each one operating at constant returns to scale, with fixed input–output coefficients, and requiring a time just equal to one period. Specifying further this model and applying it to an economy with one primary factor (labour), n produced goods and no joint production (the 'Samuelson–Leontief technology'), one defines a technique as a selection of n processes, one for the production of each good.

In this model, given any value of the interest rate, one can determine one technique that is fully appropriate for production, no matter what is the consumption basket. It then seemed natural to conjecture that techniques thus appearing as efficient at different interest rates were ordered from the less capitalistic (high interest) to the most capitalistic ones (low interest). However, this conjecture is not generally valid, even in this special model: as the interest rate progressively declines, one may have to switch at some point away from some technique but have to switch back to it at a later point: this is the case of 'reswitching of techniques' (Morishima 1966).

Is the interest rate systematically smaller when, with a given technology, one shifts from a stationary equilibrium to another one using the same labour input but more productive capital? Again, this looked like a natural property to be stated.

Since in a perfect equilibrium with no uncertainty the net rate of profit must be equal to the interest rate, the property was associated with the notion that capital accumulation must depress profit rates.

The property holds in a purely aggregated model with just one produced commodity, used both for consumption and as productive capital (Solow 1956). The significance of this model for a more general situation was at the heart of hot debates in the late 1950s and early 1960s, the main opponents being located in the two academic cities named Cambridge (Robinson 1956; Lutz and Hague 1961). A side issue was whether one could give unambiguous definitions to such aggregate notions as the volume of productive capital and the marginal productivity of capital. Eventually, both counterexamples and formal analysis of the problem showed that the property was not generally valid (Burmeister and Turnovsky 1972).

The significance of these various negative theoretical results should of course not be overstated. While reflecting the basic complexity of the relationship between the full system of discounted prices and its determinants, the results do not prove that 'pathological cases' are often empirically relevant.

Intertemporal Efficiency

In the same way as the classical theory of individual behaviour, the theory of the optimum allocation of resources can be transposed to the intertemporal framework. Pareto efficiency of a 'programme' made of a set of individual plans, also called 'Pareto optimality', is generalized in an obvious way that need not be spelled out. The two classical duality theorems directly apply as long as the horizon is bounded: the programme resulting from a competitive equilibrium of the type described above is Pareto efficient if no external effect occurs; conversely, under a convexity or atomicity assumption, to any Pareto efficient programme can be associated a set of discounted prices supporting this programme. Properties of this system of prices are similar to those of the competitive price system.

Interesting new applications of these properties may give insights on the evolution of prices

through time. In particular it is easily found that, if extraction costs are negligible, the discounted efficiency price of an exploited exhaustible resource is the same for all future dates, which means that the undiscounted price increases at a rate equal to the interest rate of the numeraire (Hotelling 1931). When forming decisions on the use of exhaustible resources, one should give as much weight to the distant future as to the present; discounting gives no comfort for such decisions.

Theoretical difficulties, however, occur when the more realistic case of an unbounded horizon is being considered. The most relevant of these difficulties concerns the Pareto efficiency of competitive equilibria; efficiency is still proved to hold if the discounted value of the productive capital that exists at date t decreases to zero when one lets t increase to infinity (Malinvaud 1953); but examples of competitive equilibria that do not fulfil this condition and are not Pareto efficient can be found. Such examples may be characterized as cases of overcapitalization, an excessive capital stock being indefinitely maintained without this ever benefiting consumption.

When attention is limited to stationary equilibria, a negative interest rate reveals lack of efficiency, whereas a positive one implies efficiency (if no external effect exists). Similarly, the interest rate of the price system supporting an efficient proportional growth programme cannot be smaller than the rate of growth (Starrett 1970). The borderline case of an interest rate equal to the growth rate corresponds to what was called 'the golden rule'. More precisely, a new notion of optimality has been defined as follows for proportional growth programmes: an optimal programme is feasible and no other feasible programme leads to larger consumptions (that is, a larger consumption of some commodity at some date and no smaller consumption of any commodity at any date). This definition neglects the conditions at the initial date since an 'optimal' programme can require a large input of capital at this date, a larger than is required by other Pareto efficient proportional growth programmes. It was proved that a price system exists that supports such an optimal programme and contains an interest rate equal to the rate of growth (Desrousseaux 1961; Phelps 1961). This is another case in which discounting does not make the distant future negligible.

When it is considered in the preceding terms, the theory of intertemporal efficiency has a somewhat unrealistic aspect; or rather it seems to be quite partial in its treatment of the various questions that intertemporal efficiency raises both for planning and for the study of actual economic evolution. Indeed, the restrictions mentioned in the first section of this article are often serious.

For the theory of planning, even restricted to the medium and long terms, for which intertemporal choices are particularly important, problems concerning the gathering and exchange of information should not be neglected. If a system of discounted prices is to be used for supporting consistency of individual decisions with national objectives, its determination must be given very serious consideration. Moreover, planning often aims at correcting handicaps, distortions or market failures preventing economic development. Its long-term achievement then depends on how well it deals with problems that are not considered here but have motivated an important literature, dealing in particular with the determination of the best shadow discount rate to be used in project evaluation (Dasgupta et al. 1972).

Similarly, for assessing the performance of actual economic systems, one has still to face many questions that again often relate to problems of information. Three of them seem to deserve particular attention. First, the vision of agents exchanging in markets abstracts too much from the complexities of actual contractual arrangements, some of which deal precisely with intertemporal choices; one does not yet clearly see how these complexities react on the behaviour of the full economy, nor even how theory could approach the issue.

Second, the notion of an intertemporal competitive equilibrium should be replaced by that of a sequence of competitive temporary equilibria. It is then known that, even if anticipations are self-fulfilling along this sequence, intertemporal efficiency is not guaranteed; more precisely, the

short-sightedness of equilibria seems to increase the likelihood of an overcapitalization of the type exhibited by the theory of the golden rule. This may occur because of too high saving propensities, because of risk aversion or because of oligopolistic market structures (Malinvaud 1981). But the question of knowing whether and when this likelihood will materialize remains obscure.

Third, the dual assumption of permanent market clearing and permanently equilibrating prices rules out of consideration many issues, such as those arising from variations in the degree of unemployment or in the stimulus given by profitability. A rather common view among supporters of the market system sees these variations as negligible from a long-term perspective, economic evolution being supposed simply to oscillate around the long-term path determined by equilibrium analysis. But critics of the market system and some other economists have the opposite view: economic disequilibria would provide the main clue for an understanding of the comparative growth of nations (Schumpeter 1934; Beckerman 1966). Theory remains conspicuously weak with respect to solving this major debate.

Intertemporal Portfolio Theory and Asset Pricing

Douglas T. Breeden

The intent of this entry is to present intertemporal portfolio theory and asset pricing models, to explain their results and to illustrate the differences between multiperiod and single-period models. To appreciate intertemporal portfolio theory and asset pricing, it is necessary to understand the state of finance theory prior to the seminal intertemporal works of Merton (1969, 1971, 1973), Samuelson (1969), Fama (1970), Hakansson (1970) and Rubinstein (1974). Section "Single-Period Portfolio Theory and Asset Pricing" presents single-period theory and some general results on portfolio statistics. Section "Intertemporal Portfolio Theory" presents intertemporal portfolio theory. Section "Intertemporal Capital Asset Pricing Model (ICAPM)" presents the intertemporal asset pricing model, and Section "Consumption-Oriented Asset Pricing Model (CCAPM)" presents the consumption-oriented representation of it. Section "Extensions and Conclusions" gives important extensions (without proof) and concludes the entry.

Single-Period Portfolio Theory and Asset Pricing

Portfolio choice in terms of means and variances of alternative portfolios' returns was rigorously modelled first in a single-period world by Markowitz (1952, 1959) and Tobin (1958). This theory was significantly extended by Sharpe (1964) and Lintner (1965). By requiring markets to clear in equilibrium, Sharpe and Lintner developed the well-known theory of equilibrium asset prices known as the capital asset pricing model (CAPM). This model was the premier general theoretical model of asset pricing, prior to Merton's (1973) development of the *intertemporal* capital asset pricing model (ICAPM). In fact, despite the development of the theoretically superior (more general) intertemporal asset pricing models, the single-period CAPM is widely used by investment practitioners today.

Portfolio Statistics

In deriving both the single-period and the intertemporal CAPM, there are a few well-known facts about portfolio statistics that are used repeatedly to expedite the derivations. Those will be presented with the notational definitions that follow. First, let $\mathbf{w}^k$ be individual k's $A \times 1$ vector of portfolio weights for risky assets; the ith element represents the fraction of total wealth that is invested in the ith risky asset. From the investor's budget constraint, the amount placed in the riskless asset must be the residual fraction, i.e.,

$$w_0^k = 1 - \sum_i w_i^k.$$

The riskless asset's return is denoted r_f, and risky assets have normally distributed returns with an $A \times 1$ vector of means, μ, and a variance-covariance matrix $\mathbf{V}$. Two statistical results permit the mean and variance of any portfolio and the covariance between any two portfolios' returns to be found from the weights of the portfolios and from the joint distribution of individual assets' returns. (The reader may verify these results from elementary statistical theory on the mean

and variance of a linear combination of random variables.)

Mean portfolio return

$$= \mu_p = w_0 r_f + \mathbf{w}'\boldsymbol{\mu} = r_f + \mathbf{w}'\left(\boldsymbol{\mu} - r_f \mathbf{1}\right). \quad (1)$$

Covariance of 2 portfolios' returns

$$= \sum_i \sum_j w_i^x w_j^y \sigma_{ij} = \mathbf{w}'_x \mathbf{V} \mathbf{w}_y = \sigma_{xy}, \quad (2)$$

where $\mathbf{w}'_x$ and $\mathbf{w}_y$ are the risky asset portfolios and $\mathbf{1}$ is an $A \times 1$ vector of ones. A useful special case of (2) is that the variance of any portfolio's return is $\sigma^2 = \mathbf{w}'\mathbf{V}\mathbf{w}$. Another useful special case of (2) is that, for any portfolio $\mathbf{w}$, the matrix product $\mathbf{V}\mathbf{w}$ gives the $A \times 1$ vector of covariance of all assets returns with the specified portfolio's return. To see this, view each row of the $A \times A$ identity matrix $\mathbf{I}$ as a 1-asset portfolio, and then apply fact (2) row by row to the matrix product $\mathbf{I}\mathbf{V}\mathbf{w} = \mathbf{V}\mathbf{w}$. For reference, these two special cases of (2) will be denoted (2′) and (2″), respectively. Armed with these definitions and facts, we can now expeditiously derive the well-known single-period portfolio theory and CAPM of Sharpe (1964) and Lintner (1965).

Optimal Portfolio Choice

Each individual chooses at time 0 a portfolio that maximizes the expected value of a von Neumann–Morgenstern utility function for wealth at time 1, i.e., $\max E\left[u^k\left(\tilde{W}_1^k\right)\right]$. Since the return on a portfolio is a linear combination of the returns on individual assets, and since the returns on individual assets are assumed to be normally distributed, wealth at time 1 is normally distributed. Thus, given initial wealth W^k, the entire probability distribution for wealth at time 1 is described by the mean and variance of the individual's portfolio return. Rewriting the individual's expected utility as a function of portfolio mean and variance and omitting superscripts for the individual's preferences and portfolio weights, the portfolio choice problem is:

$$\max_{\{w\}} U\left(\mu_w, \sigma^2 w\right) \quad (3)$$

where $\mu_W = r_f + \mathbf{w}'(\boldsymbol{\mu} - r_f \mathbf{1})$ and $\sigma_w^2 = w'\mathbf{V}\mathbf{w}$.

Since individuals like higher mean and lower variance, each portfolio that is maximal for (3) will be 'mean-variance efficient'. Efficient portfolios are those with the highest mean for a given variance, or alternatively, are lowest variance for a given mean.

The choices of the portfolio weights for risky assets are unconstrained in the above problem, since the budget constraint is imposed by making the weight in the riskless asset the residual (negative amounts indicating borrowing). Implicitly differentiating (3) with respect to the vector of risky portfolio weights and setting the partials equal to zero gives a set of linear equations. Solving these by matrix inversion gives the following optimal risky asset portfolio:

$$\mathbf{w}^k W^k = T^k\left[\mathbf{V}^{-1}\left(\mu - r_f 1\right)\right], \quad \text{for all individuals } k, \quad (4)$$

where $T^k = -(\partial U/\partial \mu)W^k/[2(\partial U/\partial \sigma^2)]$ is individual k's compensating variation in variance for a unit change in mean, holding utility constant. Thus, the higher T^k is, the higher k's risk tolerance. Dividing (4) by the sum of the risky asset weights eliminates the individual's wealth and risk tolerance from the new equation, giving the optimum mix of risky asset holdings relative to the total in risky assets.

Thus, we have a remarkable result (first attributed to Tobin 1958): the optimal mix of risky assets in the individual's portfolio depends only upon the means, variances and covariances of risky returns (as perceived by that individual). The individual's current wealth and preferences only affect risky assets' demands through a scalar that is the same for all risky assets. This shows that an individual may separate the choice of the optimal risky portfolio mix from the choice of how much to place in that portfolio and how much in the riskless asset. Sharpe (1964) showed that if all individuals have the same probability beliefs $\{\mu, \mathbf{V}\}$, then the optimal mix of risky assets is the same for all individuals. In fact, if there were a mutual fund that held all risky assets in the proportions given by $\mathbf{V}^{-1}(\mu - r_f \mathbf{1})$, all individuals could achieve their optimal portfolios with that

fund and a riskless asset holding. This property is known as 'two-fund portfolio separation'.

Market Equilibrium. Capital Asset Pricing Model

The aggregate values of individuals' asset holdings, divided by the aggregate market value of wealth of the economy (M), gives 'the market's' portfolio weights. Summing (4) over individuals k and dividing by aggregate wealth M gives the market portfolio. $\mathbf{w}^M$:

$$\mathbf{w}^M = T^M\left[\mathbf{V}^{-1}(\boldsymbol{\mu} - r_f 1)\right], \tag{5}$$

where

$$T^M = \left(\sum_k T^k\right) \Big/ M.$$

Since the market portfolio is a solution to (3) for an appropriate constant, the market portfolio is mean–variance efficient. Pre-multiplying (5) by $\mathbf{V}$ and using the statistical fact (2″), we have that the expected excess returns on assets in equilibrium are proportional to their covariances with the market's return, $\mathbf{V}_{aM}$:

$$\mu - r_f 1 = \left(1/T^M\right)\mathrm{V}_{aM}: \tag{6}$$

Pre-multiplying (5) by $\mathbf{w}'\mathbf{V}$, using formulae for the mean and variance of a portfolio, and rearranging gives the value for the risk tolerance parameter: $(1/T^M) = (\mu_\mathrm{M} - r_f)/\sigma^2{}_M$. The inverse of risk tolerance is termed risk aversion, so higher risk aversion among investors shows up as a higher expected excess return per unit of variance for the market portfolio. Substituting this into (6) gives the well known capital asset pricing model of Sharpe (1964) and Lintner (1965):

$$\text{CAPM}: \quad \boldsymbol{\mu} - r_f 1 = \boldsymbol{\beta}_M\left(\mu_M - r_f\right), \tag{7}$$

where $\boldsymbol{\beta}_M = \mathbf{V}_{aM}/\sigma_M^2$ is the $A \times 1$ vector of assets' betas relative to the market portfolio. They are analogous to the slope coefficients in regressions of assets' returns on the market portfolio's return.

To this date, this single-period capital asset pricing model has been the most widely tested general model of asset prices under uncertainty. It makes the very strong prediction that the expected excess returns across assets are proportional in equilibrium to their betas relative to the market portfolio. Alternatively, it predicts that the market portfolio is mean–variance efficient, in that it gives the highest expected excess return per unit of standard deviation, considering all possible portfolio combinations. Empirical tests of the single-period CAPM usually reject it. Higher beta assets do have higher returns, but the CAPM of (7) is rejected as a representation of the data. Virtually every assumption used in the derivation of the CAPM has been weakened and empirically examined. What follows is the generalization to *multiperiod* or *intertemporal* consumption and investment decisions – probably the most important and productive generalization.

Intertemporal Portfolio Theory

Relaxation of the single-period assumption in portfolio theory has proceeded concurrently in two very similar types of models. First, discrete-time multiperiod models consider individuals who make consumption and investment decisions at fixed points in time, where the interval between decisions is a somewhat arbitrary choice. It is unlikely that an individual would choose only to revise at fixed dates in time, regardless of what happens in between, so these models initially cause concern. However, that concern is alleviated somewhat by the fact that the qualitative properties of optimal policies in many models are unaffected by the choice of updating interval. Key works in discrete-time multiperiod frameworks are those of Samuelson (1969). Hakansson (1970), Fama (1970), Rubinstein (1974, 1976), Long (1974), Dieffenbach (1975), Kraus and Litzenberger (1975), Lucas (1978), Breeden and Litzenberger (1978) and Brennan (1979).

The other model used for intertemporal portfolio theory and asset pricing is the continuous-time model pioneered by Merton (1969, 1971, 1973), and further developed by Cox, Ingersoll and Ross

(1985a, b) and Breeden (1979, 1984, 1986). The continuous-time model assumes that individuals make consumption and portfolio decisions continuously. Although this is not realistic, since individuals do sleep and do things other than make economic decisions, it will not miss important consumption and portfolio adjustments due to the modelling of a fixed time between decisions.

In Merton's continuous-time model, the underlying random processes driving economic uncertainties are assumed to follow continuous-time stochastic processes with normally distributed increments and continuous sample paths. The underlying normality makes the continuous-time model a logical extension for the single-period CAPM and also gives it mathematical tractability that is often not found in discrete-time models. For example, with discrete-time models, a normally distributed stock return results in non-zero probability of a negative stock price. In the continuous-time model, the variance of the stock's return can approach zero as the stock's price approaches zero in such a way as to prevent negative stock prices, but have normally distributed increments at every instant in time. This entry will utilize the continuous-time model, but any important economic intuition found can also be derived in a discrete-time model.

In the intertemporal model, it is assumed that individuals choose consumption and investment policies that maximize their expected utilities across possible *lifetime* consumption paths. In both continuous-time and discrete-time models, preferences are typically assumed to be time-additive and state-independent, i.e., expected lifetime utility for individual k is: $E[\int u^{k}(c^{k}, t)\, dt]$. Although these preferences are not as general as theorists would like, much has been learned with them. It is assumed that the utility of consumption at any instant is monotonically increasing and strictly concave in consumption, in that partial derivatives are: $u_c^k > 0$ and $u_{cc}^k < 0$.

In using the techniques of stochastic dynamic programming to find the best consumption and portfolio policies, it is convenient to break the remaining utility of lifetime consumption into two parts and maximize the sum. At time t the first part is $u^k\ (c^k,\ t)$, the utility of the current consumption over the next period (or instant in time). The second part is the expected utility of consumption for all subsequent periods to that, $J^k(W^k,\ \mathbf{s},\ t)$, which will be explained more fully below. Thus, the objective function is:

$$\max_{\{c,\,\mathbf{w}\}} \left\{u^k\left(c^k, t\right) + E_i\left[J^k\left(W^k, \mathbf{s}, t\right)\right]\right\} \qquad (8)$$

The current choice of consumption affects only the first part directly, but affects the budget constraint for investments made for future consumption. Differentiating (8) with respect to current consumption, taking into account that each additional unit of consumption today is a unit less of investible wealth, gives the standard condition that the marginal utility of consumption equals the marginal utility of wealth for an optimal policy:

$$u_c^k\left[c^k\left(W^k, \mathrm{s}, t\right), t\right] = J_W^k\left(W^k, \mathrm{s}, t\right). \qquad (9)$$

The key difference between single-period portfolio theory and its CAPM and the optimal results in an intertemporal equilibrium arises from the nature of the indirect utility function for wealth. $J(W^k, \mathbf{s}, t)$. The portfolio mix decision affects only the probability distribution of future wealth and therefore only affects J in (8) – the expected utility of future consumption that wealth will be used to buy. The $S \times 1$ vector s is a set of 'state variables' that describe consumption, investment and employment opportunities. When a person expects to live not just for an instant more, but for a period of time, the investment portfolio and consumption rate should be reviewed and adjusted continually. The utility that one expects to get during one's remaining lifetime depends positively on current wealth (since higher wealth buys more goods), but also depends upon the state of investment opportunities. For example, a current wealth of $100,000 provides a lower real consumption stream if the real riskless interest rate is 2 per cent, than if the real rate is 5 per cent. In this case, the real riskless rate is one of the state variables for investment opportunities. Examples of other economic state variables are the expected inflation rate(s) of goods, the

expected productivity of capital or the expected return on the market portfolio, and the level of uncertainty about economic activity or of productivity. Of course, most of these would be considered as endogenous variables; more generally, the underlying exogenous variables could be substituted and the stochastic processes for the endogenous variables derived.

To see the effect of a stochastic investment opportunity set on the investment portfolio, consider a retiree who is relatively averse to risk and holds the single-period optimal portfolio – a little money in the market portfolio and a lot in riskless securities. With that portfolio, the investor has the same wealth if the market is up 10 per cent and the riskless rate is 2 per cent, as when the market is up 10 per cent and the riskless rate is 5 per cent. This may not be optimal, since this retiree has to reinvest his wealth and live off the income. The retiree is financially hurt in the state where the real riskless rate is 2 per cent, and is well off in the 5 per cent state. In addition to the market portfolio, this investor may optimally wish to buy some long-term bonds or interest rate futures contracts that go up in value as rates fall. Then the investor is hedged, by having more wealth to compensate for the poor reinvestment rate. If rates increase, the retiree has a capital loss on the bonds and, therefore, less wealth, but has a better reinvestment rate. Some investors may well prefer this to just holding the market portfolio. Thus, as we shall see, the single-period CAPM's two-fund theorem and the asset pricing model itself will not necessarily hold in a multiperiod economy. These are points all made clear in Merton's (1973) pathbreaking work.

Merton (1973) derived the optimal portfolio rules for an individuals in an exchange economy, and Cox, Ingersoll and Ross (1985b) verified those same portfolio rules in a general equilibrium economy with production. Let subscripts of the indirect utility function be partial derivatives, and let $\mathbf{V}_{aa}$ now be the $A \times A$ variance–covariance matrix for assets' returns and $\mathbf{V}_{as}$ be the $A \times S$ covariance matrix of assets' returns with the various state variables. The optimal portfolio of risky assets in the intertemporal economy is:

$$\mathbf{w}^k W^k = T^k\left[\mathbf{V}_{aa}^{-1}\left(\boldsymbol{\mu} - r_f\mathbf{1}\right)\right] + \mathbf{V}_{aa}^{-1}\mathbf{V}_{as}\mathbf{H}_s^k, \quad \text{for all individuals } k, \tag{10}$$

where $\mathbf{H}^k{}_s = -\mathbf{J}^k{}_{sW}/J^k{}_{WW}$. Notice that the first RHS term of (10) is the mean–variance efficient portfolio as in the single-period equations of (4). As for the other term, Breeden (1979) showed that each column j of the product matrix $V_{aa}^{-1}V_{as}$ represents the portfolio of assets that is most highly correlated in return with movements in state variable j. To see this, note that the portfolio that has the maximum correlation with state variable s_j is the one with the highest covariance with s_j, given a fixed portfolio variance. Mathematically:

$$\begin{aligned}\text{Objective}: \max_{\{\mathbf{w}_j\}} L &= \mathbf{w}_j'\mathbf{V}_{a,sj} + \lambda\left[\sigma^2 - \mathbf{w}_j'\mathbf{V}_{aa}\mathbf{w}_j\right] \\ \text{Solution}: \mathbf{w}_j &= \left[\mathbf{V}_{aa}^{-1}\mathbf{V}_{a,sj}\right](1/2\lambda).\end{aligned} \tag{11}$$

(The scalar does not matter, since all portfolios that are scalar multiples are perfectly correlated and have the same correlations with all other variables.) Thus, those S portfolios are the best hedge portfolios available for individuals to use in hedging opportunity set changes. The coefficient vector in (10), $\mathbf{H}^k{}_s$, gives individual k's holdings of those hedge portfolios (which may be positive or negative).

Aggregating individuals' portfolios gives the market portfolio. Substituting this back into (10) gives:

$$\mathbf{w}^k W^k = \left(T^k/T^M\right)\mathbf{w}^M + \left[\mathbf{V}_{aa}^{-1}\mathbf{V}_{as}\right]\left[\mathbf{H}_s^k - \left(T^k/T^M\right)\mathbf{H}_s^M\right] \quad \text{for all individuals } k, \tag{12}$$

where

$$T^M = \sum_k T^k \quad \text{and} \quad \mathbf{H}_s^M = \sum_k \mathbf{H}_s^k.$$

From this, it is clear that all individuals' portfolios can be obtained with $S + 2$ funds: (1) the market portfolio, (2) the riskless asset, (3) and the S best hedge portfolios for the state variables. No

preferences are needed to set up the mutual funds. Breeden (1984) showed that if each of the S hedge portfolios is *perfectly* correlated with the state variable it hedges, then the allocation of contingent claims is an unconstrained Pareto-optimal allocation (ex ante, as in Arrow 1951). If there is not a perfect hedge for some state variable, then preferences can be chosen so that the allocation is not unconstrained Pareto-optimal.

To complete the analysis, the $\mathbf{H}_S^k$ terms need to be examined, so we know what types of holdings different individuals should have in the hedge portfolios. Without stronger preference assumptions, analysis of the hedging terms is difficult. However, if one assumes that the vector of percentage compensating variations in k's wealth for state variables' changes $\left(\gamma_S^k = -\mathrm{J}_s^k / W^k J_W^k\right)$ are not a function of k's wealth, then Breeden (1984) has shown that:

$$\mathrm{H}_S^k = W^k\left(1 - T^{*k}\right)\gamma_s^k, \tag{13}$$

where T^{*k} is k's Pratt–Arrow measure of relative risk tolerance. Since $\mathbf{H}^k{}_s$ give individual k's holdings of the hedge portfolios for opportunity set changes, an individual will attempt to hedge if and only if his or her relative risk tolerance is less than unity. Since unity represents the logarithmic utility case, those more risk averse than the log will tend to hedge, whereas those more tolerant than the log will tend to 'reverse hedge'. This type of result has been obtained by Merton (1969), Grauer and Litzenberger (1979), Dieffenbach (1975) and Breeden (1984).

The optimality of reverse hedging if relative risk tolerance is greater than unity is a very interesting result, since one certainly cannot rule out those preferences. To understand this result, consider a stochastic expected return on investments in the stock market. Apart from holding the market portfolio, one might wish to hedge or reverse hedge changes in the expected return on the market. For both hedger and reverse hedger, let us assume that an increase in expected return on the market is a good thing, in that expected lifetime utility is positively related to that opportunity. A hedger would say that when the expected return on the market is high, he needs less wealth; on the other hand, when the expected return is low, he needs more wealth to keep up his planned lifetime consumption level.

The person who would reverse hedge would view things differently, but not irrationally. That person would wish to have a lot of wealth to invest when the expected return on the market is high, in order to take advantage of the good returns. When returns are poor, our relatively risk tolerant person would wish to have little wealth to invest. Clearly, this strategy generates a higher multiperiod mean return and a higher multiperiod variance of return than does the hedging strategy. Neither strategy dominates the other for all risk averse individuals. Which is chosen depends upon the person's marginal rate of substitution function of mean for variance.

Intertemporal Capital Asset Pricing Model (ICAPM)

Given the general portfolio theory of the last section, this section derives the general intertemporal asset pricing model of Merton (1973). The first step shows that equilibrium expected returns on all assets are linear combinations of their covariances with the market portfolio and with the S portfolios that are most highly correlated with the opportunity set variables. To see this, aggregate individuals' asset demands (12) to get the market portfolio, premultiply that by $\mathbf{V}_{aa}(M/T^M)$, and rearrange to get:

$$\boldsymbol{\mu} - r_f 1 = [\mathbf{V}_{aM}\mathbf{V}_{as}]\begin{pmatrix} M/T_M \\ -\mathbf{H}_s^M/T_M \end{pmatrix} \tag{14}$$

It is easy to verify that the covariances of assets with the state variables are the same as their covariances with the returns on portfolios that are maximally correlated with the state variables (s^*), which have weights of $\mathbf{w}_{s*} = \mathbf{V}^{-1}{}_{aa}\mathbf{V}_{as}$.

The next step is to derive the expected excess returns on the $S + 1$ mutual funds that individuals hold. Pre-multiplying (14) by the matrix of portfolio weights for the $S + 1$ funds, their expected excess returns are:

$$\begin{pmatrix} \mu_M - r_f \\ \boldsymbol{\mu}_{s*} - r_f \mathbf{1} \end{pmatrix} = \begin{pmatrix} \sigma_M^2 & \mathbf{V}_{Ms*} \\ \mathbf{V}_{s*M} & \mathbf{V}_{s*s*} \end{pmatrix} \begin{pmatrix} M/T_M \\ -\mathbf{H}_s^M/T^M \end{pmatrix}. \tag{15}$$

To see the implications of this, note that if the S hedging portfolios were uncorrelated with the market portfolio and with each other, their expected excess returns would be zero in the single-period CAPM. However, in the intertemporal model, the expected excess return on a hedge portfolio is negatively related to the aggregate hedging demand (opposite if reverse hedging), and proportional to the variance of the hedging portfolio's return. Thus, if individuals in aggregate wish to hedge investment opportunities with a portfolio, they bid up its price and bid down its expected return in equilibrium. As shown earlier, with normal hedging, those state variables with the largest compensating variations in wealth will have the largest hedging demands and will deviate the most from the singleperiod CAPM's return predictions, *ceteris paribus*.

The final step in Merton's intertemporal CAPM is to substitute expected excess returns on the $S + 1$ key portfolios from (15) for preference parameters in (14):

$$\begin{aligned} \boldsymbol{\mu} - r_f \mathbf{1} &= [\mathbf{V}_{aM} \mathbf{V}_{as}] \begin{pmatrix} \sigma_M^2 & \mathbf{V}_{Ms*} \\ \mathbf{V}_{s*M} & \mathbf{V}_{s*s*} \end{pmatrix}^{-1} \begin{pmatrix} \mu_M - r_f \\ \boldsymbol{\mu}_{s*} - r_f \mathbf{1} \end{pmatrix} \\ (\text{ICAPM}) &= \boldsymbol{\beta}_{a, Ms*} \begin{pmatrix} \mu_M - r_f \\ \boldsymbol{\mu}_{s*} - r_f \mathbf{1} \end{pmatrix} \end{aligned} \tag{16}$$

Thus, in the intertemporal economy, betas with respect to the market portfolio are not enough to describe the relevant risk of a security. Its covariances with the investment opportunity set also matter for both pricing and optimal portfolios.

Consumption-Oriented Asset Pricing Model (CCAPM)

Following seminal articles on asset pricing in discrete-time economies by Rubinstein (1976), Lucas (1978) and Breeden and Litzenberger (1978), Breeden (1979) showed that Merton's (1973) multi-beta intertemporal CAPM could be re-expressed with a single risk measure. The result found, which is derived below, is that Merton's multi-beta ICAPM reduces to a market price of risk multiplied by the asset's *consumption-beta*, which is its sensitivity of return to percentage movements in aggregate real consumption. This model is the consumption-based capital asset pricing model (CCAPM).

The optimal rate of current consumption in the continuous-time model is a function of the individual's current wealth and the state vector for investment opportunities, $c^k = c^k(W^k, \mathbf{s}, t)$. In the continuous-time model, the first-order Taylor series approximation is correct for the *stochastic* part of consumption movements. (In contrast, a second-order approximation is required to describe the *expected* change in consumption.) Thus, the stochastic movements in consumption, and the covariances of assets' returns with k's consumption changes $\mathbf{V}_{a,\,ck}$, may be written as follows:

$$\begin{aligned} d\tilde{c}^k &= c_w^k \left(d\tilde{W}^k \right) + c_s^k (\mathrm{d}\tilde{\mathbf{s}}) \\ \mathbf{V}_{a,ck} &= \mathbf{V}_{a,\;\;Wk} c_w^k + \mathbf{V}_{as} \mathbf{c}_s^k. \end{aligned} \tag{17}$$

The risk aversion and hedging preference parameters that determine an individual's asset holdings can be rewritten in terms of an individual's direct utility function for consumption. To see this, implicitly differentiate the envelope condition [Eq. (9), superscript k suppressed]:

$$T = -J_W/J_{WW} = -u_c/(u_{cc} c_W) = T_c/c_W \tag{18}$$

$$\begin{aligned} \mathbf{H}_s &= -J_{sW}|J_{WW} \\ &= -\mathrm{c}_s|c_W, \quad \text{for each individual.} \end{aligned} \tag{19}$$

Substituting these formulae into Merton's optimal asset demands, (10), pre-multiplying them by $(c^k{}_W \mathbf{V}_{aa})$ and using (17) to simplify gives:

$$\mathbf{V}_{a,\;ck} = T_c^k [\boldsymbol{\mu} - r_f \mathbf{1}], \qquad \text{for each individual } k. \tag{20}$$

This shows that each individual holds assets in proportions that result in an optimal consumption rate that covaries with each asset in proportion to its expected excess return. The next step is to

aggregate these individual optimality conditions, which shows that each asset's expected excess return is proportional to its covariance with *aggregate* consumption.

Define the 'consumption beta' for any asset or portfolio j, β_j, to be the covariance of j's return with percentage changes in aggregate consumption, divided by the variance of percentage changes in aggregate consumption. Thus, the consumption beta is the slope in the regression of the asset's return on percentage changes in (real, per capita) consumption. The consumption-oriented CAPM (CCAPM) follows easily from the aggregated version of (20), where the risk tolerance parameter is eliminated by using the expected excess return per unit of consumption beta for *any* portfolio M:

$$\boldsymbol{\mu} - r_f \mathbf{1} = [\boldsymbol{\beta}_c / \beta_{MC}](\mu_M - r_f). \qquad (21)$$

Thus, Breeden (1979) showed that Merton's intertemporal CAPM, which required $S + 1$ betas to determine an asset's systematic risks and equilibrium return, can be collapsed into a consumption oriented CAPM, with only a single beta with respect to consumption. This helps the intuition in determining which types of assets should have equilibrium returns that are substantially different in multiperiod economies than in the single-period world of the original market-oriented CAPM. How much the CCAPM representation helps in the testing of the intertemporal model is the subject of much current debate.

In the intertemporal economy, the market portfolio is no longer mean-variance efficient. The portfolio that has the highest correlation of returns with aggregate real consumption is now mean-variance efficient. To see this, pre-multiply an aggregate version of (20) by V_{aa}^{-1}: the LHS gives the maximum correlation portfolio for consumption, and the RHS shows that it satisfies the mean-variance efficiency property of Eq. (4). The reason is simply that in the intertemporal economy one gets paid to take consumption-related risk, and no other. Any portfolio that is not highest correlation with consumption has wasted risk for no additional return.

Our understanding of these results is greatly enhanced by understanding the relation of asset prices to marginal utilities. Hirshleifer's (1970, ch. 9) presentation of the time-state preference model of Arrow (1964a, b) and Debreu (1959) is used extensively by Fama (1970), Rubinstein (1974, 1976), Long (1974), Hakansson (1977), Lucas (1978), Breeden and Litzenberger (1978), Brennan (1979) and Cox, Ingersoll and Ross (1985b) in asset pricing models that were fundamental precursors to the developments here. They showed that the value and fair price of one more share of an asset is the expected marginal utility of its payoffs. The expected marginal utility of its payoffs depends on the expected sizes of the payoffs, the dates they are received and the covariances of their sizes with the marginal utilities at different dates of a unit of consumption or wealth [see (9)]. Assets that have their highest payoffs when consumption is high (positive consumption betas) are paying the most when least needed, i.e., when the marginal utility of consumption is low; they are less valuable and have higher equilibrium required returns than assets that pay most when consumption is down.

The consumption CAPM follows directly from the marginal utility insights, since with time-additive utility functions, consumption at any date t is a sufficient statistic for marginal utility in an intertemporal economy, since the quality of the investment opportunity set also affects the marginal utility of a unit payoff. The reason that covariance with the market (aggregate wealth) determines risk in the single-period CAPM is that with one period, consumption equals wealth. Since marginal utility is one-to-one with consumption, it is also oneto-one with wealth in the single-period model. In that case, consumption betas and market betas are the same and the CCAPM reduces to the CAPM.

Extensions and Conclusions

Space prohibits the proof of other important results that have been proven or can be proven. For example, Breeden and Litzenberger (1978) showed that if the capital markets allocation is unconstrained Pareto-optimal in this intertemporal economy, then each individual's consumption is monotonically

increasing in aggregate consumption and in every other person's consumption. All individuals' consumption rates should go up and down together, though not necessarily proportionally. Each individual's optimal portfolio is the one that results in the highest correlation of the individual's consumption with aggregate consumption. Breeden (1979) showed: (1) All assets have the same covariances with a portfolio that is maximally correlated with aggregate consumption as with consumption itself. As a result, the CCAPM may be stated and tested in terms of assets' betas with respect to that maximally correlated portfolio. (2) With commodity price uncertainty, the CCAPM holds in terms of expected real returns and the betas of real returns with real, per capita consumption. (3) The CCAPM holds without a riskless asset, by just replacing r_f with the expected return on a portfolio that is uncorrelated with real consumption movements. A similar result was shown earlier by Black (1972) for the single-period CAPM. Finally, Bergman (1985) showed that if preferences are time-multiplicative, rather than time-additive, Merton's intertemporal CAPM still holds, but Breeden's (1979) CCAPM extension does not. Thus, the ICAPM is more general than the CCAPM.

In conclusion, the past three decades have seen important developments in the modelling of consumption and portfolio choices under uncertainty. In my opinion, the intertemporal portfolio theory and asset pricing models presented here are the strongest and most useful theoretical models that we currently have. Finally, I must say that there were many more authors that were important to the development of this area than were described in this entry. The bibliography gives a more complete (but still abridged) listing of papers that serious students should read.

Intrahousehold Welfare

Marcel Fafchamps

Abstract

This article focuses on the allocation of tasks and consumption within the household. We first discuss the role of the household in the production of various self-consumed goods

and services. We then turn to the outcome of bargaining between household members, examining the empirical evidence to date. The last section makes the link between intrahousehold welfare and the matching of spouses in the marriage market.

O1

There is a voluminous economic literature on intrahousehold issues. This is hardly surprising given the many critical functions that households fulfil. They are the locus of most consumption decisions and human capital investments. By pooling resources, households generate economies of size and shelter members against unemployment and health shocks. Furthermore the formation and dissolution of households play a crucial role in the long-term distribution of income and wealth. Here we focus on intrahousehold welfare which, as Haddad and Kanbur (1990) have shown, is important to our understanding of inequality in general.

Becker was the first economist to become seriously interested in what happens within the household. Becker's contribution, which is nicely summarized in his *Treatise on the Family* (1981), emphasized three things: the organization of production within the household; the way decisions are made within the household; and the formation of couples. All three have a bearing on intrahousehold welfare.

The Household as a Production Unit

The household is a production and consumption unit, self-providing many services such as food preparation, child care and house chores. In developing countries, households also produce much of their own food and housing and fetch their own fuel and water. Becker (1981) pointed out that the organization of production within the household ought to follow economic principles such as the equalization of marginal returns across activities and the allocation of tasks across household members according to comparative advantage.

These simple observations have far-reaching implications because seemingly small differences between household members can have dramatic consequences. To see why, consider the allocation of wage work and household chores between husband and wife. Assume that the tasks are non-divisible and that the return to education is positive in work outside the home and zero in house chores. It follows that the husband will work outside the home if he is slightly better-educated than his wife. Anticipating this, parents may in turn decide not to invest in daughter education but rather to emphasize learning household chores among girls. This results in a self-fulfilling equilibrium in which women receive less education and are confined to household chores. To the extent that education and independent income affect bargaining within the household, such a traditional division of labour may have dramatic consequences on intrahousehold welfare.

The recent empirical literature has cast some doubt on the efficient organization of production within the household. Using data from West Africa, Udry (1996) showed that households do not equalize returns to labour and organic fertilizer across fields managed by different members. Duflo and Udry (2004) provide similar evidence, showing that household labour resources are not optimally reallocated across activities in response to weather shocks. Fafchamps and Quisumbing (2003) show that comparative advantage alone cannot explain the allocation of tasks within Pakistani households. Their evidence also suggests that most household tasks are easy to learn, contradicting Becker's conjecture that learning-

by-doing locks men and women into specific work patterns. Gender differences in career choices and intrahousehold division of labour may reflect different preferences, possibly shaped by social norms, or result from differences in intrahousehold bargaining.

Intrahousehold Bargaining

Most consumption takes place within households sharing a common budget. (In some societies, such as the coastal region of West Africa, spouses keep separate finances. However, whenever they both contribute to a household public good, they can be regarded as deciding consumption jointly.) Certain consumption goods are rival in the sense that consumption by one precludes consumption by another. Food is an example of a rival good. Other consumption goods – such as a house – are non-rival: they are consumed jointly by the members of the household. In the context of intrahousehold welfare, non-rival goods are usually referred to as (household) public goods.

When choosing how to allocate a limited budget to various rival and non-rival goods, the household takes into account the preferences of its members. Formally, let x_i denote a vector of rival goods consumed by individual i and let X denote household public goods. The household's consumption choices can be represented as the solution to an optimization problem of the form:

$$\max_{\{x_1,\ldots,x_n,X\}} \sum_{i=1}^{N} \omega_i U_i(x_i, X) \text{ subject to } \sum_{i=1}^{N} p x_i + qX = y \tag{1}$$

where ω_i is a welfare weight, N is the number of household members, p and q are prices, and y is income. Consumption choices depend not only on individual preferences $U_i(.)$ but also on welfare weights ω_i: individuals with large ω_i have more weight in the household's decision and hence achieve a higher individual welfare. Understanding intrahousehold welfare thus boils down to understanding the factors that affect ω_i.

In two seminal contributions, Manser and Brown (1980) and McElroy and Horney (1981) model intrahousehold bargaining as depending on threat points: when negotiating over how to allocate consumption expenditures, spouses can threaten to walk away from the couple. How much welfare they can achieve on their own determines how much bargaining power they have within marriage. Intrahousehold welfare is predicted to be determined by rules determining the devolution of assets upon divorce (including alimony, child support and welfare payments).

Lundberg and Pollak (1993) argue that the threat of divorce is too extreme to be credible in most everyday situations. Non-cooperation within marriage is a more realistic threat. In this case, intrahousehold welfare is expected to depend on the financial autonomy of spouses, such as rules determining who receives welfare payments or whether married women have independent access to credit. Lundberg et al. (1997) for instance, show that consumption of women's and children's clothing increased when the UK transferred a substantial child allowance from husbands to wives. McElroy (1990) provides a useful discussion of various factors thought to affect intrahousehold bargaining.

The empirical literature has explored these ideas in terms of 'unitary' versus 'collective' models of the household. A household model is said to be unitary if choices do not depend on bargaining power; otherwise it is collective. A household may be unitary for a variety of reasons, for instance because all decisions are taken by the household head, or because all household members have the same preferences over household consumption $\{x_1, \ldots x_N, X\}$. A simple way of testing the unitary model is the income-pooling test: if welfare weights do not depend on bargaining power, consumption choices should depend only on total income, not on bargaining weights. This yields a simple exclusion test that has been widely applied in the literature, often to identify variables affecting intrahousehold bargaining.

Chiappori (1988) has proposed a way of testing the efficiency of the intrahousehold bargaining process. The basic idea is that the solution to

optimization problem (1) can be written as a two-step process. The household first decides how much to allocate to household public goods X and to the rival expenditures $y_i = px_i$ of each household member, with $pX + \sum_i y_i = y$. Then each member maximizes his or her own utility U_i subject to $px_i = y_i$. Intrahousehold bargaining only affects how total expenditures are shared among members, that is, it affects only the share of rival expenditures that goes to each member. This observation yields testable restrictions on cross-equation parameters in a demand system. This is called the 'sharing rule' approach. Browning et al. (1994), for instance, apply this approach to Canadian couples without children and show that allocation of expenditures on each partner depend on their relative incomes.

Both the sharing rule and the income-pooling tests raise empirical difficulties. One difficulty arises whenever utility is transferable and all household members contribute to a household public good. In this case, Bergstrom (1997) has shown that changes in individual incomes do not affect intrahousehold welfare allocation. The reason is fungibility: reducing the income of a household member simply reduces his or her contribution to the household public good.

Another empirical difficulty is that individual preferences are not directly observable. Hence, in order to identify the effect of bargaining power on household choices, we must assume that different categories of household members have systematically different preferences over joint household consumption. The empirical literature has relied on two types of identification strategies to deal with this issue. The first strategy is to rely on stereotypes, such as 'men prefer alcohol and cigarettes' or 'women care more about children'. This strategy permits identification whenever the stereotype is correct. For instance, it has been shown that, when the bargaining power of the wife increases, the household spends more on child nutrition and schooling (see Bergstrom 1997, and the references cited therein). Based on this evidence, it has been argued that increasing the bargaining power of women is a way to improve child welfare. Such interpretation is a double-edged sword, however. It also reinforces a stereotype that could be used to argue that, since women care for children, it is acceptable for society to relegate them to a reproductive role. What we need is empirical evidence based on actual preferences, not stereotypes.

The second identification strategy is to focus on individual consumption of rival goods such as food or clothing. While this is a better strategy, it also has problems. Browning et al. (1994), for instance, show that households in which the wife earns more spend more on female clothing. They interpret this result as evidence that higher income raises a woman's bargaining power. The problem is that a spouse with a higher income probably occupies a higher job position and needs better clothes to go to work. This may generate a reverse causation between income and clothing expenditures, thereby weakening inference.

Spouses probably derive utility from each other's consumption of rival goods. This point was initially made by Becker (1981), who discusses two possible cases, one in which individuals are altruistic – someone else's *utility* enters their preferences – the other in which they are paternalistic – someone else's *consumption* enters their preferences. An example of paternalistic preferences is when a parent does not want a child to smoke, although the child wishes to. In poor countries, differences in health or nutritional status between spouses have sometimes been interpreted as the result of intrahousehold bargaining (Dercon and Krishnan 2000). Yet it would be quite foolish for even the most despotic and selfish husband to starve his wife to death as she would be of no use to him once gone. Hence, even such a husband would care about his wife's consumption.

An interesting illustration of how altruism can affect intrahousehold welfare is the so-called rotten kid theorem. In this theorem, Becker (1981) imagines a parent who, for altruistic reasons, transfers money to a child. The child can try to capture part of the household income, for instance by refusing to work or by diverting household resources. Becker shows that, as long as the parent decides the size of the transfer after capture has taken place, capture only leads to lower household income and hence to a lower transfer. As a result,

the child chooses not to capture because doing so ultimately reduces his consumption.

The Marriage Market

The marriage market is discussed in a separate entry in this dictionary and need not be discussed in detail here. What is important to realize for our purpose is that, if sufficient commitment mechanisms exist, intrahousehold allocation of welfare can be negotiated up front at the time of marriage. For instance, future spouses may anticipate that a wife who earns an independent income has more say in household decisions. As a result, the groom may insist that the bride will never work before agreeing to marry her. Similarly, if devolution of assets upon divorce affects bargaining power, the newlyweds may sign a pre-nuptial agreement that shapes how assets will be divided.

As first pointed out by Lundberg and Pollak (1993), this observation has deep implications regarding policy intervention. If intrahousehold welfare is entirely decided at the time of marriage, then changing the rules applying to married couples affects only those who are already married. Changes to what happens after marriage (for example, devolution of assets upon divorce) have no long-run effect because, once they have been introduced, they are anticipated in the marriage market.

Provided that this reasoning is empirically correct, the policy implication is that the best policy handle to influence intrahousehold welfare is the marriage market itself. The share of household consumption that women can (implicitly or explicitly) negotiate for themselves depends on the assets they bring to marriage. If this is true, helping women then is best achieved in the long run by improving female education and by changing inheritance rules in their favour.

Invariable Standard of Value

J. E. Woods

I. In Sections I–III, Chapter I of the *Principles*, Ricardo rejected Smith's labour-commanded theory of value in favour of an embodied-labour theory – for a justification of this, see Sraffa's Introduction to Ricardo (1951) or Garegnani (1984). However, in Sections IV and V, he was forced to modify his theory to take account of the effects of movements in income distribution. Thus, Ricardo had isolated two cases where the value of commodities would change – first, when there was an alteration in the amount of labour required, directly and indirectly, in production; and second, when there was a rise or fall in the value of labour, which operated through unequal capital–labour ratios in the different industries. On empirical grounds, Ricardo argued that the first would dominate the second:

> The greatest effect which could be produced on the relative prices of these goods from a rise of wages, could not exceed 6 or 7 per cent . . .. Not so with that other great cause of the variation in the value of commodities, namely the increase or diminution in the quantity of labour necessary to produce them (Ricardo [1821], 1951, p. 36)

Thus, it was assumed in the remaining chapters of the *Principles* that changes in value were caused by changes in embodied labour.

This left the theory of value in an unsatisfactory state. Central to the Ricardian scheme since 'The Essay on Profits' (Ricardo 1952) had been the rate of profits and its relation to the rate of growth; as a corollary, the determination of the laws determining income distribution was regarded as the principal problem in political economy (Ricardo [1821], 1951, p. 5). Yet, in the study of this problem, Ricardo found that the size of the national income, the quantity of capital and the amount of wages all varied with the distribution of income. Though fixed in physical composition, these variables changed because they were measured in terms of values, themselves functions of the distribution of income. What would be the effect then on the rate of profits, r, of an increase in the real wage rate, w? Would r necessarily decrease or could there be a sufficient rise in the value of net income to accommodate increases in both distributive parameters? It was in an attempt to answer such questions that Ricardo turned to the notion of an invariable standard of value and the associated distinction between relative value and real value.

Having identified the two causes of change in the values of commodities, Ricardo could define the characteristics of a standard measure of value: such a commodity would require a constant quantity of embodied labour in its production and have to be invariant with respect to changes in income distribution. 'Of such a measure, it is impossible to be possessed, because there is no commodity which is not itself exposed to the same variations as the things, the value of which is to be ascertained' (Ricardo [1821], 1951, pp. 43–44). Ricardo was defeated by this problem in *The Principles*, assuming gold to be invariable 'to facilitate the object of this enquiry, although I fully allow that money made of gold is subject to most of the variations of other things' (Ricardo [1821], 1951, p. 46). Nor was he able to achieve progress later, as evidenced by his paper on 'Absolute and Exchangeable Value' (Ricardo 1952). II. For an attempt at a partial solution to Ricardo's problem, we have to turn to the Standard Commodity (§ 23 in Chapter IV of Sraffa (1960) is entitled 'An invariable measure of value'). In *Production of Commodities by Means of Commodities*, Sraffa was 'concerned exclusively with such properties of an economic system as do not depend on changes in the scale of production' (p. v). With a given technique of production, embodied labour cannot change; hence, when investigating the existence of an invariable standard of value, it suffices to consider invariance with respect to income distribution.

Consider a single-product industries, circulating capital model, as in Part I of Sraffa (1960), with price equations given by:

$$p' = wl' + (1 + r)P'A \tag{1a}$$

$$p'(I - A)x = 1 \tag{1b}$$

$p = (p_i)$ is the relative price vector, $l = (l_i)$ the vector of direct labour input coefficients, $A = (a_{ij})$ the matrix of input-output coefficients, w and r the uniform rates of wages and profits respectively, and x is the gross output vector. (1b) states that the actual net output of the economy is the *numéraire*. From (1a):

$$p' = wl'(I - (1 + r)A)^{-1} \tag{2}$$

so that, using (1b):

$$w = 1/l'(I - (1 + r)A)^{-1}(I - A)x \tag{3}$$

Then (2) and (3) imply that:

$$p' = l'(I - (1+r)A)^{-1}/l'(I - (1+r)A)^{-1}(I - A)x \tag{4}$$

i.e., equations (1) can be solved to yield w and p as functions of r in (3) and (4) respectively.

'The key to the movement of relative prices consequent upon a change in the wage rate lies in the inequality of the proportions in which labour and means of production are employed in the various industries' (Sraffa 1960, §15, p. 12). It is a straightforward matter to show that relative prices are invariant with respect to income distribution if and only if there is a uniform value-capital/labour ratio in each industry, itself a manifestation of this underlying (mathematical) condition:

$$l'A = \lambda^*(A)l', \lambda^*(A) > 0 \tag{5}$$

i.e., l is a left characteristic vector of A corresponding to the Frobenius root, $\lambda^*(A)$. (For a proof of this statement, see Pasineti (1977) or Woods (1985).)

Assuming that (5) does not hold, what would happen if, following Sraffa, we suppose that prices are constant as the wage, measured in terms of actual national income, is reduced from one and the rate of profits increased from zero. In those industries with a sufficiently low proportion of labour to means of production ('deficit'-industries), the reduction in wage payments is insufficient to met profit payments. On the other hand, there would be industries with a sufficiently high proportion of labour to means of production ('surplus'-industries) for the proceeds of the wage reduction to exceed profit payments.

> There would be a 'critical proportion' of labour to means of production which marked the watershed between 'deficit' and 'surplus' industries. An industry which employed that particular 'proportion' would show an even balance – the proceeds of the wage reduction would provide exactly what was required for the payment of profits at the general rate (Sraffa 1960, § 17, p. 13).

An industry characterized by that 'proportion' would also exhibit it in its means of production, and in its means of production of means of production, etc. The output of such an industry would consist of the same commodities (combined in the same proportions) as does the aggregate of its own means of production – in other words, such that both product and means of production are quantities of the self-same composite commodity' (Sraffa 1960, §24, p. 19).

Sraffa's Standard Commodity, which possesses that particular 'balancing proportion', is given by the semi-positive vector x^* which solves:

$$Ax^* = \lambda^*(A)x^* \tag{6a}$$

$$l'x^* = 1 \tag{6b}$$

As characteristic vectors are unique only up to scalar multiplication, (6b) is the normalization to fix the size of the Standard System. (The connection between the Standard Commodity and the right Frobenius characteristic vector was first perceived by Newman 1962.) When measured in value terms, the ratio between gross output, x^*, and means of production, Ax^*, is invariant to changes in distribution. Calculating this ration when the wage rate is zero, we obtain:

$$\begin{aligned} p'x^*/p'Ax^* &= p'x^*/\lambda^*(A)p'x^* \\ &= 1/\lambda^*(A) = (1 + R) \end{aligned} \tag{7}$$

where R is Sraffa's 'balancing' ratio, identical to the maximum rate of profits. If A is productive, $\lambda^*(A) < 1$ so that $R > 0$. If, in addition, A is indecomposable (all commodities are basic), $x^* > 0$

and is, in fact, the only semi-positive characteristic vector of A. Thus, existence and uniqueness of the Standard proportions are derived straightforwardly from the Perron-Frobenius Theorem (see Pasineti 1977 or Woods 1978).

Let the Standard Net Product be chosen as numeraire, i.e.

$$p'(I - A)x^* = 1 \tag{8}$$

Then, from the price equations (1a) and (8), and the quantity equations (6a) and (6b), it can be shown that:

$$r = R(1 - w) \tag{9}$$

(see Newman 1962; Pasineti 1977; or Woods 1978). That is, the real wage rate–rate of profits curve for the productive technique described by $\{A; l\}$ *is a* downward-sloping straight line.

It is a straight forward matter to show that (9) holds for a one-commodity model. In a multi-commodity model, prices in general vary with income distribution, as in (4), thereby obscuring the relation between distributive parameters. 'Particular proportions, such as the Standard ones, may give transparency to a system and render visible what was hidden' (Sraffa 1960, §31, p. 23). The use of the Standard System is sufficient, not necessary, for the derivation of a downward-sloping w–r curve, for it can be shown from (3) that $dw|dr < 0$ in terms of any *numéraire*. 'It follows that if the wage is cut in terms of *any* commodity . . . the rate of profits will rise; and vice versa for an increase of the wage' (Sraffa 1960, §49, p. 40).

Thus, the Standard System always exists for the single-product industries, circulating capital model, implying a particularly simple form of the w–r curve.

There are three concluding points to be made.

1. The Standard System does not necessarily exist for the pure joint production model of Part II of Sraffa (1960). For such a model, with input and output matrices A and B, the Standard Commodity would have to satisfy:

$$Bx^* = (1 + R)Ax^*. \tag{10}$$

Sraffa considered the possibility that the Standard Commodity contains negative components. Manara (1980) has demonstrated, using simple numerical examples, that a productive multiple-product industries system does not necessarily have a maximum rate of profit; that is, the solution R,x^* of (10) may be negative or complex.

A reformulation of the system in terms of inequalities would give a simple von Neumann model; the van Neumann solution, which exhibits balanced growth, can be thought of as a generalization of the Standard proportions.

2. A positive Standard System does exist for the single-product industries, fixed capital model in chapter X of Sraffa (1960). Furthermore, as demonstrated in Woods (1984), the Standard Commodity can be used to resolve the particular question of choice of technique which arises in this model – namely, the determination of the optimal economic lifetime of machinery.
3. In any analysis of price and wage variation, some commodity must be chosen as *numéraire*. In chapter III, Sraffa (1960) operated with actual net output, as in (1b). When constructing the Standard Commodity, Sraffa supposes 'that there was an industry which employed labour and means of production in that precise proportion, so that with a wage-reduction, and *on the basis of the initial prices*, it would show an exact balance of wages and profits (Sraffa 1960, §21, p. 16, emphasis added). Clearly, this is the intuitive argument underlying the construction of the Standard Commodity. However, it could not be expressed formally other than in terms of the Standard Commodity.

Inventories

Louis J. Maccini

Inventories consist of stocks of finished goods, goods-in-process, and raw materials and supplies held by business firms. Interest in inventories among economists stems primarily from the observation that inventory fluctuations are an important feature of business cycles.

This observation was first fully documented by Abramovitz (1950) who observed that, although the level of inventory investment is a small fraction of the level of GNP, changes in inventory investment are a large fraction of changes in GNP, especially in recessions. In particular, he pointed out that in the five business cycles in the US between the two world wars the average decline in inventory investment accounted for 47 per cent of the average decline in GNP during contractions. The post-World War II data for the US are even more dramatic. As reported by Blinder and Holtz-Eakin (1983), the average drop in inventory investment was 68 per cent of the drop in GNP during post-World War II recessions. In expansions, inventory movements account for a smaller fraction of movements in GNP, so that over the cycle as a whole inventory fluctuations are less influential than the data on recessions alone would indicate. Nevertheless, the point remains: inventory movements are a key feature of cyclical fluctuations in aggregate output.

To avoid confusion, it should be stressed that inventories appear to be a propagating mechanism, not a causal force, in business cycles. There is no evidence that exogenous shifts in inventory investment are an underlying cause of fluctuations in GNP.

Microfoundations

To provide a framework for analysing movements in inventories, economists have developed optimiezation models of the firm's behaviour. These borrow heavily from models in operations research, which are designed to guide actual firms in managing their inventory positions. The models of economists have been most fully developed for finished goods inventories held by manufacturers. The prime motive for holding inventories in these models is to serve as a buffer stock, that is, to absorb random fluctuations in demand. Among models of buffer stocks, two approaches may be distinguished: the quadratic criterion–linear constraint approach and the stochastic dynamic programming approach.

The former approach was developed in the pioneering book of Holt et al. (1960). There and in other uses of the theory in economics, for example, Belsley (1969), the firm was assumed to choose levels of output and inventories to minimize expected costs subject to an accumulation equation for inventories and an exogenous stochastic process for sales. To bring the price decision into the theory, Hay (1970), Blinder (1982), and others have assumed that the firm possesses monopoly power and maximizes discounted expected profits.

The basic model presumes that the firm sets its price and output before the random component of demand is revealed, and inventories are used to absorb any shocks to demand. Let P_t be price, Q_t output, N_t real sales or demand, H_t, the stock of inventories at the end of the period, and $\in_t$ a non-negative random variable. The firm is then assumed to maximize

$$E_0 \sum_{t=0}^{\infty} \rho^t \left[P_t N_t - c_0 - c_1 Q_t - c_2 Q_1^2 - v\left(H_t - H_t'\right)^2 \right] \tag{1}$$

subject to

$$H_t = H_{t-1} + Q_t - N_t$$
$$N_t = m_0 - m_1 P_1 + \varepsilon_1$$

where ρ is a discount factor, E_0 is an expectation operator, and C_0, C_1, C_2, m_0 are positive parameters.

The motive for the firm to hold inventories is essentially contained in the inventory-holding cost function, $v\left(H_t - H_t'\right)^2$, which is a U-shaped Function of H_t that reaches a minimum at H_t'. It captures two forces: Higher inventories increase costs in the form of storage costs. But, lower inventories also increase costs in the form of lost sales, since lower inventories relative to sales increase the likelihood the firm will be caught out of stock. The holding cost function balances these forces.

The model has several advantages. It yields explicit solutions for the choice variables that are linear in the previous period's inventory stock and current and future sales. Further, certainty equivalence applies so that random variables may be replaced by their expected values. But there are disadvantages. The functional form assumptions are quite strong. The random component to demand must appear additively. And the discount rate must be constant, which limits the ability of the model to analyse the effects of changes in real interest rates through which monetary policy operates.

The stochastic dynamic programming approach to inventory-holding behaviour originates with the work of Arrow et al. (1951), who also developed a model of a firm that minimizes expected costs subject to an exogenous stochastic process for sales. Karlin and Carr (1962) later extended the model to allow for a price decision. The economic implications of the model have been drawn out by, among others, Mills (1962) and Zabel (1972).

Suppose the firm makes decisions over a planning horizon of T periods. Then, according to Bellman's Principle of Optimality, and using the earlier notation, the functional equation that describes the firm's optimal programme is

$$\begin{aligned} \Omega_T(H_{t-1}) = \max_{P_t, Q_t} \{ & P_t m(P_t) - P_t D(b_t) - c(Q_t) \\ & - A(b_t) + \rho_t \int_0^{\infty} \Omega_{T-1}(H_t) f(\varepsilon_t) \mathrm{d}\varepsilon_t \Big\} \end{aligned} \tag{2}$$

where

$$\begin{aligned} b_t &= H_{t-1} + Q_t - m(P_t) \\ H_t &= b_t - \varepsilon_t \\ D(b_t) &= \int_{b_t}^{\infty} (\varepsilon_t - b_t) f(\varepsilon_t) \mathrm{d}\varepsilon_t \\ A(b_t) &= \int_0^{b_t} a(b_t - \varepsilon_t) f(\varepsilon_t) \mathrm{d}\varepsilon_t \end{aligned}$$

and where $m' \leq 0$, $m'' \leq 0$, $c' > 0$, $c'' \geq 0$ $a' > 0$, and $a'' \geq 0$. The expression, $\Omega_{T-1}(H_{t-1})$, denotes maximum discounted expected profits over t future periods.

Observe that $D(b_t)$ is expected shortages or stockouts, capturing the real sales that the firm can expect to lose if it is caught with too few inventories, while $A(b_t)$ is the expected storage cost of holding inventories. Unlike the quadratic cost-linear constraint approach, this model permits general functional forms to be used. Moreover, the decision rules will depend in general on moments higher than the mean of the probability distribution of demand. Finally, although the model has been formulated above with additive demand errors, it can be modified to allow for non-additive uncertainty. A disadvantage of the model is that explicit solutions are not possible.

In both approaches, the incentive for the firm to hold inventories is essentially the same. To see this, observe that expected shortages, $D(b_t)$, in (2) are inversely related to initial inventories

and correspond to the cost savings to holding inventories – the downward-sloping section of the U-shaped cost curve – that appears in (1). In essence, both terms capture the benefits to the firm of holding a buffer stock in the form of finished goods inventories. Given this, it is not surprising that with additive demand uncertainty both approaches yield similar economic predictions, though of course the details will differ from model to model. Such predictions have served as the basis for much empirical work on inventories and have motivated the specification of inventory investment relationships in macroeconomic models.

One set of predictions concerns the response of decision variables to changes in initial inventories. As long as marginal production costs rise (i.e., $c_2 > 0$ or $c'' > 0$) so that there is some incentive to smooth production, both P_t and Q_t will be inversely related to $H_{t\text{-}1}$. Further, $-1 < (\partial H_1/\partial H_{t-1}) < 0$. This means that inventory adjustments will exhibit the characteristics of partial adjustment.

A second set of predictions refers to the effects of changes in exogenous variables. Generally speaking, P_t and Q_t will be positively related to exogenous shifts in anticipated demand (shifts in m_0 or the function $m(P_t)$) and inversely related to changes in inventory holding costs. Further, increases in current anticipated demand, declines in future anticipated demand, or increases in inventory holding costs will reduce inventory investment.

The basic models outlined above have been extended in numerous directions. A prominent one is that right from the beginning many authors have allowed production costs to depend on the change in the level of output as well as the level of output itself. This creates an additional incentive for the firm to smooth production beyond the incentive embodied in the assumption that $c'' > 0$. The difficulty with this notion is that the underlying rationale for including costs to changing the level of output is quite vague. A possible rationale that has been exploited in recent work – for example, Maccini (1984) – is that such costs reflect adjustment costs to changing quasi-fixed factors of production, for example, plant and equipment, or the stock of workers. But, then, a better theoretical procedure would be to incorporate decisions on quasi-fixed factors directly into the analysis. This more explicit specification of the economic forces at work permits an analysis of the important interaction between inventories and quasi-fixed factors of production.

Most inventory models that analyse price as well as output and inventory behaviour, have assumed that the firm possesses some monopoly power in output markets. This assumption facilitates a study of the relationship between price and inventory behaviour, but it is not essential. Models of a competitive industry can be formulated to yield similar predictions for movements in price, output and inventories – see, for example, Eichenbaum (1983).

So far we have concentrated, like the literature, on the holding of finished goods inventories. Theory that rationalizes the holding of inventories of goods-in-process and raw materials and supplies is much less well developed. It is common to adapt, rather casually, the earlier models designed for the study of finished goods inventories. But, this tactic fails to capture in a rigorous way the firm's motives in holding these other inventories, and may in fact generate specious predictions. This is an area that needs more research.

Finally, all the theories discussed so far are designed to explain the holding of manufacturers' inventories, and are not obviously applicable to the holding of inventories by wholesalers and retailers. The trouble is that for the latter agents the variable corresponding to Q_t – the variable that gives rise to additions to inventories – is orders of goods from manufacturers. But, the process of ordering and receiving goods from manufacturers may carry a substantial fixed cost which will induce the firm to 'bunch' rather than to 'smooth' orders and deliveries. In recent work, Blinder (1981) has used ideas associated with S-s models of inventory behaviour – see, for example, Scarf (1960) – together with an aggregation procedure to undertake an analysis of retail inventories. This is an important development because retail inventories appear to exhibit at least as much volatility as manufacturers' inventories.

Empirical Work

Empirical studies of inventories have been dominated by the use of the flexible accelerator model, first used in empirical work by Lovell (1961), and subsequently used by many authors, including Blinder and Holtz-Eakin (1983), Maccini and Rossana (1984), Irvine (1981), etc. The model takes the form

$$H_t - H_{t-1} = \lambda_1 \left(H_t^* - H_{t-1}\right) + \lambda_2 [N_t - E_t(N_t)] + u_i, \quad 0 \le \lambda_1 \le 1, \quad -1 \le \lambda 2 \le 0 \tag{3}$$

where H_t^* is 'desired' inventories, $E_t(N_t)$ is expected sales so that $N_t - E_t(N_t)$ is a 'sales surprise', and u_t captures random forces other than sales that operate on inventories. Desired inventories should depend on current and future levels of expected demand, inventory holding costs, such as real interest rates, and factor input prices which shift marginal production costs.

This model embodies the essential ideas of the buffer stock models of inventory behaviour described above. As long as marginal production costs rise with output, $c_2 > 0$ or $c'' > 0$, so that there is an incentive for firms to smooth production, it follows that $\lambda_1 < 1$ so that firms will partially adjust inventory stocks to desired levels and that $\lambda_2 < 0$ so that sales surprises will be met partly by inventory adjustments. In the extreme, as $c_2 \to \infty$ or $c'' \to \infty$, it follows that $\lambda_1 \to 0$ and $\lambda_2 \to -1$, and vice versa. Moreover, the determinants of desired inventory stocks reflect the main exogenous variables that are embedded in the models of the firm's behaviour.

This model has been estimated over a wide variety of industries, sectors, countries, and sample periods. Different assumptions have been used for expectation formation schemes, and different econometric techniques have been used to handle statistical problems.

Despite the enormous amount of empirical work done with the model, a number of empirical puzzles remain. A major one surrunds the estimates of the parameters, λ_1 and λ_2, as several authors, most prominently Feldstein and Auerbach (1976) have pointed out. The estimates of λ_1 turn out to be very low, implying that the speed of adjustment of actual to desired inventories is very slow. This is implausible when wide savings in inventory investment amount to no more than a couple of weeks of production. Moreover, the estimates of λ_2 are also quite low, implying that sales surprises tend to be absorbed largely by production adjustments. But, this contradicts the low estimates of λ_1, which suggest that it is difficult, that is, costly, to adjust production levels in order to close gaps between H_t^* and H_{t-1}. Despite the use of relatively sophisticated econometric methods in recent work to deal with statistical problems, the puzzle remains unresolved.

Another puzzle is that real interest rates have generally performed poorly in inventory equations – see, for example, Blinder and Holtz-Eakin (1983) and Maccini and Rossana (1984) for recent studies. This is a surprise since it is widely believed that changes in credit conditions have a substantial effect on the inventory positions of business firms. This result may be owing to difficulties in measuring *ex ante* rates, or to a lack of variation in real rates, or to the presence of credit rationing which is not adequately captured in the price of credit.

Finally, a number of authors (e.g. Blinder and Holtz-Eakin 1983), have observed that the variance of production actually exceeds the variance of sales in most industries. This fact appears to conflict with the above theoretical models which predict that inventories are used to smooth production relative to sales. To explain this phenomenon, the models need to be extended to allow for cost shocks in the form of, for example, real raw material prices, or more complex demand structures than serially uncorrelated random errors.

Inventory Cycles

Michael C. Lovell

The Contribution of Inventory Liquidation to Declines in GNP

Although inventory investment is a relatively small component of total GNP, even in boom years, the swing from inventory accumulation to massive liquidation is a fundamental factor in the propagation of cyclical reversals in the pace of economic activity. To illustrate, the 1981–2 decline in United States GNP of $31.8 billion dollars deserves to be called an inventory recession because the shift from positive inventory accumulation of $8.9 billion (1972 dollars) at the cycle peak to liquidation of stocks at an annual rate of $22.7, a decline in effective demand of $31.6 billion, greatly exceeded the collapse of any other component of real GNP.

As inspection of Table 1 makes clear, a drop off in inventory investment generally makes a major contribution to each recession's decline in effective demand. The short 1980 recession should probably not be counted as an exception to this rule in that inventory investment fell from $13.7 billion in the second quarter of 1979 to − $10.1 billion in the third quarter of 1980. However, the 1946 recession (which pre-dates the availability of quarterly GNP data) is atypical; this was not an inventory recession because the efforts of business enterprise to replenish stocks at the end of World War II served to soften the shock of postwar conversion. And in the Great Depression of the 1930s, the decline in inventories was overshadowed by a collapse of fixed investment that helped push the unemployment rate up to 25 per cent.

The critical importance of inventories has long been recognized, thanks in large measure to the fundamental empirical study of Moses Abramovitz (1950), who demonstrated that in

Note: All GNP magnitudes measured in 1972 dollars.

the period between the two world wars a collapse of inventory investment contributed decisively to each recession's decline in effective demand. Inventories have continued to play a destabilizing role in each United States recession since the publication of Abramovitz's study. Also, substantial empirical evidence for a number of countries establishes that inventory recessions are a general characteristic of capitalist economies. Further, there is some evidence, reviewed by Attila Chikàn (1984), that socialist economies may also experience inventory cycles.

The phrase 'inventory recession' stresses the empirical fact that cyclical reversals in economic expansion are dominated by the liquidation of inventory stocks. But to characterize most cyclical reversals as 'inventory recessions' does not explain why the declines in the pace of economic activity come about or what policy measures, if any, should be applied to mitigate the sacrifice of jobs and output occasioned by recession. Empirical observation, such as the evidence of Table 1, cannot by itself establish that inventories are in any sense a fundamental cause of the business cycle rather than only a basic symptom or but one of a number of essential ingredients of the mechanism propagating business fluctuations. Both theory and empirical evidence are essential in the study of the inventory cycle mechanism.

Modelling the Inventory Cycle

In the interwar period, members of both the psychological and the monetary schools of business cycle theory indicted inventory investment as a

particularly critical factor in the generation of business cycles. R.G. Hawtrey (1928) argued that monetary factors had their primary effect on the economy through their influence on inventory investment. Pigou (1929) also stressed the impact of systematic errors of optimism and pessimism in explaining cyclical movements.

A major contribution to our understanding of inventory cycles was made by Erik Lundberg (1937), who showed how a set of quite simple assumptions suffices to generate cycles in economic activity, as illustrated by the data for a hypothetical inventory cycle reported on Table 2. Observe that a once and for all step increase in autonomous government spending from 500 to 600 in period 5 (reported in column 1) disturbs the initial equilibrium, leading to cycles in output (column 5), sales (column 7), and inventory investment (column 8). Output rises from the initial equilibrium of 1200 to a peak of 1838 in period 8 and then slumps to a recession low of 1233 in period 13. Thus the attempts by business enterprises to use inventories as a buffer to insulate output from sales are frustrated in the aggregate; indeed, production fluctuates *more* than sales volume (compare columns 5 and 7) over the course of the inventory cycle.

The following details of this inventory cycle deserve notice: In each time period the entries are determined in accordance with the simple assumptions enumerated at the bottom of Table 2. Initially inventories serve as a buffer permitting business firms to meet the unanticipated increase in demand occasioned by the increase in government spending. The immediate impact of the increase in government spending is limited to a drawing down of inventories by 100 units in period 5, as reported in columns 8 and 9; there is no immediate change in output because business firms did not anticipate the increase in sales when scheduling production for period 5. For period 6 output of 1500 is scheduled in order to meet anticipated sales of 1350 (same as last period) plus 150 units to be added to inventory in order to both replace the items sold

out of inventories in period 5 and to increase the inventory stock to the higher level of 675 (column 4) which is desired because of increased business volume. But in spite of these adjustments, the economy does not achieve equilibrium in period 6; once again the immediate impact of an excess of sales over anticipations is met by drawing down inventories below the desired level. The boom is temporary, for eventually inventories catch up with the expanding economy. The economy gradually converges in a series of oscillations toward the equilibrium level presented in the bottom row of the table.

While the cycle displayed on Table 2 is stable, the economy converging in the limit to equilibrium, Lloyd Metzler (1941) showed analytically how the stability of the inventory cycle developed by Lundberg depended critically on the two parameters of the model, the Marginal Propensity to Consume (MPC) and the Marginal Desired Inventory Coefficient (MDIC). He proved that the model will converge toward equilibrium rather than explode only if the following stability condition is satisfied:

$$\text{MPC} \times (1 + \text{MDIC}) < 1.0$$

For the parameter values used in constructing Table 2 (MPC = 0.60 and MDIC = 0.5) we have $0.6 \times (1 + 0.5) = 0.9 < 1.0$, as required for stability; but if the reader recalculates the table with the MPC = 0.6 but MDIC = 0.7, a series of divergent cycles will be observed ($0.6 \times (1 + 0.7) = 1.02$). Metzler also considered the implications of replacing the assumption that sales are expected to be the same as last period with extrapolative expectations.

Assumptions of the Lundberg–Metzler Inventory Cycle Model

1. Government spending (column 1) increases from 500 to 600 in period 5, generating cyclical movements in sales, output, consumption and inventory investment.
2. Expectations are "static", for anticipated sales in the current period (column 2) always equal actual sales in the preceding period (carried over from column 7).
3. Planned inventories (column 3) equal the marginal desired inventory coefficient (MDIC) times anticipated sales (column 2).
4. Planned inventory change (column 4) equals the excess of planned inventories over last period's inventory stock (column 9).
5. Output (column 5) is the sum of anticipated sales plus the planned change in + column 4.
6. Consumption (column 6) is the Marginal Propensity to Consume (MPC) times output.
7. Actual Sales (column 7) equal Government Spending plus Consumption (column 1 + column 6).
8. Actual Inventory Investment (column 8) equals output less sales (column 5–column 7).
9. The Inventory Stock (column 9) increases from the preceding period by Actual Inventory Investment (column 8).

While the Lundberg–Metzler model demonstrates how the inventory cycle can result from a few quite simple assumptions, simplicity has its costs: Lundberg and Metzler did not show that their assumptions about firm behaviour were compatible with the assumption of maximizing behaviour, they neglected problems of aggregation involved in moving from assumptions about firm behaviour to macro aggregates, they neglected the influence of monetary factors, and they assumed that the adjustment to surprise is met entirely through shifts in buffer stock inventories rather than through price reductions or adjustments in advertising expenditure. Their analysis did serve to inspire the investigation of these and several other issues by a number of authors. Holt and Modigliani (1961) showed how the Lundberg– Metzler assumptions about output determination could be derived from the assumption of firm optimizing behaviour, where the task faced by the entrepreneur involved the minimization of a dynamic quadratic loss function; of course, they also found that alternative specifications of the loss function would yield an embarrassing wealth of alternative behavioural equations. Lovell (1962) showed that the Lundberg–Metzler behavioural assumptions led to instability for any reasonable set of parameters when the problem of aggregating from the firm to

the economy-wide level was addressed within the context of a multi-sector dynamic input–output model; while stability might still be obtained by replacing the Lundberg–Metzler assumption that firms attempt an immediate one-period correction of inventory imbalances with the flexible accelerator assumption that only a fraction of the gap between desired and actual inventories is eliminated each time period, he also showed that the system was necessarily unstable if firms had perfect expectations, correctly anticipating the volume of sales in the next period – that is to say, systematic expectational errors under certain circumstances contribute to stability. Lovell (1974) also showed how the real inventory cycle of Lundberg–Metzler could be influenced by monetary policy once desired inventories were assumed to depend on the interest rate as well as sales volume. In a more recent study, Blinder and Fisher (1981) find that the introduction of inventories modifies the standard rational expectations macroeconomic model in two important respects: first, cyclical rather than random fluctuations are generated when the economy is disturbed by unanticipated monetary shocks; second, if desired inventories are sensitive to real interest rates, even fully anticipated changes in money can affect real economic variables, which contradicts the policy impossibility result of rational expectations theory. Adding inventories to the simplified rational expectations model leads to an explanation of the cycle and simultaneously offers the hope for mitigating fluctuations through appropriate policy action.

Empirical Research

Recognition of the important role of inventories in recessions places a number of basic questions on the agenda for empirical research:

First, are the behavioural assumptions about firm behaviour made by Lundberg and Metzler consistent with the observations? Beginning in the mid 1950s, a number of studies established that the Lundberg–Metzler model is consistent with the evidence provided response lags are introduced; most investigators found that the flexible accelerator assumption that firms attempt only a partial adjustment of inventories toward their equilibrium level within a single period appears more appropriate than the assumption that firms engage directly in 'production smoothing'.

Second, are expectations of future sales volume subject to substantial error, are they rational, and do they have a substantial impact on inventory holdings? Investigators have in recent years been inclined to adopt the assumption of rational expectations as part of the maintained hypothesis rather than subjecting it to direct empirical test; where the rationality hypothesis has been tested, as in Hirsch and Lovell (1969), it has *not* dominated alternative models, such as the extrapolative model of Robert Ferber or the adaptive expectations model. Expectations may be subject to systematic error and forecast errors do affect inventory holdings; but the mechanism is not as simplistic as Lundberg and Metzler assumed in constructing their inventory cycle models.

Third, how big an impact do changes in nominal interest rates and anticipated price changes have on inventory holdings? Prior to the inflationary era of the 1970s, investigators were usually disappointed to find that their regressions yielded incorrect signs on interest rate variables approximately half the time, although these results often went unreported. Studies based on more recent data, of which that by Irvine (1981) may be the most notable, have found stronger indications that monetary conditions influence desired inventory stocks. If the great inflation of the 1970s sensitized business enterprises to the significance of interest rates as a component of inventory carrying costs, the inventory cycle may now be more of a monetary phenomenon than in the past.

Inventory Investment

James A. Kahn

Abstract

Interest in inventory investment's role in business cycle volatility goes back at least to John Maynard Keynes. This article examines some basic facts about aggregate inventory investment, emphasizing its highly volatile and pro-cyclical nature. It then outlines several approaches to modelling inventory behaviour, including a detailed discussion of the linear-quadratic model, and examines their implications for inventory investment's potential role in business cycle fluctuations. The article concludes with a discussion of the potential for progress in inventory control methods to have played a role in the decline in aggregate volatility since the mid- 1980s.

Inventory investment is the change in the stocks of materials, works in process, and finished goods within a firm, industry, or entire economy over a specified period of time. Because in most instances the measure encompasses a variety of goods, it is usually measured in currency units, perhaps deflated (for example, in 1999 dollars). Occasionally, however, when highly disaggregated data are available, it can be measured in physical units (for example, Blanchard 1983; Kahn 1992).

In national income accounts, aggregate inventory investment is the difference between Gross Domestic Product (GDP) and final sales of domestic product. As a share of GDP it is tiny but highly volatile in modern industrial economies. In the post-war United States, for example, it averages 0.62 per cent of GDP, but has a standard deviation of 0.83 per cent. By comparison, fixed non-residential investment averages 10.6 per cent of GDP with a standard deviation of 1.2 per cent. (Data for these calculations come from the US National Income and Product Accounts, Table 5.)

Inventory investment is also highly pro-cyclical. For example, its correlation with real GDP growth in post-war US data is approximately

0.4, and very close to the correlation between fixed non-residential investment and real GDP growth. Also, the standard deviation of real GDP growth is substantially higher than that of final sales (4.0 versus 3.3 per cent), notwithstanding the fact that for more than half of the economy GDP and final sales are identical. Thus inventory investment 'adds' to the volatility of GDP growth in the accounting (though not necessarily causal) sense. Indeed, interest in inventory behaviour as a contributor to aggregate volatility goes back at least to Keynes (1936), and includes notable contributions by Metzler (1941) and Abramovitz (1950). Blinder (1981, p. 500) writes that 'to a great extent, business cycles are inventory fluctuations'.

The pro-cyclicality of inventory investment appears inconsistent with standard microeconomic models of inventory behaviour, particularly those that stress 'buffer stock' or 'production-smoothing' motives, as noted by, among others, Blinder (1986) and West (1986). And this was not the first puzzle brought to light by research on inventory behaviour. Some ten years earlier, Feldstein and Auerbach (1976) noted the persistence of inventory-sales ratios' deviations around their means (see also Ramey and West 1999), particularly given the trivial adjustments needed to restore them to a (presumed) fixed target.

Researchers have also found inventory behaviour informative about the fundamental driving forces of business cycles (see West 1990). For example, Blinder (1986), Eichenbaum (1989), Kydland and Prescott (1982) and Christiano (1988) hypothesize supply side disturbances to account for pro-cyclical inventory investment. Others (such as Ramey 1991; Hornstein and Fisher 2000) consider non-convexities such as fixed costs or downward-sloping marginal cost. Kashyap et al. (1994) argue for the importance of credit constraints. By contrast, Bils and Kahn (2000) argue that the counter-cyclical behaviour of inventory-sales ratios casts doubt on such supply side explanations, which imply counterfactually that inventories should be relatively tight (in relation to sales) during recessions and plentiful in expansions.

The Linear-Quadratic Model

The workhorse of applied inventory research is the linear-quadratic cost minimization model developed by Holt et al. (1960). The firm is assumed to face a stochastic demand process independent of its inventory and production decisions. Consequently, whether it is a competitive price-taker or has monopoly power, the firm can condition on its expected sales process and minimize costs, which take the form

$$E_t\left\{\sum_{\tau=t}^{\infty}\beta^{\tau-t}\left[c_1 y_\tau + c_2 y_\tau^2 + c_3\left(h_\tau - h_\tau^*\right)^2\right]\right\}, \tag{1}$$

subject to

$$h_\tau = h_{\tau-1} + y_\tau - s_\tau, \tag{2}$$

where y denotes production, s sales, h the end-of-period inventory stock, h^* the desired or 'target' stock, and β a discount factor. Some versions of the model include additional cost terms such as a cost of changing production. The target h^* is usually assumed to be either a constant or proportional to expected sales. In addition, c_1 may be stochastic, and there may be additional additive stochastic terms (for example, materials prices).

A standard informational assumption is that production decisions at date t are based on period $t-1$ information, with the implication that h_t is not controlled directly. Letting $\theta = c_2/c_3$, the solution to the problem (1) and (2) is:

$$E_{t-1}\{h_t\} = \lambda h_{t-1} + \lambda E_t\left\{\sum_{\tau=t}^{\infty}(\beta\lambda)^{\tau-t}\left[\theta^{-1}h_\tau^* + \beta s_{\tau+1} - s_\tau\right]\right\} \tag{3}$$

where $\lambda \in (0, 1)$; 1Þis the smaller root of $\beta\lambda^2 - (1 + \beta + \theta^{-1})\lambda + 1$. In the limiting case with $\theta = c_2 = 0$ the solution is $E_{t-1}\{h_t\} = h_t^*$. If h^* is a constant, then the only motive for varying inventories is to smooth production. Durlauf and Maccini (1995) decisively reject this version of the model. It is worth noting that the solution (3) bears

some similarity to another widely used model, the flexible accelerator of Lovell (1961) and others

$$h_t - h_{t-1} = \lambda_1\left(h_t^* - h_{t-1}\right) - \lambda_2(s_t - E_{t-1}\{s_t\}) + u_t,$$

where u_t is a disturbance term, and both λ_1 and λ_2 lie between 0 and 1.

Both the linear-quadratic and flexible accelerator models, however, have a history of empirical difficulties. Blinder (1986) pointed out that, for the pure production-smoothing model (with h^* a constant), the model counterfactually implies that the variance of sales exceeds that of production. West (1986) showed that a more general variance inequality implied by the model with a target proportional to expected sales is also violated in US manufacturing data. Moreover, among studies of similar data, there is disagreement in the literature on the magnitudes, and even the signs, of key parameters. For example, Ramey (1991) finds negatively sloped marginal cost, in contrast to most other studies. West (1986) finds a relatively small cost of inventory deviations from their target. West and Wilcox (1994) find that obtaining precise estimates of the linear-quadratic model may be problematic with realistic sample sizes.

Regarding the flexible accelerator, Feldstein and Auerbach (1976) estimated small values for both λ_1 and λ_2, which is paradoxical because a small λ_1 implies large adjustment costs, but a small λ_2 implies that sales surprises are largely offset by within-period production responses. Their proposed solution is a target ratio that itself adjusts slowly over time. They do not provide a strong theoretical foundation for their 'target adjustment' model, however. One theme of the alternative approaches discussed in the next section is the effort to base inventory models on more rigorous microfoundations in the hope of resolving the empirical puzzles.

Other Approaches

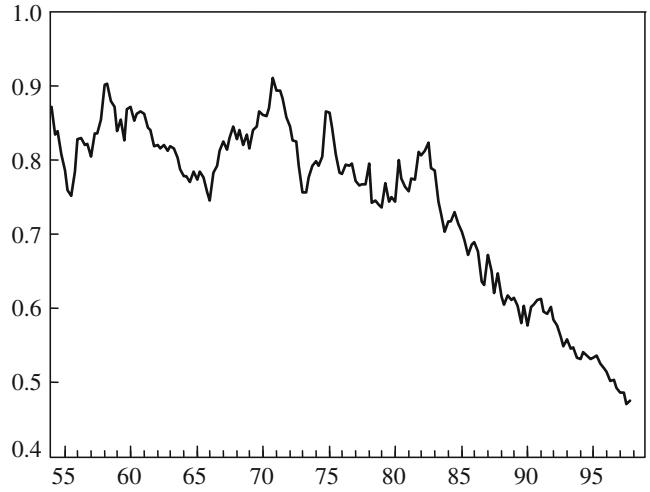
Motivated by the empirical difficulties described above, researchers have examined a number of alternative approaches to modelling inventory behaviour. One, the socalled 'stockout-avoidance' model, provides a rigorous microfoundation for the target stock. Building on Karlin and Carr (1962), Kahn (1987, 1992) considers a firm that faces a non-negativity constraint on its inventories, and must commit to production and pricing decisions each period before observing potential sales, or 'demand' x_t. Consequently, sales equal the minimum of x_t and the stock available $h_{t-1} + y_t$. If we let F denote the distribution function for x, profit maximization implies

$$p_t(1 - F(h_{t-1} + y_t)) - c_t + \beta E_t\{c_{t+1}\}F(h_{t-1} + y_t) = 0,$$

where p is price and c is marginal cost. Then, if demand uncertainty is multiplicative, for example, and p and c (and hence the markup) are constant, the firm will set $h_{t-1} + y_t$ proportional to expected demand $E_{t-1}\{x_t\}$. In addition, positive serial correlation in demand results in the variance of production exceeding the variance of sales.

Another important implication of this approach is that inventory-sales ratios depend on price–cost markups. Bils and Kahn (2000) show, in a model in which expected sales are increasing in the stock available, that the optimal inventory–sales ratio is a function of the markup and a discount rate $\beta E_t\{c_{t+1}/c_t\}$. They argue that the counter-cyclical behaviour of the inventory–sales ratio implies a counter-cyclical markup, or, equivalently, pro-cyclical marginal cost.

An alternative approach builds on the work of Scarf (1960), who modelled inventory behaviour with fixed ordering costs. Scarf provided conditions under which inventories would fluctuate between a fixed upper and lower bound, which he dubbed 'S' and 's' respectively – hence the moniker (S, s) model. (The conditions, such as i.i.d. orders, are quite restrictive, however.) Caplin (1985) showed that this model implies that the variance of orders exceeds the variance of sales, and Hornstein and Fisher (2000) extended this approach to a general equilibrium setting. Hall and Rust (2000) provide some empirical support for 'generalized' (S, s) behaviour



Inventory Investment, Fig. 1 Inventory-sales ratio, durable goods, USA, 1954–1998. Note: Inventories and sales are in chained 2000 dollars (*Source*: US National Income and Product Accounts. Durable goods inventories are from Table 5.7.6A, and final sales are from Table 1.2.6)

where the two limits depend on the spot price of the good in inventory. While the existence of fixed costs at the microeconomic level is well established, their importance for aggregate inventory behaviour at business cycle frequencies remains a matter of debate.

Inventories and the Great Moderation

Recently attention has again turned to inventory behaviour as a possible explanation for the dramatic reduction in aggregate volatility, which in the United States dates from approximately 1984 (McConnell and Perez-Quiros 2000). Kahn et al. (2002) show that reduced volatility is most pronounced in the durable goods sector, and for production more than for sales. At the same time, that sector has experienced large declines in inventory–sales ratios, as shown in the accompanying Fig. 1, and reduced volatility of inventory investment. They also provide a model in which improved information about demand shocks results in reduced output volatility. While there is much anecdotal evidence of efforts to improve inventory control by techniques such as 'just-in-time' management, there remains nonetheless considerable debate over the importance of inventories in increased aggregate stability.

Inventory Policy Under Certainty

Arthur F. Veinott Jr.

Inventories of raw materials, work-in-process, and finished goods are ubiquitous in firms engaged in production and/or distribution of one or more products. Indeed, in the United States alone, 1982 non-farm business inventories totalled over 500 billion dollars, or about 17 per cent of the gross national product that year. The annual cost of carrying these inventories, e.g., costs associated with capital, storage, taxes, insurance, etc., is significant – perhaps 25 per cent of the total investment in inventories, or about 125 billion dollars. Since the cost of carrying inventories is sizeable, a good deal of attention has been devoted to the problem of determining optimal or near-optimal inventory policies that properly balance the costs and benefits of carrying inventories. Moreover, since a firm's inventories are usually distributed among several facilities, e.g., plants, warehouses, retail outlets, effectively coordinating the inventory policies in multi-facility systems.

This essay has four goals. One is to discuss some of the main motives for carrying and distributing inventories in multifacility inventory systems under certainty. Another is to explain how the form of optimal and/or near-optimal multi-facility inventory policies depend on the particular motive(s) present for carrying and distributing inventories. The third is to outline how the special structure of multi-facility inventory models can be exploited to carry out computations efficiently. The last is to give a brief historical perspective on some of the main

developments in multi-facility inventory policy under certainty.

Since it is usually expensive to carry inventories, efficient firms would not do so without good reasons. Thus, it seems useful to ask what motivates a firm to carry inventories at a facility. For this purpose, it is convenient to differentiate *retailers*, i.e., facilities that face exogenous demands, from *wholesalers*, i.e., facilities that face only endogenous demands. Moreover, we shall assume that each facility produces a single product and that each unit output thereof consumes fixed amounts of the outputs of the other facilities that ship to it. Production at a facility is intended to have a broad interpretation, including procurement and shipments from another facility. There are known multi-period non-negative exogenous demands for the output of each facility in excess of the endogenous demands generated by the other facilities. There are temporally varying production and storage costs at each facility that depend on the respective amounts produced and stored there. The goal is to find production and storage schedules at each facility that minimize the total system cost.

Motives for Retailers to Carry Inventories

Under these circumstances, two of the most significant motives for a retailer to carry inventories are the following.

Scale Economies in Supply

Scale economies in supply occur for several reasons including procurement quantity discounts or set-up costs and production/transportation scale economies. When that is so, it is often economical to produce in a single period to satisfy exogenous and endogenous demands occurring over several periods with the aim of reducing the average unit cost of supply.

Temporal Increase in Marginal Cost of Supplying Demand

The marginal cost of supplying demand in a period is the marginal cost of producing an amount equalling the demand in the period. A temporal increase in the marginal cost of supplying demand may arise in several ways. One is where the demands are stationary and there is a temporal increase in the marginal cost of production. The latter occurs, for example, when raw-materials prices, wage rates, or marginal transportation costs increase. A second is where there is a temporal increase in demand and diseconomies of scale in production. A temporal increase in demand may arise because of long-term growth or seasonality thereof. Production scale diseconomies occur when there are alternate sources of supply, each with limited capacity, or when production at a plant in excess of normal capacity must be deferred to a second shift or to over-time with an attendant increase in unit labour costs.

Motives for Wholesalers to Carry Inventories

Each of the above motives for retailers to carry inventories must be strengthened in order to motivate wholesalers to do likewise. Three significant ways to do this for a wholesaler whose output is directly or indirectly consumed by some retailer are the following.

Inter-Facility Storage-Cost Variations

Inter-facility variations in storage costs are common, e.g., between retailers located on expensive city land and wholesalers located on inexpensive rural land. Such variations, when coupled with one of the motives for retailers to carry inventories, may also motivate wholesalers to carry inventories. To see why, consider the extreme case of a retailer with high enough storage costs to make storage there uneconomical. In that event, the retailer passes its demands on directly to any wholesaler whose output the retailer consumes – effectively making the wholesaler a retailer. Then, if either of the two motives for retailers to carry inventories is present at the wholesaler, the latter may be motivated to carry inventories. Of course, in the case of the second motive, the demand at the wholesaler is the demand passed on to it by the retailer.

Inter-Facility Variations in Supply Scale Economies

Facility-dependent supply scale economies may motivate wholesalers to carry inventories. For example, if a wholesaler and a retailer are suppliers of a second retailer and there are no production costs at either retailer, then scale economies in production at the wholesaler may motivate it to carry inventories for the second retailer.

Inter-Facility Variations and Temporal Increase in Marginal Cost of Supplying Demand

Inter-facility variations in the marginal cost of supplying demand arise because of inter-facility variations in demands or production/transportation costs, capacity limitations, etc. Such variations, when coupled with a temporal increase in the marginal cost of supplying demand, may motivate a wholesaler to carry inventories for a retailer that consumes its output. This can occur when the retailer's marginal production costs are temporally non-increasing and either there is a temporal increase in the marginal production cost at the wholesaler or there are diseconomies of scale in production at the wholesaler and rising demands at the retailer.

Formulation of Multi-Facility Inventory Problem

In order to see how the different motives for carrying inventories influence the form of desirable inventory policies, it is necessary to formulate the problem more precisely. To that end, consider a collection of *facilities*, labelled 1,. . ., *f*, each producing a single product. Facilities can be interpreted in many ways, e.g., as plants, warehouses, retail outlets, machines in a plant, etc. the facilities are linked by the fact that the production of each unit at facility *j directly consumes* $e^{ij} \geq 0$ units of the output of facility *i*. The time-lags in shipments between facilities are negligible, i.e., production at facility *j* in a period consumes output at other facilities that may be produced at those facilities either before *or during* the period. There is a given exogenous non-negative demand d_{jt} in period $t = 1,\ldots, p$ for the ouput of facility *j*. The demands at each facility in each period are met as they occur. There is a real-valued cost $c_{jt}(w)$ (resp., $h_{jt}(w)$ of producing (resp., storing) $w \geq 0$ in (resp., at the end of) period *t* at facility *j*. The cost of producing *w* units at facility *j* in a period also includes the costs of transporting e^{ij} w units of the output of each facility *i* to facility *j* in that period. We can and do assume without loss of generality that all $c_{jt}(0) = h_{jt}(0) = 0$. Let x_{jt} and y_{jt} be the respective amounts produced in and stored at the end of period *t* at facility *j*. Let $x_t = (x_{jt})$, $y_t = \left(y_{jt}\right)$ and $d_t(d_{jt})$ be respectively the *f*-element column vectors of *production. inventory and demand schedules in period t*, and let $x = (x_t)$, $y = (y_t)$ and $d = (d_t)$ be the $f \times p$ matrices of *p-period production, inventory and demand schedules*. Assume that $y_0 \equiv y_p \equiv 0$. The net production at each facility that is available to satisfy exogenous demands in, or to store at the end of, period *t* is $(I - E)x_t$ where $E \equiv (e^{ij})$ is the *consumption matrix*. The problem is to find a *production and storage schedule* $z = (x, y) \geq 0$ that minimizes the *cost*

$$\sum_{j,t} \left[c_{jt}\left(x_{jt}\right) + h_{jt}\left(y_{jt}\right)\right] \tag{1}$$

subject to the *stock-conservation constraints*

$$(I - E)x_t + y_{t-1} - y_t = d_t, \quad t = 1, \ldots, p. \tag{2}$$

Facility Network

Associated with the consumption matrix *E* is a *facility network* **F** whose nodes are the facilities and whose arcs are the ordered pairs $i \to j$ of facilities *i, j* for which $e^{ij} > 0$. There is no loss of generality in assuming that **F** is *connected*, i.e., there is an undirected path from each facility to each other facility. For if not, the problem can be solved separately for the set of facilities in each connected component, i.e., maximal connected subnetwork, of **F**.

Facility *j directly* (resp., *indirectly*) *consumes* the output of facility *i* if there is a chain, i.e., directed path, from *i* to *j* with exactly one arc

(resp., two or more arcs). Assume throughout that the facility network is *circuitless*, i.e., no facility directly or indirectly consumes its own output.

Several practical examples of circuitless facility networks are also *trees*, i.e., there is a unique simple path between each pair of facilities. Among the common special cases of trees are assembly, distribution, assembly-distribution, star and series networks. *Assembly* (resp., *distribution*) networks are rooted trees in which all arcs are directed towards (resp., away from) a distinguished facility called the root. The root is the facility at which final assembly of all products takes place in assembly networks and is the ultimate source of all product in distribution networks. *Star* networks are rooted trees in which all arcs are incident to the root, and so are assembly-distribution networks. *Series* networks are chains and so are at once assembly and distribution networks. Finally, *assembly-distribution* networks are rooted trees in which the root facility divides the tree into two subtrees, one an assembly network and the other a distribution network, both sharing the root facility. In trees, we can and do assume without loss of generality and without further mention that all products are measured in common units, i.e., $e^{ij} = 1$ for all arcs $i \to j$.

Linear Costs

In this section, we consider the multi-facility inventory problem in its simplest setting, namely, where there are neither economies nor diseconomies of scale, so the cost function (1) is linear. This allows temporal increases in unit production costs and interfacility variations in unit storage or production costs. The former may motivate retailers to carry inventories and, when coupled with one of the latter, may motivate wholesalers to do likewise.

Extreme Schedules of Totally-Leontief-Substitution Systems

The problem is a totally-Leontief-substitution system. Moreover, at least one optimal schedule is an extreme point of the set of feasible schedules, and each extreme schedule satisfies

$$y_{j,t-1}x_{jt} = 0 \tag{3}$$

for $1 \le j \le f$ and $1 \le t \le p$, i.e., facility j produces in period t only if that facility has no entering inventory in the period. This is so because production at a facility in a period and storage there in the previous period are, in the terminology of Leontief-substitution systems, 'substitute' activities, and extreme schedules in such systems do not admit substitute activities. The condition (3) assures that whenever a facility produces, it satisfies all the endogenous and exogenous demands for its output in an interval of periods. Thus, there is no 'lot splitting', i.e., the endogenous demand at one facility created by production at another facility in a period is entirely satisfied by production at the first facility in a *single* (no later) period. In this sense, each facility produces in 'larger' lots than do its followers.

Dynamic-Programming Computation of Optimal Dual Prices

Moreover, the optimal dual price C_{jt} associated with the stock-conservation constraint for facility j in period t is the minimum cost of satisfying a unit of demand at facility j in period t. It can be shown that the C_{jt} satisfy, and can be calculated from, the dynamic-programming recursion

$$C_{jt} = \min\left(h_{j,t-1} + C_{j,t-1}, c_{jt} + \sum_{i \to j} e^{ij} C_{it}\right) \tag{4}$$

for $1 \le j \le f$ and $1 \le t \le p$ where c_{jt} and h_{jt} are respectively the unit product and storage costs at facility j in period t and $C_{j0} \equiv h_{j0} \equiv 0$. Equation expresses the fact that the optimal way to satisfy a unit of demand at facility j in period t is to choose the cheaper of two options. One is to provide a unit of product at facility j in period $t-1$ as cheaply as possible and store it for one period. The other is to produce a unit at facility j in period t, thereby consuming e^{ij} units from each facility i in that period with those units being provided as cheaply as possible. Observe that it is optimal to produce a facility j in period t if and

only $C_{jt} \leq h_{j,t-1} + C_{j,t-1}$,independently of the demand schedule d.

Once the optimal periods in which to produce each product are found, the desired optimal production schedule is obtained inductively as follows. Suppose the optimal production schedules $\mathbf{x}^j = (\mathbf{x}_{jt})$ have been found for all facilities j that directly consume the output of facility i. Then, if it is optimal for facility i to produce in period t and next in period $u + 1$, it follows from (2) and (3) that x_{it} can be calculated recursively from

$$\mathbf{x}_{it} = \sum_{k=t}^{u} d_{ik} + \sum_{i \to j} e^{ij} \sum_{k=t}^{u} \mathbf{x}_{jk}. \qquad (5)$$

Form of Optimal Production Schedule

To sum up, some optimal schedule is extreme, and so a facility produces in a period only if the facility has no entering inventory in the period. If the consumption matrix and demand schedule are integer, then so is each extreme schedule. Optimal production at a facility in a period is a nondecreasing linear function of the present and future demand at the facility and all facilities that consume its output.

Running Time

The running time of this dynamic-programming algorithm is $O(f^2p)$ in general networks and falls to $O(fp)$ in planar networks, the last because the number of arcs in such networks does not exceed three times the number of nodes. Of course trees, and in particular. assembly-distribution networks, are planar, so the improved running time applies in such networks.

Nonlinear Costs

The algorithm given above for solving the problem with linear costs is also useful when the costs are nonlinear. This is because many methods for solving problems with nonlinear costs, e.g., branch-and-bound, gradient methods, etc., entail solving a sequence of linear-cost problems, each of which can be solved in linear time by the recursion (4).

Concave Costs

In this section we generalize the linear-cost multi-facility inventory problem discussed in Section Linear Cost to allow economies-of-scale by requiring the cost function (1) to be concave. Then the marginal costs of production and storage fall respectively the more one produces and stores. Since the class of additive concave cost functions contains the linear ones, all motives for carrying inventories at retailers and wholesalers with linear cost functions remain in force in this section. Beyond these, the introduction of scale economies in this section provides an added motive for carrying inventories at retailers. This fact, when coupled with either inter-facility variations in storage or production costs, both of which are allowed in this section, provide additional motives for carrying inventories at wholesalers.

Extreme Schedules

As for the case of linear costs, if the minimum is attained, it is attained at an extreme schedule and so satisfies (3). However, because of the scale economies, optimal production is no longer linear in demand. For that reason, the dynamic-programming recursion (4) no longer solves the problem.

Dynamic-Programming Algorithm for Series Networks

However, there is a polynomial-time dynamic-programming algorithm for finding an optimal schedule in series networks in which facility f is the only retailer. To describe the algorithm, observe first that on iterating a representation like (5) of any extreme schedule $z = (x,y)$, that the sum $y_{i,t-1} + x_{it}$ of the initial inventory and production at facility i in period t equals the sum $d^{jl} \equiv \sum_{k=j}^{l-1} d_{jk}$ of the demands at facility f in periods $j,\ldots, l-1$ for some $t \leq j < l$. Let $C_{it}(d^{jl})$ be the minimum cost of satisfying the demands at facility f in periods $j,\ldots, l-1$ from the stock d^{jl} available at facility i at the beginning of period t. Then the $C_{it}(d^{jl})$ can be calculated from the dynamic-programming recursion.

$$C_{it}(d^{jl}) = \min_{\substack{j \le k \le l \\ t<k}} l\left[c_{i+1,t}(d^{jk}) + C_{i+1,t}(d^{jk}) + h_{it}(d^{kl}) + C_{i,t+1}(d^{kl})\right]$$

for $1 \le i < f$, $1 \le t \le j < l \le p + 1$ and $t < p$, together with fairly obvious boundary recursions where $i = f$ or $t = p$. This recursion expresses the fact that the minimum cost of satisfying the demands at facility f in periods $j,\ldots, l-1$ from the stock d^{jl} on hand after production at facility i in period t is attained by dividing the stock d^{jl} into two parts, d^{jk} and d^{kl}, the former being sent to facility $i + 1$ for production in period t and the latter being stored at facility i for one period.

Running Time

The running time of the algorithm is $O(fp^4)$, which is $O(p^3)$ times that for the linear-cost case. If also the production and storage costs at each facility are respectively temporally non-increasing and non-decreasing in the facility are respectively index, the running time improves to $O(fp^3)$ because some optimal schedule is 'nested' in the sense to be defined shortly. For the case of a single facility, the running time drops further to $O(fp^2)$.

General Networks

The above algorithm can be generalized to arbitrary distribution networks, but the computational effort grows exponentially with the number of retailers. For that reason, we do not discuss this possibility. For the special case of one-warehouse multi-retailer networks (i.e., star distribution networks in which the root facility is a warehouse and the other facilities are retailers) in which the production and storage costs at the warehouse are respectively linear plus a set-up cost and linear, there is an algorithm for solving the problem whose running time is linear in the number of retailers, but exponential in the number of periods. However, no polynomial-time algorithm has been found for the general multi-facility problem, even for star networks.

Effective Heuristics

This suggests the possibility that optimal schedules may be too difficult to find and that heuristics may instead be necessary. One heuristic for distribution systems is to optimize over the subclass of *nested* schedules, i.e., schedules x satisfying (3) for which $x_{it} > 0$ implies $x_{jt} > 0$ for each facility j that directly consumes the output of facility i. There is a dynamic-programming algorithm for finding an optimal nested schedule in a distribution system in $O(fp^3)$ time. Unfortunately, optimal schedules need not be nested – even in one-warehouse multi-retailer networks – because, for example, it may be optimal for a retailer with low demands to order less frequently than the warehouse. However, the nested-schedules heuristic can be adapted to give a reasonably effective heuristic when the demand schedules at each facility are *proportional* to one another.

Stationary Case with Set-Up Production and Linear Storage Costs

It turns out that there is an extraordinarily effective heuristic for the stationary (demands and costs) continuous-time infinite-horizon version of the problem in which there is a set-up production cost and a linear storage cost at each facility. The *effectiveness* of a heuristic for this problem is 100 per cent times the ratio of the infimum of the average cost per unit time over all policies to the average cost per unit time incurred by the heuristic.

The heuristic for this problem decomposes the multi-facility problem into a collection of single-facility problems, one for each facility. In each single-facility problem, there is a demand rate $r > 0$ per unit time, a set-up production cost $K > 0$ and a storage cost $h > 0$ per unit stored per unit time. Then one expects that a minimum-average-cost schedule will permit production only when stock runs out, which is the continuous-time analogue of (3). Thus, since the demand rates and costs are stationary, one anticipates that a minimum-average cost schedule will entail producing every $T > 0$ periods an amount equalling the demand rT until the next instance of production. An easy calculation shows that the optimal value of T is given by the celebrated square-root formula $T^o = (2K/hr)^{1/2}$. Now if $T > 0$ is any other production interval for which $2^{-1/2} \le T/T^o \le 2^{1/2}$, then it is easy to show that the effectiveness of the new schedule is at least 94 per cent.

The heuristic for the multi-facility problem is constructed as follows. First, restrict attention to *power-of-two* schedules, i.e., those for which a facility produces only when it runs out of stock, the *production intervals* between successive times that a facility produces are identical, and the ration of the production intervals at distinct facilities is a (possibly negative) integer power of two. It is not difficult to find an expression $C(T)$ for the average cost of a power-of-two schedule $\mathbf{T} = (T^i)$ where T^i is the production interval used at facility i.

The *optimal power-of-two problem* is that of finding $\mathbf{T}$ that minimizes $C(\mathbf{T})$ subject to the power-of-two constraints and $\mathbf{T} \gg 0$. Instead of solving this problem, one next solves the *relaxation* thereof in which the power-of-two constraints are dropped. The relaxation is a minimum-convex-cost dual network-flow problem on a *cost network*. The nodes of the cost network correspond to the chains in the facility network that end at retailers. The arcs in the cost network join each node α to the node β that corresponds to the subchain formed by deleting the first node of the chain that corresponds to α. Denote by $\mathbf{T}^* = (T^{*i})$ the optimal solution of the relaxation of the optimal power-of-two problem. Remarkably and most important, the minimum average cost $C(T^*)$ of the relaxation is a lower bound on the average cost of an *arbitrary* (not necessarily power-of-two) schedule!

The cost-network problem entails reallocating the set-up costs and storage cost rates among the facilities in such a way that with the new cost parameters, each facility i's optimal production interval, when considered as a single-facility problem, is precisely T^{*i}. One then rounds off each T^{*i} to form a power-of-two schedule $\mathbf{T} = (T^i)$ satisfying $2^{-1/2} \leq T^i/T^{*i} \leq 2^{1/2}$ for each i. This assures that the effectiveness of the resulting power-of-two schedule is at least 94 per cent for each facility, and so is at least 94 per cent for the system. A somewhat more complex procedure guarantees that the system effectiveness is at least 98 per cent.

The cost-network problem can be reduced to solving a sequence of maximum-flow problems, each of which splits its predecessor into two smaller subproblems. In special cases, there are even more efficient algorithms. For example, the cost-network problem can be solved in $O(f \ln f)$ time in one-warehouse multi-retailer and assembly networks.

Convex Costs

In this section we discuss the multi-facility inventory problem in the presence of diseconomies of scale by requiring the cost function (1) to be convex. Then the marginal costs of production and storage are non-decreasing in the amounts produced and stored respectively. This allows a temporal increase in the marginal cost of supplying demand, which may motivate retailers to carry inventories.

s-additive Convex Production Cost Function

Here we suppose that the production cost function is *s-additive convex*, i.e., $c_{ji}(w) = S_t c^j(w/s_t)$ for $w \in R$ with $c^j(\cdot)$ being a $+\infty$ or real-valued convex function on the real line and s_t being a positive *scale parameter* for each t. Also assume that there are no direct storage costs, so $h_{jt} \equiv 0$, but that it is possible to represent any such costs by absorbing them in the production costs with an appropriate choice of the scale parameters s_t, e.g., as we show below for capital costs. In particular, there is a motive to carry inventories at retailer j in period t if the marginal cost $\dot{c}(d_{jt}/st)$ of supplying the demand there in that period is less than that in some subsequent period k, say. This implies, and provided $\dot{c}^j(w)$ is strictly increasing in w, is implied by $d_{jt}/S_t < d_{jk}/S_k$. The last is so if $Od_{jt} \leq d_{jk}$ and $s_t \geq s_k$ with at least one inequality being strict. This formulation is rich enough to be useful because it provides for certain storage costs and allows temporal variations in the marginal cost of supplying demand, and yet is simple enough to admit a graphical solution.

Positively-Homogeneous Convex Production Cost Function

As a particular example, suppose that the present value of the production cost at facility j is

positively homogeneous of degree $q + 1 \geq 1$, i.e., $c_{jt}(w) = \beta^t |w|^{q+1} c_j$ for some discount factor $\beta > 0$ and $c_j > 0$. This accounts for the cost of capital invested in inventories. Then the production cost is *s*-additive convex with scale parameter

$$s_t = (1 + \rho)^{t/q} \tag{6}$$

where $\beta \equiv 1/(1 + \rho)$ and 100ρ per cent is the interest rate. Observe that if $\rho = 0$, then $s_t = 1$ for all t. If instead $\rho > 0$ (resp., $\rho < 0$), then s_t expands (resp., contracts) geometrically with the precise rate being greater than, equal to or less than $|\rho|$ according as $0 < q < 1, q = 1$ or $1 < q$.

Taut-String Solution of the Single-Facility Problem

Now return to the case of an arbitrary *s*-additive convex production cost function. Then the fundamental result for the single-facility problem is the Invariance Theorem which asserts that there is an optimal production schedule that is independent of the function $c \equiv c^1$, though it does depend on the demand schedule and scale parameters. Because of the Invariance Theorem, it suffices to solve the problem for any single strictly-convex function *c*. It turns out to be felicitous to put $c(w) = (w + 1)^{1/2}$ (which is strictly convex) because the problem can then be solved graphically. To see this, observe that the cost of a schedule (x,y) is then the length $\sum_t \left(x_t^2 + s_t^2\right)^{1/2}$ of the shortest polygonal path in the plane passing in order through the points (S_t, X_t) for $t = 0,\ldots,$ p where $1\ S_t \equiv \sum_1^t s_k$ and $X_t \equiv \sum_1^t x_k$, or equivalently, the length of a taut string passing in order through those points. Now consider the taut string passing through the points $(S_0, D_0) = (0, 0)$ and (S_p, D_p), and lying above the points (S_t, D_t) for $t = 1,\ldots, p - 1$ where $D_t \equiv \sum_1^t d_k$.Let (S_t, X_t^*) be the coordinates of the taut string corresponding to S_t for each t. Then (X_t^*) is the least concave majorant of (D_t). Since the feasible cumulative production schedules are non-decreasing and majorize (D_t), it follows from the Invariance Theorem and the non-negativity of the demands that $x_t^* = X_t^* - X_{t-1}^* \geq 0$ is optimal for all t and convex c.

The above *taut-string solution* has the property that during any interval of periods in which inventories are held, optimal production is proportional to the scale parameter. Thus, if the scale parameter rises (resp., falls) over the interval, then so does optimal production. In particular, if the scale parameter is given by (6), then optimal production rises or falls geometrically in the interval according as $\rho > 0$ or $\rho < 0$.

The taut-string solution has another property that plays an important role in solving the multi-facility problem, namely, it is positively homogeneous of degree one in the demand schedule. This is easily seen because, by the Invariance Theorem, there is no loss in taking the production cost function to be positively homogeneous.

Proportional Demand Schedules

In order to obtain a tractable solution to the multi-facility problem, we shall assume that the demand schedules at each facility are *proportional*, i.e., there is a *p*-period row vector *d** of nonnegative demands and a column vector δ of non-negative *demand levels* associated with the *f* facilities such that $d = \delta d^*$. Thus the demand schedules at each facility exhibit a common pattern of temporal variation. This includes the cases in which the demands are facility-dependent and stationary, or there is a single retailer. Let π be the column vector of amounts that would have to be produced at the *f* facilities to satisfy the column vector δ of exogenous demands at those facilities. Evidently, $\delta = (I - E)\pi$. Let *x** be the (row) optimal production schedule (the tautstring solution) for the *standard* single-facility problem with demand schedule *d**, and let *y** be the corresponding row vector of inventories.

Optimal Schedule for the Multi-Facility Problem

Let **x** and **y** be the $f \times p$ matrices of optimal *p*-period production and inventory schedules at each facility. By combining the above results and the Invariance Theorem, one finds that

optimal *p*period production and inventory schedules for the multifacility problem are given by the pair of rank-one matrices

$$z = (x, y) = (\pi x^*, \delta y^*).$$

Thus, the optimal production and inventory schedules at different facilities are proportional to one another. Indeed, inventories are held at a retailer only to satisfy its exogenous demands, and are proportional to its demand level. No inventories are held at a facility to satisfy endogenous demands there because the production schedules at the facilities consuming the output of the given facility already smooth out the demand schedules. Hence, *just-in-time* scheduling, i.e. holding no inventories, is optimal at all wholesalers. This is consistent with the absence of either of the motives for wholesalers to hold inventories, namely, interfacility variations in storage costs or marginal costs of supplying demand. The last is fundamentally because there are no inter-facility variations in the scale parameters of the production cost functions and the demand schedules at each facility are proportional. Hence, up to a monotone transformation, all facilities exhibit the same temporal variation in their marginal costs of supplying demands.

Running Time

The optimal schedule x^* for the standard single-facility problem can be found in $O(p)$ time. The vector π can be computed in $O(f^2)$ time in general networks and in $O(f)$ time in planar networks. Thus, $\mathbf{z}$ can be found in $O(f^2 + fp)$ time in general networks and in $O(fp)$ time in planar networks.

Historical Perspective

The study of inventory problems has influenced and been influenced by the tools available for their analysis. The seventy odd years since the first economic-lot-size model was proposed by F.W. Harris (1915) can be reasonably divided into three phases. During the period 1915–1950, attention was focused mainly on the formulation and closed-form solution of relatively simple single-facility models under certainty using the calculus. The period 1950–1965 saw the introduction of dynamic, linear and nonlinear programming methods for the characterization and computation of optimal policies in the presence of certainty and/or uncertainty, again largely for single-facility problems.

During the period since 1960, attention has gradually shifted towards the problem of coordinating the inventory policies at several interrelated facilities. It was realized that many such multi-facility inventory problems could be formulated as dynamic nonlinear network-flow or Leontief-substitution models and that the special structure of these models permitted a unified theory of inventory control to begin to emerge. A qualitative theory of mathematical programming, namely, lattice programming and substitutes, complements and ripples, was developed to give a simple general method of studying the qualitative variation of optimal inventory policies with the problem parameters. The realization that optimal policies for multi-facility systems could be extraordinarily complex to compute and/or implement, coupled with the successful use of heuristics in several areas of combinatorial optimization, led to the development of provably effective and efficient heuristics for multi-facility inventory problems. The rapid recent development of computational geometry will no doubt stimulate further progress on multi-facility systems as we begin to be able to combine the symmetries of continuous space-time models with the computational efficiency of discrete space-time models. We close by summarizing the main sources for the material in this entry. Motives for retailers to hold inventories are discussed by Arrow (1958) and Scarf (1963). The treatment of the multi-facility linear-cost problem is taken from Veinott (1969) who applied Dantzig's (1955) theory of Leontief-substitution systems. Earlier ad hoc treatments of the single-facility linearcost case are reviewed by Arrow (1958). Clark and Scarf (1960) solved the series-network problem with stochastic demands at the last facility and linear costs at all facilities except the first one.

I

The results for the single-facility concave-cost problem begin with Wagner and Whitin (1958). The characterization of the extreme schedules for the multi-facility problem is due to Zangwill (1966), though the development using Leontief-substitution systems is taken from Veinott (1969). The algorithm for series networks is due to Zangwill (1969). The nested-schedules algorithm for distribution systems comes from Veinott (1969). Love (1972) gave conditions assuring that the last algorithm finds an optimal schedule for series networks. Erickson et al. (1981) have recently encompassed an improvement of the above algorithms for series networks in a send-and-split method for finding minimum-concave-cost network flows. This result reveals that the polynomial running time of these algorithms for series networks is explained by the planarity of the corresponding network-flow problem. The results on the 94 per cent and 98 per cent effective power-of-two heuristics for the multi-facility problem with stationary demands and costs are due to Roundy (1985a, 1986). He employed an algorithm of Maxwell and Muckstadt (1985) to solve the cost-network problem. The effectiveness of a 'nested-schedules' heuristic with proportional demand schedules is discussed by Roundy (1985b).

The Invariance Theorem for the single-facility convex-cost problem is due to Modigliani and Hahn (1955) for the case of stationary costs. The generalization to non-stationary costs and the taut-string solution are due to Veinott (1971) who encompassed this example in a theory of Invariant Network Flows. The results for the multi-facility convex-cost problem with proportional demand schedules are due to recent research of the author.

Investment (Neoclassical)

Robert M. Coen and Robert Eisner

Abstract

Investment is capital formation – the acquisition or creation of resources to be used in production. As such, it captures the production side of intertemporal consumption/ savings decisions. This entry focuses on neoclassical approaches to the study of investment. Theoretical and empirical issues are discussed.

Investment is capital formation – the acquisition or creation of resources to be used in production. In capitalist economies much attention is focused on business investment in physical capital, such as buildings, equipment and inventories. But investment is also undertaken by governments (see public capital), nonprofit institutions and households, and it includes the acquisition of human and intangible capital as well as physical capital. In principle, investment should also include improvement of land or the development of natural resources, and the relevant measure of production should include non-market output as well as goods and services produced for sale.

Thus, acquisition of an automobile by government or households is as much investment as acquisition of an automobile by a business firm. The car is used in all cases for the production of transport services. Similarly, government construction of roads, bridges and airports is as much investment as business acquisition of trucks and planes. Expenditures for research and development are investment whether undertaken by business, government or nonprofit universities. And, most important, education and training, wherever undertaken, are major forms of investment in human capital.

There is a widespread mythology that investment is good and the more investment the better. But investment may be good or bad and there may be too much as well as too little.

Classical and neoclassical economists have stressed the role of investment in providing for the future. Maintaining the current level of output requires keeping up the existing means of production. Economic growth, or the increase in the rate of output, is then seen as depending considerably on the acquisition of additional means of production, that is, investment in excess of the wearing away or depreciation of existing capital. Investment may also contribute to higher output where the new capital 'embodies' new and improved technology. That investment will contribute to economic growth presupposes, however, that the additional capital is useful. It must have a positive net product, which is to say that the additional capital must contribute more to future production than the value of the resources used to create it.

How far one should go in allocating resources to investment depends upon our preferences for current consumption versus future consumption, or our preferences between our own consumption and that of our children and grandchildren. It also depends on the production function, that is, the terms under which additional capital can be converted into additional future output. It would hardly seem desirable to sacrifice 100 dollars of current consumption to produce 100 dollars of capital that would result in future production of only 90 dollars. The notion that this is not a relevant issue stems from the assumption that profit-seeking entrepreneurs would not freely undertake investment in which the costs are greater than the returns. It is not always perceived, however, that where governments offer subsidies

or 'tax incentives' for businesses to undertake investment that would not otherwise seem profitable, such unproductive capital formation is exactly what may be expected.

A second major role for investment has been seen in the achievement and maintenance of full employment. This requires that aggregate investment plus aggregate consumption equal the total output that would be produced if all individuals who wish to work could find employment. Investment may then be inadequate not only in failing to provide sufficient resources for future production, it may also be inadequate if it is insufficient to bring about the full utilization of existing resources. This latter problem has received major attention as a consequence of the work and influence of John Maynard Keynes (1936).

Another way of stating the condition necessary for full employment is that aggregate investment must equal aggregate saving out of the full-employment level of income. In national income accounts, measured investment and saving are always identically equal, owing to the identity of output and income, which, apart from receipts from abroad, is earned only from production. That part of income not spent on consumption is saved. But that part of production not purchased by consumers must be acquired (or kept) by producers and hence is investment, though not necessarily intended investment. If we designate Y as income and output, C as consumption, S as saving and I as investment, we then have $S = Y - C = I$.

While realized investment is thus identically equal to saving, investment and saving may be more or less than investment demand, that is, intended investment. If investment demand is less than saving at the current level of income, producers will find that they cannot sell all that they produce. They will accumulate undesired inventories of finished goods (unintended investment in inventories), which should lead them to reduce production. Reduced production means less income and hence less consumption and saving. A shortfall of investment demand in relation to saving therefore brings on a cumulative reduction of output and income until saving and investment are brought down to equality with the lesser investment demand. Insufficiency of investment demand has been identified with depression and recessions and tendencies towards chronic unemployment. Stimuli to investment, such as reductions in tax rates on income from capital, have thus seemed in order to bring investment demand up to the levels of saving that would be forthcoming with full employment. Conversely, excessive levels of investment demand can create inflationary pressures, calling for policies that would restrict investment.

These Keynesian perceptions as to the costs and benefits of investment are startlingly different from those of the classical models – old and new – which assume, implicitly or explicitly, that the economy is operating at full employment and full utilization of resources. In the classical models, more current production of capital must mean less current production of consumption goods and services. And more consumption now must mean less current investment and less output and consumption in the future.

In an economy with substantial unemployed resources, however, more investment need not and probably will not bring less consumption. Expenditures for additional investment will rather constitute additional incomes for their recipients, and this income will in turn largely be spent on increased consumption. Thus the production of consumption goods and services will increase rather than decline. And more consumption may bring about more investment, as producers see a need for additional capital to increase the output of consumption goods and services.

Classical and Keynesian views also differ on the principal mechanism by which intended investment and saving are equated. In the classical view, changes in the rate of interest are presumed to perform this task. Investment demand is thought to be negatively related and very sensitive to the rate of interest, which is the cost of borrowing funds to finance capital spending. If investment demand is smaller than saving at the full-employment level of incomes, the classical analysis holds that the excess of funds in the credit market will depress interest rates, thereby inducing increases in investment demand (and possibly reductions in saving as the interest earned by savers falls) until intended investment and saving

are equal. Thus, no change in the level of economic activity (output) need occur as in the Keynesian analysis. The Keynesian view of the equilibrating process has interest rates playing a smaller role than changes in output, because investment demand is thought to be relatively insensitive to interest rates, being dominated instead by producers' expectations of future demand for their products. Even if the investment demand were sensitive to interest rates, expectations could be so pessimistic that, even if the rate of interest were to fall to zero, there would be insufficient investment demand.

Empirical studies have attempted to measure the influence of interest rates, taxes and expectations of future demand on investment decisions. Producers are presumed to acquire capital to increase their expected profits. The profitability of additional capital depends on its cost, on its expected productivity and on expectations on the price at which additional output can be sold. On the assumption that output is a fixed, 'well-behaved' function of capital and labour (strictly concave, with declining partial derivatives of output with the respect to capital and labour and positive cross-partial derivatives), producers will acquire capital to the point where its declining marginal product equals its cost. This will then define both the desired, or equilibrium, capital–labour ratio and capital–output ratio. With the supply of labour and the rate of output fixed and no change in the relative price of capital and labour, investment in equilibrium will be equal to depreciation, or what is necessary to maintain the existing capital stock, and net investment will be zero. Positive net investment will then stem from increases in the demand for output or reductions in the relative price of capital. Increases in output will generate investment demand to maintain the equilibrium capital–output ratio. A reduction in the cost of capital would generate investment in order to increase the capital–labour and capital–output ratios. In either case, maintaining increased amounts of capital will generate further investment to cover increased depreciation.

In general, the desired capital stock may be written as:

$$K^* = f(p, c, Y^*), \tag{1}$$

where p is the price of output, $c = q[i - (\dot{q}/q) + d]$ is the rental price or user cost of capital, q is the supply price of capital goods, i is the opportunity cost of capital, d is the rate of economic depreciation and Y^* is desired output. If firms minimize expected costs of producing an exogenously given or expected output Y, then the wage rate, w, would be substituted for p. The rental price, or user cost of capital, c, is the cost per period of holding and maintaining one unit of capital. In the absence of taxes, it is the price of capital goods multiplied by the sum of the real interest rate and the rate of economic depreciation. The former measures the opportunity cost in terms of forgone net earnings from lending or otherwise investing money, plus the capital loss (or minus the capital gain) associated with changing prices of capital goods.

Building on this neoclassical theory of the firm developed by Haavelmo (1960), and assuming a Cobb–Douglas production function with elasticity of output with respect to capital, b, Jorgenson (1963, 1967) arrived at a demand function for capital with a particular form that has been employed in a large number of influential studies:

$$K^* = b(p/c)Y^*. \tag{2}$$

With an implicit unitary elasticity of K^* with respect to c, this formulation implies strong effects of monetary policy, via the rate of interest, and of tax policy so far as, by accelerated tax depreciation, investment subsidies or exclusion of capital gains from taxation, it affects the value of c (see below).

The more general constant-elasticity-of-substitution (CES) production function may be used to generate a demand for capital having the form:

$$K^* = h(p/c)^s (Y^*)^r, \tag{3}$$

where s, the elasticity of substitution between labour and capital, is the critical elasticity of demand for capital with respect to the relative price of capital, and r is the elasticity of demand for capital with respect to output. The elasticity, r,

will be greater than, equal to, or less than unity as the returns to scale are decreasing, constant or increasing.

If relative prices are constant, or if technology requires that capital and labour be used in fixed proportions (in which case the elasticity of substitution is zero), then with constant returns to scale, desired capital is proportional to the demand for output. This form of the demand for capital leads to the 'acceleration principle', according to which net investment demand, arising from a desire to change the stock of capital, depends not on the level of demand for output, but on the *change* in demand for output (Clark 1917). To induce firms to invest (acquire more capital), demand for output must be expected to rise. Both the original formulation by Jorgenson of the demand for capital (2) and the more general formulation (3) underly *a* 'flexible accelerator', where the desired capital–output ratio is not constant but depends on prices and on the scale of output and, as seen below, investment is subject to a distributed lag process (Koyck 1954) affected by adjustment costs and the dynamic process governing the formation of expectations of future variables (Eisner and Strotz 1963; Helliwell and Glorieux 1970; Lucas 1976; Eisner 1978).

Many early econometric studies of investment behaviour tested the accelerator in various forms, but generally they did not allow for effects of prices on the desired capital–output ratio, which is the hallmark of Jorgenson's neoclassical approach. The major competing hypothesis was that investment depends on the level of profits, on the grounds that realized profits measure expected profits, or that capital market imperfections cause firms' capital expenditures to be constrained by the flow of internal funds (Meyer and Kuh 1957). Reviews of these earlier investigations are found in Eisner and Strotz (1963) and Jorgenson (1971). The practice in recent studies has been to capture profit expectations by including expectations of the major determinants of profits, namely, sales, prices and wages, or to approximate them by stock market valuations of firms. The flow of internal funds may play some role in investment decisions, not as a determinant of the desired capital stock but as a factor influencing the speed of adjustment of capital (Coen 1971).

To study the effects of tax policy on demand for capital, the rental price can be generalized to incorporate parameters of the tax system. For example, the after-tax cost of holding one unit of capital would be:

$$c = q\left[(1-uv)i-(1-uw)\left(q^{j}/q\right)+d\right]\times[1-k-uz]/(1-u) \tag{4}$$

where u is the rate of taxation of business income; v is the proportion of the opportunity cost of capital (such as interest, dividends and forgone earnings) that is tax deductible; w is the proportion of capital gains and losses effectively taxed; k is the effective rate of the investment tax credit or subsidy; and z is the present value of the tax depreciation expected from a dollar of investment (Hall and Jorgenson 1967).

It can be seen, in this definition, that higher values of v, k and z (from accelerating tax depreciation) reduce the value of c, as does a higher value of w, provided that capital goods prices are expected to rise. The value of c would also be lowered by decreasing the rate of interest or other measure of the opportunity cost of capital. A higher rate of inflation of capital goods prices has two opposing effects on c. In so far as higher inflation reduces the real after-tax opportunity cost of capital, it reduces c. However, if tax depreciation is based on the historical cost of assets rather than on replacement costs, inflation reduces the present value of tax allowances, z, and thereby raises c (Feldstein 1982). Finally, we may note that changes in the general rate of business taxation are ambiguous in their effects on c. If v and w are unity, and if the opportunity cost of capital is unaffected by a change in the business tax rate, then a decrease in u will reduce, leave unchanged or increase c as the present value of tax allowances on a unit of investment (including the investment credit) is less than, equal to or greater than the present value of economic depreciation (Hall and Jorgenson 1971). But then, going back to Eq. 1, the effect of any of these parameters on K^* depends upon the elasticity of the latter with respect to c.

The desired capital stock does not in itself indicate the rate of investment, which is the rate of replacement of existing capital plus the rate of net additions. Both entail a combination of financial considerations and costs of adjustment, which will in turn relate to costs of acquiring information necessary to decisions, costs of planning and the supply function for capital goods, all filtered through the expectations of agents.

If adjustment costs are an increasing function of the rate of investment, it will generally prove optimal not to adjust capital to the desired level immediately, but instead to distribute changes in the capital stock over time (Eisner and Strotz 1963). The speed of adjustment of capital to changes in its desired or equilibrium level may depend on the causes and magnitudes of the changes. An increase in the demand for output may generate investment with all due speed as expectations become firm with regard to the permanence of the increased demand. If, however, the increased demand for capital is due to a fall in its relative price (because, let us say, of a reduction in the rate of interest), thus generating a demand for more durable and hence more substantial and expensive capital, the rate of investment may be slowed by the availability of existing capacity sufficient for current production. These considerations underlie the 'putty-clay' model in which the capital–labour ratio can be varied on newly installed capacity but cannot be altered on existing capacity. A demand for additional housing services will bring on investment in housing as rapidly as cost considerations permit. A lower rate of interest, causing substantial investment in more durable brick houses to replace less durable houses of wood or straw, would cause the rate of investment to increase only as existing houses of wood and straw wear out and are replaced.

Investment equations should thus in principle involve separate distributed lag responses to changes in relative prices and to changes in output. They should also admit the possibility that the lag distribution is not fixed and may vary with other economic parameters and the expectations function.

A logarithmic transformation of Eq. 3 yields

$$\ln K^* = \ln h + \mathrm{s} \ln (p/c) + \mathrm{r} \ln Y. \tag{5}$$

Putting this in first difference form, we have:

$$\Delta \ln K^* = s\, \Delta \ln(p/c) + r\, \Delta \ln Y. \tag{6}$$

Since the change in the logarithm of capital is the relative change in capital, we may treat the ratio of net investment to existing capital stock as approximately equal to $\Delta \ln K$, which may in turn be written as a distributed lag function of changes in the determinants of desired capital:

$$I_N/K_{-1} = s[q_1(L)\, \Delta \ln(p/c)] + r[q_2(L)\, \Delta \ln Y], \tag{7}$$

where $q_1(L)$ and $q_2(L)$ are lag operators that indeed should be functions of such variables as the rate of interest, and the cost and availability of capital. Then, finally, since investments equal net investment plus replacement, we may write

$$I = I_N + R = I_N + dK_{-1}, \tag{8}$$

where d, the replacement rate, may vary over time.

Estimates of investment functions of this type have often neglected influences of economic variables and expectations on adjustment processes and the replacement rate. Lag distributions are assumed to be of some fixed functional form, and d is assumed to be constant (for evidence that d may not be constant, see Feldstein and Foote 1971; Eisner 1972; Feldstein and Rothschild 1974; Coen 1975).

Where production and lag parameters have not been unduly constrained by a priori specifications, estimates have generally yielded values of s, the elasticity of substitution, considerably less than unity, in some cases not substantially greater than zero (see Eisner and Nadiri 1968; Coen 1969; Lucas 1969; Eisner 1978; Chirinko and Eisner 1982). Lag distributions estimated from time series and cross-section data have usually extended over a number of years (Eisner 1978), and they often have inverted-U shapes. Where a putty-clay formulation has been employed with separate lags on relative prices and output, the

mean lags on prices are typically much longer than those on output (Bischoff 1971).

These findings of small price elasticities of demand for capital suggest some role, but a limited one, for monetary and tax policies in directly affecting the general rate of investment through the rental cost of capital. The long lag distributions on relative prices suggest further difficulties in the use of monetary or fiscal policy for reducing cyclical fluctuations in investment. However, policy impacts may operate not only on the desired capital stock but also on the speed of adjustment of capital.

Repeated changes in tax parameters such as k, the rate of investment tax credit or subsidy, may be used to bring about intertemporal substitution of investment even if the effects on its long-run average are small. Thus, when investment is low, the marginal rate of subsidy, k, might be raised, while if investment were deemed too great, the value of k could be reduced to zero or indeed made negative (an investment tax instead of subsidy). Paradoxically, a fluctuating and uncertain investment subsidy/tax may have substantial effects on investment where permanent subsidies or taxes would not. There is thus an asymmetry between effects of changes in the cost of capital and changes in the demand for output, the effects of which on investment will be proportional to the permanence with which they are perceived (Eisner 1978).

Most investment functions, with their ad hoc, fixed lag distributions and assumptions of static expectations, fail to capture accurately the effects of economic policies on the timing of investment or to distinguish properly between the effects of temporary and permanent policy changes (Lucas 1976). To correct these shortcomings, adjustment costs must be explicitly introduced in the firm's optimization problem, so that instead of there being a desired stock of capital towards which the firm moves in a mechanistic way, there is a desired path of capital accumulation. Along such a path, the optimal rate of investment at each point, including the present, will in general depend on expected relative prices and output over the entire planning horizon.

Obtaining solutions to the firm's dynamic optimization problem under very general specifications of technology and expectations has proven difficult. To make such an approach empirically tractable, strong assumptions are usually made, for example, that the production function is quadratic, that adjustment costs are quadratic, symmetric and separable from the rest of technology (the cost of adjusting capital, for example, does not depend on the quantities of capital and labour currently employed), and that expectations are characterized by relatively simple autoregressive processes.

The critical role in current investment of unobservable adjustment costs and of uncertain, shifting (and generally not directly observable) expectations of the future, stressed by Keynes, has sparked interest in a formulation of an investment function that directly relates demand prices and supply prices of capital. Going back to Keynes's *General Theory,* we have investment undertaken to the point where the expectation of marginal profit on investment (the 'marginal efficiency of investment') is equal to the rate of interest or, alternatively, the present value of expected returns from the marginal investment, using the rate of interest as the discount factor, is equal to the marginal supply price of newly produced capital goods. Building on this, Brainard and Tobin (1968) and Tobin (1969), presented a 'q-theory', which sees investment as a positive function of the ratio, q, of the market value of capital to its replacement cost. The former may in principle be observed in the trading prices of stock shares along with bonded indebtedness of business firms. With proper adjustment for tax considerations, when the value of q is greater than unity, investment will take place because the cost of additional capital will be less than the market evaluation of the present value of returns from capital. Conversely, when q is less than unity, business demand for capital may be better satisfied by acquisitions taking over existing firms and their facilities than by new investment. In general, the rate of investment should be greater the greater the value of q.

Empirical estimation of 'q' investment equations and predictions based on these estimates have not, however, proved very successful (von Furstenberg 1977; Abel 1980; Summers 1981;

Hayashi 1982; Abel and Blanchard 1986). Suggested explanations of the difficulties include the fact that market values of firms may relate to much more than the tangible capital generally included in business investment, and the failure to distinguish marginal and average values of the cost of new capital versus the acquisition costs of existing firms (Chirinko 1986).

Investment decisions are but one element of producers' plans for hiring or acquiring factors of production. Interrelationships between investment demand and demands for other inputs have been a subject of growing interest. Since factor demands are derived from a given production function, they share common technological parameters and may be estimated as a system of demand functions (Coen and Hickman 1970). Such an approach calls attention to effects of investment stimuli that are often overlooked. For example, at a given level of output, the direct impact of an investment tax credit is to reduce the demand for labour, since it raises the relative cost of labour. Employment may eventually be raised, but only if the expansion in aggregate output induced by the increase in investment demand is large enough to offset the adjustment to a higher capital–labour ratio.

Additional interrelationships may arise when capital is not the only factor of production subject to adjustment costs. If labour input is also costly to change, then the rate of investment may depend not only on the desired adjustment in capital stock but also on the desired adjustment in employment (Nadiri and Rosen 1969; Brechling 1975; Epstein and Denny 1983). Furthermore, since a firm must operate on its production function, factor adjustments cannot be entirely independent. If output is exogenously given and there are n inputs, $n - 1$ inputs can be independently adjusted, but the nth is determined by the production function, the level of output, and the quantities of the other inputs (Gould 1969). It may be unreasonable to view the production function as a binding constraint, however, because it is difficult, if not impossible, to measure perfectly all inputs and their utilization rates.

With the development of dynamic optimization models of interrelated factor demands in which various types of capital and other inputs are subject to adjustment costs, and expectations are not treated as static, it is possible to estimate the magnitude of adjustment costs for capital, to see how they affect and are affected by adjustments of other inputs, and to study the impacts of changes in producers' perceptions of the *processes* generating prices, output and policy parameters. As we noted above, this approach necessitates strong restrictions on functional forms to obtain explicit decision rules for accumulation of capital and employment of other inputs (Meese 1980). Where general forms of the production, adjustment cost and expectations functions are assumed and the model cannot be solved completely, it is still possible to estimate the first-order conditions (Euler equations) that implicitly define the evolution of the optimal inputs (Pindyck and Rotemberg 1983; Shapiro 1986). Such estimates do not give a complete account of the dynamics of investment behaviour for any initial conditions and stochastic environment, but they do give insights about differing short- and long-run responses to, say, an unexpected increase in the price of energy starting today versus the same increase beginning 5 years from now but anticipated today. An important empirical development in the study of investment is the use of more disaggregated data-sets; an important example is Cummins et al. (1994), which analyses the effects of major tax reforms on investment based on firm-level panel data. The paper is important in providing much stronger evidence on the importance of the user cost of capital than appears in aggregate studies. Chirinko (1993) is still of value as a survey.

Yet, as noted in the valuable review of Caballero (1999), a general dissatisfaction with the empirical performance of the neoclassical model led to change in investment research which emphasized the role of irreversible. See irreversible investment for these new developments.

Investment and Accumulation

Stephen A. Marglin

The standard view of accumulation goes something like this. In the short period, fraught with frictions and maladjustments, the demand for investment interacts with the supply of saving, more or less *à la* Keynes, to determine the growth of the capital stock. Keynesian policies may have fallen into disrepute, but for the short period the representative economist continues to use the tool box developed in the *General Theory* and its wake: accumulation falls out from the determination of national income.

In the longer period the same economist falls back on very different arguments: the mainstream of the profession takes accumulation to be determined by saving propensities, with nary a side glance at investment demand. That Japan has over the last quarter century devoted 30 per cent of gross output to fixed capital formation and Great Britain 20 per cent is conventionally explained in terms of higher Japanese saving propensities, not in terms of a greater propensity to invest.

In a still longer time frame, even saving propensities become irrelevant. In the asymptotic future beyond all future, accumulation is determined solely by population growth and technical change. Saving propensities may affect the steady-state capital: output ratio if the technology admits of substitution between labour and capital, but that is the limit of their influence.

Economists of a Marxian bent share the mainstream view, up to the asymptotic future, which they rightly dismiss as an irrelevant construct. The terminology may differ: difficulties of 'realization' is favoured for describing a shortfall of aggregate demand relative to aggregate supply, and hence (abstracting from foreign trade and government surpluses or deficits) for a shortfall of investment relative to saving. But for Marxians realization problems are generally confined to the short period; in the long run it is once again the saving propensities of capitalists, along with the rate of profit determined by class struggle, which determine the rate of accumulation. To be sure, neoclassical and Marxian theories of the determination of saving propensities differ, but for present purposes this is a secondary issue; the short run apart, the two theories agree that investment propensities are irrelevant to accumulation.

Investment in the General Theory

Against these views stands the Keynesian view, which, applied to the long run, tells a very

different story of the accumulation process. In the *General Theory* Keynes formalized his view of investment demand in terms of a 'marginal efficiency of capital' schedule which showed the amounts of investment that would be forthcoming at different rates of interest. The basic idea behind this schedule can be captured by supposing there to be a set of projects indexed by $i = 1, \ldots, n$, each requiring a unit of investment and returning, respectively, a cash flow of $r_1, \ldots, r_n$ in perpetuity. If the n projects are arrayed in descending order of r_i, then with the simplifying assumption that each investment costs one dollar, r_i is the *marginal* rate of return on the investment of i dollars. In Keynes's language, r_i is the marginal efficiency of capital.

Suppose now that the interest rate d, which represents the cost of capital to the investor, is also expected to be constant in perpetuity. Then the present value of the ith project's return is r_i/d. The profit-maximizing investor will go down the list until he reaches the project at which $r_i = d$, that is, the point at which the marginal rate of return just equals the cost of capital. In Keynesian terms, investment is determined by equating the marginal efficiency of capital to the cost of capital. More precisely, the array of projects being discrete, the profit-maximizing rule is to undertake all projects for which $r_i > d$ and to reject those for which $r_i < d$. If there is a project for which the relationship between r_i and d is one of exact equality, it is a matter of indifference whether the project is undertaken or not. The main point is that the discounted present values of returns, $r_i/d - d$ acts as the discount rate – exceed the assumed unit cost of the investment provided $r_i > d$.

So far there is nothing novel in this theory. Knut Wicksell would have had no problem making the argument his own, and indeed the schedule of the marginal efficiency of capital bears a close resemblance to the marginal productivity of capital schedule of mainstream theories of accumulation. Even the overall theoretical structure which Keynes builds by joining this schedule to schedules of consumption and liquidity preference would not have been uncongenial to Wicksell, particularly if its application is confined to the short period. This is presumably why Wicksell's Swedish followers chided Keynes for indulging 'the attractive Anglo-Saxon kind of unnecessary originality' (Myrdal 1939, p. 8; the comment naturally refers to the *Treatise*, not to the *General Theory*).

Probably because of the affinity to a Wicksellian version of neoclassical economics, the mainstream of American economists has been able, as was suggested at the outset of this essay, to accept a version of the Keynesian analysis for the short period – much to the annoyance of Keynes's Cambridge disciples, like Joan Robinson and Nicholas Kaldor, who all their lives insisted that Keynes's main message was being lost in the translation. In the standard American view, the main point of Keynes was the limit of monetary policy, conceived of in terms of its affect on d, to affect investment demand, either because of a low elasticity of the marginal efficiency schedule, or, in the limit, because of the impossibility of reducing the interest rate (the famous 'liquidity trap', of which Keynes said in the *General Theory* that it was, as yet (1935), a theoretical possibility of which there had been no actual instances). The bottom line was the need not only for state intervention in the form of an activist monetary policy – this was fully present in Wicksell's analysis – but also in the form of fiscal policy. Indeed it does no disrespect to Keynes to accept that his influence owed as much to the intellectual justification he provided for an activist, interventionist state – for the end to *laissez faire* – as to the intellectual power of his ideas, certainly as these ideas were, reflected through the prism of the mainstream of the American economics profession.

An Alternative Reading

But there is another reading of Keynes. The real departure of the Keynesian theory of investment from the orthodox one, in my judgment, starts from a recognition that the formalism of his theory of investment demand obscures its real content. The starting point is the recognition that the returns of any project, lying in the future, are inherently uncertain. The r_i's are not objectively

given reality but a subjective construction of the investor. It has become fashionable to blur the old Knightian distinction between risk, objective and quantifiable, and uncertainty, subjective and qualitative, by means of the theory of subjective or personal probability. Even if the axioms underlying this theory are neither compelling (particularly the assumption of a complete ordering and the assumption of 'independence', what Leonard J. Savage called the 'sure thing' principle), nor borne out empirically in the behaviour of untutored individuals, subjective probability theory still has some heuristic value in modelling investment decisions, particularly in its emphasis on the psychology of the decision maker.

Subjective probability allows us to go behind the r_i's of present value calculations like the simple perpetuity formula r_i/d to more complex sums of the form

$$r_i^h = p_1^h u_1^h r_{i1}^h + p_2^h u_2^h r_{i2}^h + \cdots + p_m^h u_m^h r_{im}^h,$$

in which the generic term $p_j^h u_j^h r_{ij}^h$ is composed of these elements: p_j^h is Mr h's subjective probability of the occurrence of a particular complex of events (a 'state') in which his marginal utility of income (normalized) is u_j^h and his estimated return from project i is r_{ij}^h. The central point is that in the Keynesian view, each of the constituents – the probability p_j^h, the marginal utility of income u_j^h, and the state-specific return r_{ij}^h – owes as much to the imagination of the investor as it does to an objective reality. The more optimistic are investors, the higher the probabilities they will attach to states in which the returns and the marginal utilities of these returns are high, and the consequence will be higher values of r_i^h. Conversely, the more pessimistic are investors, the lower the r_i^h's that will be attached to the same projects. Thus the 'animal spirits' of investors play a crucial role in investment demand.

The recognition of a crucial role for animal spirits directs one's attention away from movements *along* the marginal efficiency schedule. The question becomes, what determines the position of this schedule? Evidently, according to what has just been said, it is, in the last instance, investors' evaluations of probabilities of various states, of the relative utility of income in different states, and of returns in different states.

It is equally evident that this makes a cumbersome theory. A more tractable model can be constructed by making the prospective returns the r_i^h's, depend on the general anticipations of capitalists. The higher is the general expectation of profits, the higher will be the anticipated rate of return on specific projects – a rising tide will be anticipated rate of return in specific projects – a rising tide will presumably lift all boats. In this view, movements of the entire marginal efficiency schedule, triggered by changes in expectations of profitability, not movements along a given schedule induced by changes in the interest rate, are the key to understanding the ups and downs of investment and output.

Such reasoning – this is of course a 'rational reconstruction' – permitted Keynes's heirs, Roy Harrod in Oxford and Robinson and Kaldor in Cambridge, who re-situated the *General Theory* in a long-period context, to recast the marginal efficiency schedule in terms of variables related to expected profits. Robinson's investment demand function, for example, and the argument of Keynes's own formulation, the rate of interest, disappears into the background of *ceteris paribus*.

The rationale for ignoring the cost of capital is the assumption of a highly insensitive responsiveness of investment and saving to plausible interest rate changes. Clearly, there are strong assumptions at work here about the relevant range of interest rate variation. As long as the anticipated returns are finite, there must be *some* level of the interest rate at which even the most attractive projects appear to all and sundry as uneconomic. Thus, unless saving is negatively related to the rate of interest *and* highly elastic, sufficient variation in interest rates could, with enough time, adjust the demand for investment to the supply of saving.

For most of the postwar period, however, the range of variation of interest rates has been too modest to test this possibility, at least if we identify the interest rate with the difference between the nominal rate on government or high grade corporate bonds and the rate of inflation. Indeed, from 1945 until 1980 this 'real' rate of interest

never moved very far from zero in the United States. In the post-1980 disinflation and recession, real interest rates rose to levels which must give pause to even the most devoted neo-Keynesian. It is certainly too early at this writing to determine whether in the sweep of history this was a momentary aberration or the dawn of a new era; my own leaning is towards aberration, but that may reveal my neo-Keynesian predilections rather than a reasoned guess about the future.

The rate of profit generally expected on the capital stock as a whole (*re*) is itself no more observable than any other variable that lies in the future. In the neo-Keynesian literature *re*'s customarily are taken to be a function of a small number of variables which summarize the relevant information available to investors. The standard version of the theory simply extrapolates the current or immediate past rate of profit.

With simplifying assumptions like constant returns to scale, homogeneous capital, and a uniform, exogenously given rate of capacity utilization, it must be true *ex post* that the average rate of profit on new investment (which is the marginal rate of profit on the capital stock) turns out to equal the average rate of profit on all capital. Under these assumptions it might appear reasonable for the expected average rate of profit on the entire capital stock *re* to equal the expected rate of profit on new investment, which would impose, in the spirit of 'rational expectations', a consistency requirement for each investor

$$r^e \equiv \sum_i r_i^h \equiv \sum_i \sum_j p_j^h u_j^h r_{ij}^h.$$

But no such inference is warranted. Neo-Keynesian theory in my view is compatible with rational expectations – insofar as this notion makes any sense at all under conditions of subjective uncertainty. But an important measure of realism would be lost by constraining the theory in this way, for even under the stringent assumptions that lead to a uniform realized profit rate', there is no good reason to believe in rational expectations. The general expectation of a 4 per cent return is perfectly consistent with individual expectations that special gifts, opportunities, or kismet will result in a 10, 20 or even 50 per cent return on one's own projects. As P.T. Barnum would have it, a sucker is born every minute.

Self-Fulfilling Prophecy

Keynes made Barnum's sucker into a kind of hero: in Keynes's view it was doubtful that capitalism could function without such a 'spontaneous urge to action'. Neo-Keynesian theory makes an even stronger assertion, which has its roots in Keynes's *Treatise on Money*. As long as there are enough of them, the 'suckers' can turn the tables on the rest of us. Capitalists, as a class, have the power to shape conditions so that their expectations come true, at least in large enough part to maintain their confidence.

Unique among economic actors, this class has the power of self-fulfilling prophecy. Not only do actual profit rates affect capitalists' beliefs about future profits, capitalists' beliefs also have an impact on actual profits. This is not the same thing as the ability Joan Robinson imputed to capitalists to make the profit rate anything they liked, but it is a formidable power nonetheless.

There are two mechanisms by which capitalists' prophesies about profits become self-fulfilling, the distribution of income between capital and labour and the level of capacity utilization and employment. The first is the less familiar one, except to readers of Keynes's *Treatise on Money*. Suppose a closed economy with no government spending or taxation in which the starting point is a long run equilibrium characterized by equality both between desired saving and investment and between expected and actual (average) rates of profit. Imagine a change in 'animal spirits' which makes capitalists willing to undertake more investment at the going rate of profit than earlier was the case. In other words, imagine an outward shift in the investment demand function. In the simplest neo-Keynesian story, this addition to aggregate demand increases spending relative to income – remember *income* has remained unchanged – and drives the price level upward. Assuming money wages are fixed or at least sluggish, this reduces the real wage and shifts the

income distribution in favour of profits. The process continues since higher realized profits lead to further expectations of higher profits and still more investment demand. But it does not continue indefinitely, because capitalists are assumed to save a higher proportion of their incomes than do workers. The upward spiral of prices and investment continues only until the extra saving induced by higher profits absorbs the extra investment, at which point the economy comes to a new equilibrium where desired saving and investment and actual and anticipated profits are agains equal, albeit at a higher level. In addition to the existence of an investment demand function that is distinct from the saving function, the sluggishness of money and wages and the difference in saving propensities between classes are crucial to this result.

Several observations are in order here. First, although the *fons et origo* of this theory is Keynes's *Treatise*, the theory has much in common with the model outlined in Josef Schumpeter's *Theory of Economic Development*. There are two important conceptual differences however. First, the neo-Keynesian equilibrium is formulated as a steady growth rather than stationary (zero growth) state that dominated in Schumpeter's time. Thus shifts from one equilibrium to another involve changes in the rate of growth rather than changes in the level of output.

A second difference is more fundamental. In both the Schumpeterian and the neo-Keynesian view, an outward shift in the investment demand function plausibly involves an expansion of the array of projects yielding returns in excess of the cost of capital. And in both views, the psychology of the capitalist class is crucial. Schumpeter no less than the neo-Keynesians recognized the subjective element in the estimation of returns. 'Invention', for Schumpeter, was necessary but not sufficient for 'innovation'. But here the resemblance ends. In the neo-Keynesian view invention is neither necessary nor sufficient for innovation. Investment can be a pure boot-strap operation; the theory requires nothing more than a change in business psychology to change investment demand, and a change in investment demand can lead the economy to a new equilibrium with a different rate of growth. Within the limits of saving propensities and the malleability of real wages, capitalists wishes are self-fulfilling. Prices and profit rates change to validate the changes in capitalists' expectations!

The Crucial Assumptions

There must be a trick. In fact, there are four crucial assumptions, two of which – the flexibility of real wages and the difference in propensities to save between capitalists and workers – have already been mentioned. The assumption that wages are set in money terms plays a central role in the analysis. Money wages need not be fixed once and for all, but Robinson's version of the neo-Keynesian story (and the Schumpeterian story for that matter) cannot be told at all without the assumption of sluggish money wages. Evidently it is the income distribution that adjusts saving and investment to each other. So if the income distribution is fixed, then it cannot do the job which neo-Keynesian theory assigns it.

A difference in saving propensities is equally important to the neo-Keynesian view of capitalism. There are various versions of the so-called Cambridge saving equation, and a fair amount of confusion about the content of alternative versions exists two decades after the most important contributions to this debate. But all versions of the theory take it for granted that capitalists' propensity to save exceeds workers'. By contrast, the principal neoclassical theory of saving, Franco Modigliani's life-cycle hypothesis, suggests that the propensity to save out of wages will exceed the propensity to save out of property income: wages will be disproportionately in the hands of people preparing for retirement and profits disproportionately in the hands of retirees. Theoretical dispute is of course nothing new in economics. What is more surprising is that we lack persuasive empirical evidence of one view or the other two decades after the theoretical battle was fairly joined.

The essential role that flexible real wages and differences in saving propensities play is relatively transparent, so perhaps 'trick' is not an

appropriate description for either of these assumptions. But a third assumption is necessary to make capitalists' investment spending into a 'widow's cruse' (Keynes's metaphor), filling up with saving as fast as it is emptied in investment. This assumption is better hidden. We can see its role more clearly by asking how the process described for moving from one equilibrium in consequence of a shift in investment demand ever gets started. How is it that an increase in *desired* investment gets translated into *effective* demand? (The same question, it may be noted, might be asked about any displacement from macroeconomic equilibrium, for instance, the textbook displacement of a short-period equilibrium by a shift in the investment function.)

One possibility is that desired saving increases in line with desired investment, but this assumption in essence requires us to abandon the idea of separate saving and investment schedules. A second possibility that can be dismissed almost as easily is the just-so story fashionable in my youth: we were told to think in terms of cash 'hoards', with 'dishoarding' as the essential mechanism for initiating the disequilibrium transition from one steady state to another. That story won't wash because under contemporary conditions there simply aren't cash hoards of the requisite magnitude – if there ever were.

There *is* a better answer, and interestingly Wicksell, as well as Schumpeter and Keynes, give it in about the same way. Schumpeter is the clearest of the three, in contrast to whom Keynes is practically incoherent, perhaps because he thought the main point of the story so obvious that it did not require elaborate explanation. The main point, in two words, is credit money. The process of expanding investment can get started with no accompanying increase in desired saving if capitalists are assumed to have access to an accommodating banking system which one way or another can create claims on scarce resources out of whole cloth. Here the psychology of financial capital joins the psychology of industrial capital, for unless the financiers share the optimism of industrialists, there is no way, absent those mythical cash hoards, by which investment can increase without a contemporaneous increase in desired saving, as the neo-Keynesian and the Schumpeterian story, with their reliance on price level and profit rate shifts to accommodate capitalists, would have it. Or for that matter, the Wicksellian story. Although ultimately it is the interest rate which adjusts desired investment and saving, Wicksellian disequilibrium is not a Walrasian virtual or hypothetical imbalance of *tâtonnement* with false trading, but an imbalance in real time which is sustained by credit money.

The importance of an accommodating banking system, or passive or endogenous money – these are all approximate equivalents – to the neo-Keynesian system explains why partisans of this view are necessarily hostile to the quantity of money theory of prices (the so-called 'quantity theory of *money*', but this is an obvious misnomer). The dispute is evidently not about the relationship between the quantity of money and the price level, a definitionally true relationship in its customary form, but about causality. In the neo-Keynesian view it is aggregate demand which drives *both* sides of the quantity equation, not MV (the product of money and velocity) which drives PX (the product of prices and quantities).

In an earlier essay on this subject (Marglin 1984a), I suggested that in the neo-Keynesian story capitalists, as a class if not individually, were approximately in the position of the present Aga Khan, who in his student days is reputed to have asked his Harvard economics instructor how the theory of consumer choice worked *without* the budget constraint. V. Bhaskar has persuaded me that the analogy is misleading. The point is not that capitalists, even as a class, face no budget constraint: capitalists must be assumed to repay whatever debts are contracted to finance investment. The point is rather that, as a class, capitalists are able to change what are normally regarded as parameters of the budget constraint. By increasing relative demand, capitalists drive up the prices of the goods they sell relative to costs of production. The consequent increase in profits provides the wherewithal to retire debt as it becomes due.

There is a final assumption which must be introduced in order to make the neo-Keynesian argument that the longer run growth of the

capitalist economy, as well as the share of investment in output and the profit rate, is sensitive to capitalists' animal spirits. This is the assumption of slack resources, specifically, slack labour-force growth must lead to continued capital deepening, which has finite limits both in the real world and in the textbook world of smooth substitution between capital the labour. The simplest, as well as the most realistic, justification of slack labour, is the argument that the capitalist sector of the economy is embedded in a larger entity from which it can, if needed be, draw labour. I refer here to a long run 'reserve army' constituted both by sectors of the national economy (the farm in an earlier day, the kitchen more recently) and by sectors of the international economy (the immigrants who provided labour for 19th- and 20th-century expansion in the United States and for the post-World War II boon in Europe).

Without this assumption, the power of capitalists to shape the history of capitalist economies would be much closer to the power any group has in a standard Arrow–Debreu model to influence relative prices through its preferences or, in a stochastic model, through its expectations. On the assumption of a limited quantity of land suitable for growing tobacco, a shift of smokers' preferences with respect to the pleasures of nicotine and the horrors of lung cancer will affect the equilibrium price of cigarettes. In a stochastic model, the belief that sunspots or any other exogenous variable matters may be sufficient to make the variable matter, even with the assumption of rational expectations (Azariadis 1981; Cass and Shell 1983). At issue in both these cases however is the distribution of a given pie, which stands in sharp contrast to neo-Keynesian theory, where distribution bears on the size of the pie itself.

Observe that the existence of slack resources is much more problematic in the long run than in the short period which was originally the focus of Keynes's analysis. For the short period, although controversy is not lacking even here, mainstream economists will generally accept it is the exception rather than the rule that capacity or manpower constrains output. It is in the long run that the true proportions of the neo-Keynesian departure from orthodoxy reveal themselves.

The Level of Real Wages: Effect or Cause of Accumulation?

In a sense, this version of neo-Keynesian theory, like Keynes's own *General Theory*, proves too much. One cannot ask many of the more interesting questions about how changes in investment demand change the economy. For most of these questions turn out to be about movements along the demand curve rather than changes in its position, which mean that they are necessarily transitory if the initial position was one of equilibrium. For instance, one cannot ask what the effect of lower (or higher) real wages might be because the real wage, determined ultimately by the price level, is a consequence rather than a thermostat. Thus to find a thought experiment which illustrates the neo-Keynesian theory requires some care; it would not have done, for example, to take as the premise of a shift in the investment demand function that Mrs Thatcher and Mr Reagan had abolished collective bargaining. For while this might plausibly lead to the expectation of a higher profit rate, this expectation would translate into a movement *along* the existing investment demand schedule rather than a shift of the schedule. And supposing the economy was at equilibrium in the first place, a movement along the investment demand schedule is not sustainable unless the saving schedule shifts simultaneously.

In fact questions about the effect of changes in real wages on equilibrium come out of a very different approach to capitalism than that embodied in the *General Theory*. There Keynes calls this approach 'classical', even though the economists Keynes apparently had in mind as its exemplars were more neoclassical than classical. Classical may still be the right label since the Marxian strand of the classical theory, as typified by Michal Kalecki, even more than the neoclassical strand, makes the level of real wages a central determinant in the theory of accumulation, a thermostat rather than a thermometer. But if real wages are given exogeneously, whether as a rate or a share, something else has to adjust if both investment and saving propensities are to continue to play a determining role in the accumulation process.

I

There are at least two ways out, besides the possibility of partitioning outcomes by 'regimes' in which one or another consideration – wages, investment, or saving – is a nonbinding constraint. One possibility is to allow each of the three determinants to operate with diminished force; this is the tack followed in Marglin (1984a, b).

Capacity Utility as an Adjustment Mechanism

Another possibility is to allow capacity utilization to enter the discussion more fully both as cause and as effect. This is not entirely unproblematic since it can be argued that the appropriate assumption for the long run (as distinct from Keynes's short period) is that capacity utilization settles down at some 'normal' rate, in other words, that it is not a variable. But it is hard to regard this issue as resolved; both the view that capacity utilization is endogenous and the view that it is exogeneous in the long run can claim some empirical support.

The endogenous view, which Amit Bhaduri and the present author are currently developing, builds indirectly on the work of Kalecki and more directly on the work of Bob Rowthorn (1982). This view entails a significant reformulation of the investment demand function: investment demand is no longer a function of the expected profit rate but rather is a function of two of its constituents, the expected profit *margin* qe and the expected rate of capacity utilization ze. Definitionally $re = qezey$, where y represents the output:capital ratio at full capacity utilization, but with capacity utilization variable, there is no compelling reason why qe and ze should affect investment demand symmetrically, as they do in this formula. If, for example, the expected rate of profit is high because the profit margin is high and the expected rate of capacity utilization is low, the impact on investment demand may be very different from what a high expected rate of profit based on lower profit margins and higher capacity utilization would induce. In the second case there would be relatively little need for investment in order to have sufficient capacity to meet expected demand. Investment demand would be limited to new products, new processes, or the substitution of capital for labour. Thus the formulation of the expected rate of profit from a project as

$$r_i^h = p_1^h r_{i1}(q^e, z^e) + \cdots + p_m^h u_m^h r_{im}(q^e, z^e)$$

is at once more general and more plausible than the formulation in which r_i^h turns on re alone.

In this model, unlike the model in which aggregate investment turns on the expected rate of profit, one *can* ask questions about exogenous shifts in real wages. Profit margins are determined in large part by struggles over real wages, so an increase in the expected wage lowers qe and leads to a reduction in investment demand, that is, to a movement down the investment demand schedule. But the movement may be permanent since there is now another degree of freedom, capacity utilization, to accommodate the change.

A word of caution: the outcome of a change in real wages cannot be predicted solely on the basis of the qualitative structure of the model. Whether higher wages and lower profit margins will increase capacity utilization and accumulation depends on the relative strength of two opposing tendencies. On the one hand, from the capitalists' point of view, a decrease in profit margins makes investment less desirable at a given rate of capacity utilization. On the other hand, a shift in the distribution of income from capital to labour may be expected to increase consumption demand and thus to stimulate capacity utilization. Since investment is by assumption sensitive both to profit margins and to capacity utilization, the relative strength of these two influences becomes crucial. This framework is thus broad enough to accommodate both the 'stagnationist' interpretation of Keynes with its emphasis on high real wages as an engine of accumulation and an 'exhilirationist' interpretation, which emphasizes high profit margins.

Evidently a variety of theories, and an even wider variety of models, is possible within the broad Keynesian vision that aggregate demand matters. The essence of that vision is the role of investor psychology, the strength, in Keynes's words, of 'animal spirits' that 'urge to action

rather than inaction'. Perhaps a paraphrase of Marx puts the main point best: capitalists make the history of capitalist economy, but not in circumstances of their own choosing. Whatever the mechanism of adjustment, whether income distribution or capacity utilization or some combination of the two, capitalists occupy a position of singular privilege in the neo-Keynesian conception, possessing the ability to impress their subjective construction of the future on the present functioning of the economy.

Investment Decision Criteria

Jack Hirshleifer

Investment is present sacrifice for future benefit. Individuals, firms, and governments all are regularly in the position of deciding whether or not to invest, and how to choose among the options available. An individual might have to decide whether to buy a bond, plant a seed, or undertake a course of training; a firm whether to purchase a machine or construct a building; a government whether or not to erect a dam. Under the heading of investment decision criteria, economists have addressed the problem of how to choose rationally in situations that involve a tradeoff between present and future.

The Economic Theory of Intertemporal Choice

The object of investment is taken to be to optimize one's pattern of consumption over time. The elements needed to determine an individual's investment decision are: (a) his *endowment*, in the form of a given existing income stream over time; (b) his *preference function*, which orders in

desirability all possible time-patterns of consumption; and (c) his *transformation set*, which specifies the possibilities for transforming the original endowment into other time-combinations of consumption.

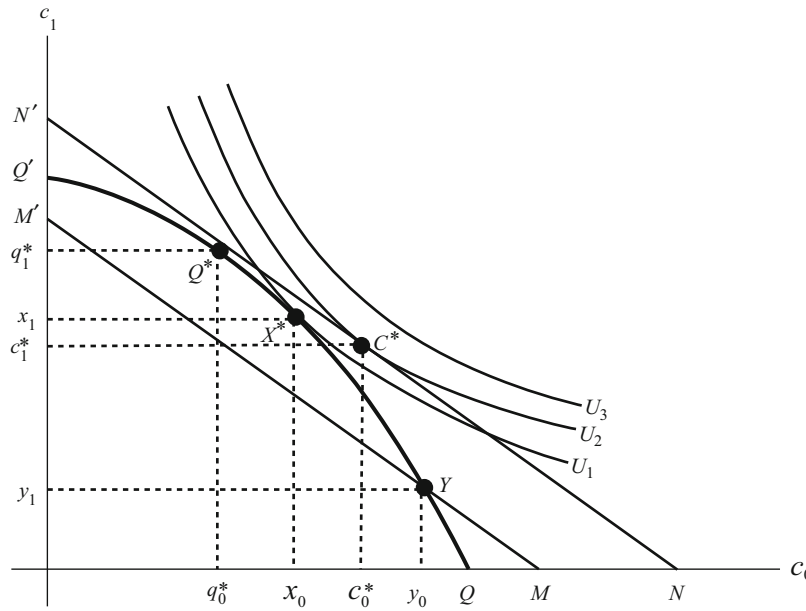
Figure 1 illustrates an artificially simple case of only two periods (say, this year and next) under conditions of certainty. Each point represents a combination of current consumption c_0 and future consumption c_1. The *endowment* combination Y has coordinates (y_0, y_1). *Time-preferences* are portrayed by the indifference curves U_1, U_2, U_3,. . ., each such curve connecting combinations yielding equal satisfaction. The curve QQ' through the endowment position Y pictures the intertemporal *productive opportunities*. By sowing seed, for example, a person can sacrifice current consumption for future consumption – represented in the diagram by a movement from Y along QQ' to the northwest. (There may also be disinvestment opportunities, i.e., the individual might be able to draw upon the future so as to augment current consumption, which would be represented by a movement from Y along QQ' to the south-east.)

For a Robinson Crusoe, the optimum balance of present and future consumption – which in his isolated state must necessarily be identical to his provision for present and future production – occurs at point X^* along QQ'. In the situation pictured he achieves this optimum by *investing* the quantity $y_0 - x_0$ of current consumption claims. For example, having at hand a current corn endowment of y_0, he retains x_0 for current consumption and plants the remainder as seed. Next year he will reap as return from investment the amount $x_1 - y_1$ to augment his endowed availability of future corn.

If markets for trading between present and future income claims exist, however, in contrast with the Robinson Crusoe situation the individual will be able to disconnect the amount he *invests* from the amount he *saves*. These trading opportunities are shown in Fig. 1 by the family of 'market lines' whose general equation is:

$$c_0 + c_1/(1 + r_1) = W_0 \tag{1}$$

Here r_1 is the *interest rate* that discounts one-year future claims c_1 into their equivalent value in terms of c_0 claims. Along each market line the parameter W_0 represents the associated level of *wealth*. Put another way, wealth in Eq. (1) measures the *present worth* of any specified



Investment Decision Criteria, Fig. 1 Investment and saving in a 2-period model

(c_0, c_1) vector – the future-dated element being 'discounted' at the given market interest rate r_1. In the diagram two market lines are shown: MM' through the endowment vector $Y = (y_0, y_1)$ indicates the individual's endowed wealth $W_0^y = y_0 + y_1/(1 + r_1)$, while NN' represents the maximum attainable level of wealth $W_0^* = q_0^* + q_1^*(1 + r_1)$.

If an individual has both productive and market opportunities, his optimizing decision in Fig. 1 can be thought of as taking place in two stages. First he locates his 'productive solution' $Q^* = (q_0^*, q_1^*)$ by moving along QQ' so as to maximize attained wealth at the tangency with market line NN'. Second, he then transacts in the funds market, by lending or borrowing (exchanging current for future claims or vice versa) along NN' to find his 'consumptive solution' $C^* = (C_0^*, C_1^*)$ at the tangency of NN' with indifference curve U_2 in the diagram. Notice that his preferences do not at all affect the productive solution, but only how he chooses to 'finance' the investments made. Specifically, in the diagram here the amount he *invests* $(y_0 - q_0^*)$ exceeds the amount he *saves* $(y_0 - c_0^*)$. By borrowing on the market, in effect he has been able to get others to undertake part of the saving necessary to finance his projected investments.

This disconnection between the individual's productive and consumptive decisions in a regime of perfect markets is known as 'Fisher's Separation Theorem'. The essential implication is that individuals with diverging time-preferences can nevertheless come together and agree upon joint productive investments. Business firms and (to some extent) governments can be regarded as institutions designed for undertaking joint investments whose scale is too large for any single individual. The underlying principle is that those investment choices maximizing wealth value or present worth of the mutual undertaking will also maximize wealth for each and every participant therein.

The Present-Value Rule

The economic theory of intertemporal choice leads immediately to what is known as the *Present-Value Rule* for investment decision. This rule can be expressed in two essentially equivalent forms:

(i) Among the opportunities available, adopt the set of investments that maximizes wealth W_0.
(ii) Adopt any single investment project if and only if its present value V_0 is positive. (Taking into account, of course, any repercussions of that project upon the returns yielded by other members of the adopted investment set.)

As an obvious corollary, if two available projects are mutually exclusive, the one with the larger present value V_0 should be chosen.

Generalizing to the multi-period context, wealth as maximand becomes:

$$W_0 = q_0 + q_1/(1 + r_1) + q_2/[(1 + r_2)(1 + r_1)] + \cdots + q_T/[(1 + r_T)\cdots(1 + r_2)(1 + r_1)] \quad (2)$$

Here the q_t are the coordinates of points along the T + 1-dimensional productive opportunity surface

$$\varphi(q_0, q_1, \ldots, q_T) = 0,$$

a generalization of curve QQ' in Fig. 1. T is the 'economic horizon', which may be infinite. And the r_t represent the successive short-term interest rates, each of which discounts prospective payments at any date into its wealth-equivalent at the next preceding date.

For a single project in the multi-date context, present value is defined as:

$$V_0 = z_0 + z_1/(1 + r_1) + z_2/[(1 + r_2)(1 + r_1)] + \cdots + z_T/[(1 + r_T)\cdots(1 + r_2)(1 + r_1)] \quad (3)$$

Here the z_t are the dated payments or 'cash flows' associated incrementally with the project considered. Normally the z_1 elements for earlier dates would include some with negative signs – or else the project could not be described as an investment – while those for later dates would have predominantly positive signs. In the special case where $r_1 = r_2 = \ldots = r_T = r$ – that is, where

interest rates are expected to remain constant at the level r over time – the Present-Value formulas reduce to the more familiar forms:

$$W_0 = q_0 + q_1/(1+r) + q_2/(1+r)^2 + \cdots + q_T/(1+r)^T \quad (2')$$

$$V_0 = z_0 + z_1/(1+r) + z_2/(1+r)^2 + \cdots + z_T/(1+r)^T \quad (3')$$

The Present-Value solutions can also be formally generalized to allow for continuous rather than discrete time. As an illustrative simplified example, consider a project whose scale of current input or investment sacrifice i_0 is fixed while the output date is subject to choice (e.g., when to cut a growing tree). In Fig. 2, horizontal distances represent time t and vertical distances value V_t at each date. Present Value V_0 is indicated by height along the vertical axis. The curve GG' represents productive growth of the asset – in the case of a tree, market value of the standing timber at any date. The 'discount curves' $D, D', D'', \ldots$, are analogous to the 'market lines' of Fig. 1. Each such curve represents the growth of a specific sum of present dollars by continuous compounding at a constant market rate of interest r, or alternatively the Present Value of any future payment continuously discounted at r. The optimal investment period $t = t^*$ is then the one that maximizes Present Value V_0, subject to the constraint on the available V_t described by the curve GG', in the equation:

$$V_0 = -i_0 + V_t e^{-rt} \quad (4)$$

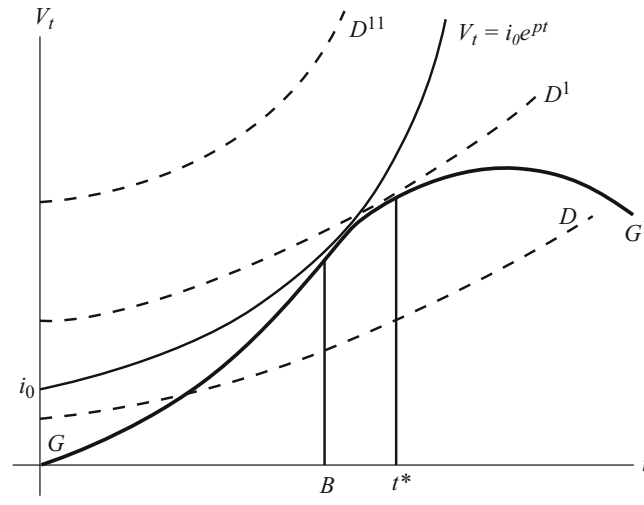
Geometrically, t^* is determined by the tangency of GG' with the highest discount curve (constant-wealth curve) attainable. The solution condition is then:

$$V_t'/V_t = r \quad (5)$$

Other Investment Criteria

Certain investment criteria employed in business practice are definitely erroneous. One such is rapidity of 'payout' (the date when cash inflows first balance initial outlays), a formula that obviously fails to allow properly for time-discount. Controversy among theorists has centred upon a more interesting concept known variously as the 'internal rate' or the 'rate of return'. The internal rate for a project (or set of projects) is defined as ρ in the discrete discounting equation:

$$0 = z_0 + z_1/(1+\rho) + z_2/(1+\rho)^2 + \cdots + z_T/(1+\rho)^T \quad (6)$$



Investment Decision Criteria, Fig. 2 Optimal during of investment

As before the z_t here are the successive terms, positive or negative, of the paymentsreceipts sequence associated incrementally with a particular project. In the special 'deepening' case illustrated in Fig. 2, the corresponding concept under continuous compounding is defined implicitly in:

$$0 = -i_0 + V_t e^{-\rho t} \tag{7}$$

where once again the V_t at any date is described by the productive opportunity curve GG'. Under these conditions ρ represents an average compounded rate of growth.

There has been some confusion between two quite different investment decision *rules* that both employ the internal-rate measure ρ: (i) choose projects so as to maximize ρ, versus (ii) adopt projects incrementally so long as $\rho > r$.

Maximum ρ Rule

If the internal rate ρ is interpreted as the average rate of growth, it may seem plausible that the investor should maximize ρ rather than wealth W_0. (Of course, maximizing a growth *rate* would scarcely make sense unless the initial outlay or scale of investment were held constant, which would not in general hold true.) The solution of (7) that maximizes ρ is shown in Fig. 2 as $t = B$, notably earlier than the Present-Value solution $t = t^*$.

In favour of B over t^* it has been argued that, if the growth opportunity were to be replicated in perpetuity, returns from choosing the earlier 'rotation period' B must ultimately dominate those associated with cutting on each cycle at t^*. That is certainly true. However, if the decision problem concerns infinite rotation rather than a one-time cutting, for a valid comparison the relevant Present-Value measure would have to be a generalized one that allows for the associated infinite sequence of discounted returns. It can be shown that this generalized Present-Value does coincide with B if the growth opportunity can be reproduced on an ever-broadening scale (e.g. on new land) – but only as funds are freed by cutting the tree or trees. This turns out to be an impossible or uninteresting case, because it implies that the productive opportunity must be of *infinite* market value if the maximized ρ exceeds the market interest rate r (and of zero value otherwise). In contrast, if the opportunity is a unique one which cannot be reproduced after cutting, as pictured in Fig. 2, the simple $t = t^*$ solution remains correct. Another solution, $t = F$, found by the German forester Faustmann, is appropriate when the opportunity can be reproduced over time by cutting and replanting but cannot be broadened in scale. F would be found by maximizing the Present Value V_0 of an infinite sequence of rotations, each being a constant-scale replication of the original opportunity. Like all the correct solutions, it is equivalent to maximizing the present worth of the opportunity under the stated assumptions. (F is not shown in Fig. 2 but would lie between B and t^*.)

ρ vs. r Comparison Rule

The Comparison Rule says to adopt any project whose internal rate ρ exceeds the market rate of interest r. This rule remains popular in business practice, in part because it offers a convenient division of labour: calculation of the ρ's on individual projects might be delegated to subordinates, while top decision-makers choose the cutoff rate r that corresponds to the relevant market interest rate faced by the firm. Unfortunately, however convenient such a decision of labour may be, once again this is not in general a correct method of project selection.

The difficulty with the Comparison Rule first came to be appreciated when it was discovered that a sequence of positive and negative cash flows could have more than one ρ serving as solution of Eq. (6) above. A project represented by the annual payments sequence $-1, 5, -6$, for example, has two solutions: $\rho = 1$ and $\rho = 2$. (It can be shown that a project with $T + 1$ dated elements may have as many as T solutions.) This of course destroys the idea that the internal rate can generally be identified with a growth rate; an outlay of one dollar cannot be said to grow at both 100% and 200%. Various answers have been offered to the puzzle of which ρ to use in such cases. But the difficulty is

immediately explained and resolved if we think instead in terms of Present Value. It turns out that the sequence $-1, 5, -6$ has positive V_0 (and is therefore worth adopting) for any constant market interest rate r *between* 100% and 200%, but at other values of r has negative Present Value (and should not be adopted). Perhaps even more illuminating is the project described by cash flows $-1, 3, -2\frac{1}{2}$. This sequence has no real solution for ρ in Eq. (6), the reason in Present-Value terms being that V_0 investment opportunity. After all, there is no justification for postulating (as is implicitly done by the Comparison Rule) that the anticipated sequence of market interest rates $r_1, r_2, \ldots, r_T$ must be constant over time (always equal to a common r). It turns out that the cash-flow pattern $-1, 3, -2\frac{1}{2}$ has positive Present Value (i.e., the project would be worth adopting) for many possible non-constant interest-rate sequences – for example, $r_1 = 100\%$ and $r_2 = 200\%$.

Summing up, therefore, the Present-Value Rule for investment decision – corresponding as it does to the principle of maximizing wealth within the opportunities available – is correct itself and also serves to define the range of validity of all the other rules considered.

Generalizations and Extensions

The preceding analysis needs to be extended in at least two important ways, so as to allow for: (1) uncertainty, and (2) imperfect and incomplete markets.

Uncertainty

Investment choices, involving as they do present sacrifice for future benefit, are peculiarly sensitive to uncertainty. However, so long as we can continue to assume a regime of complete and perfect markets, the Present-Value Rule is robust enough to retain validity even in a world of uncertainty. For, the proximate goal of any individual (or group of individuals organized in a firm or other joint enterprise) will still be to undertake productive activities so as to maximize wealth. Having achieved that goal, each and every individual investor will be in a position to distribute his attained wealth as desired over all possible dated contingencies in accordance with his time-preferences, degree of risk-aversion, and probability beliefs.

Economists use two main models for the analysis of uncertainty – state-preference and mean-versus-variability analysis. Since the latter, under certain assumptions, can be regarded as a special case of the former, for our purposes attention can be limited to the state-preference model. If markets for state-claims are complete and perfect, any pattern of varying returns over states of the world at a given date has a *certainty-equivalent* in value terms as of that date. In Eqs. (3) and (3′), the z_t for any project can now be interpreted as certainty-equivalents (rather than as simple cash flows) defined by:

$$z_t = P_{t1}z_{t1} + P_{t2}z_{t2} + \cdots + P_{tS}z_{tS} \qquad (8)$$

Here z_{ts} represents the cash flow at date t contingent upon state of the world s obtaining – there being S distinguishable such states – while P_{ts} is the price at which a unit claim to income in state s at date t can be converted into (traded for) current certainty income.

Incomplete or Imperfect Markets

Markets are said to be *incomplete* if some objects of choice are non-tradeable. For example, futures markets for some commodities at far-distant dates do not exist, nor is it possible to trade in claims contingent upon each and every conceivable future uncertain event. Markets are said to be *imperfect* if there are costs of trading – for example, brokerage fees, transaction taxes, or expenses in locating exchange partners. Any real-world regime of markets will necessarily be both incomplete and imperfect, but for some purposes the assumption of complete and perfect markets may be a usable idealization. Unfortunately, once we depart from this idealization the problem of investment decision criteria becomes very difficult. The reason is that the Separation Theorem fails. Only under complete and perfect markets is the concept of wealth or Present-Value unambiguously defined, so that the choice of productive investments can be entirely disconnected from

individuals' personal time-preferences, risk-preferences, beliefs etc. Failure of the Separation Theorem particularly subverts the ability of investors to join together in undertaking large projects or groups of projects.

However, two different lines of analytical approach have yielded results of interest. (i) A number of techniques have been devised for locating 'utility-free' or 'efficient' investment choices. In general such techniques cannot determine an optimal project set, but they can serve to filter out options whose payoff patterns over dates and/or states are dominated by other available projects or project combinations. (ii) While investors' personal circumstances may diverge in innumerable ways, there should be some tendency for those similarly situated to group together. Thus, a firm whose investment opportunities yield far-future payoffs should tend to be owned by a 'clientele' consisting of individuals with moderate time-preferences, willing to forego current dividends in the hope of large long-term gain. It follows that unanimity as to the investment choices to be made may after all govern *within* the firm, for example as to the discount rate to employ in calculating Present Value, even in the absence of perfect and complete markets.

Bibliography

The modern theory of investment and intertemporal choice was set down in classic form by Irving Fisher as part of his great works on interest (1907, chapters 8–9; 1930, chapters 10–13). The seminal works on uncertainty theory include Arrow (1953) for the state-preference approach and Markowitz (1959) and Sharpe (1964) for the mean-versus-variability model. Choice over time and choice under conditions of uncertainty are integrated in the treatise by Hirshleifer (1970) that builds upon these foundations. All these topics have been followed up in an enormous literature, of which only a few illustrative instances can be cited here: on investment decision formulas, Samuelson (1976); on utility-free or dominant choices, Pye (1966), Hanoch and Levy (1969), and DeAngelo (1981). A survey of investment decision criteria used in current business practice appears in Schall, Sundem, and Geijsbeek (1978).

Investment Planning

Joseph Halevi

The theories discussed here consist of two complementary formulations originating in India and in the United Kingdom in the 1950s and 1960s. Both deal with investment planning when development starts with virtually no capital goods industry. Thus they represent an expansion of the model of the Soviet economist Feld'man, since in the latter the economy did possess an investment sector albeit in a limited dimension (Feld'man 1928a, b).

The first approach, due to Dobb (1954, 1960) and to Sen (1960), deals with the choice of techniques and the sectoral distribution of investment and labour. The second approach, elaborated by a number of Indian scholars – Raj and Sen (1961),

Naqvi (1963) – is more concerned with the sectoral allocation of investment goods under conditions of stagnant export earnings. The definition of sector is the same as in the Marx-based Feld'man model with the difference that the capital goods sector itself is divided into two branches. One branch consists of an intermediate sector producing equipment usable only in the consumption goods sector. The second branch is formed by *machine tools* which can reproduce themselves as well as be installed in the intermediate sector.

The emphasis on this kind of structural relations is aimed at providing analytical support to the view that sectoral investment planning by the State is a necessary, although not sufficient, condition for the emancipation from backwardness.

The starting point of both approaches is the historical consideration that colonialism has destroyed the traditional home industries, thereby making expansion dependent on the exports of primary products having low demand elasticities (Raj and Sen 1961). It is this particular condition which justifies investment priority in the capital goods industry for a growth strategy oriented toward the home market (Dobb 1967). Industrialization would then imply the creation of capital goods well in advance of any market demand for them, a process called by Dobb *the Accelerator in Reverse*.

Developing economies face the task of investing in a manner largely independent from the preexisting material structure. In this context, indivisibilities of capital equipment – which 'are likely to be significantly large (relatively to the scale of the economy) at early stages of development' (Dobb 1960, pp. 11–12) – may make the expansion of a certain branch unprofitable although its growth can be of crucial importance for the formation of other industries. State planning of the sectoral allocation of investment performs the role of securing overtime the construction of complementary industries.

It must be noticed that some of the views put forward by Dobb and the Indian economists were part of the intellectual climate of the period. In the mid-1950s Prebisch started the debate over the terms of trade between industrialized and underdeveloped countries, arguing the long-term nature of the latter's unfavourable position. Politically, the first meeting of the non-aligned nations, held in the Indonesian city of Bandung in 1955, asserted the necessity to embark on a road privileging the domestic market. Institutionally, sectoral planning by the State seemed to have gained a firm hold also in a non-socialist country as important as India. Practically, the experience of the People's Republic of China suggested that a developing country could reduce the dependency on foreign exchange by building a machine tools industry (Raj 1967).

Given this cultural and political framework, Dobb's pioneering work has a special place in the theories of planned development. It singled out the fact that the domestic economy of underdeveloped countries does not generate a surplus of wage goods large enough to allow a more or less smooth process of growth. Indeed, with most of the work force employed in subsistence activities, it would be impossible to set in motion the Accelerator in Reverse unless the bottleneck of a limited surplus is widened. The technical form of investment must therefore reflect this initial constraint. In setting forth the answer to the question of the choice of techniques, Dobb challenged the view that 'since a scarcity of capital relative to labour is a usual characteristic of underdeveloped economies, capital investment needs there to take the form of projects of "low capital intensity"' (Dobb [1954] 1955, p. 139).

The gist of his and Sen's argument (Sen 1960) can be presented as follows:

Consider an economy where fixed capital in the capital goods industry is so small that machines can be thought of as being produced by labour alone. Thus, employment in the capital goods sector multiplied by the productivity of labour – denoted by x – gives the total output of equipment. But employment in the capital goods sector is limited by the surplus produced in the wage goods sector. If 20 people work in the wage goods sector, where the productivity of labour (z) is 20 units per person and the real wage rate (w) is uniform throughout the economy and fixed at 10 units, then 20 people can be put to work in the capital goods sector. The crucial ratio is given

by $(z - w)/w$, where $z - w$ is the surplus per unit of labour in the wage goods sector. If the bottleneck in the production of wage goods has to be widened without lowering the real wage, all newly produced machines should be installed in the wage goods sector. On the assumption that these do not depreciate and that each machine employs one worker, total output of capital goods will be equal to the increment in employment in the wage goods sector. The growth rate of the economy is therefore equal to the growth rate of employment in this sector. Given the above mentioned allocation policy, the growth rate is nothing but the productivity of labour in the capital goods sector multiplied by the ratio of the surplus to the wage rate. Hence:

$$g = x(s/w); \quad \text{where} \quad s = z - w. \tag{1}$$

Assuming no production lags, maximization of (1) yields:

$$-(\mathrm{d}x/x) = (\mathrm{d}z/z)(z/s). \tag{2}$$

According to Eq. (2), the growth rate would be maximized by using more costly methods of production in the capital goods industry, lowering the productivity of labour in this sector. At the same time, the delivery of improved and more expensive equipment would *ipso facto* raise labour productivity in the wage goods industry. With a positive wage rate – implying a *z/s* ratio greater than unity – this gain need not be as large as the loss of productivity in the capital goods industry. It is the asymmetrical change in the sectoral productivities of labour which leads to an overall increase in capital intensity.

The results do not change if unassisted labour builds machine tools for the intermediate investment sector. In this case the gains in the intermediate sector multiplied by *z/s*, should equal the losses in the machine tools industry.

With a construction based on a number of simplifying assumptions, Dobb and Sen provided the rationale for raising the capital intensity of production under conditions of abundant labour supply. Yet the assumptions turned out to be restrictive not so much in relation to traditional theory, but in relation to the scope and objective of the exercise.

Analytically the model does not succeed in giving a criterion for the choice of techniques when the economy embarks on a path of self expansion of the machine tools sector. The only possible observation is that this sector's productivity does not depend on any other branch of the economy, thus there is no constraint on the degree of capital intensity (Johansen and Ghosh, in Dobb 1960). Dobb's and Sen's results depend very much on the assumptions of no production lags and of immortal machines. In macroeconomic terms, an increase in capital intensity generates a higher growth rate only if the share of investment in national income is raised more than proportionately, which may not be immediately feasible. In the interim period the economy will experience a lower growth rate and a lower share of consumption (Kalecki 1972a). In turn, the notion of immortal machines becomes untenable whenever Dobb analyses the possibility of drafting the whole of the labour force in the two investment industries for the purpose of building the machine tools sector. If wear and tear is taken into account, as soon as no equipment flows to the wage goods sector its capital stock will shrink and so will the output of consumables. The wage rate will cease to be a parameter, becoming instead a variable conditioned by the proportions in which labour and machines are distributed. Hence, wear and tear and the socially minimum wage rate show the limit of the percentage in which machine tools can be reinvested in their own sector. This is a major structural and social aspect of any process of accelerated accumulation (Lowe 1976; Halevi 1981).

Dobb's contribution will remain a classic in the field because it introduced a novel perspective on the reasons for, and the modalities of, socialist-oriented development for the ex colonial countries. The fact that this approach is no longer followed can only in part be attributed to the limitations outlined above. Perhaps, in addition to the ever present ideological factor, one explanation lies in the change of the historical framework. There are, by now, significant instances in which a process of fast accumulation has taken

place hand in hand with the persistence of phenomena such as landlessness and urban poverty. In countries like Brazil, Mexico and India, these are the problems that must be reflected in any planning strategy. The issue is not so much that of building a capital goods sector from scratch, but to conceptualize the economic and political nature of the phenomena (Kalecki 1972b, c; Taylor and Bacha 1976).

The second approach, coming mainly from India, is a substantial improvement on the Mahalanobis variant of the Feld'man model (Mahalanobis 1955). It uses the same hypothesis of two capital goods industries to discuss the sectoral allocation of machinery imported through a fixed sum of foreign earnings *F*. Raj and Sen (1961) assumed negligible amount of equipment in the intermediate investment sector *I* and in the machine tools industry *M* Furthermore, machine tools are used also for the extraction of raw materials *R*. The planners can freely choose the initial share of consumption over national income, production coefficients are given. In this context, if *F* is used to import *I* goods for the production of consumption goods *C*, the output of *C* goods will rise but its absolute increase will tend to nought because raw material requirements will also rise. A constant increment in *C* goods production can be obtained when *F* is used to import *M* goods for the production of *I* goods and for the extraction of *R*. In this case raw materials set a limit to the expansion of the *I* sector output. Finally, the output of consumption goods will grow at a constant absolute rate if *M* goods are imported in order to produce machine tools to be installed exclusively in the *I* and *R* sectors.

The original Raj–Sen paper did not discuss the proportions in which machine tools are reinvested in the *M* sector itself. In the literature that followed, the point was raised by Naqvi (1963) and later by Cooper (1983). Naqvi noted that reinvestment in the *M* goods sector would allow for a proportionate growth in *C* goods also in the presence of a limited amount of import earnings. Moreover he observed that central control of the *M* goods sector can be used to limit the creation of a luxury goods industry catering for the well to do. Cooper, on his part, argued that planners can more effectively influence the share of consumption by selecting the ratio in which *M* goods are to be reploughed in their own sector. This is because the share of consumption over national income cannot be freely determined by planners, since it is fixed by the initial distribution of equipment. Planning models based on sectoral relations and on the principle of the Accelerator in Reverse, showed a greater longevity than choice of techniques models. The assumption of given production coefficients did not prevent the analysis of alternative growth paths and the introduction of limiting conditions such as minimum wage rate and stagnant export earnings (Das 1974). The capital goods-consumption goods model has been used also as a framework for the application of optimal control theory in development planning (Stoleru 1965), as well as for the analysis of unused capacity caused by a slow growing agricultural output (Patnaik 1972; Raj 1975).

Contributions to investment planning using analytically a Marxian sectoral approach have come mostly from Great Britain and from India. The Soviet mathematical economists seem to be more inclined toward generic multisectoral optimisation models. This may reflect a belief that a purely capital goods-consumption goods approach ceases to be relevant when a socialist economy possesses a developed industrial structure. Yet, as it emerges from reading the works of some Soviet economists of the mathematical school, generic multisector models cannot give a stylized picture of growth paths (Dadayan 1981). Indeed, in the Western literature on growth, the crucial issue of the transition between two growth rates – a process called Traverse – is dealt with an analytical apparatus closer to Marx's sectoral characterization of the economy (Hicks 1965; Lowe 1976).

I

Invisible Hand

Mark Blaug

Abstract

Adam Smith employed the term 'invisible hand' twice in his published writings, and a considerable secondary literature has explored the multiple meanings he intended to convey by the use of this metaphor. I argue that, whatever he did mean, he certainly did not mean that competition or the market mechanism promoted efficiency: instead it promoted the growth of income, even for the poor.

The 'invisible hand' was a metaphor used by Adam Smith to describe 'the principle by which a beneficent social order emerged as the unintended consequence of individual human action'. This is Vaughn's succinct summary of Smith's intentions in employing the metaphor (1987, p. 997). More recently, Grampp (2000) has reviewed nine different interpretations of the famous metaphor, concluding that the three references to the invisible hand in Smith's works are not expressions of the same concept, an opinion share by many other commentators.

Smith referred to the 'invisible hand' twice in his published writings (there is a third reference in his unpublished 'Essay on Philosophical Subjects'), and he did so at greatest length in Book IV, Chapter 2, of the *Wealth of Nations*. It is easier to say what he did *not* mean by the invocation to the 'invisible hand' than to spell out precisely what he did mean. What he definitely did not mean is the so-called first fundamental theorem of modern textbook welfare economics, although that reading has been frequently ascribed to him (for example, Arrow and Hahn 1971, p. 1; Mas-Colell et al. 1995, pp. 308, 327, 524, 545, 549). The first fundamental theorem states that, subject to certain exceptions such as externalities, economies of scale, public goods and imperfect information, every competitive equilibrium is Pareto-optimally efficient. It is indeed possible to find statements in Chapter 2 of the *Wealth of Nations* on mercantilism that appear to endorse something like the first fundamental theorem. Capitalists have a preference for domestic over foreign investment for reasons of security, Smith asserts, but the result of the free movement of capital is nevertheless of benefit to society as a whole:

> As every individual, therefore, endeavours as much as he can both to employ his capital in support of domestic industry, and so to direct that industry that its produce may be of the greatest value; every individual necessarily labours to render the annual revenue of the society as great as he can. He generally, indeed neither intends to promote the public interest, nor knows how much he is promoting it. By preferring the support of domestic to that of foreign industry, he intends only his own security; and by directing that industry in such a manner as its produce may be of the greatest value, he intends only his own gain, and he is in this as in many other cases, led by an invisible hand to promote an end which was no part of his intention. (Smith 1776, pp. 455–6)

The natural interpretation of this passage is, at least for domestic industry, that total product is maximized by free competition. This is almost the first fundamental theorem – but not quite.

First, a presumption of maximization is not a mathematical theorem and, secondly and more significantly, free competition or free unrestricted entry into industries is a far cry from *perfect* competition without which the notion of the price-taking behaviour of numerous, small competitors, adjusting only the quantities they buy or sell, falls to the ground. Cournot invented the concept of perfect competition de *novo* in 1838 and, since the proof of the first fundamental theorem absolutely requires the concept of perfect competition, the idea that Adam Smith somehow stated a primitive version of the first theorem must be wrong; it is in fact a historical travesty.

Adam Smith clearly believed in competition, or rather 'the simple system of natural liberty', but his idea of competition was a behavioural one, not defined by the number of firms in the market as in Cournot. Competition, for Smith as for all the classical economists, implied rivalry by price and non-price means, rivalry among consumers bidding for a limited supply and rivalry among producers to dispose of that supply on the most advantageous terms. In other words, he had what I have called a 'process conception of competition', nowadays associated with Austrian economics, in contrast to the orthodox conception of economics, in which all the emphasis is directed to the nature of the final equilibrium, regardless of how that final equilibrium is attained (Blaug 1997, p. 678; see also Coase 1997, p. 318; Kirzner 2000).

Although the first theorem cannot be found in the *Wealth of Nations*, what can be found is the notion that competition has desirable properties, namely, that it promotes the rate of growth of

national income or what he labelled 'the wealth of nations', which results in the material improvement of the standard of living even of the poorest members of society. This idea is not only the mainspring of the famous opening chapter of the book on 'The Division of Labour' in the pin factory, but it accounts for the emphasis on capital accumulation and the crucial distinction for Smith's theory of economic growth between 'productive and unproductive' labour in Book II, not to mention the content of the whole of Book III with its revealing title 'The Different Progress of Opulence in Different Nations', which translated into modern jargon reads 'On Differences in the Growth Rate of Different Countries'. Much of Book III is devoted to persuading the reader that there had been material progress since Elizabeth I, a thesis which surprisingly was frequently denied at the time. In short, what was good about what he called 'the commercial society' was that it grew rapidly, not that it was efficient, a term and indeed a concept that never appears in the *Wealth of Nations*.

Smith's references to an 'invisible hand' in the *Wealth of Nations* have attracted an enormous secondary literature (for example, Hayek 1973, ch. 2; Vaughn 1987; Persky 1989; Grampp 2000; Rothschild 2001, pp. 116 ff. Streissler 2003, Minowitz 2004; Vivenza 2005), no doubt because they express three closely connected but separable ideas: (*a*) the *private* actions of individuals can have unforeseen and unintended *social* consequences; (*b*) these private self-interested actions and unintended social consequences may be harmonious in mutually promoting the interests of all members of society; and (*c*) there is an order in these harmonious outcomes as if private self-interested actions were centrally coordinated to produce a coherent overall pattern. This is a profound assembly of ideas that captures the doctrine of 'spontaneous order' employed by many thinkers of the Scottish Enlightenment to explain the emergence of such social institutions as language, the law, private property, the monetary system and even the market mechanism itself, not by central design or collective regulation but by individual action undertaken for quite different reasons. It arises most clearly in Adam Ferguson's *Essay on the History of Civil Society* (1767), published a decade before the *Wealth of Nations,* and even earlier in Hume's *Treatise of Human Nature* (1740). But important as the idea of a 'spontaneous order' may have been to Ferguson and Hume, as well as to Mandeville, Turgot and Dugald Stewart, it was not actually in the forefront of Adam Smith's thinking and, in any case, he never characterized the price system or even free competition as an 'invisible hand'. This is a modern reading of Smith under the influence of Walras and Pareto as translated by Arrow and Debreu.

It was only in the last quarter of the 19th century (as a result of German critics of Smith) that the phrase 'invisible hand', which after all occurs only once in the *Wealth of Nations*, was elevated to a proposition of profound significance. Rothschild deals expertly with the subject and concludes that 'the image of the invisible hand is best interpreted as a mild ironic joke' (2001, p. 116). This may be going a little too far in the opposite direction to the now prevailing interpretation, but there is no doubt that Smith himself did not attach great importance to the idea of an invisible agency channelling the behaviour of self-interested individuals and instead regarded the metaphor of the invisible hand as a sardonic, if not ironic, comment on the self-deception of all of us, including moral philosophers.

Support for this view of his intentions is found in the one reference to the 'invisible hand' in The *Theory of Moral Sentiments,* a reference that is frequently ignored in the exegetical literature on Smith. In that passage in the *Theory of Moral Sentiments* (1759, pp. 184–5) Smith argues that mankind has progressed in the face of pronounced and persistent inequalities and that the rich, despite their natural selfishness, end up unintentionally sharing their wealth with the poor, who for their part end up no worse than the rich themselves. Both Grampp and Minowitz, alone among all the Smithian commentators, object to this conclusion as too Panglossian. Be that as it may, this passage soon dispels the belief that Smith meant one thing and one thing only by the metaphor of 'the invisible hand'.

The notion of a spontaneous order in the sense of a self-regulating system accounting for the

existence of economic institution went underground after the Scottish Enlightenment, and references to an 'invisible hand' are rarely encountered in any of the classical economists, although the idea that economics studies an underlying invisible reality beneath the surface appearance of a free market economy continued to dominate the thinking of Ricardo, J.S. Mill and particularly Karl Marx.

The most common and analytically useful definition of involuntary unemployment is based on the labour supply curve: if workers are off the labour supply curve – so that there is an excess supply of labour at the current real wage – then, by definition, there is involuntary unemployment. The amount of involuntary unemployment is equal to the amount of excess labour supply. If workers are on the labour supply curve, then, by definition, there is no involuntary unemployment. One could analogously define involuntary overemployment as a situation of insufficient supply of labour at the prevailing real wage (as may occur during

wartime with wage and price controls), but the term is seldom used.

In a static, deterministic, utility maximization framework, the labour supply curve is simply the set of real wage and employment pairs for which the marginal rate of substitution of income for leisure is equal to the current real wage. Hence, involuntary unemployment can be equivalently defined using the utility function: if the real wage is greater than the marginal rate of substitution of income for leisure, then, by definition, there is involuntary unemployment. If the marginal rate of substitution of income for leisure is equal to the real wage, then there is no involuntary unemployment.

Historical Examples of Usage

This definition of involuntary unemployment is very close to that used by Keynes (1936). In Chapter 2 of the *General Theory*, Keynes writes '. . . the equality of the real wage to the marginal disutility of employment . . . corresponds to the absence of "involuntary" unemployment' (p. 15). (Keynes makes the simplification that the marginal utility of income is constant, so that the marginal disutility of employment is the same as the marginal rate of substitution of income for leisure.) Keynes excluded frictional unemployment from involuntary unemployment. However, it is important to note the Keynes also excluded unemployment 'due to the refusal or inability of a unit of labour, as a result of legislation or social practices or of a combination for collective bargaining or of a slow response to change or of mere human obstinacy, to accept a reward corresponding to the value of the product attributable to its marginal productivity' (Keynes 1936, p. 6). Thus, Keynes chose to exclude union wage differentials as well as minimum wage legislation as sources of involuntary unemployment. Clearly, Keynes wanted to focus on a particular type of involuntary unemployment.

Patinkin (1965, ch. 13) also used the static labour supply definition in his well-known analysis of involuntary unemployment:

> The norm of reference to be used in defining involuntary unemployment is the supply curve for labor . . . as long as workers are 'on their labor supply curve' – that is, as long as they succeed in selling all the labor they want to at the prevailing real wage rate – a state of full employment will be said to exist in the economy. (pp. 314–15)

Although Keynes developed and emphasized the idea of involuntary unemployment much more than economists had done before, the above definition based on the labour supply curve predates Keynes writings. In fact it was used by the 'classical' economists. For example, in 1914 Pigou proposed measuring involuntary unemployment of a group of persons by the number of hours' work by which employment '. . . falls short of the number of hours' work that these persons would have been willing to provide at the current rate of wages under current conditions of employment' (see Casson 1983, p. 39). According to Keynes, however, classical theories (such as Pigou's) did not admit the possibility of involuntary unemployment. Unemployment of a particular group caused by union wage differentials or minimum wage legislation was admitted by the classical theory, but as mentioned above Keynes chose to classify this as voluntary.

Criticisms of the Definition of Involuntary Unemployment

Despite the analytical simplicity of the above definition based on labour supply, the term involuntary unemployment has resulted in many critiques and controversies.

One of the criticisms stems from simple conflicts between the above technical definition and everyday non-technical usage of the term involuntary. For example, Fellner (1976) wrote, '. . . distinguishing elements of voluntariness from elements of involuntariness in the unemployment problem is a hopeless endeavour . . .' (p. 134) and that 'Keynes' definition is unhelpful and so are all variants inspired by that definition' (p. 53). Fellner and others have been concerned that one can never determine the intentions of a given unemployed person so that the broad

classification of unemployment into involuntary and voluntary is meaningless.

Although the many connotations of the term involuntary may cause semantic difficulties (as may other concepts in economics such as 'rational' or 'marginal'), focusing on the technical definition given above would seem to avoid these difficulties.

A second criticism arises in the practical use of the concept of involuntary unemployment for public policy. From the above definition, one criterion of good macroeconomic performance would be zero, or very small, involuntary unemployment. (Strictly speaking, this is true only if the measured real wage is equal to the marginal productivity of labour, an equality that might not hold if optimal contracts of the type described below are important in the economy.) Since government unemployment statistics are commonly taken as an indicator of economic performance, one might hope that measured unemployment could be related to the concept of involuntary unemployment. However, this is very difficult and any attempt is bound to be criticized. Government unemployment statistics typically attempt to measure the number of unemployed who are looking for work, but who have not yet found work. However, aside from the problem of determining whether someone is looking for work, or how intensively, unemployment statistics obviously include frictional unemployment and other types of unemployment that would not be included as involuntary according to the above definition. Even in a condition of relatively full employment, there exists some 'normal' unemployment, which government statistics need to be corrected for. Milton Friedman (1968) used the term 'natural' unemployment for the amount of unemployment that would exist, without excess supply, in equilibrium after wages and prices have adjusted. Another concept of normal unemployment is the non-accelerating inflation rate of unemployment (NAIRU), defined as the amount of unemployment that would exist when there is no tendency for wage or price inflation to rise or fall. Measuring the 'natural' rate or NAIRU in practice entails looking for an unemployment rate for which inflationary pressures are small and adjusting this rate for known changes in the demographic characteristics of the labour force. The natural rate of unemployment is not a constant, however, and these measurements have considerable error. Nevertheless, a practical alternative to involuntary unemployment as a measure of economic performance is the difference between the actual unemployment rate and the natural unemployment rate. For policy purposes, this may serve as a reasonably close approximation to involuntary unemployment, but clearly it is a different concept. In particular, note that this measure can be negative, as when the unemployment rate falls below the natural rate in boom times. Fellner (1976) suggested focusing on this measure and hence on inflation stability, rather than on involuntary unemployment, and he argued that demand management (monetary and fiscal policy) should promote the maximum amount of employment that can be achieved without inflation instability. This measure is also the criterion used in stabilization studies that characterize a macroeconomic trade-off in terms of the fluctuations of unemployment about the natural rate versus the fluctuations in inflation (see Taylor 1980).

A third reason for criticism of the term involuntary unemployment is that the standard definition is essentially static and deterministic. In fact, the static, deterministic labour supply and demand model does not admit an explicit theory of frictional or natural unemployment. Without such a model it is difficult even to discuss whether a given level of unemployment is voluntary or optimal or not.

Research on the microfoundations of unemployment (see for example Phelps et al. 1970), had as a major goal the development of a model of equilibrium unemployment – using search and matching theory. Some search models generated unemployment that was Pareto optimal (see Lucas and Prescott 1974, for example), but others included trading externalities and generated unemployment which could be non-optimal (see Diamond 1982, for example). While not yet definitive, at the least this research shows that for many public policy questions it is necessary to go beyond the simplest model of labour supply, and

thereby beyond the simple definition of involuntary unemployment.

In the *General Theory* Keynes presented a more convoluted definition of involuntary unemployment, and this has been a fourth source of controversy. According to Keynes (1936, p. 15),

> Men are involuntarily unemployed if, in the event of a small rise in the price of wage-goods relatively to the money-wage, both the aggregate supply of labour willing to work for the current money-wage and the aggregate demand for it at that wage would be greater than the existing volume of employment.

One can clearly envisage a point off the labour supply curve from this definition. However, there is much more. Embedded in the definition of involuntary unemployment are some of Keynes's other ideas that were part of his *theory* of involuntary unemployment, but logically distinct from the *definition* of involuntary unemployment. Within the definition it is noted that workers would be willing and able to have a reduction in their real wage (and still increase their work) if it occurred through an increase in the price level, but not if it occurred through a decline in the nominal wage. This 'stickiness' of nominal wages, which is generated as part of the market mechanism, is of course crucial to Keynes's theory. Also embedded in the definition is the assumption that firms are in their labour demand curve, so that a lower real wage would stimulate unemployment, an idea that is much less crucial for Keynes's ideas, as Leijonhufvud (1968) has emphasized. Why did Keynes emphasize this convoluted definition of involuntary unemployment? It seems clear that he wanted to highlight the crucial difference between his theory of unemployment and what he called classical theory. This difference centred on the inability, given the way labour markets and the whole economy interact, of individual workers to reduce unemployment simply by reducing nominal wages. As indicated above, Pigou based the definition of involuntary unemployment on the labour supply curve in much the same way that Keynes did, but the classical reason for its existence – simply that real wages were too high – was much different from the theory of deficient aggregate demand put forth by Keynes. In retrospect Keynes would have added clarity to his discussion by unbundling his theory and his definition of involuntary unemployment.

Implications of Recent Technical Research for the Concept of Involuntary Unemployment

Five research developments since the 1960s have had great relevance for the concept of involuntary unemployment: equilibrium macroeconomics, optimal contract theory, disequilibrium macroeconomics, efficiency or incentive wage theory, and staggered- wage setting theory. However, this relevance must be inferred from the research, because the term involuntary unemployment is seldom used explicitly, and perhaps avoided by many recent researchers.

Equilibrium Macroeconomics

One strand of research macroeconomics has established a strategy of trying to explain the observed fluctuations in unemployment by equilibrium models in which workers are always on their labour supply curves. Wages and prices are perfectly flexible, and all markets clear in these models. Lucas and Rapping (1969) and Kydland and Prescott (1982) represent some of the seminal work in this strand of research. Clearly if these models turn out to be successful and to dominate other models, then the idea of involuntary unemployment would become useless for macroeconomics. Shifts of the labour supply curve – caused by intertemporal substitution of labour supply in response to temporary actual or perceived fluctuations in the real wage – are the main source of employment variability in these models. Research in this area is continuing and branching out into 'real business cycle' theory which ignores monetary factors in the cycle altogether. It appears, however, that a very high labour supply elasticity – by the standards of recent microeconomic empirical research (see MaCurdy 1981) – is required for these models to be able to explain the observed fluctuations in employment.

Optimal Contract Theory

Studies by Azariadis (1975), Baily (1974) and others attempted to explain why involuntary unemployment would arise when there exist optimal contracts between firms and workers stipulating for fixed wage payments. However, when firms and workers have equal access to information, these studies have shown that, in the relevant sense, involuntary unemployment does not exist despite the fixed wage bill. In these optimal contract models the marginal rate of substitution of income for leisure is equal to the marginal productivity of labour – the condition for the optimality – in all possible states. Although workers are off their labour supply curve *ex post* (since the real wage is not necessarily equal to the marginal rate of substitution), this discrepancy has no welfare significance. Models in which firms have more information than workers about the nature of the shock can lead to a breakdown in the marginal conditions for optimality, but unless firms are more risk averse than workers the result is involuntary *over*-employment: the marginal productivity of labour is less than the marginal rate of substitution of income for leisure (see Green and Kahn 1983; Grossman and Hart 1983). Viewed as an attempt to explain involuntary unemployment this research, therefore, has been unsuccessful. Taken literally, it shows that much of the unemployment that may have appeared as involuntary is, in fact, voluntary or at least efficient!

Disequilibrium Theory

Malinvaud's (1977) careful examination of fixprice multimarket equilibria, following the tradition of Clower (1965) and Barro and Grossman (1971), has greatly helped to clarify the conceptual difference between Keynes's explanation of involuntary unemployment due to insufficient aggregate demand (where firms are constrained in product markets), and the classical unemployment associated with the real wage being too high (where firms are not constrained in product markets). This research also has had considerable policy relevance in the early 1980s because the high rates of unemployment in western Europe were diagnosed as classical rather than Keynesian by many economists.

Efficiency or Incentive Wages

Calvo (1979) and others have argued that involuntary unemployment can occur because high wages must be paid to give workers the incentive to work hard, to be productive, and not to shirk. As firms attempt to bid up their wages relative to other firms, an equilibrium is reached with all firms paying more than the wage in the absence of incentive effects and with involuntary unemployment: an excess supply of labour with unemployed workers willing to work at the going wage. This type of unemployment is not of the deficient demand type emphasized by Keynes, and given Keynes's willingness to lump other minimum wage unemployment in with frictional unemployment, it is likely that Keynes would have classified this type of unemployment as voluntary. Incentive wages would increase the normal unemployment (natural or NAIRU) rate, but there is little empirical evidence of how quantitatively important the effect is.

Staggered-Wage Setting Theory

In these models (see Taylor 1980, for example), wages are set with an aim to maintain relative wages unless there is a reason for relative wages to adjust. This relative wage setting leads average nominal wages to adjust with a lag described by a predictable dynamics to changes in demand. In these models prices are set as a markup over wages, and for this reason aggregate prices are almost as sticky as nominal wages. Combined with an elementary model of aggregate demand and an aggregate demand policy that does not fully accommodate inflation, these models are designed to be compared directly with the data and in fact lead to fluctuations in unemployment which have features similar to the real world. The unemployment in these models comes close to the usual definition of involuntary unemployment, but since explaining empirical regularities is a primary objective, unemployment enters the model directly as the deviation of unemployment from the natural rate – a more readily measurable quantity than involuntary unemployment. These models show that wage rigidities need not be very long to generate the type of fluctuations in unemployment that characterize the business cycle.

Like the equilibrium models discussed above, and unlike the other three research developments described above, these models are dynamic and can therefore be directly tested against time series data.

Although there has been a tendency for much recent research to avoid the term involuntary unemployment, and instead to define unemployment as appropriate to the theoretical or empirical objectives of the research itself, the term involuntary unemployment will probably continue to be used. Despite the criticism and controversy discussed above there is little harm in this usage, as long as the technical definition is emphasized. Its usage may encourage researchers to point out the connection of new results to past achievements.

IQ and National Productivity

Garett Jones

Abstract

A recent line of research in economics and psychology hypothesizes that differences in national average intelligence, proxied by IQ tests, are important drivers of national economic outcomes. Cross-country regressions, while showing a robust IQ-growth relationship, cannot fully test this hypothesis. Thus, recent work explores the micro-foundations of the IQ-productivity relationship. The well-identified psychological relationship between IQ and patience implies higher savings rates and higher folk theorem-driven institutional quality in high average IQ countries.

Experiments indicate that intelligence predicts greater pro-social behavior in public goods and prisoner's dilemma games, supporting the hypothesis that high national average IQ causes higher institutional quality. High average IQ countries also have higher savings intensity by a variety of measures. Other possible IQ-productivity channels are discussed, as are possible environmental causes of differences in national average IQ.

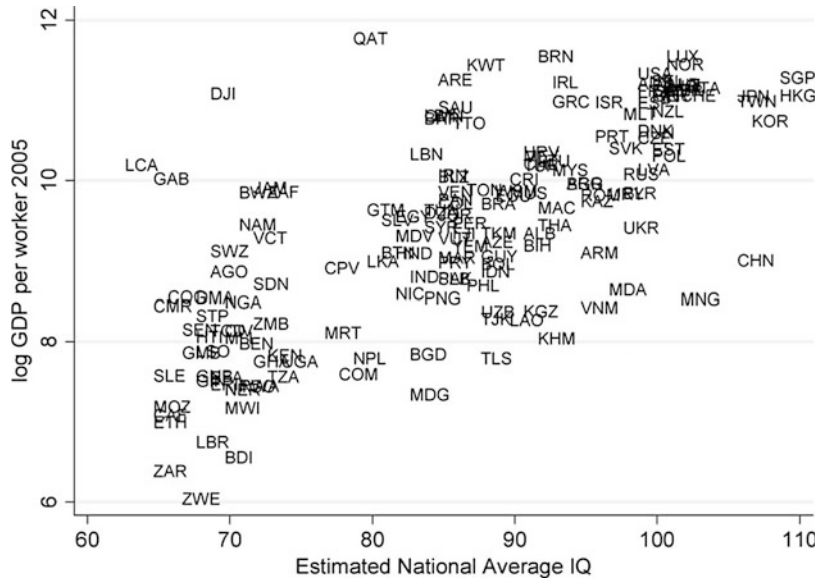
In recent years, some economists and psychologists have proposed that the average level of intelligence in a country – measured by conventional IQ tests – is an important independent driver of economic outcomes. As psychologists have known for decades, average IQ scores differ when given to large samples in different nations, and recent estimates indicate national average IQ correlates 0.7 with log GDP per capita (Fig. 1).

The macroeconomic question of interest is why IQ, which has a modest relationship with individual wages within a country, has such a strong relationship with average worker productivity across countries. When IQ is normalised in conventional IQ points (UK mean = 100, standard deviation = 15), one IQ point is associated with approximately 1% higher wages, but 6 to 7% higher national productivity. While higher national productivity almost certainly raises IQ for the poorest countries, this reverse causation may not be the whole story, and indeed channels running from income to IQ have been widely studied already (Jones and Schneider 2006, 2010, and citations therein.). This article focuses instead on potential cognitive spillovers, channels through which national IQ could have payoffs to nations that only indirectly reward high-IQ individuals. These possible channels include better-informed voters, more cooperative workers and political elites, more saving (in a world of capital frictions) and access to higher-quality production functions (in a world of complementarities to worker quality).

A brief summary of IQ testing and of the possible drivers of national IQ differences is provided



IQ and National Productivity, Fig. 1 National average IQ and year 2000 GDP per worker (Notes: Y-axis shows GDP per worker in logarithmic scale. The sample covers 164 countries. Pearson and Spearman correlation both equal 0.7. One IQ point predicts 7.7% higher GDP per worker. Source: Lynn and Vanhanen (2006) and Penn World Tables 7.0 for IQ and GDP data, respectively)

below; the discussion includes possible methods of raising national average IQ.

The essay proceeds as follows. We begin by summarising modern psychometric estimates of intelligence and the major databases of national average IQ. We then discuss the labour literature on IQ and wages, followed by growth regressions that control for national IQ. Two channels – patience and skill complementarities – by which intelligence might influence national GDP per capita are then considered, before turning to institutional channels. Methods that could raise national average IQ, including environmental, nutritional, and health interventions, educational interventions, and immigration policies are discussed, and finally we look at areas for future work and draw conclusions.

Measuring Intelligence

What is intelligence? Can it be measured? The answers to the first question range from 'intelligence is what intelligence tests test' (Peak and Boring 1926, p. 71) to the more useful statement that intelligence is a model of mental ability built around 'the empirical fact that all mental abilities are positively correlated' (Jensen 1998, p. 45). In other words, people who are better at mathematical reasoning tend to do better than average on trivia tests, whereas people who are worse than average at pattern-finding tend to be worse than average at vocabulary tests or memorizing long lists of numbers. The precise value of the correlation across mental tasks varies across tasks but in large, diverse samples it is non-negative. (For a candid consensus document on the nature of intelligence authorized by the American Psychological Association, see Neisser et al. (1996).)

Psychologists have found this positive correlation so often that in academic research, intelligence is often operationalized as the '*g* factor', the first principal component from a large battery of mental tests (Jensen 1998, Ch. 3). This one summary statistic, *g*, is often translated into units known as an IQ score. IQ is normed at a mean value of 100 within the UK, and the standard deviation of IQ within the UK is defined as equal to 15 IQ points. In practice, and within this essay, other types of IQ test that use other metrics are converted into the IQ scale with UK mean 100 and standard deviation of 15.

A vast literature across the social sciences has documented the many conditional and unconditional correlates of IQ: within affluent countries, individual IQ scores correlate positively with lifespan, wages and (*sic*) myopia; it correlates negatively with criminality, tendency to smoke and number of motor vehicle accidents (Jensen 1999, Ch. 9). These correlates are well-known. Some less-well-known correlates of individual IQ include *in vivo* brain size measured with MRIs and CT scans (typically +0.3 to +0.4, cf. Wickett et al. 2000), nerve conduction velocity between the eye and the vision centers of the brain (+0.4), and reaction time and inspection times (respectively, speed with which one presses a lighted button and the minimum amount of time one needs to decipher whether a quickly-flashed symbol was, say, an 'I' or an 'L') (Jensen 1998, Ch. 6; Deary 2001). These newer correlates of IQ are much less subject to the criticism that people with high IQs are just people who test well. Instead, they are something more: they are quicker.

Can IQ be measured across countries, even in developing countries? And if so, do these tests have similar real-world reliability to IQ tests given within OECD countries?

The answer to both questions is yes, with some modest grounds for caution. IQ tests have been translated into dozens of languages, and private companies who sell IQ tests to schools, hospitals and firms have often created nation-level standardization samples of 1,000 or more. Although non-psychologists often think of IQ tests as 'pencil and paper tests', in fact the widely used Wechsler IQ tests involve mostly talking with a psychologist and answering her verbal questions; a few subtests involving solving wood block puzzles, assessing pictures or (occasionally) writing some answers with pencil and paper.

Further, IQ tests exist that are entirely non-verbal: the Catell Culture-Fair test, Raven's Progressive Matrices and the Draw-a-Man test are three prominent examples. So any researcher who

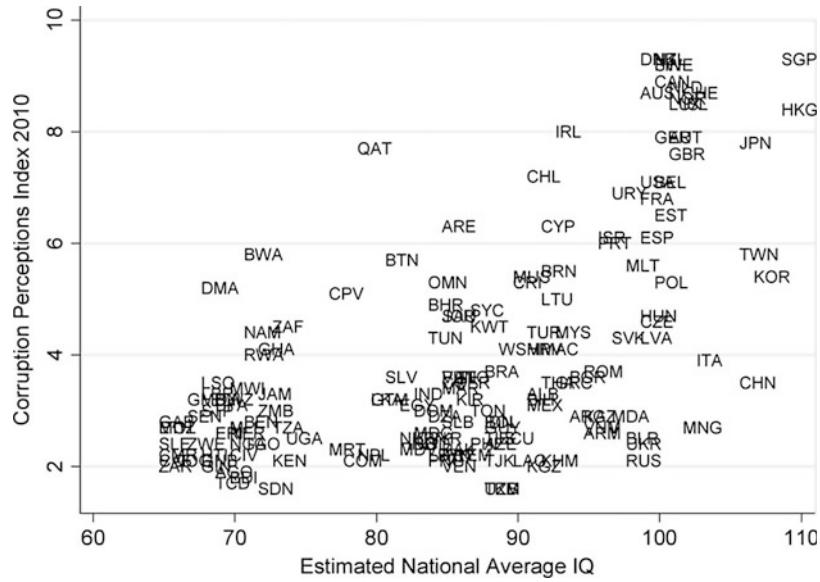
chose to estimate a nation's average IQ score would have a wide variety of tests from which to draw.

The psychologist Richard Lynn and the political scientist Tatu Vanhanen (henceforth LV) assembled two collections of IQ scores by scouring the academic and practitioner literatures for reported IQ in a total of 113 countries (2002, 2006). They included some IQ standardisation samples and some national tests of mathematical ability, but most of the studies they used were 'opportunity samples', studies of an ostensibly typical classroom or school in a particular country. As Jones and Schneider (2010) show, the high-quality samples and opportunity samples are highly correlated, and have a mean absolute deviation of 3.2 IQ points.

Recall that the LV IQ estimates correlate 0.7 with log GDP per capita. Because the LV sample includes many types of IQ test and because LV describe the IQ tests that make up each nation's IQ estimate, Jones and Schneider (2010) were able to show that this correlation holds if one uses only IQ estimates from non-verbal IQ tests. The correlation between Ravens IQ and log GDP per capita is between 0.9 and 0.7, depending on the form of the test; the Ravens was the only single test used often enough to calculate test-specific correlations. And regardless of the type of IQ test used, rank order across countries is little-affected.

LV used these data to create estimates of national average IQ; theirs were the first databases of national average IQ, but not the last. When LV had multiple plausibly representative IQ estimates for a country, they took the mean (2002) or the (likely superior) median (2006) from across the studies. In their 2006 dataset, they have data from 113 countries, and for most countries they have more than one study to draw upon. The global mean IQ (unweighted by population) is 90, 2/3 of a UK standard deviation below the mean, and the standard deviation across countries is 11 IQ points. In recent work, Rindermann (2007a, b), Rindermann and Thompson (2011) and Lynn and Meisenberg (2010a) have created new average national IQ estimates using more rigorous methods but for fewer countries; since their estimates correlate strongly with the larger LV 2006 sample, we largely use the latter in this essay (LV also interpolate national IQ estimates for countries that lacked IQ scores: In LV (2006) they present evidence that their LV (2002) interpolations were reliable. Figures 1 and 2 use both interpolated and actual IQ estimates; correlations are unaffected when interpolated values are omitted).

One question is whether these IQ measures across countries are reliable: whether they



IQ and National Productivity, Fig. 2 National IQ and corruption (Notes: Higher values on Y-axis indicate lower perceived corruption. The sample covers 165 countries. Pearson and Spearman correlations both equal 0.6. *Source*: Lynn and Vanhanen (2006) and the 2010 Corruption Perceptions Index)

measure differences in the same battery of mental skills across countries as they do within countries. On a variety of measures, one can say that the answer is yes. Leaving aside the purely psychometric measures of cross-cultural IQ validity (a longstanding research area in psychology; see citations in Jensen (1998, Ch. 11)), economists have found that within low average IQ countries, IQ scores have approximately the same relationship with wages as they do in rich countries. In both rich and poor countries, 1 IQ point is associated with between 0.5% and 1.25% higher wages. One study in rural Pakistan using the Ravens IQ test (Alderman et al. 1996) found that 1 IQ point was associated with 0.9% higher wages, very close to the Zax and Rees (2002) estimate of males in Wisconsin; and other examples can be multiplied (Behrman et al. 2004).

Some social scientists have criticized the LV datasets (Volken 2003; Wicherts et al. 2010a and citations therein); early criticisms included claims of one-to two-point errors in recording or interpreting the underlying data. In only one case was a misinterpretation substantial (Equatorial Guinea, mistakenly given an IQ estimate of 59; Lynn has dropped this observation from his most recent update). Random errors in the one-to two-point range are regrettable but almost surely irrelevant for empirical work; and to the extent that they introduce errors in variables, they will understate the true relationship in bivariate regressions (Durbin 1954).

More recent criticisms arose in a series of papers by Wicherts et al. (2009, 2010a, b) focusing solely on LV's sub-Saharan African IQ estimates. These critics note that LV exclude many studies of African IQ from their sample, and include some studies where the researchers reported health problems or enormous irregularities in test administration (for instance, some children taking a test in rural Africa were inexperienced in the use of pencils). Lynn and Meisenberg (2010b) responded to this critique in part by noting that tests preferred by Wicherts sometimes included college student samples or otherwise elite populations, samples likely to be unrepresentative in undeveloped countries; indeed, LV always omitted college-only samples when estimating IQ for rich countries, so their treatment was symmetric across rich and poor. This exchange is highly recommended for insight into how databases are constructed; and Young (2010) is recommended as a parallel reminder of the weaknesses of African GDP data.

On the question of student health, if poor health hurts both measured IQ and the underlying skill the IQ test is designed to measure, then researchers should *hope* that such samples of students are included in a national IQ estimate: while there is certainly real interest in knowing what a nation's average IQ would be if all students had first-world health and nutrition, it is also of great interest to know how student's brains are performing in the world as it currently exists.

In a surprise ending to the dispute between Lynn and Wicherts et al., the latter chose (2010b) to look at individual studies that used only large, nationally representative samples, samples that met all of their quality requirements. In their K-12 samples, the median IQ across a variety of sub-Saharan African countries was 76.5 – about half an intra-UK standard deviation away from Lynn's own estimate of average sub-Saharan African IQ: 70. By either measure, sub-Saharan African nations currently have the lowest average IQs of any region of the world. As Wicherts et al. themselves conclude, '[t]here can be little doubt that Africans average lower IQs than do Westerners' (Wicherts et al. 2010a, p. 17). Wicherts et al. (2010a, p. 17) propose some methods of increasing average African IQ: 'These include improvements in nutrition and health [care], increases [in] educational attainment, improvements in educational practices, urbanization, large-scale dissemination of visual–spatial toys, etc. Although it cannot be precluded that genetic effects play a role in the low IQ performance of Africans, we view environmental circumstances as potentially more relevant to the present-day difference in mean'.

Thus, the academic critics and Lynn agree on the point that is of most interest to economists: IQs differ across countries, and the rank order of the difference has broad agreement. As we shall see below, in applied cross-country work researchers have both Winsorized the data to 80 or 90 or

included sub-Saharan African dummies, partly to take account of the possibility that these scores are inaccurately low. Researchers have taken the Wicherts et al. critiques into account.

IQ and Wages

A routine finding in labor economics is that childhood and adolescent IQ scores in developed countries are positively correlated with adult wages (Bowles et al. 2001; Neal and Johnson 1996, and citations therein). This holds whether or not one controls for education. In a conventional diminishing returns, price-taking setting, the relationship between IQ and wages is the relationship between IQ and the marginal product of labor. Jones and Schneider (2010) use this fact to estimate the microeconomic effect of differences in national IQ on national productivity.

Using their preferred estimate for ease of exposition, 1 IQ point is assumed to cause 1% higher micro-level productivity.

Based on Ramsey and Solow model intuitions, economists might expect that at the national level, in steady state, this would cause an even greater effect on macro-level productivity: IQ raises the marginal product of labor, and since in a Cobb–Douglas production function this is observationally equivalent to an increase in TFP, this would raise the marginal product of capital as well. In steady state, one would expect this to increase the level of capital in order to reduce the marginal product of capital back to its steady state level. All of these channels are correct, but nevertheless conventional theory predicts that for conventional production functions, the micro level IQ–productivity relationship is identical to the macro steady state IQ–productivity relationship.

The micro and steady-state macro effects are identical because the micro relationship among human capital, wages, and productivity already assumes that capital is drawn to highly productive labor. Consider the case of two types of workers with IQ levels IQ_{L} and IQ_{H}, $IQ_{\mathrm{H}} > IQ_{\mathrm{L}}$. The size of each group of workers is normalized to unity. The workers share a fixed homogenous capital stock $K_{\mathrm{L}} + K_{\mathrm{H}} = K$ and use the production function

$$Y = K_L^{1/3} IQ_L^{2/3} + K_H^{1/3} IQ_H^{2/3}.$$

If capital can flow freely and the representative firm is a price-taker, then capital will flow toward the high IQ workers until the marginal product of capital is equalized across the two categories of workers. In equilibrium, workers with 10% higher IQ will have 10% more capital, because they provide 10% more effective labor. One can place quotation marks in the previous sentence around either ‘more effective’ or ‘effective labor’: the management science interpretation is different, but the implications for the capital–labor ratio are the same. Thus, micro-level cross-section wage regressions include the endogenous effect of physical capital’s attraction to workers with higher levels of human capital.

One can use the cross-sectional relationship between IQ and wages within a country to test the validity of the LV IQ measures. In an ideal test, one would want to randomly select workers from different countries and place them into a new country, wait a few years, and then measure their wages. One could then determine whether the average immigrant from a country with an LV IQ 10 points lower than her new country earns 10% less than the average person in the new country. This experiment would hold institutions, capital and many other features constant, and only vary the country of origin of the experimental subjects.

Such an experiment is impossible and undesirable in its pure form, but immigrants to the USA provide a useful approximation. Using Hendricks’s (2002) data on wages of immigrants to the USA, Jones and Schneider (2010) regress the average income of immigrants from each country (whether or not adjusted for education) on that nation’s LV IQ. They find approximately the same 1:1 IQ/wage relationship that others find in the labor literature: immigrants from higher LV IQ nations earn modestly more after arrival in the USA than immigrants from lower LV IQ nations. A one-point increase in national average IQ predicts an approximate 1% increase in average income of immigrants from that country. In a simple calibration Jones and Schneider find that this private marginal product of labor channel can

explain approximately 1/6th of the cross-country variation in log productivity per worker. Workers from higher LV IQ countries are typically more productive, although this private productivity channel is likely far from the whole story.

National IQ in Growth Regressions

Growth regressions also support the hypothesis that higher LV IQ causes better economic performance. LV themselves ran bivariate correlations and one-and two-variable growth and level regressions, always finding a strong relationship between national average IQ and the outcome of interest. Weede and Kampf (2002) ran more conventional Mankiw–Romer–Weil/Barro-style cross-section growth regressions, controlling for institutional quality, schooling and starting GDP per capita; again, national IQ was a reliable growth predictor. While some regressions had been reported, the question of LV IQ's overall robustness was unclear.

Jones and Schneider (2006, henceforth J/S) answered the question of LV IQ's robustness by including (*inter alia*) 455 cross-section growth regressions using the dataset and combinations of the control variables from Sala-i-Martin et al. (2004, henceforth SDM). J/S only included the 18 growth regressors that were robust in SDM's Bayesian Averaging of Classical Estimates exercise. They included geographic dummies, years open to trade and ethnolinguistic fractionalization among other controls. Their regressions included three fixed controls (the three most robust SDM regressors: log GDP per capita in 1960, primary schooling in 1960 and the price of investment goods) and all 455 possible permutations of the remaining 15 robust controls taken three at a time. Thus seven controls were included in every regression. National average IQ was statistically significant at the 1% level in *every* regression.

J/S provide additional Bayesian model averaging robustness tests that accord with this result. Ram (2007) also found that national IQ was a statistically significant growth regressor in multiple specifications. Using the structural equation methods common in psychology, Rindermann and Thompson (2011) have found a reliable positive relationship among national average cognitive skills, good pro-market institutions, and good economic performance. Notably, that paper includes a separate estimate of the cognitive skills of the highest-scoring 5% of the population in his OECD-heavy sample; they find that the skills of the top 5% have disproportionate predictive power for good outcomes.

J/S use their mean IQ growth regression coefficient to calculate the predicted steady-state relationship between LV IQ and GDP per capita. This calculation, derived from Jones (2000) and Barro and Sala-i-Martin (2001, pp. 466ff.), is both practical and rarely used. Recall the conventional cross-sectional growth regression, where y_i is GDP per capita for country i at the beginning of the time period, $\Delta\ln(y_i)$ is the log change in GDP per capita over the sample period, β is the speed of convergence to steady state (typically found to be 2% per year (Barro and Sala-i-Martin 2001, pp. 496, 521; for an early critique see Quah 1996)), X_i is a column vector of other controls, and θ' is the row vector of coefficients corresponding to those controls:

$$\Delta\ln(y_i) = \gamma - \beta\ln(y_i) + \theta' X_i + \varepsilon_i$$

If we assume that technology grows at an exogenous rate (a conventional motivation for treating γ as exogenous to a particular country is that the growth rate of useful technical knowledge is overwhelmingly external to any one country) and appropriately demean the other variables, then γ is the steady-state growth rate of GDP per capita, conventionally considered 2% per year over the past century. Under the Solow-style assumption of conditional convergence, all steady-state growth in per capita GDP is caused by γ: so any growth seen over the sample period greater or less than γ is caused by convergence to a nation's steady state path of GDP per capita. This suggests the following transformation:

$$\Delta\ln(y_i) = \gamma + \beta[\lambda' X_i - \ln(y_i)] + \varepsilon_i$$

where $\lambda = \theta/\beta$. By factoring out a β from the coefficient on the so-called growth regressors,

we see that under the assumption of conditional convergence 'growth regressors' are actually steady-state log-level regressors. Therefore the coefficients θ on these growth regressors are actually coefficients for the steady-state log-level effect λ multiplied by the rate of convergence, β. The term in square brackets has a straightforward interpretation: it is the gap between starting log GDP per capita and steady-state log GDP per capita. (Strictly speaking, $\theta' X_i$ is log steady-state GDP per capita as of the end of the sample period: given the exogenous growth rate, each nation's log steady-state GDP per capita increases by γ every period.) The gap between the two closes at rate β per year.

Jones and Schneider find that 1 IQ point is associated with slightly more than 0.1% faster annual GDP growth; given their β estimate of slightly less than 2, they estimate that 1 IQ point predicts 6% higher steady-state GDP per capita. As noted already, this is at least six times greater than most estimates of the micro-level relationship between IQ and individual productivity, and it is consistent with the hypothesis that IQ has positive spillovers. The next two sections discuss what some of those cognitive spillovers might be.

Skill Complementarities and Patience

This section considers two channels for IQ spillovers: complementarities to worker skill and the well-identified link between patience and intelligence.

Kremer (1993) notes that much of modern production is fragile: He discusses the explosion of the space shuttle *Challenger*, destroyed by the failure of a single O-ring, a band that sealed the burning rocket engine. Less tragically, and more routinely, many production processes have such 'weakest link' elements, where many workers toil on a project, and where failure at any one step of the production process can destroy the value of the whole. As Kremer notes, clothing with minor flaws is sold at steep discounts and computer chips with the smallest flaws are unusable.

In weakest link settings, Kremer shows that it is privately rational and socially efficient for workers to sort across firms by quality. To take the simplest example, assume two types of worker of quality q_{H} and q_{L}, with effective labour of $q_{\mathrm{L}} = 0.5q_{\mathrm{H}}$. The production process has two steps and output is multiplicative in worker quality: $Y = q \times q$. This production function could represent, as Kremer notes, the process of making a vase, where any worker has some probability $1-q$ of dropping the vase (the probability of completing a particular vase is then q^2); or where an error at any step in the production process would reduce the value by some fraction q.

Given a fixed supply of workers and equal amounts of both types of workers, it is efficient to sort workers into firms where all workers are of the same quality:

$$q_H^2 + q_L^2 = 1.25q_H^2 > 2q_H q_L = q_H^2.$$

Within a given firm that had both types of workers, the firm would voluntarily sort the workers to maximise output. Kremer shows that this result is generalisable to decentralised economies with physical capital stocks and large varieties of worker skill: If production functions have complementarities to skill, market forces will tend to sort workers into firms by skill level.

Kremer draws on this finding to help explain why rich countries tend to have higher levels of human capital: higher average levels of worker skill open the door to using more advanced technologies (which may demand longer production chains), while nations with lower skill levels will be able to produce little output, since long production chains dramatically increase the probability of a value-destroying error.

The Kremer model thus provides a new reason for believing that returns to human capital may be large; but how could one reconcile the hypothesis that human capital returns are large across countries with the routine finding that returns to human capital are modest within countries? The model of Jones (2010) provides one resolution: the model proposes that there are two production technologies available in each country, a Kremer-style O-ring technology and a diminishing returns to

scale, Cobb–Douglas 'Foolproof' technology that works according to the conventional model of Part II. (The diminishing returns in the Foolproof sector reflect multiple ways in which non-O-ring technologies are less productive as they expand as a fraction of the economy: it can represent nontradable personal services, demand for which is limited; it could represent the use of well-understood production processes that were perhaps once O-ring in nature but are now relatively 'Foolproof' (such as the production of aspirin); and it could represent traditional, nonscalable agricultural and manufacturing methods.) In this Cobb–Douglas sector, workers of different skill levels can readily work together in the same production process, and average skill level is a sufficient index of worker quality. In the Foolproof sector, workers that are 1% lower in average quality might early only 1% less; whereas in the O-ring sector, 1% average lower worker quality causes a much larger decline in output and hence wages.

Consider the case of two types of workers, again q_H and q_L: high-skilled workers voluntarily sort between the two sectors until wages for q_H workers equalize. The model's key result is that as long as there are not too many lower-skilled workers, the q_L workers will voluntarily sort into the Cobb–Douglas sector, producing slightly less output and earning only slightly lower wages than other, higher skilled workers in the same country. The q_L workers would not want to use the O-ring technology since they are much less productive with that technology; lower quality workers are poor substitutes in the O-ring sector but good substitutes in the Foolproof sector.

But a nation of q_L workers would produce little with the O-ring production technology; they would likely crowd into the Cobb–Douglas sector, producing little indeed, though still more than if they used the O-ring technology. The Foolproof sector is appealing to low-skilled workers when there are few people in it; because it faces diminishing returns (or limited demand for Foolproof goods and services), a nation of q_L workers in the Foolproof sector will have very low average productivity. Returns to human capital will be small within countries but large across countries. The model is thus consistent with the empirical observation that IQ has a strong relationship with cross-country productivity but a weaker relationship with intra-country productivity.

While the O-ring/Foolproof model matches this fact, further work can investigate whether other implications of the theory hold true: do low-skilled and low-IQ workers take on more complex, delicate tasks when living in nations with low average IQ? Do high-skilled, high-IQ workers take on more mundane tasks when working in high-average IQ countries? Within a country, are new technologies massively more productive when used solely by higher-IQ workers? Production functions, so widely used in economics, are still under-tested in empirical work.

Another link between IQ and national productivity is driven by IQ's reliable correlation with patience. In intertemporal optimising models of national economies, the rate of time preference is always a key parameter, one that influences long-run interest rates, investment, and the capital stock. Growth economists typically assume the rate of time preference is identical across countries. Is this assumption tenable? Psychological research and behavioural economics research combined with LV IQ estimates suggest the answer is no. And recently, Banerjee and Duflo (2011) have written that reduced willingness to delay gratification may be of first-order importance in explaining global poverty: 'the poor... often behave as if they think that any change that is significant enough to be worth sacrificing for will simply take too long. This could explain why they focus on the here and now...'.

Psychologists have known for decades that patience and IQ are almost always positively correlated. Shamosh and Gray (2008) survey this literature, finding that in 23 out of 26 experimental studies, high IQ individuals are more likely to delay gratification.

Shamosh and Gray suggest one channel through which intelligence could directly cause patience: through the ability to keep multiple facts simultaneously in one's mind. One strong correlate of overall intelligence – indeed, one subtest of some IQ tests – is memory span: the quantity of numbers or letters that can a person

can recall a few moments after hearing them. Since considering the opportunity cost of consuming now versus later requires keeping four hypothetical situations in mind (consuming vs. not consuming now; not consuming vs. consuming later), memory span provides one cognitive foundation for the IQ–patience relationship. Further work can investigate other possible channels.

In one well-known study of delayed gratification Mischel et al. (1972), the experimenter gave a 4–6 year-old child a marshmallow, and then told the child that he was going to leave the room. He told the child that if she waited until he returned to eat the marshmallow, the child would get a second marshmallow. The experimenter then waited long enough that almost all children eventually ate the marshmallow (or other treat); minutes until marshmallow eaten was then recorded as the key experimental outcome.

Children used many innovative methods to avoid thinking about the marshmallow on the table in front of them, such as 'covering their eyes with their hands or talking to themselves' so they would think less about the marshmallow (p. 205). These innovations are suggestive of a link between delayed gratification and intelligence. And the evidence supports such a suggestion: in a 1990 follow-up of the adolescent behavior of these same test subjects, Shoda et al. found that children who waited longer before eating the marshmallow had higher SAT verbal ($\rho = 0.42$, $p < 0.05$), and SAT quantitative ($\rho = 0.57$, $p < 0.001$) scores.

Since children's differences in waiting time are measured in mere *minutes*, then any attempt to convert this study's results into a parameter linking SAT (and its strong correlate, IQ – cf. *inter alia* Frey and Detterman (2004) and Beaujean et al. (2006)) to the *annual* rate of time preference would involve astronomical numbers. With half a million minutes per year, any IQ-delay finding from such an experiment extrapolated to the annual β or ρ parameters familiar from growth economics would predict that low average IQ countries would have negligible savings. In the original study, Mischel et al. found that older children waited longer; this suggests that this is not an age-invariant parameter. While the IQ–patience relationship is well-documented, economists will have to search further for a parameter relevant for national economies.

Two recent studies by economists have provided evidence that among adults, the IQ–patience relationship *can* be mapped into the familiar space of choices over long time periods. Dohmen et al. (2010) using a sample of German adults find that in both hypothetical and actual choices of money now versus a year from now, a one intra-US standard deviation increase in cognitive skill is associated with a decline in the discount factor. Further evidence comes from the US peace dividend of the early 1990s: when the US military downsized, it offered enlisted personnel who wanted to separate early the option of an immediate lump-sum payment or an attractive annuity with an internal rate of return greater than 17%. Even controlling for income, years served, age, education and many other factors, scores on an enlisted person's Armed Forces Qualifying Test was a statistically significant, correctly signed predictor of one's likelihood of accepting the attractive annuity (Warner and Pleeter 2001).

Jones and Podemska (2010) convert these estimates of the relationship between cognitive skill and time preference into a parameter, $d\rho/d(IQ)$. Their benchmark estimate is that one IQ point lowers the discount rate by five basis points. They then use that data in a conventional Ramsey growth model. In a closed economy, differences in national IQ would predict less investment and hence lower steady-state capital–output ratios; Jones and Podemska show that indeed high IQ countries tend to have higher capital–output ratios and higher rates of savings. (The empirical relationship between national IQ and savings, or national IQ and capital intensity, is quantitatively larger than one would expect from a simple Ramsey growth model when estimated in logs; it is close to the predicted relationship when estimated in levels. Peer effects on saving deserve attention as one possible reason for a stronger country-level relationship; Maurer and Meier (2008) find moderate peer effects on individual consumption spending using the Panel Study of Income Dynamics.)

This is an IQ externality because the capital stock with which one works and from which one earns interest is determined by the average IQ of one's national compatriots; if one were permitted to move to a higher-IQ country, one would be able to work with a larger capital stock through no effort of one's own. The missing market here is the market for global labour (or equivalently, frictionless global capital flows).

In an economy fully open to capital flows, Barro and Sala-i-Martin (2001, pp. 164–5) describe the quite extreme steady state. In a purely theoretical discussion, they rank countries by order of time preference, denoting Country 1 as the most patient. Their theoretical result is stark:

> Asymptotically, Country 1 owns all the wealth... [all] claims on capital and the present value of the wage income in all countries... All other countries own a negligible amount (per unit of effective labor) in the long run.

The reason for their result? Because the market interest rate – identical around the world – will eventually be set by the most patient country, and less-patient nations will voluntarily borrow money at that interest rate to consume more than their income until they have promised their entire future income stream (minus an epsilon amount, under the Inada conditions) to repay the debt.

Because this conclusion is considered unrealistic, growth economists typically assume that there are frictions that keep any one nation from promising its entire future income stream as collateral. But as barriers to international finance have fallen in recent decades, then one might expect the world to move, if not entirely to the Barro/Sala-i-Martin steady state, at least in that direction.

Jones and Podemska (2010) claim that for many countries, holdings of US Treasuries, a liquid form of wealth, are one indicator of whether a nation is building up its stock of global savings. Omitting a few offshore banking havens and OPEC countries, they find that high LV IQ countries hold a disproportionate share of US Treasuries as a share of their nation's GDP: high LV IQ countries have high Treasury/GDP ratios, a result that holds after controlling for GDP per capita.

The Treasury/GDP ratio is an imperfect index of global saving; they are gross measures, not net. If nations with high Treasury/GDP ratios were also massive net borrowers, the Jones and Podemska (2010) result could be completely overturned. Fortunately, holdings of net foreign assets are also available, with annual data from 1970 to 2004 (Lane and Milesi-Ferretti 2004, 2007). This ratio of net foreign assets to GDP has the same positive predicted relationship with LV IQ. Omitting the OPEC countries, the phosphorous-rich micronation of Kiribati, and Liberia, the world's most FDI-intense nation, the correlation between LV IQ and net foreign assets to GDP in 2005 was +0.4; including all of these outliers increases the estimated regression coefficient, since Liberia is a massive recipient of foreign capital, though the *t*-statistic on IQ falls to 5. The relationship has strengthened over the period as barriers to capital flows have fallen since the end of Bretton Woods; in 1970 the correlation was +0.2.

Thus, mainstream growth theory combined with a conventional result in psychology (IQ's link to patience) can partially explain why some nations hold more financial and physical capital than others: Nations with higher average intelligence are more patient, and the patient inherit more of the earth.

Institutional Channels

Caplan and Miller (2010) find that within the USA, voters with higher IQs are more likely to support market-oriented policies, even controlling for income, education and political orientation. This might come as little surprise to those of us who have taught economics: The invisible hand is hard for some students to see, whether it comes to the unintended consequences of price controls or the power of the law of comparative advantage. Spontaneous order, multipliers, the law of unintended consequences: on average, the same individuals who on an IQ test can spot what is unusual in a drawing of a room full of children (one of the kids is facing the wrong way) are the same individuals who can see how doubling the

minimum wage is likely to hurt employment opportunities for the poor.

Since politicians tend to respond to the demands of citizens, whether wise or unwise, nations (especially democracies) with higher LV IQ are more likely to support the market liberalising policies that have been routinely found to be growth-promoting. And if individuals have a modest tendency to conform to their neighbour's views, the conventional finding of sociology, then the Caplan and Miller channel will become even stronger: people in slightly higher-IQ countries will have slightly higher-IQ neighbours, and tend to reinforce each other's slightly more liberal economic policy views. The urge to conform will create an IQ-voter quality multiplier.

O'Rourke and Sinnott (2006) provide preliminary cross-country evidence for the Caplan and Miller view: in the majority of countries, high-skilled workers are more supportive of trade than low-skilled workers. In the poorest countries, this relationship weakens, and it may reverse for countries at the GDP per capita level of the Philippines or below – nations with productivity 1/10th or less of frontier nations. Future research should investigate whether cognitive skills are good predictors of policy views in less developed countries.

Based on Caplan and Miller's results, one would predict that across the range of actually existing variation, high-IQ countries would tend to rank as freer on most indices of economic freedom. Unsurprisingly, this is the case: the Freedom House economic freedom measure correlates 0.6 with LV IQ (LV 2006, p. 251), and as we will see below national IQ also correlates positively with institutional quality.

Finally, smarter groups are more cooperative, more trusting, and more trustworthy in laboratory experiments (Pinker 2011, p. 611). If wealth-promoting political institutions depend partly on tacit cooperation among political elites, then this channel may help explain why high LV IQ nations are so much more prosperous. Jones (2008) was the first to find that high IQ groups were more cooperative in repeated prisoner's dilemmas: he collected data on repeated prisoner's dilemma experiments run at dozens of universities and found that when such experiments were run at high-SAT universities, students cooperated more often. This result held after controlling for whether the school was private or public, and a variety of experimental protocols such as number of rounds and whether students played for real money.

Later work has reinforced this result: Burks et al. (2009) in an experiment run on students in a truck driving school, found that in a one-round, two-move sequential prisoner's dilemma (similar to a Berg et al. (1995) trust game), high IQ players were more likely to cooperate in the first move, and were more likely to reciprocate cooperation in the second move. The first move corresponds to 'trust' and the second to 'trustworthiness'; high-IQ individuals possessed more of both traits in their sample.

Further, Putterman et al. (2010) found that among students at Brown playing a repeated public goods game, high-IQ players were more likely to contribute more in early rounds of the game, and contributed more overall. (Recall that the prisoner's dilemma is a two-action version of the public goods game.) And returning to Caplan and Miller's voter-quality channel, Putterman et al. found that when a voting round was added to the middle of the game, high IQ voters were more likely to vote for the efficient constitutional rule for punishing free riders. That IQ predicted pro-social behaviour at an Ivy League university reduces the likelihood that the results in other studies are driven by extreme social deprivation of low IQ individuals, anti-cooperation cultural norms among the families of low IQ individuals, or other similar sociological and environmental stories: among some of the world's most elite students, differences in IQ predicted differences in pro-social behaviour.

One unconventional measure (Jones and Nye 2011) finds that national average IQ and education levels are good predictors of law-abiding behaviour in a nearly lawless setting: the world of diplomatic parking in New York City. Until 2003, United Nations diplomats in New York were not required to pay parking tickets. Fisman and Miguel (2007) assembled this unpaid parking ticket data by country and found that diplomats from high-corruption countries were far more likely to earn parking tickets: corruption travelled

with the diplomat. But Jones and Nye find that when controlling for the national average IQ of the home country, the home country education level, or both, the statistical significance of home-country corruption is reduced or eliminated. The corruption channel may be operating through a human capital channel.

These results matter for political institutions, because politics is a repeated game where politicians are tempted to sacrifice long-run benefits for short-run benefits: high-level officials are tempted to take bribes that destroy transparency rather than reap the rewards of better institutions; judges and lawyers are tempted to collude rather than neutrally abide by the rule of law; members of parliament are tempted to confiscate capital after it has been invested in their nation (Jones 2011).

Repeated games abound in the public choice and political economy literatures, and in such models, a key parameter is always the discount factor, β. The discount factor is central to the folk theorem of repeated games: When players are more patient, they are better able to reach the Pareto-efficient solution. And as we have seen already, high-IQ individuals and groups appear to be more patient by a variety of measures. In a nation of patient players, politicians care more about long-run reputations (Persson and Tabellini 2000, Ch. 4), central banks find it easier to solve the time consistency problem (Barro and Gordon 1983) and thereby sustain a low-inflation equilibrium, and officials engaged in Rubenstein bargaining problems will split rents more equally, likely reducing social conflict.

Potrafke (forthcoming) finds cross-country evidence that national IQ is a reliable predictor of low national corruption as measured by the Corruption Perceptions Index, even when including a variety of historical and policy controls (Fig. 2). Surplus-destroying rent-seeking appears less common in high LV IQ countries.

If the links between IQ, patience, and pro-social behavior remain as strong as they appear in recent research, then differences in LV IQ are likely causing differences in the quality of institutions across countries. The political externalities of IQ may be large.

Maximizing Intelligence

What can be done to raise a nation's average level of intelligence? The public health literature has a set of obvious and data-driven answers: environmental improvements, childhood nutrition improvements, and better prenatal care all appear to be ways to increase IQ. A vast literature on the topic is summarized in Armor (2003); a few key pieces of evidence will need to suffice for the purposes of this essay. The link between environmental lead and intelligence is well-established; one recent paper, Ferrie et al. (2011) found that among Second World War draftees in the USA, higher exposure to lead through lead water pipes caused an IQ drop of five points. And in the Philippines, Solon et al. (2008) found that a 1 microgram increase in lead per litre of blood was associated with a 2.5 to 3.3 IQ point decrease in children. In the Filipino sample, children averaged 7.1 micrograms of lead per litre, a level that, extrapolated linearly, would predict at least a 15 IQ point decrease.

Until 2006, almost every sub-Saharan African country used leaded gasoline (United Nations Environment Programme 2002, 2005). The end of leaded gasoline in Africa will likely increase measured IQ in coming decades.

Experimental studies in developed and less-developed countries both suggest that for some individuals, IQ can be increased by providing proper micronutrients (Armor 2003; Jensen 1998, pp. 325–6). Nutritional channels are likely important in developing countries: in Pune City, India, a mere 10 weeks of zinc supplementation caused a 15–25 percent increase in student scores on the Ravens test (Tupe and Chiplonkar 2009). Notably, zinc supplementation increased the speed with which students pressed lighted buttons: Reaction time improved. Behrman et al. (2004) also survey evidence that increases in maternal and child health will increase IQ: iron and iodine deficiencies appear to be barriers to riches in the poorest nations.

A finding of the greatest importance is the Flynn Effect (1987), the well-known and conclusively documented trend of rising IQ across the rich countries. At least until the last decade, it appears that IQ scores have risen by two to three points per decade

across at least the second half of the twentieth century in the developed countries; while the debate continues over how much of this is nominal versus real (e.g. test-taking skill versus real-world problem solving and memory skill), there are sound reasons for believing that some portion is a genuine increase in mental ability. (One piece of evidence for a real increase in cognitive skill: human head size has increased by one standard deviation during the same time period when measured IQ in rich countries has increased by approximately the same amount (Jensen 1998, p. 325). If this is so, then economists should bring their unique tools to bear on the important question of why IQ has risen in the rich countries. Perhaps they will find ways to spur and strengthen a Flynn effect in the world's poorest countries. The most comprehensive discussion of the Flynn Effect is contained in a volume edited by Neisser (1998).

Finally, Eppig et al. (2010) have used the LV national average IQ data to argue that parasite prevalence, which correlates negatively with LV IQ, in fact helps to cause low national average intelligence.

If IQ provides some of the long-run positive externalities discussed in this essay – raising voter quality, improving institutions, providing access to frontier technologies, and raising capital intensity – then the benefits to improving public health are greater than currently believed.

Education may also increase overall intelligence; here the evidence is more scattered, but at the very least it appears plausible that increases in the quality and quantity of education raise measured IQ. Winship and Korenman (1997) drawing on the NLSY and comparing their results to other studies, conclude that one extra year of ostensibly exogenous education increased IQ by 'somewhere between 2 and 4 points' (p. 218). Hansen et al. (2004) used non-experimental methods to come to a similar conclusion. Card and Rothstein (2007) used plausibly exogenous variation in residency driven by desegregation court orders in the USA as in instrument for exogenous quality of schooling and peers. They found that an end to racial segregation in schools closes 'about one-quarter of the raw black-white gap in SAT scores', an IQ proxy (p. 2158).

The question remains whether these increases are what Jensen calls 'hollow IQ', mere test-taking skill rather than an increase in intelligence: perhaps future work can investigate whether the pattern of nerve conduction velocity and response times also moves in the expected direction when students exogenously receive increases in the quality and quantity of education.

One can also increase national average IQ quite reliably by allowing high-IQ individuals to immigrate. A decision to admit high-IQ immigrants as voting citizens would yield both the neoclassical and the institutional benefits of higher national average IQ. And since IQ correlates positively across generations, if high-IQ immigrants raise families in their destination country, then they will likely provide long-lasting benefits to the country that admits them.

If IQ has the sizeable positive externalities posited here, then there may be room for a Coasian bargain between countries with low current LV IQ and higher IQ individuals in other countries. One purely suggestive possibility: if the ratio of private to public benefits of higher IQ are even half as large as the 6:1 ratio suggested by Jones and Schneider (2010), a low LV IQ country could rationally offer a 100% subsidy for any wages a high-IQ immigrant earns in excess of that nation's median wage. In practical terms, a ten-year income tax holiday for permanent immigrants with engineering degrees could accomplish the same goal of encouraging high-IQ immigration.

A closing word on the question of possible genetically driven differences in national average IQ is needed. In developed countries, at the within-country, within-ethnicity level, it is clear that a substantial fraction of variations in IQ are genetically driven – around half or more (Caplan 2011; Boomsma et al. 2008; Plomin et al. 2000; Devlin et al. 1997). But the tools that behavioural geneticists use to establish the heritability of IQ or features such as height, eye colour or personality – twin studies and adoption studies – are rarely applicable for studying ethnic differences in intelligence, and of little use in studying cross-country differences.

Recent psychology textbooks and surveys (Loehlin 2000; Hunt 2010; Mackintosh 2011) discuss the issue of ethnic differences in

intelligence, partly drawing on adoption studies of children of East Asian and African descent adopted by families of European descent; here I discuss only the East Asian data. (Hunt's discussion of the James Watson affair (pp. 416–17) is recommended as a dispassionate summary of an important moment in the public discussion of the possible relationship between human genetics and intelligence.) One study cited by Loehlin and Mackintosh notes that adoptees of East Asian descent performed better than average on IQ tests; another repeated finding noted by these authors is that Native Americans, closely genetically related to East Asians, have a similar pattern of relatively high visual-spatial intelligence compared to whites. Together with other pieces of evidence, these findings induced both authors to either tentatively accept (Loehlin) or at least consider plausible (Mackintosh) the hypothesis that the higher average IQ of East Asians is at least partly genetic in origin. The hypothesis that at least some portion of cross-country IQ differences is genetic in origin has mainstream support from within the psychology profession.

But genetic differences do not imply intractable differences. The myopia common among high-IQ individuals is partly genetic in origin, yet eyeglasses and laser surgery have turned this genetic difference into a nuisance or less in wealthy countries. If IQ provides some of the long-run positive externalities discussed in this article – raising voter quality, improving institutions, providing access to frontier technologies and raising capital intensity – then the benefits to finding medical solutions for differences in IQ – whatever their origin – are greater than currently believed.

Conclusion

Since at least the work of Hanushek and Kimko (2000), economists have known that years of schooling are a poor measure of human capital; these authors found that national average test score measures were far better predictors of long-run economic performance. One weakness of the test score literature is that standardised mathematics, science and language scores are available for only a few dozen countries; another weakness is that little is known about non-school, non-wage individual-level correlates of such test scores (for expansions of these datasets, see Hanushek and Woessmann (2007, 2010)).

By using national average IQ as an index of human capital, growth economists can tap into a century of research by psychologists, sociologists, neuroscientists, geneticists and microeconomists into the causes, correlates and effects of IQ differences. Patience, pro-social behaviour and better-informed voting are among a few of the correlates of higher IQ discussed here, and others may exist. In cross-country growth regressions and calibrations, national IQ appears to have a much larger influence on economic outcomes than one would predict from conventional wage regressions; one can hope that future research will uncover practical methods for raising every nation's average level of cognitive skill.

Ireland, Economics in

Tom Boylan and Renee Prendergast

Abstract

This contribution provides an overview of Irish economic thought from the 17th to the late 20 century. Broadly speaking, the pioneering contributions of the 17th and 18th centuries were concerned with the issue of improvement or economic development. The 19th century saw the formal institutionalization of political economy in Ireland and seminal contributions to value, distribution, and international trade theory in addition to work on public finance and methodology. The achievement of independence in the 20th century led to new concerns with development and policy experiments aimed at promoting lasting growth.

The 17th and 18th Centuries

William Petty and Richard Cantillon are commonly regarded as the founders of classical political economy. Both had connections with Ireland. Petty, English by birth, came to Ireland with the Cromwellian army in 1652 and became interested in 'political anatomy' in the course of surveying the country in preparation for the confiscation of Irish lands. Cantillon was born in Ireland but spent his adult life in as a banker in Paris, where he

wrote what many regard as the first systematic treatise on economics. Despite his nationality and his importance, Cantillon's work is not considered here. It was not written in Ireland; it was neither inspired by Irish conditions nor known to contemporaries living in Ireland.

Political Anatomy of Ireland, written in 1671–2, was Petty's first attempt to uncover the symmetry, fabric and proportion of the body politic by means of political arithmetic. Like all of Petty's writings, it contains pregnant theoretical suggestions, but our interest here is in its systematic approach to economic development. Petty sought to identify Ireland's development potential by considering the distribution and value of land and by estimating the number of 'spare hands' who could potentially add to local or universal (tradable) wealth. Petty identified the main causes of Irish underdevelopment as constraints on Ireland's trade with England and the plantations, insufficient coin, underdeveloped consumption patterns, perceived illegitimacy of rulers, rent-seeking and low population density. Petty's proposed remedies as set out in a *Report of the Council of Trade in Ireland,* 25 March 1676, included regularization of money, restoration of trade with the plantations and (particularly the cattle trade) with England, a bank based on landed property as security, reformation of the housing of the poor, legislative union with England and later the transportation of large numbers from Ireland to England. Despite a reference to discountenancing the use of certain foreign commodities in the report, Petty seems not to have favoured protection, arguing in *Political Anatomy* that the proceeds of exports would be more than sufficient to pay for imported products.

Partly as a result of prohibitions on the export of live cattle to England, farmers turned their attention to sheep, with the result that towards the end of the 17th century Irish wool and woollen yarn were among its most important exports. This promising development was nipped in the bud by restrictions introduced under the Wool Acts of 1698–9. This added to the fragility of an already weak economy, resulting in widespread poverty and unemployment in the early decades of the 18th century. Despite their confused and somewhat contradictory Irishness, the new generation of planter stock, including the likes of Prior, Dobbs, Browne, Molesworth, Hutcheson, Swift and Berkeley, responded with a steady stream of pamphlets advancing various proposals for improvement. These included increased agricultural investment, drainage and reclamation of bogs, improvement of inland waterways, encouragement of sea fisheries, mining and manufacturing, the setting up of a mint, consumption of locally produced goods, taxation of absentee rents, removal of restrictions on foreign trade and deportation of the undeserving poor (Kelly 1991). The main differences were between those such as Browne and Berkeley, who were relatively positive about Ireland's development prospects, and those such as Swift, who believed that plausible sources of improvement had little realistic chance of being implemented by those with the power to do so. Swift's position was vigorously expressed in *A Modest Proposal* (1729), a powerful satire on the pamphlet literature of his own time and one of the most telling critiques of positive economics ever to have been written anywhere.

While most authors emphasized the need to remove the constraints on trade, Berkeley argued that it would be more prudent to concentrate on those branches which were permitted, including Ireland's domestic trade (Berkeley 1752). Development would be possible even if the country were surrounded by a wall of brass. This, however, would require the substitution of domestically produced goods for the imported luxuries consumed by the elite as well as an expansion of the wants of the poorer classes in order to make them industrious. An argument for the reform of consumption patterns had already been made in 1726 by Francis Hutcheson in his 'Remarks upon the Fable of the Bees' in the course of controverting Mandeville's claim that luxury and vice were inseparable from economic development. Berkeley, who was also an implacable adversary of Mandeville, was even more emphatic than Hutcheson in his opposition to luxury, and he showed himself willing to contemplate sumptuary laws to achieve this objective. While Berkeley's proposals for development on the basis of the

domestic market were innovative at the time, his most radical proposals related to the adoption of paper money and the setting up of a national bank. Real wealth, Berkeley argued, consisted not in gold or silver but in the plenty of the necessaries and comforts of life and the power to command the industry of others. Money was simply a ticket or a counter for conveying or recording such power. As such, paper money and bank deposits were perfectly adequate and had some advantages over coin. The ruinous effects of the Mississippi and South Sea schemes were not due to paper money as such but to its use for speculative purposes rather than as a catalyst of industry. Private banks being subject to frauds and hazards, Berkeley proposed the setting up of a public bank, which he assumed would not suffer from these disabilities. The radicalism of Berkeley's position can be appreciated if we bear in mind that support for a fiduciary credit system as opposed to metallic money was in his time very much a minority view and remained so until recently (Murphy 2000).

The recovery of the Irish economy which took place in the second half of the 18th century was partly due to the success of the linen industry, which had been encouraged as a replacement for wool, and partly to the gradual weakening of commercial restrictions as Britain's population grew and Ireland became an important source of food and agricultural raw materials. During a brief period of legislative independence from 1782 to 1800, the Irish Parliament took steps to encourage domestic industry with various protective measures. It also introduced a corn law to encourage corn production for the British market.

The 19th Century

Following the Act of Union in 1801, Ireland was assimilated into the administrative and political jurisdiction of the United Kingdom. Many of its newly established industries went into gradual decline and corn production became a major source of employment. Population increased and with it poverty culminating in the Great Famine of 1845–50. These conditions influenced developments in political economy in Ireland and elsewhere. The need to counter the argument that high rents were a major cause of Irish poverty was a catalyst for the development of Malthus's rent theory (Prendergast 1987). The attention devoted by John Stuart Mill to the incentive effects of different forms of land tenure was partly a response to Irish land conditions. The scale of the human tragedy of the Irish famine influenced the perception and standing of laissez-faire political economy in Ireland and elsewhere. Irish economists became pioneers of the Historical School, which emphasized the specificity of time and place.

The formal institutionalization of political economy in Ireland began with the establishment of the Whately Chair in Trinity College in 1832. The chair was funded by Richard Whately, the Protestant Archbishop of Dublin, who came to Ireland from Oxford in 1831. The chair was part of a larger crusade by Whately to promote the dissemination of political economy with a view to encouraging more economically responsible behaviour. The Whately chair was to be filled by a number of outstanding occupants, which included Mountifort Longfield, John Elliot Cairnes and Charles Bastable. Chairs in jurisprudence and political economy were also established in the new Queen's colleges set up in at Belfast, Cork and Galway in 1845 (Boylan and Foley 1993). Outside of the universities, the principal institutional development was the founding in 1847 of the Dublin Statistical Society, later the Statistical and Social Inquiry Society of Ireland, which had Whately as its first president (Daly 1997). The society aimed at 'promoting the study of Statistical and Economical Science' and its participants included the academic, administrative and professional elite of Irish society. By the mid-19th century an extensive institutional infrastructure for the teaching and dissemination of political economy was in place (Boylan and Foley 1992).

Irish political economists in the 19th century made original contributions to a number of theoretical areas within the discipline. In value theory, the seminal contribution of Longfield, the first holder of the Whately Chair, has received

considerable attention and is recognized as providing one of the earliest attempts at formulating a subjective theory of value (Moss 1976). A number of Longfield's immediate successors, including Isaac Butt, James Anthony Lawson and William Neilson Hancock, also subscribed, albeit in a limited way, to a subjective theory of value, which led R.D.C. Black (1945) to suggest that the early Whately professors constituted a 'Dublin school' of subjective value theorists who anticipated by 30 years the marginal revolution of the 1870s. Longfield's contribution contained in his *Lectures on Political Economy* (1834) is by far the most original offering reflecting his disagreement with the dominant Ricardian framework of analysis in value and distribution theory.

Longfield approached value and distribution as pricing problems. The theory of value, in which commodity prices were determined in markets by supply and demand, was at the centre of his analysis. Longfield did not neglect the influence of cost on market price through changes in supply, but his main emphasis was on demand. The concept of a demand schedule was introduced, in which market demand was conceived as a ranking of individual demands according to their intensity, where 'the market price is measured by that demand, which being of the least intensity, yet leads to actual purchases'. Longfield invoked the concept of the individual's demand schedule as being composed of 'several demands of different degrees of intensity' (Longfield 1834, pp. 113, 114). This is now interpreted as a seminal statement, foreshadowing the principle of marginal utility that was to find its more formal articulation in the marginalist writers of the 1870s. Though not a member of the Dublin 'school', William Edward Hearn's *Plutology: Or the Theory of the Efforts to Satisfy Human Wants* (1863) was a significant contribution to the debate on the subjective theory of value. Hearn was appointed the first Professor of the Greek Language in Queen's College Galway in 1849. He left Galway in 1854 and became Australia's first professor of economics (Boylan and Foley 1984b). *Plutology* contained an extended and sophisticated taxonomy of the different kinds and degrees of human wants. Hearn went on to examine how demand could influence the impact of changes in the cost of production for different kinds of commodities; he distinguished between the demand for essential commodities or 'necessities' and non-essential or 'superfluities'. In this analysis Hearn provided a valuable extension to Longfield's earlier contribution, which was well regarded by contemporaries and later writers including Jevons and Marshall.

If Longfield and the Dublin 'school' represented an anti-Ricardian position in value and distribution, the Ricardian tradition was powerfully represented by Cairnes, the sixth holder of the Whately Chair at Trinity from 1856 to 1861 and Professor of Jurisprudence and Political Economy at Queen's College Galway from 1859 to 1870. Cairnes was arguably the most distinguished of the 19th-century Irish academic economists, and contributed to a number of areas of economic theory and contemporary policy issues. Cairnes was a close personal friend of J. S. Mill and was strongly influenced by Mill's analysis, but he produced a more complicated version of the theory of value than Mill. In *Some Leading Principles of Political Economy Newly Expounded* (1874), Cairnes provided a cost-of-production theory of value. But it is clear not only that Cairnes's 'normal value' is to be identified as cost of production, but that cost should be interpreted as real cost or sacrifice. In the course of his analysis he made the innovative move of applying Mill's proposition of the determination of international values by reciprocal demand in the case of factor immobility between countries to the internal economy of a country. In the latter situation, the existence of internal factor immobility gave rise to what is arguably Cairnes's most original application of the concept of non-competing groups. Cairnes's tenure in the Whately Chair broke the intellectual continuity of the Dublin 'school' by virtue of his commitment to the Ricardo–Mill approach.

In the domain of distribution theory one of the most interesting contributions was made by William Thompson (1775–1833), an Owenite and supporter of the French Revolution. Thompson pursued the aim of formulating an alternative economic system based on the rights of the primary

producer. He emerged as the most analytical and original thinker of the Owenite movement, which later became identified with the Ricardian socialists. Thompson was a personal friend of Bentham and it has been argued that Thompson's originality as a thinker consisted in his appropriation of the greatest happiness principle as a basis for fundamental social reform (Duddy 2002). While radical utilitarianism provided him with a critical component of his rationale for social reform, it was the adoption of Owen's system of mutual cooperation by Thompson, as a model of social organization, that would deliver to individual primary producers the fruits of their labour, which was fundamental to the Ricardian Socialists' doctrine.

In contrast to the Irish contributions to the Ricardian tradition of distribution theory, Longfield was forging a rather different approach in his *Lectures on Political Economy* of 1834. As Moss (1976) has argued, if the classical economists found the unifying principle for their theories of distribution in the concept of cost of production on the supply side, then Longfield could be said to have discovered his unifying principle of factor pricing in his supply and demand analysis. His identification of the role of marginal demand in the commodity market and marginal productivity in the factor market, justifies Longfield's claim as one of the leading progenitors of the neo-classical marginal theory of commodity and factor pricing.

In the area of international trade, the originality of Irish economists matched their contribution to value and distribution theory. In his *Three Lectures on Commerce and One on Absenteeism* (1835), Longfield extended the theory of comparative cost in significant directions, including the addition of both the multi-commodity and multi-factor case. He also addressed the issue of the incidence of tariffs and traced their effects on the relative price ratios between trading countries. Isaac Butt, Longfield's successor in the Whately Chair, considered the case for protection in his *Protection to Home Industry: Some Cases of Its Advantages Considered* (1846). This work, which was influenced by conditions in Ireland, was both methodologically engaging and analytically perceptive in its assessment of the benefits and weaknesses of protection in the context of particular circumstances.

Cairnes's reputation in the area of international trade rests on his systematic integration of the concept of non-competing groups into his analysis. This allowed him to distinguish between the role played by costs of production in determining international prices where effective competition existed; but where competition was absent, as in the case of non-competing groups, the fundamental determinant of international prices was not costs of production but reciprocal demand between noncompeting groups. He also provided an account of the factors determining the movements and range of a country's prices and money incomes arising from international trade, along with an original analysis of the process of international borrowing and the effects of loans on the equilibrium of international trade. This contribution that has been described as 'perhaps of greater permanent merit than any of his doctrines' in this area (Angell 1926, p. 94).

If the early and middle parts of the 19th century are associated respectively with the writings of Longfield and Cairnes, the latter part of the century must be identified with the work of Charles Bastable, who occupied the Whately Chair for 50 years, from 1882 to 1932. Bastable's *Public Finance,* first published in 1892, was a pioneering treatise that integrated, for the first time since McCulloch's *Taxation and the Funding System* (1845) what had become a rapidly expanding field of enquiry. Reviewing *Public Finance* in the *Economic Journal,* L.L. Price (1892) suggested it was the most comprehensive treatment of the topic since Adam Smith's *Wealth of Nations.* Bastable also made important contributions to international trade. In *The Theory of International Trade* (1887), he introduced varying elasticities of demand, increasing and decreasing returns and an extended analysis of obstacles to competition. In *The Commerce of Nations* (1892b), he provided a stringent critique of protection, while his name is associated with the celebrated 'Mill–Bastable' condition, which became an important part of the extended analysis of protection (Chipman 1965).

A distinguishing characteristic of many Irish economists in the 19th century was their commitment to an inductive method of approach. This was certainly true of the early Whately Professors. Isaac Butt maintained a robust scepticism with respect to the generality of economic principles, while Lawson was highly critical of Senior's efforts to reduce political economy to an axiomatic basis. It was not that the Irish writers called into question the validity of the deductive method in political economy. Rather, their position was that empirically observed facts should provide the basis for deductive reasoning. The methodological bias towards the inductive approach has been linked to the fact that the majority of the Irish professors were lawyers by training and profession and this allied to the preoccupation with the land question influenced their concentration on detailed studies of applied issues (Black 1947). Two of the most important representatives of the inductive approach were Thomas Edward Cliffe Leslie and John Kells Ingram. Both were major figures in the English-speaking world as pioneers of the Historical School of political economy. They were critics of the classical method of deduction and stressed the absolute necessity of an inductive approach to the study of economic issues, which in their view could never be separated from the larger social matrix of relations. The exception among the Irish contributions to economic methodology in the 19th century and to the inductivist position in particular was Cairnes who, in *The Character and Logical Method of Political Economy,* provided the most rigorous exposition of the deductive method that was produced in the course of the century.

The 20th Century

At the beginning of the 20th century, Belfast was Ireland's leading industrial centre, with strengths in linen, shipbuilding, rope making and engineering. Elsewhere agriculture predominated, and manufacturing was limited mainly to the food and drink industries. Against this background, the nascent independence movement regarded the development of industry as a matter of strategic importance. Drawing on the German economist Friedrich List, Arthur Griffith, the founder of Sinn Fein, proposed a programme for balanced economic development using protection on a broad scale. Protection was not to be permanent and was to be removed when the protected industries were strong enough to meet international competition (Griffith 2003). Industrial Development Associations throughout the country urged people to purchase Irish-made goods. Although the validity of the infant industry argument was widely acknowledged, in the main professional economists were not advocates of protection. Professor Oldham of University College Dublin argued that the relative openness and small size of the Irish economy meant that the protection of the home market could not provide a basis for development. Oldham was also concerned about the hidden costs of protection and suggested that bounties should be preferred to tariffs on grounds of their greater transparency and controllability (Oldham 1908, 1917).

During the 1921 Treaty negotiations with Britain, which were led by Arthur Griffith, professional economists including Riordan, O'Brien and Smiddy played a valuable role in securing the right of the Irish Free State to determine its future tariff regime (Girvin 1989). However, despite this and the fact that partition, which accompanied independence in 1922, involved the loss of Ireland's leading manufacturing centre, the new Free State government was cautious in its approach to economic policy and favoured free trade, fiscal prudence and the maintenance of the link with sterling. Bastable of Trinity and George O'Brien of University College Dublin were members of a committee set up in 1923 to consider the case for greater protection. The committee came out strongly against tariff protection for industry. Among the grounds given were that protection would raise costs for exporting industries, including the all-important agricultural sector, whose increasing efficiency and exports were seen as the main motor for growth.

The Great Depression of the late 1920s and the widespread protectionism to which it gave rise made a re-evaluation of the free-trade position necessary. In any event, a new government with

a different electoral base placed strong emphasis on self-sufficiency in both agriculture and industry. A bitter Anglo–Irish dispute over land annuities added further momentum to the protectionist drive. This led the Trinity College economist Joseph Johnston to argue in his polemical *Nemesis of Nationalism* (1934) that the Anglo–Irish dispute had been provoked by Eamon de Valera, the prime minister, in order to expedite his drive towards self-sufficiency. To judge from the contents of the Statistical and Social Inquiry Society journal during the period, the most prominent academic economists were also opposed to the policy of self-sufficiency. One of the few economists to comment favourably on the policy was J. M. Keynes, who also cautioned that only a modest degree of self-sufficiency could be achieved in such a small economy without a drastic impact on the standard of living (Whitaker 1983, p. 59).

The protectionist policies were successful in increasing industrial output and employment, but, as predicted by Keynes and as understood by Sean Lemass, the industry and commerce minister, and his top civil servant, the real challenge was to nurture industry to international competitiveness and to maintain the impetus for development once the initial easy phase of import substitution was over. In the event, the onset of the Second World War in 1939 and the growing scarcity of imported manufactures forced a further intensification of the policy of self-sufficiency. As elsewhere, the exigencies of the war economy led to greater government involvement in the allocation of resources and entrepreneurial activity generally. This continued after the war and, as late as 1959, Professor Charles Carter, formerly of Queen's University Belfast, commended the southern government for its willingness to engage in state enterprise if private enterprise failed to work, and contrasted this with the view taken in Northern Ireland that the function of government was to create the conditions for development and offer appropriate inducements but no more than that (Carter 1969).

In preparation for the aftermath of the war, policy debate on appropriate strategies for agriculture and employment took place in the early 1940s. A committee on agricultural policy chaired by T. A. Smiddy, De Valera's economic advisor, emphasized the importance of agricultural efficiency and the restoration of exports as a means of earning the foreign exchange that was necessary for the purchase of raw materials for industrial development. The other major policy debate of the period was occasioned by the publication in the UK of the Beveridge Report and the *White Paper on Employment.* The spectrum of Irish attitudes towards Keynesianism was reflected in a discussion of the problem of full employment held by the Statistical and Social Inquiry Society on 27 April 1945 (Lynch et al. 1945, 438–59). Opening the debate, Patrick Lynch, an economist in the Department of Finance and later Professor at University College Dublin, argued that the time had come to accept the Keynesian analysis of the economic system (Lynch et al., 438–41). The problems of the Irish economy were acute and required increasing state intervention. Government had to concern itself with the economy as a whole and not just its own expenditure as in the past. Lynch argued that government proposals for rural electrification and building were appropriate forms of intervention by means of which employment and further development could be stimulated. On the other hand, T. K. Whittaker, then number two at the Department of Finance, argued that Ireland was less exposed to cyclical fluctuations than Britain and America (Lynch et al., 446–9). Its unemployment problem was not primarily of a cyclical nature but the result of the insufficient investment in industry and agriculture. The problem was one of underinvestment rather than fluctuations in investment. Whitaker implied that increased investment in industry or agriculture would yield bigger returns at lower cost than the social investments mentioned by Lynch. Summarizing the debate, George O'Brien felt that there was general agreement that the Beveridge analysis did not apply to Irish circumstances (Lynch et al., 456–9). He noted that the main way in which Ireland had solved its unemployment problem during the last one hundred years was through the export of its people. Dr Beddy's recent paper comparing Irish and Danish agriculture (Beddy 1943–1944) had

shown that a more efficient agriculture was likely to employ fewer rather than more people. While the comparison with Denmark showed the possibilities offered by secondary industries, O'Brien himself felt that tertiary industries such as tourism had considerable potential.

While there were some attempts at policy and institutional innovation in the late 1940s and early 1950s, these involved attempts to make existing policy more effective rather than any major policy shifts. The performance of the economy was sluggish with low or sometimes negative rates of growth, and high levels of emigration. The publication of *Economic Development* (Department of Finance 1958) prepared by the Secretary of the Department, T. K. Whitaker, is commonly regarded as a major turning point in policy. The report demonstrates a remarkable consistency of position with the positions expressed by Whitaker in the 1945 debate on the *Beveridge Report.* The emphasis was on the need for productive investment. Whitaker argued that investment for which part if not all of the cost of servicing must be paid by the taxpayer was redistributive rather than productive, and should be replaced by productive investment. Despite the emphasis on the importance of investment, Whitaker cited A. K. Cairncross to the effect that entrepreneurial capacity was an even more important factor (1958, pp. 6–7), and in the body of the report he argued that the problem was not so much one of obtaining capital as securing 'know-what' as well as 'know-how' (1958, p. 154). These, it was suggested might have to come from external sources including foreign direct investment. The report also argued that, since the home market had been largely catered for, further development would have to depend on exports.

The 1958 Programme for Economic Expansion based on *Economic Development* involved a shift of emphasis from the promotion of domestically owned import-substituting industry to foreign-owned export-oriented industry. The implementation of the shift in policy over the following decade involved the easing of restrictions on foreign ownership and the implementation of incentives in the form of grants and tax exemptions on export generated profits. It also involved a shift from state-led enterprise to private enterprise, although Whitaker himself recognized that, since private investment was limited, productive investment would have to be engaged in by the public sector for some time to come. Another feature of the programme was its argument against existing policies of decentralization and in favour of the concentration of industries in large population centres with good internal and external communications and pools of skilled labour. A similar position on the concentration of new enterprises and infrastructure was later put forward in the Buchanan Report on regional development, which was published in 1968 and led to considerable debate (Buchanan and Partners 1968).

The introduction to the Programme for Economic Expansion emphasized that it was a not a plan and argued that the setting of detailed targets was inappropriate in a private enterprise economy exposed to fluctuations in external trade (Chubb and Lynch 1969). A few years later, there was much greater optimism about the value of planning. A second programme, which was developed in cooperation with the newly created Economic Research Institute (currently Economic and Social Research Institute, ESRI) and with input from Professor Louden Ryan of Trinity College, was much more specific in its targets. However, the actual performance of the economy in the period covered by the programme deviated from the planned targets, which were then abandoned. Drawing on this experience, the third programme emphasized the conditional nature of targets (Chubb and Lynch 1969). Despite this, the policies which were evolved in the programmes for economic expansion are widely regarded as providing the underpinning for the subsequent expansion of the economy. Governments also engaged in mildly expansionary fiscal policy, which helped to avoid the deflationary impact of Whittaker's own proposals. During the 1970s an attempt was made to counter the effects of oil price shocks by means of deficit spending. As the expected recovery failed to materialize, Ireland's debt burden grew and by the 1980s had reached unsustainable levels. During this period, Irish economists were vocal in their criticisms of fiscal policy and earned something of a reputation

as hard-nosed monetarists. The world recession of the early 1980s resulted in the closure of some foreign plants and made it difficult to attract new investment, so that there were net job losses in the foreign-owned sector. Irish economists criticized the Industrial Development Authority for subsidizing capital as a means of job creation. The Telesis review of industrial policy proposed a more selective approach to foreign direct investment, a shift of emphasis towards building strong indigenous national champions, the substitution of employment grants for capital grants and the setting up of a national linkage programme (NESC, 1982). The emergence of the economy from the 1980s recession, sometimes characterized as expansionary fiscal contraction, was achieved through a partnership agreement involving trade unions, employers and government. Partnership agreements have remained in place and are now regarded by economists in Ireland and elsewhere as an important industrial relations and development innovation (Teague and Donaghey 2004). In the decades since the 1960s, other policy issues with which economists engaged were the Anglo–Irish Free Trade Agreement, entry into European Economic Community, the Common Agricultural Policy and European Monetary Union. More recently, there has also been increasing emphasis on the factors governing the productivity and competitiveness of the economy as a whole.

When Ireland achieved independence in 1922, its cadre of professional economists was small, and the Statistical and Social Inquiry Society and its journal provided the main discussion forum for academic economists and government officials. Although some academics, including O'Brien, were literary in their approach, others such as George Duncan of Trinity College and John Busteed of University College Cork used a variety of statistical and empirical techniques. Duncan produced estimates of Irish national income to supplement T.J. Kiernan's pioneering efforts. Given that Duncan could be not regarded as anti-statistical, it is perhaps surprising that he was one of the main protagonists in a protracted debate between economists and Roy Geary. Geary was Ireland's foremost statistician but he also made important technical contributions to economics, including the Stone–Geary utility function as well as methods for updating input–output tables, for making international comparisons of real income, and for calculating the change in real income arising from changes in the terms of trade (Neary 1997; Spencer 1997). Geary argued that economics could become a science only through measurement and that economists' failure to appreciate the value of statistical work was due to their lack of awareness of the power of modern statistics. Geary also felt that economic theory was of very little value in the solution of practical problems and that academic economists were not sufficiently active in researching the social problems of the day. Duncan countered that the collection and manipulation of data could not by themselves advance knowledge of economic behaviour (Fanning 1984, pp. 151–5). He also pointed out that the Irish universities were seriously underfunded and had very little resources with which to carry out research. Part of the problem was a difference in attitude. Duncan, who had Austrian sympathies, disapproved of government intervention in general and of the protectionist policies of the day in particular. Geary, on the other hand, viewed policy issues as problems that could be solved with the correct technical means.

The present generation of Irish economists are more numerous and better trained than their predecessors in the early years of the 20th century. Many are the products of graduate schools in United States and in Britain. A recent examination of the journal output of Irish economists over the period 1970 to 2001 identified a total of 659 individual authors and 1,610 contributions, of which 218 were in the 1970s, 406 in the 1980s and 1,013 in the 1990s (Barrett and Lucey 2003). Of the total over the full period, half were in the main Irish journals: the *Economic and Social Review,* the *Journal of the Statistical and Social Inquiry Society of Ireland* and the *Irish Banking Review.* Other popular outlets for Irish economists were *Regional Studies Applied Economics* and the *Economic Journal*. A relatively small number of Irish economists contributed to the top international journals during the period surveyed by Barett and Lucey. Of these, Peter Neary made important contributions to the theory of international trade

as well as consumer theory, industrial organization and macroeconomics. In international trade, he is best known for work on Dutch Disease and the implications for trade of imperfect competition and technology policy.

In his seminal work on 20th century Ireland, the historian Joseph Lee (1989) argued that Irish economists have been impressive in the analysis of short-term movements but have contributed little to understanding the long-term development of the economy and have failed to contribute to development economics more widely. Whatever its truth in the past, this statement is no longer an accurate reflection of the state of affairs. Since the early 1990s, the Irish economy has experienced rapid growth so that its GDP per capita is now among the highest in Europe. This has led to considerable interest in understanding the nature and timing of the forces at work in Ireland's catch-up (Honohan and Walsh 2002). Meanwhile, however, Ireland's own development challenges have changed from those of catch-up to those of innovation and growth on the frontier. Meeting these challenges will require not only the strengthening of R&D capabilities but also addressing the special challenges of innovating in a small open economy.

Irish Crisis: Origins and Resolution

John FitzGerald

Abstract

The Celtic Tiger years in the 1990s saw the standard of living in Ireland converge rapidly to the EU15 average. However, in the middle 2000s the rapid growth continued and demand rose well above potential output, driven by a property market bubble. Either appropriate fiscal policy or appropriate financial regulation could have prevented the ensuing crisis.

The management of the crisis after 2008 and the economic turnaround, which began in 2012, was reasonably successful. There was initially a period of very severe fiscal tightening, which brought the crisis in the public finances under control. Also, pre-emptive action by the government in building up liquid assets in 2008 and 2009 facilitated management of the crisis, though it did not obviate the need for extensive liquidity support through a bail-out programme.

While the tradable sector of the economy suffered from the boom and bust cycle it still survived reasonably intact. As a result, once the fiscal adjustment was completed, and with a return to world growth, the economy bounced back. The rapid recovery has been facilitated by the low interest rate environment and the fall in oil prices. While some of the lost ground as a result of the crisis will be made up, undoubtedly there will be a permanent loss of output as a result of the very severe crisis.

Introduction

In the early years of the 2000s, many foreigners sought answers as to how Ireland had turned out to be such a successful economy. An exceptional period of growth began in 1994, continuing into the 2000s. However, the bust of 2008 punctured such illusions – the behaviour of the Irish economy can be understood within a standard economic framework, albeit one that takes account of the unusual openness of that economy.

A key factor in the sustained period of economic growth was the past failure of the Irish economy. When Ireland became independent in 1922, it was substantially less well off than the UK. However, it was also better off than many other countries in Southern or Eastern Europe. In spite of this head start, its relative standard of living fell behind that of many other countries in Europe, especially in the years after the Second World War. Ó'Gráda (2002) argues that this underperformance owes much to domestic policy failures. It was only when these failures were addressed that the standard of living in Ireland converged to the EU15 average.

The major policy failings were the decision not to open up to free trade in the 1950s, the failure to invest in education in the immediate post-war years and unwise fiscal policy in the late 1970s. Exceptionally high tariff barriers were maintained against the outside world until the end of the 1950s, and it was only with EU membership in 1973 that the economy fully embraced the benefits and rigours of free trade. However, the way in which the Irish economy adapted to free trade depended, to an unusual extent, on foreign direct investment (Barry 2002).

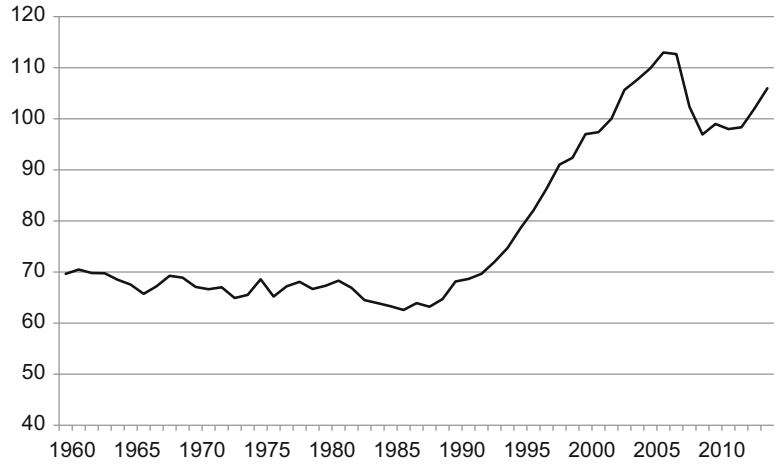
Free second level education was only introduced in 1967. At that time only around an eighth of children went on to third level education. This policy failure was gradually rectified over the next 20 years, but it was a slow process. It was only really in the 1990s that the effects of two decades of increasing investment in education began to impact on growth.

The convergence process, bringing the relative standard of living to where it should have been, was delayed by very unwise budgetary policies adopted at the end of the 1970s, which resulted in a fiscal crisis that took much of the 1980s to address. Thus it was only in the 1990s that the Irish economy converged to the EU15 average standard of living (Crafts 2014). When convergence happened, as shown in Fig. 1, the convergence process was very rapid.

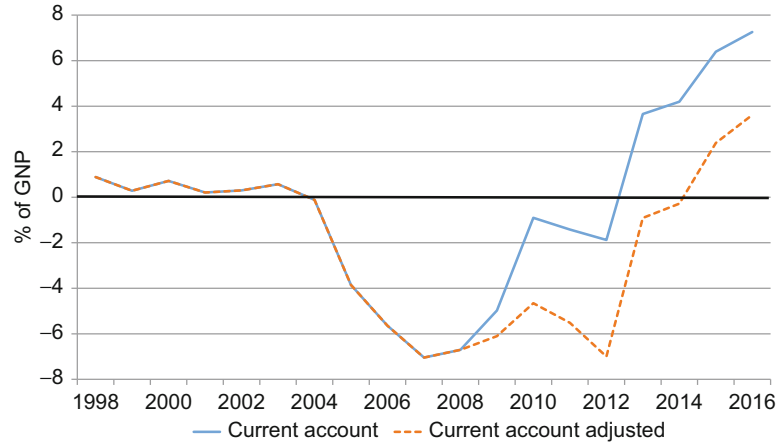
The next section examines the fit of hubris which resulted in a major real estate bubble in the middle of the last decade. We then consider the extent of the ensuing financial crisis and how the multiple problems were addressed through major policy changes. The penultimate section considers the nature of the economic recovery which began in 2012 and, finally, conclusions are drawn.

Hubris

The fact that the economy underwent a period of exceptional growth in the second half of the 1990s, when the increase in GNP averaged 9% a year, lulled policymakers into a false sense of security: after 2000 there was a growing feeling



Irish Crisis: Origins and Resolution, Fig. 1 GDP relative to EU15, adjusted for PPS, % (GNP for Ireland) (*Source*: Eurostat and CSO *National Income and Expenditure* for Irish GNP)



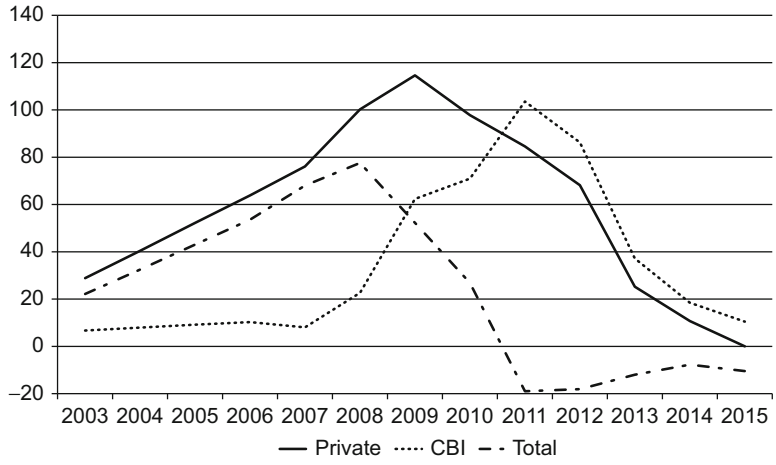
Irish Crisis: Origins and Resolution, Fig. 2 Current account of the balance of payments, % of GNP (*Source*: CSO Balance of Payments and additional data on inflow through redomiciled plcs. The adjusted figures exclude the revenue of these companies (FitzGerald 2015). Redomiciled plcs. are investment companies headquartered in Ireland, which don't generate real activity in the economy in terms of employment or purchases of domestic inputs)

that Ireland had found the elixir of eternal growth. (Throughout this article GNP is used rather than GDP because of the exceptional outflow of profits from multinationals, profits that are not part of national income.) As discussed earlier, the growth in the 1990s represented a catching-up process.

When, in 2001, the EU Commission suggested that the government needed to tighten fiscal policy to rein in the growth in demand, which appeared to be running ahead of potential output, this fell on deaf ears. The then government was very critical of this intervention by the EU Commission and it may have discouraged the EU Commission from criticising policy later in the decade. This policy advice, while not unreasonable, was probably premature: the bursting of the dotcom bubble in 2002 took some of the steam out of the economy, and the current account of the balance of payments remained in surplus till 2003 (Fig. 2).

Key factors in the rapid growth in the economy in the early years of the 2000s were foreign demand, which continued buoyant till 2007, and an investment boom. The economy needed to rapidly expand its infrastructure, private and

Irish Crisis: Origins and Resolution, Fig. 3 Investment as a share of GNP, % (*Source*: CSO National Income and Expenditure)



Irish Crisis: Origins and Resolution, Fig. 4 Net foreign liabilities of the banking system, % of GNP (*Source*: Central Bank of Ireland, Table A.4.1)

public, to cater for the growing population and the continuing increase in output. As shown in Fig. 3, investment, having run at between 25% and 30% of GNP up to 2003, peaked at over 35% of GNP in 2006. In the EU15 investment averaged around 20% of GDP over the last decade so the level of investment in Ireland was exceptional.

A significant factor in driving the investment share of GDP/GNP above 30% in the peak of the boom was the expansion of investment in housing. While Ireland had a greater need for investment in housing than many other EU15 countries because of the rapid growth in the population (Conefrey and FitzGerald 2010), housing investment accounted for an exceptional share of output in 2005 and 2006: around 14%, compared to the norm for other EU15 countries of around 4%.

Though domestic savings were enough to finance the high level of investment up to 2003, the further increase in investment thereafter generated a substantial and growing deficit on the current account of the balance of payments (Fig. 2), as domestic saving proved inadequate (Lane 2015a). Much of the investment in property was funded though the banking system. As shown in Fig. 4, the net foreign liabilities of the banking system rose from around 30% of GNP in 2003 to

almost 100% in 2008, peaking at over 110% in 2009.

The banks funded the expansion of their property lending by short-term borrowing on the interbank market. The resulting maturity mismatch posed massive problems for the banks when the crisis hit. The short-term funding dried up and they became hugely dependent on borrowing from the Central Bank (ECB), as shown in Fig. 4.

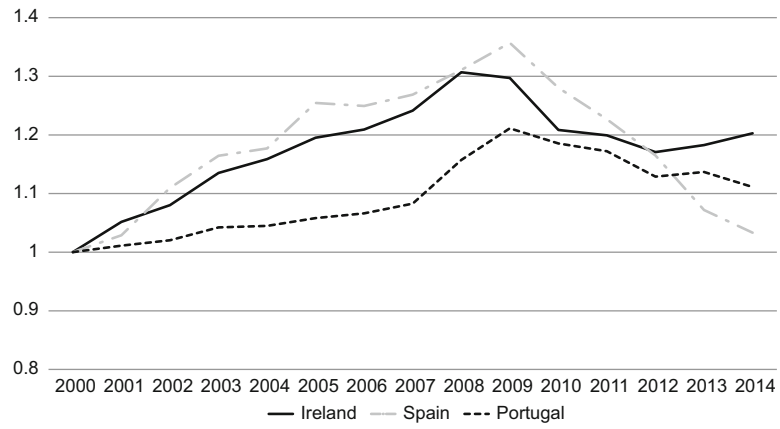
All of this pointed to the fact that the economy was growing beyond its potential. The labour market was also very tight, with large-scale immigration to meet the very rapid growth in employment. The unemployment rate was around 4.5%, full employment by Irish standards.

In the late 1990s the traditional outflow of emigrants from Ireland had been reversed and there was a substantial inflow of people coming to work in Ireland. They were generally well educated and played an important role in expanding the productive capacity of the economy (Barrett et al. 2002).

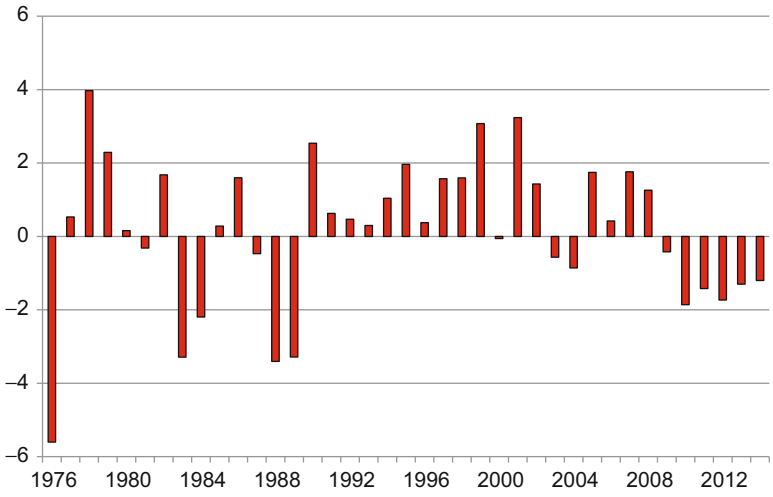
After EU enlargement in 2004 this inflow dramatically increased. Whereas before immigrants generally filled skilled jobs, a significant part of the post-2004 inflow moved into less skilled employment, including construction, possibly reflecting a lack of linguistic skills rather than a lack of education (Barrett and Bergin 2009). While the inflow of immigrants (and returning emigrants) helped relieve some of the labour market pressures, it also put upward pressure on the cost of accommodation.

The tightness in the labour market resulted in a rapid rise in wage rates relative to other EU15 countries (Fig. 5). The sectors related to building had to bid up wage rates to attract employees from other areas of the economy and from outside Ireland. This loss of competitiveness adversely affected the tradable sector of the economy: it was being crowded out by the growth in the size of the building and construction sector of the economy. In the run-up to the crisis, job losses occurred in the more labour-intensive parts of the tradable sector. The growth in the parts of the tradable sector employing predominantly skilled labour disguised the competitiveness problems faced elsewhere in the export sector. These less skilled, jobs lost in the tradable sector after 2005, have not reappeared, even with a reversal of the competitiveness loss.

While some domestic policy advice suggested that a significant tightening of fiscal policy was appropriate to prevent a property market bubble (FitzGerald et al. 2005; FitzGerald and Morgenroth 2006; Kelly 2007), this advice fell on deaf ears. As shown in Fig. 6, the stance of fiscal policy between 2000 and 2007 was generally stimulatory. In 2001 and 2002 the stimulus averaged over 2% of GNP a year. Again in 2005–2007 the stimulus averaged over 1.25% a year. (2002 and 2007 were election years and fiscal policy was generally stimulatory in the run-up to each election.) Much of this stimulus came from a rapid increase in public investment in infrastructure. However, this further aggravated



Irish Crisis: Origins and Resolution, Fig. 5 Average annual earnings relative to EU15 (*Source*: AMECO Database)



Irish Crisis: Origins and Resolution, Fig. 6 Fiscal stance, % of GDP. Positive is expansionary and negative is contractionary (*Source*: FitzGerald 2013a)

pressures in the building sector, given the concentration on investment on infrastructure projects.

Finally, as we now know (Honohan 2009, 2010; Oireachtas 2016) banking regulation was exceptionally lax. The result was a domestic banking system which was exceptionally exposed to a collapse in the property market in 2008: its assets were very illiquid, backed by very short-term borrowing.

Unlike Estonia, which saw a similar property-led bubble and collapse in 2007–2008, the bulk of the Irish banking system was domestically owned. While a few foreign banks (e.g. RBS) were also serious players in the market, making similar mistakes to the Irish banks, when the crisis hit the Irish government found itself responsible for the financial crisis in the Irish-owned banks. In the case of Estonia, because all of the banks were foreign-owned, the collapse in the economy did not result in the government having to assume a very large debt burden to bail out banks, though they still had to deal with the fiscal effects of the resulting economic crisis.

The Crisis

Over the course of 2007, house prices, which had risen rapidly for more than a decade, plateaued and began to slowly decline. Difficulties in the financial sector in the UK and the USA gave a warning of possible dangers for the Irish economy, but exports continued to grow rapidly. While some analysts published warnings concerning the housing market and the financial system (Barrett et al. 2007; Kelly, 2007) they were not heeded. With the benefit of hindsight, it was probably too late to avert a financial disaster, but earlier action would have reduced the subsequent damage.

The Budget for 2008 was published in December 2007 and it was based on an expectation of continuing growth, albeit at a lower rate than in the past. The dependence of government revenue, directly and indirectly, on the building and construction sector was not understood. The collapse in economic activity in the first half of 2008 began to have a dramatic effect on the fiscal position.

Banking Crisis

When Lehman Brothers was liquidated in mid-September 2008 it produced an even more concentrated focus on the potential problems of the Irish banking system. As a result, the Irish-owned banks faced a major funding crisis towards the end of the month. To deal with this the government provided a very extensive guarantee, covering most of the liabilities of the Irish-owned banks.

While the guarantee was supported in parliament in autumn 2008 by three of the four main political parties (Fianna Fáil, Fine Gael and Sinn Féin) the very wide scope of the guarantee has

been extensively criticised since it was introduced. It exposed the Irish government to huge liabilities, which crystallised in 2010 and 2011. Honohan (2009) argued that some form of guarantee was essential to prevent the collapse of the financial system, but that the guarantee as implemented was too wide.

The very wide criticism of this measure domestically must been seen against evidence that the ECB (and Ireland's partners within the EU) were not sympathetic to measures to impose losses on bondholders (Cardiff 2016). This restricted the government's freedom of movement, both in 2008 and again in the run-up to the bail-out in late 2010 and in the early months of 2011 (Oireachtas 2016). While the additional costs imposed on Ireland as a result of the refusal by the ECB to countenance the burning of bondholders probably amounted to at most 10% or 15% of the total cost of bailing out the banks, the ECB's action still rankles with the population.

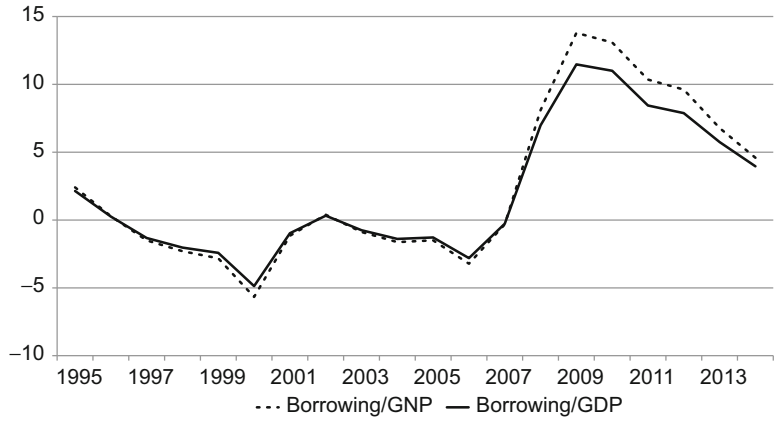
Fiscal Adjustment

The Budget for 2009 was passed early in October 2008. The major parameters of the budget had already been determined before the banking crisis of late September, and the forecasts for 2009 and the resulting estimates of revenue and expenditure proved totally unrealistic. This became apparent well before the end of the year. In spite of additional budgetary measures early in 2009, government borrowing, which had reached 11.5% of GNP in 2008, peaked at almost 14% of GNP in 2009 (Fig. 7). Because of the unexpected fall in inflation, the budget for 2009, even after amendment, was only mildly contractionary (Fig. 6). The real value of welfare payments actually rose significantly in 2009 because of the fall in prices.

Well before the gravity of the crisis became apparent to the wider public in late 2008, the National Treasury Management Agency (NTMA) began a major drive to fund the government. Because the gravity of the situation was not fully apparent, they were able to raise a large amount of money at reasonably attractive interest rates in 2008. They continued this funding drive in 2009, converting short-term borrowing into bonds with longer maturities.

As a result, by the end of 2008 government holdings of cash amounted to 16% of GDP, increasing to 18% of GDP by the end of 2009, in spite of the huge deficit in both years. This move to provide a large liquidity buffer contrasted with the positions in Portugal and Greece, other troubled economies. In the case of Portugal, the move to provide a large liquidity buffer only began in 2011.

While there was an understanding that problems in the banks would require a significant injection of capital by the government, the full magnitude of the problem was not understood in 2009. As a result, the government felt that the liquidity buffer, which amounted to the expected funding needs for 2009 and 2010, would be sufficient for Ireland to ride out the financial storm based on its own resources. However, the problems in the banking sector proved to be much greater than anticipated, and the crisis in the EU



Irish Crisis: Origins and Resolution, Fig. 7 Government borrowing, % of GDP and GNP (*Source*: CSO National Income and Expenditure and Government Financial Statistics)

financial markets, which began with the problems in Greece, meant that even the large cash buffer available at the beginning of 2010 was not adequate. The ECB's refusal to countenance imposing costs on senior bondholders in the banks added to the government's financial pressures in 2010–2011.

In 2009 the government had set up the National Asset Management Agency (NAMA) to buy bad property loans from the banks at a suitably discounted price. Initially in 2009 there were fears that NAMA would overpay for the loans, providing a subsidy to the troubled banks. However, when NAMA took on the first major tranche of loans early in 2010 it applied a fairly severe discount. This made it apparent to the government that a major cash injection into the banks would be needed. However, when NAMA took on the second major tranche of loans in early summer 2010, and applied an even bigger discount, it became apparent to the financial markets that the banks would need a very large government injection, an injection which made even the large cash buffer that the government held look inadequate.

The result was a loss of confidence in the financial markets in the autumn of 2010, which eventually forced the government to seek assistance from its EU partners and the IMF in November 2010. Before this assistance was sought the government published a medium-term adjustment plan which promised a very severe Budget for 2011, to be introduced in December, together with further major adjustment in the following three years. The planned borrowing for 2011–2013 is shown in Table 1. The 'Troika' of the EU Commission, the ECB and the IMF accepted the fiscal adjustment plan, which was already in place, without seeking significant changes. Thus the adjustment programme was not 'imposed' by the Troika, but decided by the Irish government.

In an election at the beginning of 2011 the outgoing government suffered massive losses and was replaced by a new administration. However, the incoming government adopted the broad parameters of the adjustment plan already in place, while making significant changes in the detailed measures.

Source: Department of Finance Budgets and CSO: *National Income and Expenditure*

Table 2 shows the headline increases in taxation and cuts in expenditure in each budget from 2009 to 2013 (FitzGerald 2013a). (*Ex post* the outcome is different, as the effect of the fiscal tightening reduced activity and, hence, reduced tax revenue and increases expenditure.) This shows the 'fiscal effort', but it takes no account of inflation. In particular, what looked like a very severe budget in 2009 turned out to be much less severe (Fig. 6), due to the fall in the price level, which turned nominal cuts in welfare into real increases. The cumulative adjustment was very large, with about 40% of the effort coming from increases in revenue (taxes) and the rest from cuts in expenditure, including a large cut in public service pay rates.

A feature of the adjustment plan put in place by the outgoing government in November 2010 was that it 'under-promised'. The plan took a deliberately conservative view on the public finances in spite of the fact that the government faced an imminent election. When the incoming government took power it was able to adopt the plan knowing that the targets set in it, while very

tough, would be achievable. As a result, the new government was able to exceed the agreed fiscal targets every quarter for the next three years. This helped restore confidence in the Irish economy among financial markets and, eventually, among citizens.

Irish Adjustment in an EU Context

As Table 1 shows, while the outgoing Irish government under-promised, facilitating the incoming government over-delivering, the position was different in Spain. There the outgoing government set unrealistic adjustment targets in 2011, which meant that the incoming government appeared to fail against this unrealistic benchmark. This made the adjustment in Spain look less successful than in Ireland in the early years of the new Spanish government, in spite of the substantial fiscal tightening that was actually taking place.

The crisis in Ireland, which was reflected in an unsustainable current account deficit, resulted from excessive investment, in particular in housing and commercial property, not from excessive private or public consumption. This investment bubble seriously damaged the rest of the economy: the inflated building and construction sector sucked resources from the rest of the economy through raising prices, especially the price of labour. With the benefit of hindsight, while the collapse of the property market that occurred in 2008 was triggered by the global financial crisis, the price level and the size of the building sector were not sustainable (Whelan 2014).

When the bubble burst the investment demand collapsed, driven by market forces, and this produced a dramatic turnaround in the current account deficit, helping put the economy on a sustainable footing. This reduction in demand was not caused by fiscal policy, although it had massive consequences for the public finances. Thus it happened 'automatically' without a need for approval by parliament.

The pattern was rather similar in Spain, Estonia and Latvia: an unsustainable investment boom which collapsed, helping to restore balance on the external account (FitzGerald 2013b). In these countries the public finances were in surplus in the boom years, but developed very large deficits with the collapse in investment. After the event it was clear to most people that the investment bubble had been unsustainable and that governments could not protect those directly affected working in the building-related sectors.

For Greece the situation was rather different. There the imbalance on the external account arose from an excess of consumption: public and private. Investment as a share of GDP was not excessive. Addressing this problem required major fiscal action and, hence, parliamentary approval. However, it was much more difficult politically to undertake such an adjustment, which was going to directly affect the living standards of the whole population. While a collapsing bubble happens very rapidly, producing a rapid adjustment in the external imbalance, undertaking a major fiscal adjustment programme takes a number of years.

Distributional Effects

From its peak in 2007 to the trough early in 2012, employment fell by almost 16%. The fall in employment was particularly severe in the building and related sectors. In spite of very substantial net emigration, especially by those who had lost their jobs, the unemployment rate rose from 4.6% in 2007 to over 15% of the labour force in 2011. The families of those who lost the jobs were the biggest losers from the crisis.

While the unemployment rate rose from under 5% of the labour force before the crash to peak at 15% in 2011, it could have been much worse. Employment fell by 16% points from peak to trough and there was a continuing large net inflow into the working age groups. However, as had happened on many occasions over the previous century, when the Irish labour market suffered a major downturn many of those who lost their jobs sought employment elsewhere. This applied to both the foreign workers who lost their jobs in the construction sector and to Irish-born of working age. This pattern of immigration and emigration, depending on prevailing labour market circumstances, reflects the extreme openness of the Irish economy. It has been a major shock absorber for the economy over the last century.

At the same time as unemployment increased, many of those on very high incomes, earned from

involvement in the property boom, also lost heavily. However, the losses at the top of the income distribution did not compensate for the losses at the bottom of the distribution, so that the distribution of market income, which was already quite unequal by EU standards, became even more unequal. Figure 8 shows the Gini coefficient, based on market income, before government transfers, for Ireland and the EU15. (The higher the coefficient the more unequal the distribution of income.)

Figure 8 also shows the Gini coefficient after transfers and taxes for both Ireland and the EU15. This illustrates how, as a result of transfers, inequality fell slightly in Ireland from the boom years of 2006–2007 to 2013. The widening gap between the Gini coefficient for Ireland on a market incomes basis and on an after tax and welfare basis reflects a decision made by successive governments to protect welfare recipients, only making a moderate reduction in welfare rates in nominal terms.

As shown in Table 3, the share of transfers in GDP rose by 6% points over the course of the crisis, putting huge pressures on the budget. With a collapse in revenue, this increase in the welfare budget necessitated even more severe increases in tax rates and cuts in other areas of expenditure. In Greece, Spain and Portugal, which underwent a similar crisis, the increased share of transfers in national income was significantly lower than in the case of Ireland.

The Recovery

While the fiscal adjustment was still having a negative effect on the economy in 2012 and into 2013, the tradable sector had continued to grow through the very deep recession. With growth in

the world economy, especially in the USA and the UK, and a restoration of competitiveness, the economy turned the corner in 2012, showing a return to growth in GNP in the latter part of that year. By 2013 the economy was growing rapidly, and that rapid growth continued into 2016.

Initially the growth was driven by the external sector. However, there was a significant increase in investment in 2014 (Fig. 3) from a very low base and, in 2015, there was eventually a return to growth in consumption. Because of the fact that the recovery has been led by the growth in external demand for Irish goods and services, the current account, which was still in deficit in 2012, had moved back into balance in 2014 (Fig. 2), suggesting that the recovery is sustainable.

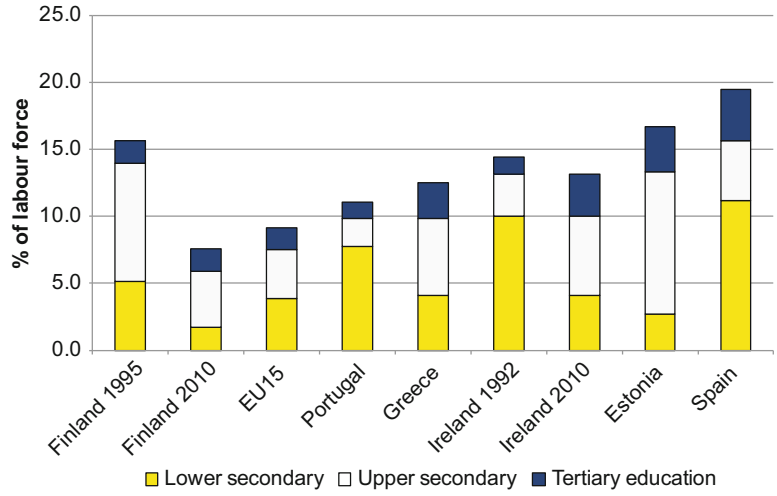
During the recession years it was feared that the dramatic rise in the unemployment rate would be very difficult to reverse. Experience in other countries, and also the experience of the exit from the 1980s crisis in Ireland, suggested that the recession might have a permanent effect on the labour market. People out of work for some time may lose skills and may find re-entry into the labour market difficult.

As shown in Fig. 9, the educational attainment of those who were unemployed in Ireland as the crisis was at its worst in 2010 was very different from when Ireland was exiting from the previous crisis in 1992. In 1992 over two-thirds of those who were unemployed had at most lower secondary education. In 2010 the situation was reversed, with over two-thirds having at least upper secondary education. This contrasts with the situation in Spain and Portugal, where most of those out of work in 2010 had very limited education.

For those with at least an upper secondary education the prospect of finding work in a recovering Irish economy was good. Also, past experience had shown that, for those with a good education, where suitable jobs are not found in Ireland, they tend to emigrate to find work in other buoyant labour markets.

Since 2012 the rate of unemployment has fallen continuously in Ireland (Fig. 10). Also the rate of long-term unemployment has declined in nearly every quarter, indicating that a feared hysteresis effect on unemployment was exaggerated. The figures certainly suggest a smoother return to work after the recent crisis than was the case in the 1990s.

Another legacy of the crisis, which impacted on the recovery, was the very high level of indebtedness in the household sector. Having borrowed heavily to fund the building boom of the last decade, many households found themselves in 2012 heavily indebted and in negative equity, in spite of some growth in property prices. However, there is a cohort effect operating here: for those under 35 the level of indebtedness is low, with many households having some savings (Byrne



Irish Crisis: Origins and Resolution,

et al. 2014). This is because they were either too young or too wise to buy during the boom years. It is the 35–45 cohort who are particularly indebted and constrained in their consumption behaviour.

Initially this high level of indebtedness prevented a return to consumption growth. In addition, with falling prices there was little incentive for households to buy new dwellings in the period to 2012. However, growing demographic pressures, combined with a return to growth in house prices, have resulted in serious pressure on the housing market. To date the supply response has been very limited, with housing investment well below the 'normal' level of the last 40 years. This is reflected in rapidly rising rents.

If and when housing supply responds, this will add to the growth in domestic demand. The lessons from the past suggest that such a recovery will need careful management. While demographic pressures require at least a doubling in housing output, it is not clear that domestic savings will be adequate to fund such a recovery. The Central Bank has introduced macroprudential measures to prevent households and banks making the same mistakes as they did in the last decade.

At the height of the crisis there were major fears that the level of government debt would be unsustainable. Figure 11 shows the origins of the government debt as a percentage of GNP. As discussed earlier, and illustrated in the figure, there is a significant difference between the gross debt and the debt net of government cash holdings.

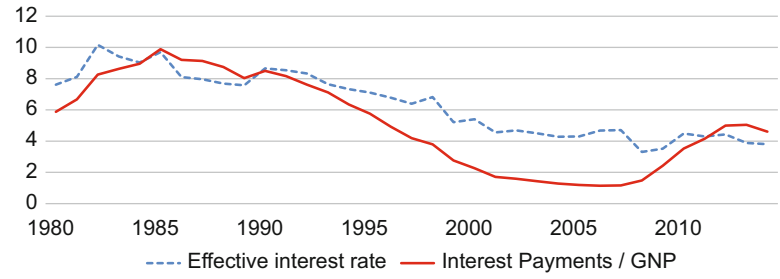
The injection of capital into the banks at its peak in 2011 accounted for 47% of GNP. However, between 2007 and 2013 the bulk of the increase in indebtedness was accounted for by the accumulated borrowing to fund the huge deficit (55% of GNP).

Since 2013 the burden of the debt has begun to fall, with growth in the economy and some initial repayments from the banking system. In the long run, if the recovery continues and is successfully managed, the state could benefit from the eventual sell off of the state-owned banks, recovering some, but not all of its forced investment in the banks.

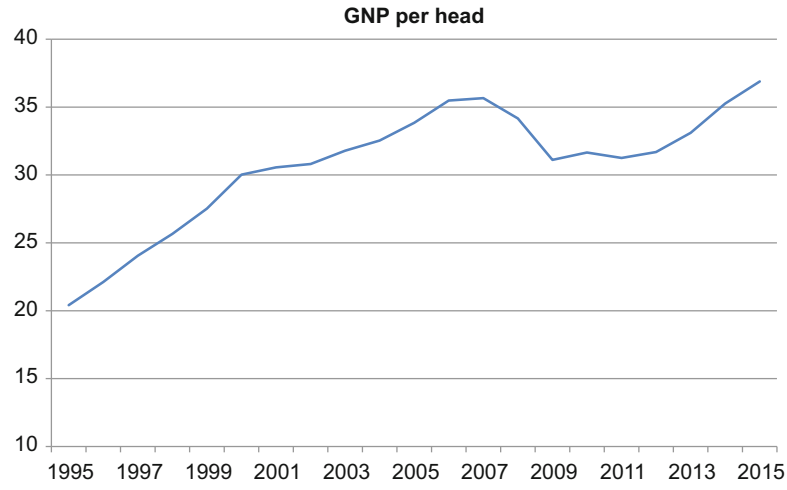
While the debt to GNP ratio is extremely high, the low rate of interest on new borrowing by the government has allowed it to refinance much of the debt on favourable terms. As shown in Fig. 12, interest payments accounted for just over 4% of GNP in 2014. In the previous crisis they peaked at 10% of GNP. Also, the average interest rate on the debt was around 4% in 2014, and this is likely to fall as the existing debt is refinanced at current low bond yields.

Conclusions

Over the last decade the Irish economy has experienced an exceptionally deep recession and a financial collapse, imposing a huge burden on the state because of the need to recapitalise the domestically owned banks. As shown in Fig. 13, GNP per head fell by 13% between 2007 and 2009. This fall in output was concentrated in the non-tradable sector of the economy, especially those sub-sectors related to building and construction. The tradable sector of the economy came through relatively unscathed. With a return to competitiveness and a return to growth in external markets, the tradable sector has led the economic recovery.



Irish Crisis: Origins and Resolution, Fig. 12 Debt burden (*Source*: CSO National Income and Expenditure)



Irish Crisis: Origins and Resolution, Fig. 13 GNP per head (*Source*: CSO National Income and Expenditure)

As shown in Fig. 13, by 2014 GNP per head had almost returned to the pre-crisis level, and continued growth in 2015 saw that level exceeded. However, substantial long-term damage remains. The level of employment is still significantly below its previous peak, and as a consequence unemployment is well above the pre-crisis level. The major dislocation of the labour market during the crisis was reflected in a return to large-scale emigration.

Given the openness of the economy, Ireland could never have escaped the impact of the great recession that affected the world economy. However, the costs could have been dramatically reduced if wise policies had been pursued over the 2000s. In particular, as argued in Bergin et al. (2011), a gradual tightening of fiscal policy, together with targeted fiscal measures affecting the property market (such as a tax on mortgage interest payments), could have prevented the bubble in the domestic housing market and protected the competitiveness of the economy. The UK Treasury, when it considered the implications for the UK of possible membership of EMU, recommended such a use of targeted fiscal policy action to manage the housing market within EMU (HM Treasury 2003).

Alternatively, or in addition, if appropriate action had been taken by the Central Bank and the financial regulator (a subsidiary of the Central Bank) to prevent the massive expansion of credit to fund investment in property, this could also have prevented the property market bubble. Even if funding for the bubble had been found from sources other than domestic banks (as, for example, in Estonia), appropriate regulatory action would have protected Ireland from the costs ensuing from the collapse of the domestic financial system.

The crisis has led to the largest political upheaval in Ireland in the last 50 years. The main government party (Fianna Fáil) lost the vast bulk of its seats in the 2011 election, something that was unprecedented. Again in the 2016 election the then governing parties (Fine Gael and Labour) lost very heavily. This reflected the fact that the population as a whole were exceptionally angry about the extent of the financial crisis and it also reflected a popular understanding that the origin of the crisis lay in domestic policy mistakes.

While the recovery has reflected the tough fiscal action undertaken by successive governments and the underlying strength of the tradable sector of the economy, it would not have been possible without the support of Ireland's EU neighbours and the IMF. The recovery shows that what Ireland experienced was a liquidity crisis, not a problem of insolvency. The recovery has also been facilitated by the low interest rate environment, which has made the legacy of debt much lighter than was the case with the previous crisis in the 1980s.

Although governments made the mistakes that resulted in huge costs to the economy in the crisis years, the management of that crisis by subsequent successive governments has been quite effective. There can be no doubt now that, while very costly in the short term, there was no alternative to the fiscal adjustment undertaken. It did not seriously damage the underlying fabric of the productive sector of the economy, as evidenced by the return to sustained quite rapid growth since 2012.

While it might be argued that it would have been better to have implemented the adjustment more rapidly, as in Estonia and Latvia, it took some time for Irish policymakers to understand the full severity of the crisis, especially the size of the problem in the banking system. On the other hand, to have delayed the adjustment in Ireland so that the necessary austerity spanned three parliaments, instead of two, would not have been politically sustainable. The Irish electorate has shown its displeasure with the three main political parties in two elections. If further fiscal adjustment had been necessary today it would have been very difficult to implement politically.

The root and branch reform of financial regulation has now been strengthened by the move to the Single Supervisory Mechanism. New macroprudential tools have been developed to manage the exposure of the financial system (and of individuals) to the housing market, and they were deployed in 2015 to prevent the strong recovery getting out of hand. The importance of such

regulation, and its absence in the past, has been highlighted by the Irish crisis. The costs from lax regulation are likely to be dramatically higher than those from over-zealous regulation.

The task of undertaking a large fiscal adjustment in Ireland would have been greatly eased if, at the level of the euro area, a counter-cyclical fiscal policy had been pursued by countries that did not face major financial problems. Instead, fiscal policy in the 2010–2013 period was strongly pro-cyclical (Euroframe 2013). Current EU fiscal rules hold out no prospect of a more appropriate policy response if such a crisis should affect some euro area members in the future (Lane 2015b).

The experience of countries like Estonia and Latvia, which were outside the euro area in 2008, shows that the availability of cheap money allowed an inappropriate expansion of domestic credit independent of EMU membership. EMU was not the cause of the problem; rather unwise domestic policies lead to the crisis in Ireland, Portugal, Spain and Greece. However, the experience of Ireland, in contrast to that of Estonia and Latvia, shows that if a crisis hits, countries receive more generous support when they are members of the euro area.

Iron Law of Wages

Mark Blaug

Iron law of wages; Lassalle, F.; Market price of labour; Natural price of labour; Natural wages; Population growth; Real wages; Ricardo, D.; Subsistence' theory of wages

JEL Classifications

J3

The 'iron (or brazen) law of wages' is a term invented by Ferdinand Lassalle (1862) to describe the inexorable tendency of real wages under capitalism to adhere to a level just sufficient to afford the bare necessities of life. This law, he claimed, was not just a socialist indictment of capitalism but was authorized by leading 'bourgeois' economists such as Malthus and Ricardo. He failed to point out, however, that in Malthus and Ricardo the so-called 'subsistence' theory of wages was predicated on a theory of population growth according to which the supply of labour responds automatically to any gap between the going 'market price' and 'natural price' of labour, the latter being defined as a real wage sufficient to reproduce a working population of given size and composition. Lassalle, however, being a socialist, followed Marx in rejecting the Malthusian theory of population; what ensured the 'iron law of wages' for Lassalle, as for Marx, was the tendency for any rise in real wages to generate unemployment, thus setting in motion forces that reversed the rise. This threw the entire weight of argument for equilibrium adjustments in the labour market on the side of employers' demand; it provided no explanation of the supply of labour and thus failed to furnish a determinate theory of wages in long-run equilibrium. Ironically, therefore, there may be an 'iron law of wages' in Malthus and Ricardo, but there is certainly no such iron law in socialist economics. The question whether Malthus and particularly Ricardo can be said to have held the iron law or subsistence theory of wages was a favourite debating question in the latter half of the 19th century (see, for example, Marshall 1890, pp. 508–9). There is no doubt that they held the view that real wages tend to fluctuate around a natural point of 'gravity', namely, the minimum level of food and other necessities required for existence. But, in the first place, these fluctuations, depending as they did upon decisions to marry and to have children, involved a lag of at least 15–18 years, a point which Malthus (but not Ricardo) conceded explicitly. In the second place, the minimum-of-existence level of 'natural wages' was admitted to be a matter of custom and habit and therefore subject to a secular upward drift. It was therefore perfectly possible to argue for the existence of something like a normal long-run supply price of labour – a constant real wage, everything else being the same – while at the same time granting that the 'market price' of labour fluctuated around an ever-rising trend. In short, rising living standards under capitalism do not violate the iron law of wages, understood as a theory about the long-run equilibrium price of labour. But that is only to say that the iron law or subsistence theory of wages amounts for all practical purposes to accepting customary wages as an institutional datum (Schumpeter 1954, p. 665).

There has been a revisiting of the old debate about whether Ricardo held the iron law of wages, but in an entirely new form: did Ricardo hold real wages to be constant at the subsistence level in stationary equilibrium or did he allow for an initial stage of increasing real wages followed by a final stage of declining wages alongside a secular fall in the rate of profit (Hollander 1983)? It is doubtful whether this question yields one simple, neat answer, since it is clear that Ricardo operated with a number of different models regarding the determination of the 'natural price' of labour. In the very opening paragraph of the chapter on wages in Ricardo's *Principles of Political Economy of Taxation*, the 'natural price' of labour is defined as 'that price which is necessary to enable the labourers, one with another, to subsist and to perpetuate their race, without either increase or diminution'. This defines the natural price of

labour to be the commodity wage that ensures a zero rate of population growth. But a page or two later, the natural price of labour is said to be that commodity wage which ensures a rate of growth of population equal to the rate of growth of the capital stock, so that market wages only rise above natural wages when capital accumulates faster than the growth of population. It is possible to make sense of this in terms of modern growth theory, and many have done so (see Casarosa 1978), but it is questionable whether Ricardo himself was aware of what he was doing, the more so as he frequently resorts to the constant-subsistence-wage assumption in the later tax chapters of the *Principles*.

Irreversible Investment

Janice C. Eberly

Abstract

The cost of an irreversible investment cannot be recovered once it is installed. This restriction not only truncates negative investments, but also raises the threshold for positive investment. The threshold return that justifies an irreversible investment increases with uncertainty, or more precisely, with the probability mass in the lower tail of outcomes. Irreversibility constrains the ability to redeploy capital in 'bad' states, so the agent is particularly sensitive to these states when investing *ex ante*.

This finding is analogous to valuation and exercise of financial options, and irreversible investments are valued and understood by using option pricing techniques.

JEL Classifications

D4; D10

Irreversible investment acknowledges that the value of capital may not be fully recoverable when resold.

This simple generalization has rich implications for investment. Beyond truncating disinvestment, irreversibility changes the dynamics of investment by creating a threshold level of returns for positive investments. Below this threshold, investment is zero – which immediately implies intermittent rather than continuous investment activity. Moreover, the threshold return that justifies investment exceeds the required return on a reversible investment.

Investment and Options

Marschak (1949) raised the potential role of irreversibility in factor accumulation by emphasizing the convertibility or liquidity of capital. Work by Arrow (1968) and Henry (1974) considered when irreversible actions in environmental applications were justified and emphasized the idea of an option value. This idea was extended by Bernanke (1983) to the role of uncertainty in delaying investment decisions.

McDonald and Siegel's (1986) article 'The Value of Waiting to Invest' provides the first explicit valuation of investment allowing for irreversibility, incorporating option valuation (real options) into investment theory. McDonald and Siegel analyse a project of fixed size, so the timing of the project is the only choice to be made. They show that the value of the project includes an 'option value of waiting', that can be valued and interpreted using option pricing theory. The additional value of being able to choose when to invest, rather than a 'now or never' investment decision, can be quantitatively large, and has interesting implications for the investment decision. First, the presence of this option implies that it is optimal to delay the investment, rather than undertaking it immediately, even when immediate execution has positive value. Instead, value can be increased by waiting for additional information. Second, like most options, the value of the option to wait is increasing in uncertainty. This feature implies an effect of uncertainty on the value and timing of investments that is absent in most conventional models.

Later work by Pindyck (1988) and Bertola (1988), allows for incremental investment, so that the firm chooses both the timing and the size of its investments. They show that there is a threshold for investing with irreversibility that exceeds the return that would justify a positive reversible investment. Instead of a single investment decision, as in McDonald and Siegel, there is an infinite sequence of investment decisions, where each satisfies the threshold condition.

An Illustrative Model

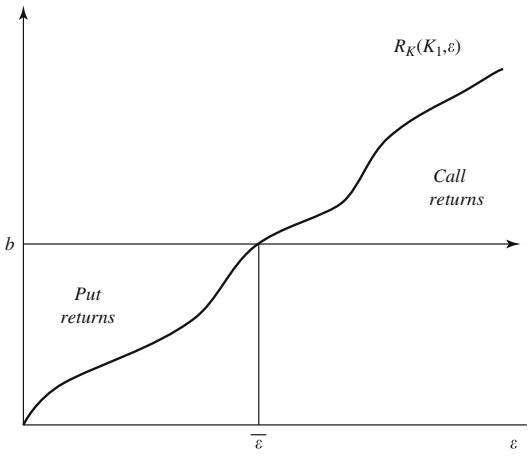
Most irreversible investment models work in continuous time, so that optimal investment timing can be calculated exactly. An introduction to these techniques, as well as a broader overview, is found in Dixit and Pindyck's (1994) *Irreversible Investment*. The intuition can be understood in a discrete time framework, adapted from Abel et al. (1996), specialized to the case of irreversible investment.

Consider the decision of a single firm to undertake a capital investment at time 1. In the first period, the return to installing capital K_1 is $r(K_1)$. The total return $r(K_1)$ is strictly increasing and concave in K and satisfies the Inada conditions. The firm pays a price b per unit of capital to purchase capital. In the second period, the return to capital is uncertain and equal to $R(K, \varepsilon)$, where ε is stochastic. The derivative of $R(K, \varepsilon)$ with respect to K,R_K $(K, \varepsilon) \geq 0$, is continuous and strictly decreasing in K, continuous and strictly increasing in ε, and $R(K, \varepsilon)$ also satisfies the Inada conditions. Define a threshold value of ε by

$$R_K(K_1, \overline{\varepsilon}) = b, \tag{1}$$

as illustrated in Fig. 1.

Assume that the resale price of capital is zero, or complete irreversibility. In the second period, the capital stock is optimally chosen at a level equal to $K_2(\varepsilon)$, subject to the irreversibility constraint. When $\varepsilon > \overline{\varepsilon}$, the optimal capital stock rises to satisfy the first-order condition $R_K[K_2(\varepsilon), \varepsilon] = b$. However, when $\varepsilon > \overline{\varepsilon}$, the marginal return to capital is less than its purchase price. If the firm could resell capital at its acquisition price b (costless reversibility) it would do so. However, the available resale price is zero, so the firm prefers to keep its capital stock, which has positive marginal return; in this case $K_2(\varepsilon) = K_1$. The optimal second-period marginal return to capital is graphed in Fig. 1 as the lower envelope of $R_K(K_1, \varepsilon)$ and b.



Irreversible Investment, Fig. 1 The second period marginal return to capital

Conditional on the optimal second-period capital stock, the firm chooses its capital stock at time 1 to maximize $V(K_1) - bK_1$, where $V(K_1)$ is the first period value of the firm equal to $r(K_1)) \gamma E[R(K_2, \varepsilon)]$ and $0 < \gamma < 1$ is the discount factor. The first-order condition for the optimal capital choice is

$$V'(K_1) \equiv r'(K_1) + \gamma \int_{-\infty}^{\bar{\varepsilon}} R_K(K_1, \varepsilon) \mathrm{d}F(\varepsilon) + \gamma b[1 - F(\bar{\varepsilon})] = b, \tag{2}$$

where $F(\varepsilon)$ is the cumulative distributive function (CDF) of ε.

Notice that the term $V'(K_1)$ is the marginal value of an additional unit of capital, or marginal q. The standard investment first-order condition equating marginal q to the marginal cost of capital still holds with irreversibility. The effects of irreversibility are incorporated into the value of marginal q, so when investment is non-zero the standard q-theory first-order condition equating the marginal value and the marginal cost of investment still holds.

Embedded Options

Now rewrite this first-order condition to highlight the investment options and their implications for the investment decision. Rewrite Eq. (2) as

$$q(K_1) \equiv V'(K_1) \equiv n(K_1) - \gamma c(K_1) \tag{3}$$

where

$$n(K_1) \equiv r'(K_1) + \gamma \int_{-\infty}^{\infty} R_K(K_1, \varepsilon) \mathrm{d}F(\varepsilon) > 0 \tag{4}$$

and

$$c(K_1) \equiv \int_{\bar{\varepsilon}}^{\infty} [R_K(K_1, \varepsilon) - b] \, \mathrm{d}F(\varepsilon) > 0. \tag{5}$$

The marginal value of an additional unit of capital is decomposed into two terms. The first term, $n(K_1)$, is equal to the present value of marginal returns to capital, evaluated at its current level, K_1. The second term subtracts the discounted value of a call option, $c(K_1)$, to add more capital, as illustrated in Fig. 1, where the returns to the call option are represented by the area under $R_K(K_1, \varepsilon)$ and above the line b. The call option reduces the marginal value of capital because additional capital irrevocably reduces the marginal return to capital owing to the concavity of the revenue function. If one combines these two terms, the marginal value of capital is the discounted sum of marginal revenues on the assumption that the capital stock is fixed, less the marginal value of the option to increase the capital stock. Note that the concavity of the revenue function is crucial to this mechanism. Hence, models such as Abel and Eberly, (1997) which assume constant returns to scale, do not generate these option values.

The effects of uncertainty are not transparent in the above formulation, since both terms in Eq. (3) depend on the distribution, $F(\varepsilon)$. To better discern the effect of uncertainty, rewrite Eq. (2) instead as

$$q(K_1) \equiv V'(K_1) \equiv j(K_1) - \gamma p(K_1) \tag{6}$$

where

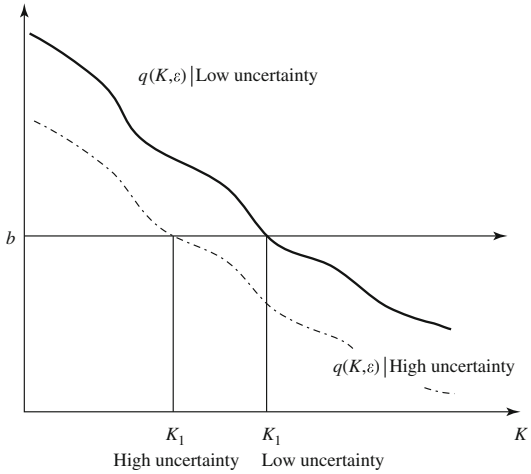
$$j(K_1) \equiv r'(K_1) + \gamma b > 0 \tag{7}$$

and

$$p(K_1) \equiv \int_{-\infty}^{\bar{\varepsilon}} [b - R_K(K_1, \varepsilon)] \, \mathrm{d}F(\varepsilon) > 0. \tag{8}$$

The marginal value of an additional unit of capital is again decomposed into two terms. The first term, $j(K_1)$, is the discounted marginal return to costlessly reversible capital: the firm earns the marginal revenue in period one and can sell the capital for the same price b in period two. This is the Jorgensonian marginal return (Jorgenson, 1963); notice that it is independent of ε and risk free. The second component of q is the put option to sell capital at price b. When investment is irreversible, the put option is not available to the firm, since it cannot sell capital at any

positive price. The value of the put option must be subtracted from the Jorgensonian valuation (where resale at price b would be permitted) to obtain the marginal value of irreversible capital. Marginal q can thus be written as a frictionless value less the value of the put option that is eliminated by the irreversibility constraint. This is illustrated in Fig. 1 by subtracting the returns to the put option (the area under the line b and above the function $R_K(K_1, \varepsilon)$) from the frictionless return b.



Irreversible Investment, Fig. 2 Marginal q and the optimal capital stock under low and high uncertainty

Effects of Uncertainty and Put–Call Parity

To calculate the effect of uncertainty on marginal q from Eq. (6), one need only calculate the effect of uncertainty on $p(K_1)$, since $j(K_1)$ is risk free. The effect of uncertainty on $p(K_1)$ is clear: $p(K_1)$ is an option value, and an increase in uncertainty increases the value of an option. In this case specifically, a second-order stochastic dominant shift in the distribution of ε shifts the CDF up for every value of ε. Since $R_K(K_1, \varepsilon)$ is increasing in ε, the term $[b - R_K(K_1, \varepsilon)]$ is decreasing in ε. Hence, greater uncertainty in ε shifts more weight of the CDF towards the large option payoffs in the left tail and unambiguously increases the value of the option, $p(K_1)$. Greater uncertainty unambiguously lowers the value of $q(K_1)$. Since $q(K_1)$ is decreasing in K_1, a downward shift in $q(K_1)$ reduces the optimal value of K_1 for a given value of b, as illustrated in Fig. 2. This decrease is the incremental investment counterpart to McDonald and Siegel's finding that greater uncertainty increases the option value of waiting, lowering the value of investing immediately.

This formulation of $q(K_1)$ also demonstrates Bernanke's (1983) 'bad news principle' of irreversible investment. The distribution of ε only appears in the expression for q in Eq. (6) via the put option $p(K_1)$. The put option only depends on the lower tail of the distribution of ε, below the threshold $\bar{\varepsilon}$. That is, the only part of the distribution of shocks that affects the value of $q(K_1)$ is the lower tail – or the 'bad news'. The upper tail is irrelevant, since in that region, the firm invests until the marginal product of capital equals its price. The exact realization of the shock in this region is irrelevant to the marginal return. In the lower tail, on the other hand, the firm neither invests nor disinvests, and the realization of the shock determines the marginal return to capital.

Figure 1 illustrates these arguments. The second period return to capital is the lower envelope of the price of capital, b, and the second-period marginal return, $R_K(K_1, \varepsilon)$ evaluated at K_1. The value of these returns depends on ε only in the lower tail of the distribution of ε (the bad news principle). The lower envelope can be expressed as either the function $R_K(K_1, \varepsilon)$ less the area labelled *call returns* in Fig. 1; adding this difference to first-period marginal returns $r'(K_1)$, we obtain the expression for q in Eq. (3). Equivalently, the second-period marginal return can be expressed the line b less the area labelled *put returns* in Fig. 1. Adding the first-period marginal return $r'(K_1)$, we obtain the expression for marginal q in Eq. (6). The fact that the second-period return can be written in two equivalent ways using options follows from put–call parity, a fundamental property of options prices. In fact, in this setting put–call parity is found simply by setting the two expressions for q in Eqs. (3) and (6) equal to each other. Equating these two expressions for q and simplifying, we find

$$\gamma p(K_1) + n(K_1) = \gamma c(K_1) + j(K_1). \quad (9)$$

This expression equates the value of a portfolio containing a put option and the underlying security, $n(K_1)$, to the value of a portfolio containing a call option and a risk-free asset. For a financial security such as a stock with price S, put–call parity analogously states that $P(S, \tau) + S = C(S;, \tau) + X/(1+r)^{\tau}$, where X is the strike price of the options and τ is the time to maturity. The terms $P(S, \tau)$ and $C(S, \tau)$ are the value of the put and call, respectively, on the underlying stock, S. $X/(1 + r)^{\tau}$ is the present value of a risk-free payoff (a zero coupon bond) of X in τ periods.

Extensions and Applications

The above analysis assumes complete irreversibility. However, less stringent forms of the constraint deliver similar implications. Abel and Eberly (1996) examine costly reversibility, where capital can be disinvested and resold at a price less than the purchase price of capital. In this case, the gap between the investment and disinvestment thresholds opens quickly, even for small differences between the purchase and sale prices of capital. Moreover, this formulation has assumed kinked, linear adjustment costs, so that the degree of irreversibility is summarized by the ratio of the purchase and sale prices of capital. However, with more general cost formulations, such as Abel and Eberly (1994), capital may have a positive resale price and still be effectively irreversible when other costs of reselling capital exceed any potential benefits. In addition to a resale market discount, convex adjustment costs and fixed costs, for example, may induce irreversibility.

Research on irreversibility has branched out both empirically and theoretically. Initial applications included energy and natural resource markets (Brennan and Schwartz, 1985), with extensions to virtually all types of quasi-fixed capital, including durable goods, real estate and equipment investment. Modelling has been extended to include multiple types of quasi-fixed capital goods (Eberly and van Mieghem, 1997). Aggregating models with infrequent adjustment to incorporate equilibrium effects is challenging, and the results remain controversial. Except in very special cases (Caplin and Spulber, 1987) aggregating requires tracking a distribution of agents. However, it is precisely this feature that can match the observation that much of the volatility in empirical investment arises from the extensive margin (the number of agents adjusting) rather than the intensive margin (the average size of the adjustment). Much progress has been made in this direction (for example, Caballero and Engel, 1999), though the quantitative implications vary with modelling strategy (Veracierto, 2002).

Islamic Economic Institutions

Timur Kuran

Abstract

The economic institutions of the classical Islamic world include Islamic contract law and the waqf, a form of trust. Until modern times, these two institutions were generally beneficial to economic performance. However, each had limitations that eventually blocked modern economic growth. Islamic contract law discouraged the formation of large and long-lived partnerships, thus obviating the need for business techniques and organizational forms associated with economic modernization. The waqf, designed as a rigid organization, locked capital into inefficient uses. Not until modern times has the corporation, a more flexible organizational form, entered the legal systems of the Islamic world.

Prior to the eighteenth century, the Islamic world did not appear economically underdeveloped to outside observers. Comparative studies by economic historians confirm that it became 'poor' in relation to Europe during the Industrial Revolution. Until that point, economic institutions grounded in Islamic law had afforded a respectable level of wealth by standards of the day. They had also facilitated the spread of Islam across Asia, southern Europe, and the coasts of Africa.

Law of Contracts

The first few centuries of Islam – *c.* 622–1000 AD – witnessed the gradual development of an elaborate law of contracts. It enabled the pooling of labour and capital through several forms of partnership, including ones providing limited liability to passive investors. Profit shares, negotiated in advance, could be unequal or contingent. Islamic partnership contracts were enforced, with minor variations, wherever Muslims ruled. As merchants and producers moved, they carried Islamic law with them, helping to spread Islam. Huge numbers of people converted in order to gain acceptance into lucrative commercial networks managed according to Islamic law.

Islamic law limited neither the size of a partnership nor its duration. However, in practice the typical Islamic partnership consisted of two people, who pooled resources for a single economic venture expected to last just a few months (Çizakça 1996). Lacking a life of its own, it was not what we call a firm. If a partner died during the contract period, the partnership became null and

void, and the decedent's share of the assets fell to his heirs. There could be numerous claimants, for the Islamic inheritance system, by medieval standards remarkably egalitarian, assigns mandatory shares to a possibly long list of extended relatives. Accordingly, reconstituting a dissolved partnership could be very costly. Merchants and investors minimized the risk of dissolution by keeping their partnerships small and ephemeral (Kuran 2003b).

A long-term consequence is that Islamic partnerships remained structurally simple, which obviated pressures to develop the sorts of organizational forms and business techniques that, in western Europe, gradually led to the modern economy. For instance, double-entry bookkeeping did not develop, and no markets arose for trading enterprise shares. This institutional inertia made it impossible to borrow new organizational forms, except as part of a comprehensive legal reform. Advanced organizational forms, such as the joint-stock company and the corporation, reached the Islamic world in the nineteenth century through the imposition of secular commercial law. By that time the financing and organization of the region's external trade was largely under Western control; and, as a result of the Industrial Revolution, productivity was much higher in the West than elsewhere. The very commercial institutions that had served Muslims well through the Middle Ages were now hindering the exploitation of modern technologies.

Role of Minorities

The religious minorities of the Islamic world might have escaped the limitations of Islamic commercial institutions, because they enjoyed 'choice of law' – the privilege to do business under legal systems of their own. Yet as individuals non-Muslims could opt unilaterally to take anyone to an Islamic court, whose decision would trump that of a non-Muslim judge or arbitrator. To achieve predictability in their economic relations, non-Muslims thus tended to base their financial and commercial contracts on Islamic law; their claims induced their own court systems to emulate Islamic legal practices. Consequently, until the eighteenth century the economic performance of non-Muslim peoples of the Islamic world did not diverge significantly from that of Muslims. Most non-Muslim communities started pulling ahead, however, as western Europe developed the legal infrastructure of modern capitalism. Vast numbers of Christians, Jews and other non-Muslims gained an economic advantage over Muslims by doing business under western or western-inspired laws (Kuran 2004b; Issawi 1982).

The Waqf

Another contributor to the Islamic world's economic successes and also to its subsequent economic retardation is the waqf, Islam's distinct form of trust. From the eighth century to modern times, Muslim-governed states provided few public goods directly, beyond law and order. They left the supply of public goods largely to waqfs established in a decentralized manner. Vast resources flowed into waqfs; by the early eighteenth century they owned between a quarter and half of all real estate, depending on the country. The services financed through waqfs included mosques, schools, hospitals, water fountains, roads, parks, inns, bathhouses, orphanages and soup kitchens.

A waqf is an unincorporated trust established under Islamic law by an individual owner of immovable property for the perpetual provision of a service. It emerged in the early Islamic period, a time of weak property rights, partly to enable landowning high officials to shelter wealth. Converting property into waqf yielded considerable immunity against confiscation, because waqf-owned assets were considered sacred, and this made legitimacy-seeking rulers reluctant to expropriate them. In addition to social status and religious satisfaction, the founder usually obtained pecuniary benefits. He could make himself the waqf's mutawalli (trustee and manager), set his own salary, appoint relatives to paid positions, and designate his successor. This last prerogative enabled circumvention of the Islamic inheritance system. In founding a waqf, then, an individual did not simply engage in charity. In

return for shouldering social responsibilities, he obtained the privilege of sheltering wealth for personal use. Local norms determined the share of a waqf's income that its mutawalli could reserve for himself and his family.

For a millennium this system for supplying public goods remained a distinguishing feature of the Islamic world. It owed this remarkable longevity to identifiable benefits that it yielded to huge groups. Property owners achieved a measure of material security. Rulers unburdened themselves of the responsibility to provide public goods. And the average person received diverse forms of philanthropy. Nevertheless, the waqf system had a flaw that became increasingly serious over time. Although some opportunities existed to reallocate resources to new uses, the waqf was designed to serve its founder's wishes for ever. As such, it could not adapt quickly to changing social needs, and it locked capital into inefficient uses. By the nineteenth century, a time of massive technological change, the waqf system had become conspicuously dysfunctional, and reformers took to dismantling it (Çizakça 2000; Kuran 2001).

Up to that time, services to the Middle East's great cities were supplied mostly by waqfs. The nineteenth century saw the establishment of the region's first municipalities, under secular laws. These municipalities, which attained corporate powers, could reallocate resources relatively quickly. Within a few decades, they assumed most of the functions previously relegated to the waqf sector.

Absence of the Corporation

Islamic law, which borrowed from various pre-existing legal systems, had spurned the Roman concept of the corporation. Limiting legal standing to natural persons supported Islam's political mission, which was to turn Arabia's feuding tribes into an undivided religious community. Corporations might have undermined that goal by enabling tribes to form autonomous organizations. During the formative period of Islam – from the seventh through the tenth centuries – the Middle East thus experienced no incorporation wave analogous to that observed in contemporaneous western Europe. One reason is that the waqf, by providing the means for delivering perpetual services with large sunk costs, alleviated the need for corporations. Another is that the waqf system spawned constituencies with a stake in preserving its key features; yet another that merchants and producers who stood to benefit from corporate powers could not muster the collective action necessary to reform the legal system. Not until the modern era did the concept of the corporation enter legal systems of the Islamic world.

In the late twentieth century, certain predominantly Muslim countries started to revive their waqf sectors, though in modernized and secularized form. Unlike the traditional waqf, a modern waqf enjoys legal personhood, and its founder may be a group. It is managed by a mutawalli board rather than a single caretaker appointed for life. Most critical, as a self-governing organization it can remake itself. Secularists, civil rights groups and economic liberalizers are the key constituencies of coalitions formed to promote waqf founding. These groups see their mission as a vehicle for shrinking the state, strengthening local governance, and promoting democratization (Çizakça 2000). Thus, having played an enormous role in Islamic economic history, the waqf is now turning into an agent of political and economic modernization.

Because the Qur'an does not mention the waqf, many Islamists are indifferent to ongoing efforts to reinvigorate the waqf sector. Their overriding goal is to purge interest from financial transactions, largely in the belief that the Qur'an bans interest categorically (Saleh 1986; Lewis and Algaoud 2001; Kuran 2004a). In fact, Islam's prescriptions concerning interest have always been a matter of interpretation, and throughout Islamic history interest-based transactions have been common (Rodinson 1966). Nevertheless, Islamists treat Islamic banking, intended to be free of interest, as the sine qua non of a properly Islamic economy. Yet Islamic banking is a modern creation. Pre-modern economies based on Islamic law had moneylenders but no banks (Udovitch 1979).

The first banks of the Islamic world, all foreign-owned and -managed corporations, date from the mid-nineteenth century (Kuran 2005).

Property Rights

Until modern times economies of the Islamic world suffered from a lack of institutions to tie the hands of governments. This meant that private property rights remained weak. Although material insecurity varied across time and space, taxation was often arbitrary, and states resorted to compulsory labour. Private property rights did not achieve credibility even in the eyes of state officials – one reason why endowing waqfs was so popular. A scribe could be plucked out of obscurity to become a prosperous statesman, and then, all of a sudden, fall into disgrace and lose everything. The expropriation of large estates was especially common, all the more so in times of financial crisis. Because this practice violated the Islamic law of inheritance, typically it was based on the ground that the deceased was not the rightful owner of his estate (Findley 1989).

In the seventh century, the first Islamic state in Arabia had instituted a tax-and- subsidy system that might have strengthened property rights. Known as zakat, it required the payment of taxes to the state in specific forms of income and wealth at predetermined rates. In providing the state the resources to fund various activities, including charity, it also capped taxation (Rahman 1974). However, precisely because of the inflexibility of its rate structure, within a couple of generations revenue-hungry rulers abandoned it for taxes that gave them greater latitude. Thereafter zakat metamorphosed into a narrow religious duty, incumbent on people of means, to assist the poor on an annual basis (Kuran 2003a). Modern Islamists have tried to turn zakat into a state-run social welfare system to which the wealthy make obligatory contributions. But throughout the Islamic world taxation remains an essentially secular matter. It has also become more predictable. The wealthy classes of the present have far better defences than those of the past against government predation.

Taxation can be arbitrary without being devoid of logic. In pursuing opportunities to raise revenue, rulers sought to limit transaction costs, in particular to minimize the costs of measuring income, identifying assets, and collecting taxes. To that end they tended to collect fixed taxes directly, leaving the collection of variable taxes to local officials (Coşgel and Miceli 2005). They also made extensive use of tax farming, which assigns collection rights to people knowledgeable about tax units.

Islamic Finance

Mahmoud El-Gamal

Abstract

Islamic laws on financial matters date back to medieval times. They were reinterpreted in the 20th century to provide guidelines for the burgeoning Islamic financial sector. Compliance with religious law is a driving force in this sector, and a variety of financial instruments have been developed that are adjudged to be acceptable for use by Muslims. These continue to evolve, and the rules could be considered to merit reinterpretation to better enable Islamic financial institutions to deal with risk factors and obey the spirit, rather than merely the letter, of medieval Islamic jurisprudence, which was regulatory in nature.

The notion of 'Islamic finance' was born during the tumultuous identity-politics years of the mid-20th century. Indian, Pakistani and Arab thinkers contemplated independence from Britain, and the independence of Pakistan from India, within a context of 'Islamic society'. Islam was assumed to inspire political, economic and financial systems that are distinctive and independent of the Western (capitalist) and Eastern (socialist) models of the epoch. The term 'Islamic economics' was coined by Abu al-A'la Al-Mawdudi, whose students and followers worked to develop an ostensible Islamic social science (Kuran 2004). Mawdudi's influence on Arab Islamists began with the writings of Sayid Qutb, the father of modern Arab political Islam, whose quasi-exegesis *Under the Qur'anic Shade* referred exclusively to Mawdudi's writings on economic matters. Mawdudi's migration from majority-Hindu Indian society to majority-Muslim Pakistan thus became a prototype for Islamist migration away from secular political and economic systems.

From Islamic Economics to Islamic Banks

In the first few decades of its existence, Islamic economics focused on comparative economic systems (a fashionable field at the time) as well as neoclassical and Keynesian modelling with a highly stylized *homo islamicus* (a moral and ethical individual who shuns excessive greed and consumerism) in place of mainstream economics' *homo economicus* (a selfish utility and profit maximizer) (Haneef 1995).

As a byproduct, Islamic banking emerged in the Islamic economists' literature as a financial system based exclusively on profit-and-loss sharing, which was argued to be more equitable and stable (Chapra 1996; Siddiqi 1983). In the process, Islamic economists focused on the Islamic prohibition of *riba* or usury, which they interpreted as a prohibition of all interest-based lending, in accordance with earlier interpretations of the Judeo-Christian canon.

Classical Islamic jurisprudence had interpreted interest-based lending, the cornerstone of fractional-reserve depositary banking, as riskless – and therefore illegitimate and inequitable – return for idle capitalists. Indeed, the importance of credit and counterparty risk for any financial analysis remains conspicuously absent from the writings of the Islamic-economics faithful. The preferred financial model, they postulated, would be based on the ancient silent-partnership model known in Islamic writings as *mudaraba*, corresponding to the Jewish *heter iska* and the Christian-European *commenda* (Udovitch 1970).

An 'Islamic bank' was envisioned as a two-tier silent partnership. Thus, deposits seeking a return (as opposed to fiduciary deposits, for which 100 per cent reserves are required) would not be guaranteed loans to the bank, but rather silent-partnership investments in the bank's portfolio. In turn, the bank's investments of those funds would not consist of loans and acquisition of debt instruments, but rather profit-and-loss sharing investments in other silent partnerships. Thus, the Islamic bank would serve its financial intermediation function (pooling of return-seeking savings and diversification of investments) through profit-and-loss sharing. This idea continues to serve as the cornerstone of Islamic banking today, despite being thoroughly debunked by prominent jurists (Tantawi 2001; El-Gamal 2003).

Potential loss of return-seeking deposits was assumed by Islamic-banking proponents such as the Islamic Financial Services Board (IFSB) to encourage depositor-monitoring and risk-mitigating market-based discipline. Thus, the grossly inadequate depositor-protection measures supported by the industry have focused on transparency of operations and profit-distribution mechanisms (IFSB 2006).

The Practice of Islamic Banking

This risk-sharing model has continued to shape the liabilities side of Islamic banks' balance sheets, with a few exceptions in Europe and the United States, where regulators have required Islamic financial providers that function as banks to guarantee deposits. The assets side of Islamic banks and financial providers, on the other hand, has utilised multiple structured-financial models to replicate loans and fixed-return securities that limit the banks' exposure to credit risk. The transformation from the idealistic profit-and-loss sharing model of Islamic economics – which continues to be hailed as the 'Islamic ideal' by industry practitioners and commentators – to replication of modern financial products and markets in 'Islamic' garb coincided with the increased importance of classical methods of Islamic jurisprudence and a limited rhetorical role for Islamic economics.

Early models in the subcontinent during the 1950s and in Egypt during the 1960s notwithstanding, the true beginnings of Islamic banking and finance occurred in the mid-1970s. Islamic jurists including the Shiite scholar Baqir al-Sadr and many Sunni scholars in Egypt, Saudi Arabia and elsewhere collaborated with Islamist bankers to replicate loans using ancient contract forms. Baqir al-Sadr, in his classical work *The Non-Usurious Bank in Islam* (long out of print), had attempted to use similar structured products to replicate guaranteed bank deposits on the liabilities side. However, since risk-sharing depositors were clearly beneficial to the shareholders of Islamic banks, and because the latter drove innovation in Islamic banking through the retention of lawyers and religious scholars, most of the 'innovations' were restricted to the assets side of the balance sheet.

Murabaha (Cost-Plus Sale) Financing

The workhorse of Islamic banking has been the *murabaha* (cost-plus sale) contract. The logical evolution of this form of finance is indicative of the general methodology of Islamic finance to this day. In the early 1980s, Islamic banks in the Gulf were flush with petrodollars, and Western corporations were eager to borrow from them as Western-bank credit dried up following the petrodollar-driven Latin American debt crisis. Islamic banks resorted to the easiest ancient trick: introducing a property to separate lent principal from repaid principal plus interest.

In the simplest ruse, the bank could have sold some commodity to its potential borrower on credit (for principal plus interest payable later), and then bought it back for cash (principal paid immediately), thus effectively replicating the cashflows of the loan, with the commodity making a round trip from bank to customer and back. However, this ancient ruse was forbidden by name as same-item sale resale (*bay' al-'ina*). In practice, one credit sale and one spot sale of liquid commodities were still used to accomplish the desired goal by conducting the second spot sale with a third party.

Interestingly, Al-Rajhi Investment Company in Saudi Arabia, which has one of the strictest religious-scholar boards, received a question on the legitimacy of the credit sale of gold, and ruled that such sales were disallowed because gold is a monetary commodity. Promptly thereafter, the same board was asked if platinum can be sold on credit, and issued a *fatwa* that this was permitted. Thus, Islamic banks could simply trade precious metals, acquiring an amount of platinum (or other metal excluding gold and silver) equal in value to the desired loan principal. The metal was then sold on credit to the Western borrower under a *murabaha* contract, with a credit price equal to the desired principal plus interest. The customer was then able to sell the metal quickly to receive the desired borrowed principal, perhaps less a small transaction cost.

This was the juristic solution first popularised by the late banker Sami Humud in his book *Evolving Banking Transactions in Accordance with Islamic Law* (1976). The prohibition of *riba* (usury) in the Islamic canon and subsequent juristic analysis left room for such ruses. The Qur'an merely mentioned *riba* in the abstract without specifying precisely which transactions were thus forbidden. The Prophetic tradition merely listed six commodities: gold, silver, dates, wheat, barley and salt, all of which were used at some point as commodity monies in the ancient world, stipulating that those may be traded only hand-to-hand and in equal amounts measured by weight or volume. One school of jurisprudence (*Hanafi*) expanded the prohibition to all commodities measured by weight or volume, but still did not treat them as money. Therefore, while trading platinum now for platinum later, or trading gold now for silver later, would both be deemed impermissible based on the *Hanafi* interpretation, trading platinum now for dollars later was considered permissible.

Interestingly, the *Halacha*, developed by Jewish scholars prior and in parallel to the development of Islamic *Fiqh*, forbade such embedded-interest credit sales (Reisman 1995, p. 112). In contrast, all major schools of Islamic jurisprudence (four Sunni and four Shiite) have allowed credit sales at prices possibly exceeding the spot price. Initially, this was only a method for seller financing. Thus, the financier needed first to acquire the property before selling it on credit. In addition, to give the contract an Islamic flavour, the industry adopted the name of an ancient cost-plus sale – *murabaha*, a contract devised to protect buyers who were unfamiliar with market prices, allowing them to negotiate prices by negotiating markup over revealed cost.

The contract that emerged in the 1970s was formally known as 'cost-plus sale to the customer who ordered the initial purchase' (*murabaha lil-'amir bil-shira*'). It was initially subject to scholarly controversy, especially as bankers added provisions to eliminate all forms of risk other than customer credit. In order to eliminate property-related risks, which were ironically the basis on which jurists allowed earning a return on the transaction, they allowed banks to stipulate that the eventual buyer must guarantee to buy the property on credit once the bank acquires it. Eventually, wide consensus emerged and the contract became the workhorse of Islamic banking practices, from large multi-million-dollar loans to Western corporations to retail-bank secured lending.

Tawarruq (Monetization) Financing

In order to reduce transaction costs, especially for retail customers who wished to borrow cash, Islamic banks in Gulf Cooperation Council (GCC) countries revived another ancient financial trick: monetization. This transaction is very

similar to the cost-plus commodity-sale finance model, with the added complication that the Islamic bank executes all three legs of the transaction: (i) buying the principal's worth of metals at the spot price, (ii) selling said metals to the customer on credit for principal plus interest, and (iii) selling the metals back to the dealer, as the customer's agent, for the spot price less a small fee. All three transactions can be concluded within minutes via fax.

This transaction avoids the forbidden two-party sale–resale trick by adding not only one commodity as a degree of separation between lent principal and repaid principal plus interest, but also a third-trading-party degree of separation (the metals dealer) so that every two parties formally trade the commodity only once. The commodity still completes a round-trip (dealer → bank → customer → dealer), spot cash in the amount of desired principal completes one trip (bank → dealer → customer), and the credit-sale-price payment of principal plus interest occurs in the future (customer → bank). This three-party variation on same-item sale resale was also known in ancient and medieval practice, and deemed forbidden or reprehensible by most schools of law. Some medieval scholars within the *Hanbali* school of jurisprudence, which is dominant in the GCC, had permitted this practice. Despite the fact that the most respected 14th-century scholars ibn Qayim and ibn Taymiya forbade the transaction (as merely an expensive and potentially more hazardous type of usury/*riba*), contemporary *Hanbali* jurists who dominate one juristic council in Saudi Arabia permitted the practice in 1998. The same council later forbade the organised practice of Islamic banks using this contract in 2003, but the practice continued to thrive.

Ijara (Lease) Financing, Securitization and *sukuk* (Islamic Bonds)

Despite juristic approval of credit-sale-based financing methods, the practice remained suspect in scholarly as well as general Islamist circles. In addition to objections that the practice merely replicated interest-based financing with interest characterised as profit or markup, there were problems with securitization and trading of receivables from *murabaha* and *tawarruq* facilities. Those problems arose from the fact that most jurists, with the notable exception of those in Malaysia, forbade trading of debts, except under very strict transfers at face values and resale to the debtor. This prevented the development of secondary markets that would allow banks to diversify their portfolios and sources of funds. Lease financing provided a partial solution to both problems: it was ostensibly based on real assets that continued to play a role throughout the life of the financial facility, and it was possible to trade lease receivables on secondary markets as ostensible shares in the leased assets.

Jurists were adamant that Islamic lease or *ijara* financing must be truly asset-based, and therefore must be structured as operating rather than financial leases. However, recent advances in structured finance – which helped corporations such as Enron to move debts and interest payments off balance sheets through sale-leaseback structures – had blurred the line between operating and financial leases. As a result, a prestigious juristic council declared in 2008 that more than 80 per cent of lease-based bond (*sukuk*) structures were unIslamic, since material ownership of the underlying assets was not real.

Developed initially as another mode of secured lending, lease financing proceeded by acquiring durable assets and leasing them with an option to buy – principal plus interest passing to the lessor as rent plus potential final payment. For banks in countries that forbid them from owning real estate, special purpose vehicles (SPVs) received credit that were used to acquire the assets and lease them till maturity. Shares in those SPVs were treated as shares in the leased properties, thus allowing them to trade on secondary markets. In the United States, such structures were used to originate mortgage loans that were then securitized through Fannie Mae and Freddie Mac, and marketed both domestically and in the cash-rich GCC, especially after the second wave of petrodollar flows began in 2001.

Bond structures were easily adapted from these financial forms. An entity that wished to issue a bond would create an SPV, which sold shares for the amount of financing desired. The proceeds of that sale were used to buy some asset from the originator, which asset was promptly leased back. The originator would thus collect the proceeds of the sale of its asset as principal, and pay principal plus interest in the form of rent and/or a final repurchase price, which payments were passed through to the *sukuk* or bond holders. An added advantage of this structure is that the payments were made ostensibly on shares in ownership of the real asset, thus the contract could be advertised as a form of partnership, which appealed to the earlier political-Islam inspired literature on Islamic economics.

Jurists further facilitated securitization of debts by allowing a portfolio of asset-based and purely debt-based receivables (that is, lease-based and credit-sale-based, respectively) to be traded as long as the asset-based component exceeded 51 per cent of the total face value (Usmani 1998). This strange provision clearly imposed no significant constraints on securitization, since successive portions of pure-debt receivables could be bundled iteratively with the same asset-based ones, which could be bought back repeatedly for the purpose of bundling with pure-debt tranches. Thus, Islamic finance became an equal partner in the credit bubble the ensued in the first decade of the 21st century. In fact, the volume of *sukuk* remained sufficiently small (relative to demand by Islamic banks) to merit abnormally high prices and low yields relative to conventional debts issued by the same entities.

Islamic Mutual Funds

A widely publicised area of Islamic finance was the development of 'screening' methods to identify '*Shari*'*a* compliant' stocks. These screens excluded stocks of companies with significant forbidden activities (such as breweries), and also of firms with excessive debt or interest income. The debt screen chosen by the industry was particularly perplexing, as it excluded firms with debt to market capitalization ratios exceeding one-third. This rule clearly forced fund managers to buy high and sell low in highly volatile markets. Moreover, the rule diverted funds away from Muslimowned companies, which were not allowed any degree of unsecured-loan leverage, in favour of western firms with moderate levels of leverage. The financial screens themselves had no foundation in Islamic law or reasonable economic analysis, starting as they did at 5 per cent debt to assets and evolving during the tech-stock bubble of the late 1990s into 33 per cent of debt to assets and then 33 per cent of debt to market capitalization. It is not clear whether and when these rules can be replaced with sensible ones.

Takaful (Islamic Insurance) and Derivatives

One of the fast-growing sectors in Islamic finance is an Islamic alternative to commercial insurance known as *takaful* (mutual support). The rhetoric of this sector is based on the idea of mutual protection against losses, but most *takaful* companies to date have not been structured as mutual insurance companies (in which policyholders and shareholders are the same individuals). Instead, *takaful* companies are generally shareholder-owned and act through silent partnership or agency to invest the policyholders' premiums and pay legitimate claims in the form of 'voluntary contributions' – thus avoiding the Islamic prohibition of *gharar*, which includes trading known amounts (policy premia) for uncertain future amounts (on potential valid insurance claims). The prohibition of *gharar* was also invoked to forbid derivative securities, but forwards and options were easily synthesised from the ancient contracts of *salam* (prepaid forward sale) and '*urbun* (downpayment call option), respectively.

Substance and Form

El-Gamal (2006, 2008) has argued that the essence of the ancient religious law was

regulatory. It is well known in financial economics that financial innovators eventually find means to circumvent outdated regulation, thus increasing systemic risk. Financial crises later propel political and economic authorities to impose further regulations for innovators to circumvent. In this regard, the ancient religious regulations enshrined in medieval Islamic jurisprudence, especially if interpreted naively as prohibitions of certain contracts and permissions of others, are woefully out of date, and therefore ceased to perform their regulatory function centuries ago. Indeed, that is precisely why majority-Muslim societies had abandoned those outdated contract-based frameworks before the Islamist revisionism of the mid-20th century. The ancient law, which is not uniquely Islamic, does contain many lessons for today's societies – Muslim and otherwise. However, rent-seeking behaviour by bankers, lawyers and religious scholars on the one hand, and incoherent pietism and adherence to fictional Utopian history on the other, have prevented societies from adapting this centuries-old accumulated human wisdom for any purpose beyond short-term self-enrichment and identity-political appeasement, both of which increase rather than ameliorate systemic risks.

IS–LM

Steven N. Durlauf and Donald D. Hester

Abstract

The IS–LM model is a short-run macroeconomic analytical construct for studying an economy with idle productive resources. The diagram has been especially influential because its constituent curves are loci on which the goods market (IS curve) and the money market (LM curve) are respectively in equilibrium, making it possible to infer changes in fiscal policy and monetary policy, both separate and simultaneous. The model is prominent in elementary and intermediate macroeconomic textbooks, yet it fails to accommodate the main features of modern macroeconomic theory, although modern dynamic models are sometimes interpreted as having IS–LM type features.

The IS–LM model is a short-run macroeconomic analytical construct for studying an economy with idle productive resources. In the form exposed by Hansen (1949), it is a two-dimensional diagram with the abscissa measuring real income and the ordinate the real interest rate. It has been widely and successfully employed in interpreting macroeconomic policy and is prominent in elementary and intermediate macroeconomic textbooks. A close antecedent, the SI–LL diagram, first appeared in print in an influential article by J.R. Hicks (1937) that proposed an interpretation of Keynes's *General Theory* (1936) and effectively made Keynes's contribution accessible to large numbers of students ever since. Hicks's diagram had nominal income measured on the abscissa and was unclear about whether the interest rate was real or nominal. If prices are fixed or 'sticky' these differences are immaterial, but assumptions about prices and their measurement loomed large in subsequent controversies and applications of the diagram. Lange (1938) appears first to have required that variables were real magnitudes. Reflecting the times of its origin, the model describes a closed economy.

The diagram has been especially influential because its constituent curves are loci on which the goods market (IS curve) and the money market (LM curve) are respectively in equilibrium. The intersection of the two curves is a point where both markets (and, through Walras's Law, the bond market) are in equilibrium. The labour market is not required to be in equilibrium. Because fiscal policy affects the goods market through tax, transfer and expenditure changes, the effects of fiscal policy can be inferred from the change in the intersection of the IS curve with a stationary LM curve. Similarly, because changes in the money stock affect only the LM curve, the effects of monetary policy can be inferred from the change in the intersection of the LM curve with a stationary IS curve. Finally, the effects of simultaneous changes in both fiscal and monetary policies can be predicted from the change in the intersection when both curves are moved.

By way of background, the *General Theory* contains no formal mathematical model and has only one diagram. 'Keynes believed economics was over-addicted to "specious precision" – making perfectly precise what was in reality vague and *complex*. It is significant that he refused to present the "model" of the *General Theory* in mathematical form, even though he assembled its (verbal) elements in chapter 18' (Skidelsky 1994, p. 540). 'The mathematicisation of the *General Theory* started immediately it (*sic*) was published but it was left to Hicks to map the mathematics on to a two-curve diagram which became the accepted form of the *General Theory*' (Skidelsky 1994, p. 611).

Hicks's article emerged from the September 1936 European meetings of the Econometric Society at Oxford where a symposium on 'Mr. Keynes' System' was held. Other important papers from the symposium interpreting Keynes were by R.F. Harrod (1937) and J. Meade (1937); both were published slightly earlier than Hicks's paper, but contained no trail-blazing graphical apparatus. Young (1987, p. 29) claims that all three papers had the same underlying equation system, which differed from that of the *General Theory* but may have appeared in Keynes's lectures at Cambridge as early as 1934. All three papers analysed the relation between their interpretation of what underlay the

General Theory and the pre-existing theoretical framework. Keynes apparently did not object to the specifications of Hicks, Harrod and Meade, but stressed the importance of expectations and uncertainty in his subsequent discussions (1937) of the general theory; expectations do not appear formally in the three authors' equation systems. If one accepts Keynes's (1936, ch. 12) discussion of how long-term expectations are formed, it may indeed be specious to describe commodity market equilibrium as if it were lying on a stationary curve, but that in no way reduces the usefulness of the model for designing and interpreting policy. The effects of monetary and fiscal policy actions are unaffected by random shocks to the two curves. However, the effects might be affected if the curves are moved by expectations about present or future policy moves, as has been suggested by Lucas (1976). Subsequently, J. Robinson (1975) and R. Kahn (1984), two of Keynes's contemporaries when the *General Theory* was being drafted, objected strenuously to the IS–LM formulation and Hicks himself (1982) indicated dissatisfaction with it.

Basic Theoretical Structure

In the standard formulation of the IS–LM model, the endogenous variables to be determined are the level of aggregate output Y and the real interest rate *r*. Aggregate demand in the goods market is modeled via the output identity:

$$Y = C + I + G + NX$$

where C denotes consumption, I investment, G government spending and NX net exports. The identity is given substance by replacing C with a consumption function and I with an investment function. Typically, IS–LM analysis assumes that consumption depends positively on disposable income, which equals output Y minus taxes $T(Y)$ (income taxes induce dependence of the level of taxes that are collected on income) whereas investment depends on the real interest rate; one could also endogenize government spending and net exports. This leads to the IS equation:

$$\text{IS}: Y = C(Y - T(Y)) + I(r) + G + NX.$$

Money market equilibrium is defined by equating money demand and money supply. Real money demand, denoted by L to capture the idea that the demand for money is the demand for liquidity, is assumed to depend negatively on the nominal interest rate, which by definition equals the real interest rate plus the expected inflation rate, π. Throughout, expected inflation will be treated as exogenous; as noted below a defect of the IS–LM framework is that it does not embody expectations in an interesting way. The real money supply, $\frac{M}{P}$, is treated as exogenous, as are the price level and inflation rate. The LM equation is:

$$\text{LM}: \frac{M}{P} = L(r + \pi, Y).$$

If the demand for money does not depend on the nominal interest rate, then the LM curve uniquely determines the level of output. This special case is of historical importance in understanding the monetarist perspective on macroeconomics. In contrast, if the demand for money is infinitely elastic at some exogenous nominal interest rate, the LM curve uniquely determines the real interest rate. This case is also of historic interest as it is the first version of a liquidity trap. It should also be noted that the LM curve can be replaced with a more sophisticated system of asset price equilibrium conditions; a significant component of James Tobin's work on monetary economics well summarized in Tobin (1969), represented an effort to enrich IS–LM analysis via a richer specification of financial markets.

Regardless of the specific assumptions on the shapes of the IS and LM schedules, the equilibrium pair (r, Y) is determined by the simultaneous solution of these two equations. Comparative static analysis may be done by changing the various exogenous variables in the IS and LM equations. Notice that this system is entirely demand driven in the sense that it does not consider resource constraints in the determination of output.

The IS–LM model has a number of well-known implications with respect to the effects of changes in government policy. Increases in government

spending G increase the equilibrium levels of r and Y and decrease the equilibrium level of I. The reduction in investment induced by an increase in government spending is known as crowding out. When money demand does not depend on the nominal interest rate, there is complete crowding out in the sense that the increase in G is completely offset by a decrease in I, so that aggregate demand is unaffected; the independence of money demand from the nominal interest rate has often been treated as a hallmark of monetarism, since in this case changes in fiscal policy have no real effects. Similar results occur when one considers tax changes; a reduction in either lump sum taxes or the income tax rate increases both Y and r. With respect to monetary policy, an increase in M leads to an increase in Y, a decrease in r and an increase in I. Hence, unlike expansionary fiscal policy, expansionary monetary policy increases investment, and so causes crowding in. The exception to this result is a liquidity trap in which changes in the supply of money are accepted by the public at the initial nominal interest rate.

Beyond the evaluation of exogenous changes in government policies on aggregate outcomes, the IS–LM model has also been used to evaluate alternative government policies. Poole (1970) is particularly notable in this regard. Poole compares the stabilization properties of a monetary policy that fixes the nominal money supply with one that fixes the real interest rate. He shows that, if macroeconomic volatility derives from shocks to the IS schedule, then a fixed money stock policy stabilizes an economy more than a fixed interest rate policy; in contrast, when aggregate fluctuations are generated solely by shocks to the LM schedule, a fixed interest rate completely eliminates aggregate fluctuations. The idea that the effects of a monetary policy rule depend on the type of shocks an economy experiences has proven to be of importance in contexts far beyond the IS–LM model; one sees echoes of Poole's reasoning in discussions of the Taylor rule for interest-rate setting.

The IS–LM model has also been used to study the effects of changes in other exogenous (from the perspective of the model) variables on the macroeconomic equilibrium. An especially important issue concerns changes in the price level, because one wants to know whether price adjustments can move aggregate output towards a level consistent with full employment. In the specification so far described, a decrease in the price level raises Y and lowers r because a lower price level increases the real money supply, thereby shifting the LM schedule. This property was considered important in early expositions of IS–LM such as Modigliani (1944) that considered the possibility of a liquidity trap.

However, as argued by Pigou (1943, 1947), there is another channel through which lower prices can raise demand. Pigou argued that the level of consumption depends on the level of wealth as well as on disposable income. Since a component of wealth is nominal money, price reductions can increase demand through increases in the real value of money and, hence, wealth. This is called the Pigou (or real balance) effect. Work on the real balance effect, in turn, affected the study of monetary policy in the IS–LM framework. The seminal paper in this regard is Metzler (1951), who argued that the real balance effect implied an important difference between the effects of a helicopter dropping of money, that is, an increase in the money supply in which additional money are simply added to individual portfolios, and an open market operation, in which an increase in the money supply is generated by the trading of money for bonds, so that one nominal asset is swapped for another, thereby keeping the aggregate nominal supply of assets constant.

Another well-known property of the model concerns the equilibrium effects of an increase in the (exogenously given) inflation rate. In the IS–LM model, an increase in π increases Y and lowers r. Intuitively, an increase in inflation reduces money demand, requiring an adjustment of the real interest rate and output to compensate. The fact that increases in inflation lead to less than one-to-one increases in the nominal interest is known as the Mundell–Tobin effect (Mundell 1963a; Tobin 1965). As before, this property depends on the dependence of money demand on the nominal interest rate.

From the perspective of modern macroeconomic theory, the IS–LM model has very serious deficiencies. One problem is that the model lacks

I

well-defined microeconomic foundations. The price level is treated as exogenous; while prices may be sticky, the complete rigidity found in the IS–LM model is unappealing. Further, the consumption and investment functions are typically specified in an ad hoc fashion, rather than as the outcome of solving explicit decision problems.

Also, the IS–LM model fails to embody aggregate dynamics. The model constructs a snapshot of the macroeconomy without accounting for the fact that the snapshot is really one frame of a motion picture. While expectations variables can be introduced into the model, its static nature precludes one from considering many implications of the intertemporal government budget constraint for the real effects of changes in fiscal policy or the effects of expectations about monetary policy on the sequence of equilibrium price levels over time. This lack of dynamics was recognized early on as a defect of the model; heuristic analyses include Patinkin (1956) who tried to link IS–LM with tâtonnement adjustment of prices à la Walras. Indeed, Patinkin's book was the high point of efforts to link IS–LM with the conceptual structure of general equilibrium models. But this type of work disappeared rather quickly. Later on, efforts were made by Blinder and Solow (1973) and Tobin and Buiter (1976) to account for changes in the stocks of various assets on the IS–LM equilibrium, with particular attention paid to understanding how permanent changes in fiscal policy affect output in the presence of the requirement that the government budget balance with respect to the present discounted value of debt and taxes. These analyses found that accounting for such effects could imply that the long-run effect of a change in government spending exceeds the short-run change. One reason for this is the increased holdings of government debt induced by a fiscal expansion will increase consumption. This type of work also failed to have much effect on the use of the IS–LM framework.

To be fair, a number of recent authors have attempted to provide more rigorous microeconomic foundations to the IS–LM model; McCallum and Nelson (1999) is the most important example. See King (2000) for evaluation of such models. While progress has been made in producing better microeconomics for the IS–LM model, it seems fair to say that much of its use, especially in pedagogical and policy contexts, relies on the model we have described.

Mundell–Fleming Model

A variant of the IS–LM model that has proven important in international economics is due to Mundell (1963b) and Fleming (1962); its value derives from the consideration of how the effects of monetary and fiscal policy are altered when one considers the role of the exchange rate. In this framework, a small country is assumed so that the income of the rest of the world, Y^{ROW}, is unaffected by events in the country. However, actions of the country may affect the exchange rate e, defined as the number of units of foreign currency one unit of the country's currency can purchase. Net exports for the country are assumed to obey

$$NX = NX\left(Y, Y^{ROW}, e\right).$$

Higher exchange rates are assumed to lead to a lower level of net exports; this is known as the Marshall–Lerner condition.

The effects of changes in monetary and fiscal policy will critically depend on the effects of a policy on the exchange rate. This, in turn, depends on the degree of integration of international capital markets. Following the classic Mundell–Fleming analysis, suppose that international capital markets are fully integrated. In this case, the real return on investments cannot differ across countries and so r is fixed since the economy under study is small. An increase in government spending by a small economy, in this case, will have no real effects. An increase in G will be entirely offset by exchange rate appreciation, that is, an increase in e, so that there is no net fiscal stimulus as the increase in government spending is fully offset by a reduction in net exports. In contrast, an increase in the money supply will induce an increase in output via exchange rate depreciation. These outcomes, of course, presume that the exchange rate is allowed to float.

In contrast, suppose that the central bank authority is committed to maintaining a given exchange rate, $\bar{e}$. In this case, the effects of monetary and fiscal policy are quite different. Maintenance of the exchange rate eliminates any independent role for the central bank in the sense that any action it takes to raise output will have to be undone in order to preserve the exchange rate. In contrast, a fiscal stimulus will induce a subsequent increase in the money supply in order to overcome the associated exchange rate appreciation, which reinforces the effects of the stimulus that are found in the closed economy model.

While current thinking on the interactions of the exchange rate regime with policy effects has moved far beyond the details of the Mundell–Fleming model, the ideas in the model not only proved of direct value for much subsequent research (for example, Tobin and Braga de Macedo 1980) but has also, via its limitations, defined the agendas of alternative research directions (Obstfeld 2001).

IS–LM in the Light of Macroeconomic History

Despite its theoretical limitations, the IS–LM model is illuminating in interpreting macroeconomic policy and events in the post-war period, especially in the United States, which could reasonably be viewed as a closed economy in the early years. Between the end of the Second World War and 1951, the Federal Reserve was committed to a policy of restricting upward shifts in the yield curve in order to reduce the cost of financing the US government's large war debt. During this period, the Federal Reserve effectively 'pegged' the short-term nominal interest rate, so that monetary policy was expansionary whenever the real rate was negative and especially so when inflation was increasing. In the inflationary period between 1945 and 1948, the real short-term interest rate was substantially negative. Although deflation accompanied the recession of 1949, when the real rate turned briefly positive this unsustainable pegging policy together with the onset of the Korean War in 1950 led to the 'Accord' of 4 March 1951, which permitted the Federal Reserve to undertake discretionary monetary policy. This early inflationary monetary policy bias may not have been inappropriate, because demobilization after the Second World War led to a massive leftward shift of the IS curve due to falling government spending and essentially stagnant real net foreign and gross domestic investment until 1950. Inflation occurred with the suspension of price controls in 1946, but did not begin to accelerate until the war started in June 1950.

The Korean War led to a 75 per cent increase in real government spending and a sizable increase in the real government deficit between 1950 and 1954. An expansion of accelerated depreciation allowances in 1954 was associated with a ten per cent increase in real investment in producers' durable equipment in the subsequent three years. Both events caused a rightward shift in the IS curve. However, the shifts were rather insidiously being offset by 'fiscal drag' that resulted from increases in the marginal income tax rate that existed when the economy was at full employment. The tax rate rose because progressive tax schedules applied to nominal income, not income adjusted for inflation. Following the Accord, the Federal Reserve used open-market operations to fight inflation by raising nominal interest rates on several occasions with unsatisfactory results. Unemployment rates rose as interest rates rose, as might have been predicted from the resulting leftward shift in the LM curve. However, it was not widely understood that the IS curve was also shifting leftward because of the cumulative effects of fiscal drag. Seemingly, restrictive monetary policy induced three recessions in this decade with unemployment rates at troughs successively higher in each recession. Inflation temporarily abated during or shortly after each recession, but then returned, in part, because real short-term interest rates were infrequently positive until 1959.

The 1960 elections resulted in John F. Kennedy becoming president and, of greater significance for this discussion, a generation of economic advisors who understood and were intent upon applying the IS–LM model. The US Council of Economic Advisors' *Economic Report of the President* explicitly

focused on the importance of the full-employment budget surplus (1962, pp. 78–81) and, thus, fiscal drag. The Council of Economic Advisors also worried about the fact that real gross private domestic investment had been below its 1955 peak for the subsequent six years, a possible consequence of high interest rates. The administration negotiated an arrangement with the Federal Reserve whereby it would attempt to twist the yield curve through open-market operations by increasing short-term interest rates to protect the US gold stock from foreign withdrawals and lowering long-term interest rates to stimulate investment. The Treasury assisted in this effort with its debt management policies (1962, pp. 86–91). The administration increased federal government spending significantly beginning in the 1962 fiscal year and would subsequently stimulate the economy with tax cuts. The federal government deficit rose over the four years after 1960 and the IS curve shifted rightward. Because twisting of the yield curve involved two interest rates, it cannot be interpreted directly with the LM curve; however, between 1961 and 1964 the interest rate on three-month treasury bills rose 50 per cent, the rate on three–five year issues rose 6.4 per cent, and between December 1960 and December 1964 the level of Federal Reserve credit outstanding rose by 37 per cent. In part because of continuing gold outflows, the last was the largest rate of growth of Federal Reserve credit until that date over any four-year span since the Accord. Net of gold flows Federal Reserve credit expanded by 28 per cent in this period of relatively low inflation. It is hard to argue that the LM curve didn't also shift rightward.

Tax cuts were phased in 1962 in the form of an investment tax credit that effectively reduced the required rate of return that profitable firms needed to undertake an investment project and in 1964 and 1965 in the form of 10 per cent reductions in corporate and personal income tax rates. The investment tax credit and accommodating monetary policy was associated with a 50 per cent increase in real gross private domestic investment between 1961 and 1966; the tax credit implies a rightward shift in the IS curve. The large tax rate cuts in 1964 and 1965 did not lead to an increase in the federal government deficit, partly because GDP rose considerably in response to rising investment. The unemployment rate fell from 6.7 per cent in 1961 to 3.8 per cent in 1966 and the average annual rate of inflation from the end of 1960 to the end of 1966 was less than two per cent, although it began to rise in the fourth quarter of 1965.

Because of rising inflation, a policy change occurred at the end of 1965 when the Federal Reserve signalled with an increase in its discount rate that it would begin to restrict credit. All interest rates (real and nominal) rose sharply in 1966 and the real money supply fell for four successive quarters; the LM curve was shifting leftward. The Federal Reserve was briefly successful in reducing the rate of increase in prices at the end of 1966, but then inflation rose sharply in 1967 and 1968 as large deficits resulted from the Vietnam War. One reason inflation rose was that the Federal Reserve was focusing on nominal rather than real short-term interest rates; the latter were negative on average in the last three quarters of 1967 and so monetary policy was actually expansionary. The IS curve was shifting rightward until a temporary ten per cent income tax surcharge was imposed in January 1968 on corporate income taxes and in April 1968 on personal income taxes. The federal budget deficit in the national income accounts turned into a surplus in the third quarter of 1968. Beginning in early 1968, the Federal Reserve began to raise real interest rates dramatically. With both the IS and LM curves shifting leftward, the economy began to slow and the unemployment rate began to rise in 1969, as the model predicts.

During the 1960s it was becoming less tenable to view the United States as a closed economy. Although the percentage of US exports to GNP had risen from six per cent in 1946 only to seven per cent in 1969, international events were beginning to impair the usefulness of the original Hicksian model. The quasi-fixed exchange rate system that had been established in the 1944 Bretton Woods Conference began to collapse in 1968 when the US gold stock reached a critically low level. In light of the aforementioned important contributions by Mundell and Fleming, which argued that monetary policy is ineffective and fiscal policy is powerful in a fixed-exchange regime with perfect capital markets, it is necessary

to digress to explain how the model applied before the actual collapse in 1971–3 and afterwards.

At the end of the Second World War many countries restricted currency and capital flows, which allowed both fiscal and monetary policy to be effective, as in the world Hicks envisioned. These restrictions were gradually relaxed during the subsequent years. As they disappeared, the efficacy of monetary policy weakened, although imperfect capital markets allowed it to have some residual potency. Monetary policy was weakened because countries were obliged to maintain quasi-fixed exchange rates by not allowing real interest rates to vary across countries. In contrast, fiscal policy was strengthened because central banks were obligated to take actions that offset the effects of fiscal actions on real interest rates, essentially causing the LM curve to shift in the same direction that the IS curve shifted.

By 1973 the world was in a 'dirty' floating exchange rate system where various countries attempted to maintain some fixed bilateral exchange rates with their major trading partners. Mundell and Fleming had argued that in a pure floating exchange rate system with perfect capital mobility fiscal policy would be ineffective and monetary policy would be very strong, because any action to change a country's real interest rate relative to other countries would be reinforced by a change in its trade balance. In other words, a shift in its LM curve would be reinforced by a shift in its IS curve in the same direction because its trade balance was negatively related to its exchange rate, which was positively related to the value of its real interest rate relative to those of its trading partners. Because countries were unwilling to have their exchange rates be completely flexible, fiscal policy was considerably weakened relative to the fixed exchange rate period but still continued to have some power. Monetary policy was strengthened.

This open economy extension of the IS–LM model has proven to be illuminating about monetary and fiscal policy in the post-1971 period, again particularly in the United States. With the change in the exchange-rate regime, the trade-weighted value of the dollar fell about 20 per cent between 1971 and 1973, which, together with a recession in 1974, was sufficient to allow the United States to have a trade surplus on average through 1976. Between 1973 and 1979 the Federal Reserve allowed the real short-term (federal funds) rate to be negative on average, which led to substantial inflation and a bubble in the housing market. However, the international trade-weighted value of the dollar was essentially unchanged between the middle of 1973 and the middle of 1978, because average nominal short-term interest rates and inflation in major trading partners of the United States moved in tandem. Beginning in 1977 the US trade deficit began to increase and after mid-1978 the value of the US dollar fell unevenly until July 1980.

In July 1980 the Federal Reserve began to reduce the real money stock and, with accompanying large tax cuts in 1981–3, real and nominal interest rates rose to record levels, actions that were not offset by matching policies in foreign countries. As a result, the trade-weighted dollar appreciated from 84.65 (March 1973 = 100) in July 1980 to 158.43 in February 1985 and the trade deficit soared. The IS curve shifted to the right because the increase in the federal deficit was larger than the increase in the trade deficit during these years; the LM curve shifted to the left. As the IS–LM model predicts, the expansionary effects of the 1981–3 tax cuts, as measured by changes in real GDP and the unemployment rate, were much smaller than those of the similarly sized 1964–5 tax cuts, because of both the non-accommodating monetary policy and the dollar's appreciation.

In September 1985 a meeting of representatives of five major nations in New York resulted in a successful coordinated effort to reduce the trade-weighted value of the dollar, which fell 30 per cent in the succeeding two years and was followed by a sharp reduction in the US trade deficit. US short-term real interest rates fell until the middle of 1988 and the unemployment rate reached a low of 5.2 per cent in 1989. As the extended IS–LM model predicts, monetary policy was quite effective. Monetary policy effectiveness would be repeatedly evident in the following years.For example, the Federal Reserve raised real short-term interest rates between July 1988 and December 1990 to combat inflation, which

resulted in a short recession in 1991. It successfully responded to rising unemployment by cutting its real overnight federal funds interest rate to near zero in 1993, which dramatically lowered the unemployment rate in 1995. By sharply raising this interest rate in 1994, the Federal Reserve managed to continue to lower the unemployment rate with negligible inflation until a stock-market bubble burst in 2001. Both fiscal and monetary policies were strongly expansionary between 2001 and 2005. The real federal funds rate had on average been negative since the end of 2001. As might have been predicted from the Mundell–Fleming model, the trade deficit expanded enormously; its increase was roughly equal to the increase in the federal government deficit.

Finally, a troubling problem with prolonged periods of negative short-term interest rates is that they have tended to manifest themselves in rapid rates of inflation in prices of houses – both in the 1970s and in the 2000s. As Keynes and his followers warned, expectations are at the heart of the *General Theory* and they are not prominent in the textbook expositions of the IS–LM model. Many macroeconometric models can be interpreted as extensions of the textbook IS–LM model, and as time has passed many of them have increasingly attempted to incorporate expectations formation. Expectations are prominent in the Federal Reserve's recent model (Brayton et al. 1997), but their formation may not yet be accurately represented.

Conclusions

The IS–LM model occupies an awkward position in modern macroeconomics. It is still a workhorse of undergraduate teaching and still widely used by economists in developing intuition about short-run macroeconomic phenomena, including policy counterfactuals; see Colander (2004) for discussion of these roles. However, the model fails to accommodate the main features of modern macroeconomic theory, although modern dynamic models are sometimes interpreted as having IS–LM type features. We expect this dichotomy and this anomalous use to continue.

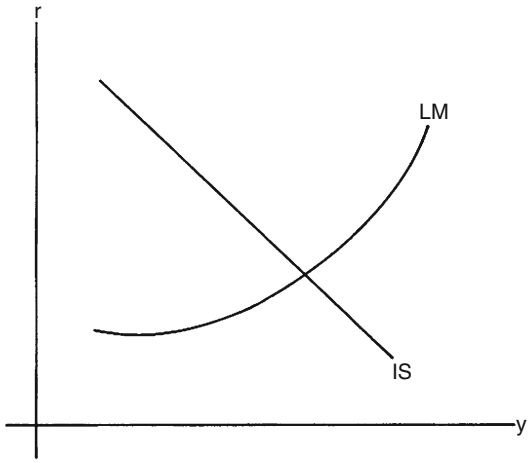
IS–LM Analysis

Axel Leijonhufvud

The original IS–LM model was introduced by Sir John Hicks as a framework for clarifying the relationship between Keynes's theory and that of his predecessors. (In Hicks's famous paper, 'Mr Keynes and the "Classics"' (1937), however, the now so familiar diagram bore the notation SI-LL.) Further attempts to define Keynes's theoretical contributions precisely within the basic IS–LM structure were made by Alvin H. Hansen (e.g. Hansen 1953), Franco Modigliani (1944), Lawrence Klein (1947) and Don Patinkin (1948) among others. IS–LM became in this way not only the vehicle for popularizing Keynesian ideas and the mainstay of macroeconomic textbooks but, for several decades, the main organizing conception for macroeconomics in general. Even the very large macroeconometric models of several hundred equations were generally disaggregated IS–LM structures. When Modigliani (1963) surveyed the major developments in macroeconomics in the early 1960s, he did so by presenting an 'updated' IS–LM model. As late as 1971, Milton Friedman and his critics debated the issues between Monetarism and Keynesianism in accordance with IS–LM groundrules (cf. Gordon 1973). From the late 1970s on, the grip of IS–LM on the macrotheoretical imagination began to loosen as the rational expectations movement came to rely on smallscale general equilibrium and game-theoretic models instead.

The equations of the basic model come in three blocks. The IS block, in the simplest version, consists of a consumption-(or savings-) function, an investment function, and a saving-equals-investment equilibrium condition. Government expenditures and taxation are optional features. The LM block, consists of a money demand (or liquidity preference) equation, a money supply equation, and an equilibrium condition for money. The employment block has an aggregate production function, from which is derived a labour demand function: the unemployment version of the model is usually completed by adding the restriction that the money wage cannot fall below a certain specified value ('rigid wages'); the full employment version has instead a labour supply function and an equilibrium condition for the labour market.

Each of the first two blocks can be reduced to a single relationship between income and the interest rate. The two reduced forms in turn produce the familiar diagram shown in Fig. 1.



IS–LM Analysis, Fig. 1 IS-LM

The number of analytical uses of this Hicksian construction remains amazing. Generations of students have learned their macroeconomics by mastering the standard IS–LM exercises: a decline in the marginal efficiency of capital shifts IS leftwards and thus reduces both income and the interest rate; an increase in the money supply shifts LM rightwards and hence raises income while lowering the interest rate, etc. But while Hicks succeeded in compressing a lot of macroeconomics into these two dimensions, such simplification naturally came at a cost. In the later literature, it has often proven difficult to keep the inevitable limitations of the apparatus in clear perspective. Three sets of such problems deserve mention.

The stock-flow dimensional aspects of the model is one problem area and the one with which Hicks himself has been most preoccupied. The IS-schedule is a locus of alternative *flow*-equilibria. But a flow-equilibrium has to be defined over some interval of time and in the case of production this interval has to be fairly long – Hicks (1983) suggests that we think of it as a 'year'. The LM-schedule shows alternative *stock*-equilibria. These can be defined for a point in time. But to insist that realizations stay consistent with expectations so that stock-equilibrium is maintained over an entire 'year', leaves so little uncertainty in the model that the demand for liquidity part of the LM-curve becomes difficult to rationalize. Hicks, therefore, sees a basic tension in the IS–LM construction between the periods appropriate to the two reduced forms. In still another reappraisal of IS–LM, Hicks (1986) points out that the IS–schedule summarizes the behaviour of the industrial sector and the LM that of the financial sector of the economy. This means that one of the characteristic simplifications of IS–LM analysis is, in effect, to disregard the balance-sheet of the industrial sector and the income-statement of the financial sector. This tends to direct attention away from cases where the two schedules are interdependent as, for instance, when an increase in current production is financed by bank credit so as to increase the money stock. It also makes IS–LM rather unsuitable for the analysis of many balance of payments problems.

A second set of problems has to do with a curious tendency for reliance on IS–LM to end up in a confusion of *nominal* and *real* (particularly real *intertemporal*) maladjustments. Consider, for instance, how the Phillips curve was used at one time to determine the expected pricelevel/ output composition of a change in the level of money income. But a change in money income of some given magnitude can be brought about by either a real disturbance (an IS-shift) or a nominal disturbance (an LM-shift). Why the price/quantity 'trade-off' of a nominal shock should ever have been expected to be the same as for a real shock appears in retrospect as a riddle but the nominal/ real distinction was seldom appropriately drawn in the Phillips curve controversy.

The most important instance of this nominal/ real confusion, however, occurred much earlier and is embedded in the outcome of the 'Keynes and the Classics' debate. This debate made use of IS–LM by investigating what restrictions on the static form of the model would produce an unemployment solution. Initially, two hypotheses seemed of interest (e.g. Modigliani 1944). One had the exogenous money supply set too low for nominal income to reach the level required for full employment at the given rigid money wage. the other had the liquidity preference function so specified that it kept the interest rate above the level required for saving and investment to be coordinated at full employment. In the course of the debate, however, this second possibility was

eliminated. It was pointed out by Pigou, Patinkin and others that, if it were possible to reduce the money wage rate to an arbitrarily low value, then the so-called 'Pigou effect' would reduce the propensity to save to whatever extent is necessary in order to bring saving and investment into line at full employment no matter what the level of interest rate happens to be. This Pigou-effect argument was taken to dispose of Keynes's intertemporal disequilibrium case. Thus the debate came to the distinctly odd conclusion that Keynes had revolutionized economic theory by asserting the classic platitude that when money wages are too high for equilibrium in the labour market unemployment is the result.

Losing sight of Keynes's intertemporal coordination failure ('saving exceeds investment') has proved costly to the Keynesian tradition. It deprived Keynesians of their natural response to Friedman's hypothesis that the lag in the adjustment of money wages is the only obstacle to employment finding its natural rate. Instead of pointing out that the natural rate of unemployment hypothesis is true only when the interest rate equates saving and investment at full employment, Keynesians tended to reply that money wages are even less flexible than Monetarists would like to believe. But if unemployment is due to money wages being too high in relation to the money supply and if one cannot afford to wait for wages to adjust, inflation will come to seem the normal remedy for unemployment. This tendency is reinforced by the fact that the rationale for the traditional Keynesian fiscal remedies is also lost when removed from the original context of intertemporal coordination failure. If saving exceeds investment (so that there is an excess supply of present resources and an implicit excess demand for future ones) it makes sense for the government to spend now and tax later. If, however, it can be presumed that real interest rates efficiently coordinate intertemporal activities, it may also be presumed that Ricardian equivalence is likely to hold.

A third problem area concerns the precise nature of the 'short-run' for which the IS–LM 'equilibrium' is defined. Comparative statics exercises with IS–LM often produce solution states that obviously represent situations of *incomplete* adjustment. The assumptions that might motivate such incomplete adjustment are, however, often unstated and not always obvious. By varying the information assumptions of the model, it is easy, for instance, to make both schedules shift in response to the standard disturbances. Such interdependence rather undermines the basic modelling strategy which presumes that one reduced form will stay put while the other shifts, so that the IS–LM diagram can be used to generate predictions in the same straightforward way as the Marshallian supply and demand apparatus. Moreover, when the information assumptions are not spelled out, confusion easily arises over whether elasticities or interdependence of the schedules are at issue in a particular controversy (Leijonhufvud 1983).

These points may be illustrated with reference to the theory of the monetary transmission mechanism. In vintage Keynesian theory, an increase in the money supply would shift LM rightwards while IS stayed put. If the interest elasticity of LM was high and that of IS low, monetary policy was seen to be 'ineffective' in the sense that, 'in the short run', the change in money income would be small. In a rational expectations model, a fully anticipated monetary impulse shifts both IS and LM in parallel fashion. In the short run, money income increases in full, constant-velocity proportion to the money injected into the system and this takes place independently of the interest elasticities of the two schedules. The older, Keynesian version can be rationalized in two distinct ways. Either one maintains that agents do not know of the nominal impulse or otherwise are unable fully to anticipate its eventual consequences; or else one interprets the increase in money, not as a pure nominal shock, but as an expansion of bank credit and inside money in, for instance, a regime with convertible money. IS–LM by itself, of course, will not help to settle the matter.

IS–LM in Modern Macro

Edward Nelson

Abstract

The IS–LM framework is associated with traditional macroeconomics, but versions of IS and LM functions can be justified using dynamic general equilibrium models that assume optimizing behaviour on the part of the private sector. The baseline version of these optimizing IS–LM relationships is discussed. Relative to the traditional IS–LM specification, the IS relationship in the optimizing IS–LM framework involves an extra term, which reflects the dependence of real aggregate demand on the expected level of spending next period. This extra term is implied by the intertemporal behaviour of households.

Background: Traditional IS–LM

Some discussions use the term 'IS–LM' as a catch-all label for the approach of traditional Keynesian economics. The treatment here, however, will follow Sargent (1987, p. 53) in interpreting 'IS–LM' narrowly (and literally) as a pair of structural equations describing real aggregate spending as a function of the real interest rate, and real money demand as a function of scale and opportunity cost variables. From that perspective, it is not strictly accurate to talk of an 'IS–LM model' (since IS–LM is only a portion of a macroeconomic model) or to refer to the 'sticky-price assumption' of IS–LM (properly specified IS and LM equations are structural and should be independent of what is assumed about price behaviour, whose specification belongs to the supply side of a model; and IS–LM analysis in conjunction with price flexibility was considered even in Hicks 1937). Nor should models that have separate equations describing consumption and investment behaviour be considered models containing IS–LM equations, since deriving an IS equation necessarily involves eliminating the components of aggregate demand in favour of an expression for total demand.

It follows that, to find descendants of traditional IS–LM in modern macroeconomics, one should focus on cases where general equilibrium models produce a pair of equations clearly recognizable as corresponding to IS (real aggregate spending) and LM (real money demand)-type relationships.

IS–LM in Modern Macro: Early Literature

Early attempts to link IS–LM with dynamic optimizing macroeconomics include Aiyagari and Gertler (1985) and Fane (1985). These attempts, however, did not use infinite-horizon agents (the standard assumption in modern macroeconomics) and usually left more endogenous variables than output and the real interest rate in the equation for total spending, so this equation was not clearly recognizable as an IS relationship.

This early literature did show that it was possible to derive a conventional money demand equation from an optimizing model. This was also shown by McCallum and Goodfriend (McCallum and Goodfriend 1987) using an infinite-horizon model. A semilogarithmic version of McCallum and Goodfriend's money demand equation is:

$$rm_t = c_1 c_t + c_2 R_t \tag{1}$$

where $c_1 > 0$, $c_2 > 0$, and rm_t and c_t denote log-deviations of real money balances and real household consumption from their respective steady-state levels, with R_t being the short-term net nominal interest rate minus its steady-state value.

In light of the feasibility of deriving an LM relationship from an optimizing general equilibrium model, most discussions concentrated on whether IS-type relationships, and therefore IS–LM as a whole, are compatible with optimizing behaviour. A symposium on the subject of IS–LM and modern macroeconomics (Young and Zilberfarb 2000), which largely predated the recent literature, was generally negative about the prospects of linking up modern macroeconomics with IS–LM.

IS–LM in Modern Macro: Later Literature

In discussing the recent literature, it is worthwhile first stepping back to Hall (1978, p. 974), who showed that an infinite-horizon dynamic general equilibrium model implied an equation for aggregate household consumption (C) of the form

$$C_t^{-(1/\sigma)} = \beta(1 + r_t)\mathrm{E}_t C_{t+1}^{-(1/\sigma)} \tag{2}$$

where r_t is the short-term net real interest rate, β is the household's discount factor and $\sigma > 0$ is a utility function parameter (with a large σ value implying high intertemporal substitution in consumption). A log-linearized version of this equation is:

$$C_t = -\sigma(r_t - \mathrm{E}(r)) + \mathrm{E}_t c_{t+1} \tag{3}$$

where $\mathrm{E}(r)$ denotes the steady-state value of r_t. Consumption equations such as (3) continue to be present in the dynamic stochastic general equilibrium models prevalent today. What is different in the recent literature is a change in emphasis in interpreting the equation. Hall (1978) treats the real interest rate as fixed and focuses on the implied univariate behaviour of consumption. The recent literature does not treat the real interest rate as fixed, and instead builds up from the consumption condition (3) to an economy-wide description of aggregate real spending behaviour. If consumption is the only component of aggregate demand (implying the relation $c_t = y_t$), then eq. (3) implies an aggregate relationship – the optimizing IS equation – of the form:

$$y_t = b_1(R_t - \mathrm{E}_t \pi_{t+1}) + \mathrm{E}_t y_{t+1} \tag{4}$$

where $b_1 = -\sigma < 0$, π_t is inflation minus its steady-state value, and the Fisher condition $(r_t - \mathrm{E}(r)) = R_t - \mathrm{E}_t \pi_{t+1}$, has also been substituted in. Under the same approximation that output equals consumption, log output becomes the scale variable in the money demand function, so that eq. (1) implies an LM relationship:

$$rm_t = c_1 y_t + c_2 R_t. \tag{5}$$

Alternative assumptions to that of strict equality between consumption and output will deliver much the same IS relationship as eq. (4). For example, one could assume constant but non-zero investment, or random-walk exogenous investment behaviour (as in McCallum and Nelson 1999), or proportionality between

consumption and investment, and in each case derive an IS equation isomorphic to eq. (4).

Whatever the precise derivation, the common element in the recent literature that starts from the Euler consumption condition is that, instead of making restrictions, as Hall did, that lead to conclusions about the unforecastability of consumption growth, it sees the condition as underpinning a structural relationship describing the level of total real spending. In this relationship total spending is a function of the real interest rate, expected future spending levels, and exogenous shocks. The negative coefficient on the real interest rate allows a parallel with the traditional interest-elastic IS relationship $Y = f(r)$. That parallel has been highlighted by the later IS–LM literature, including Koenig (1989, 1993), McCallum (1989, p. 105), Woodford (1995, 2003), Kerr and King (1996), Rotemberg and Woodford (1997), and McCallum and Nelson (1999).

Shocks

It is straightforward to justify the addition of exogenous shock terms to the optimizing IS and LM equations. Preference shocks in the household's utility function can deliver this result: for the IS equation the shock is to the marginal utility of consumption; the LM shock, on the other hand, is a combination of the shocks to the marginal utility of consumption and to the marginal utility of services generated by real money balances. In addition, the portion of government spending that is not well approximated by a (log) random walk will produce a further rationale for an IS shock.

Treatment of Capital

As noted above, a restrictive assumption about investment (that is, that it is constant or random-walk exogenous) is needed to derive the optimizing IS eq. (4). Dupor (2001) criticizes such approximations on the grounds that investment is a sizable portion of aggregate demand and a major contributor, in arithmetic decompositions, to real GDP fluctuations. These facts can be accommodated, however, without making investment endogenous. One can simply assume that investment has a random-walk and a stationary component, both exogenous. The exogenous stationary component becomes a further IS shock and can be assumed to be highly variable.

General Equilibrium Status

Early discussions of dynamic general equilibrium models stressed the interdependence of aggregate demand and supply relationships, and, that being so, the infeasibility of labelling a subset of equations specifically 'aggregate demand' equations (see, for example, Sargent 1982). By contrast, the approach that derives IS and LM relationships from a general equilibrium analysis emphasizes that a subset of equations may be labelled 'aggregate demand' relationships; and that other conditions describing private sector behaviour (such as firms' pricing and hiring decisions and households' labour supply condition) constitute the aggregate supply block. Common separability assumptions regarding the private sector's preference and cost functions justify this division of equations. The central assumption is that the terms involving consumption, leisure, and real balances are additively separable in the private households' utility functions.

Is it an IS Equation?

The optimizing IS function has been criticized as not descriptive of the original 'investment–saving' acronym, as its baseline version comes from a model with no investment fluctuation and with saving zero or constant in equilibrium. But 'IS' was always a description of how aggregate spending fluctuations related to interest-rate variations – an 'income sensitivity' or 'interest sensitivity' equation rather than really an 'investment–saving' relationship. Detailed discussion of saving issues typically would not use the assumptions (for example, those regarding

infinite horizons for agents) underpinning baseline optimizing macroeconomic models.

Alternatively, the old 'investment–saving' label could be justified on the grounds that the IS equation forms part of a model describing the process by which investment and saving are equated. That description remains true of the optimizing IS equation; it happens that in the baseline model underlying this equation, the equilibrium occurs with saving and investment at constant or zero values.

Other Interest Rates

It is tempting to suggest that the optimizing IS eq. (4) is subject to the monetarist critique of traditional IS–LM because it excludes money from the IS equation. But in fact monetarists did not argue that money belonged in the structural IS equation. Instead, they argued that many yields mattered for aggregate demand and that these yields could not be summarized by a single interest rate (see, for example, Brunner and Meltzer 1973). Variations in money acquired significance because this spectrum of yields also appeared in the money demand function. The monetarist critique amounts to the suggestion, first, that different financial assets are not perfect substitutes, and second, that the discrepancies between the yields might be related to the behaviour of money. Baseline IS–LM, both old and new, presumes perfect substitutability between assets, in which case the short-term real interest rate is tightly related to other real returns prevailing in the economy. McCallum and Nelson (1999) defend the perfect-substitution assumption as the appropriate benchmark for many purposes. Nevertheless, as Bernanke and Reinhart (2004) argue, for some policy issues this assumption is not appropriate and so it would be desirable to break the link between different returns on assets, and investigate the effect of monetary policy actions on various yields. Such a generalization of IS–LM would tend to put extra real yields into the IS equation and extra nominal yields into the LM function.

French engineer and economist, Isnard was born at Paris on 25 February 1749; he died at Lyons on 25 February 1803. There are no details of his family history except that he had a devoted brother, J.L. Isnard, who was a lawyer and a judge, and who often interceded on his behalf. At the age of 17, Isnard entered the Ecole des Ponts et Chaussées which, even at this early date, inspired interest in political economy and exposed its students to heavy doses of mathematics and statistics. On successfully completing his studies, Isnard began his career as an apprentice engineer in the district of Besançon. While engaged in various works of construction in these environs, he took the time to write his remarkable two-volume work, *Traité des richesses,* which was published in 1781.

Isnard's *Traité* is a highly original work, despite the fact that its theoretic core is embedded in otherwise unexceptional arguments against Physiocratic doctrines. By this fact, we may infer that Isnard knew the Physiocratic literature, but we can only speculate on his acquaintance with other writers. Given his background and training, the authors he would have most likely known are Boisguilbert and Vauban (Boisguilbert's ideas were represented in 19th-century course outlines at the Ecole des Ponts et Chaussées, and Vauban's views on the professionalization of engineers were largely responsible for the establishment of the Ecole). Boisguilbert certainly had a vision of an interconnected economy and of a kind of general equilibrium, although he failed to render his conception concrete by erecting any kind of formal, theoretic structure of a mathematical nature.

Isnard, on the other hand, was the first writer to attempt a mathematical definition and a mathematical proof of an economic equilibrium. Furthermore, he gave specific form to the general equilibrium concept by constructing a set of simultaneous equations which, in general form and content, anticipated the major elements of the Walrasian system, including the general interdependence of markets and quantities, the technical specifications of the exchange ratios, and the mathematical determination of the *numéraire.* It remained for Walras to add the engine of utility maximization and to adapt Isnard's model to his own purposes, something which, according to Jaffé (1969), he did with persistence, if not with ease. Isnard's pioneer efforts do not in any way denigrate Walras's monumental achievement, but they do lend force to the conviction that the development of economics was, and remains, a cumulative process.

Isnard's *Traité* is now extremely rare. However, the mathematics of his equilibrium analysis of exchange are partially accessible in Robertson (1949), Baumol and Goldfeld (1968), Jaffé (1969), and Theocharis (1983). The significance of Isnard's performance is that he discovered early on the truth that value is not an intrinsic thing but rather is a magnitude which necessarily varies in relation to other goods, whose worth is also interdependent. Specifically, Isnard anticipated the two- good world of Walras in which, for example, the demand for eggs is the supply of

wheat and the demand for wheat is the supply of eggs. This elaboration of commodity interdependencies in real terms consumes approximately the first half of Walras's *Eléments*. Mathematically, Isnard treated value as an exchange ratio, moreover, and he worked out the equilibrium process of exchange both with and without money.

It is noteworthy that Isnard extended the subjects under his analytical purview to include, besides the theory of exchange, the theories of production, capital, interest and foreign exchange. Jaffé (1969) has demonstrated that Walras's economic theory bears the imprint of Isnard in each of these areas. Underscoring merely the most striking example of the calibre of Isnard's analysis, Jaffé (1969, p. 40) emphasized his theory of capital and interest, which correctly laid down the rule for optimum resource allocation in the following terms:

> Capitals are distributed among different employments in agriculture, industry, and commerce in such a way that the ratios of their values to receipts from the sale of their products less the costs of upkeep, repair, and replacement – that is, the ratios of [invested] funds to [net] returns – are everywhere the same in all enterprises. This uniformity is achieved and equilibrium established because funds flow to and abound in places where the yield [intérêt] is highest and because like things have one and the same value. When things have a higher price in one place than in another, they rush there and equilibrium is re-established. Let F be the value of the funds employed in agriculture and F′ that of the funds employed in industry; let B be the payments for the value of the products of agriculture less the cost of upkeep, repairs and replacement and B′ the payments for the products of industry less the same costs, then the ratio of F to F′ must be equal to the ratio of B to B′ for the ratio of F to B to be equal to the ratio of F′ to B′ or for the rate of interest [in the sense of rate of capitalization] to be everywhere the same. This uniformity [in the rate of capitalization] is realized not only between agriculture and industry in general, but also among individual enterprises.

It is, of course, necessary that perfect knowledge obtain for this conclusion to hold, but even without always making his assumptions explicit, Isnard anticipated much of modern microeconomic theory.

The scope and sweep of his analysis unquestionably entitle Isnard to a position of prominence in the history of economic thought. Yet appropriate recognition took a long time. Despite the filiation of ideas between Isnard and Walras, the 'father' of general equilibrium analysis mentioned Isnard's name in only one place, and that an obscure bibliographic article (a French reprint of Jevons's famous bibliography of mathematico-economic works) published in the *Journal des Economistes* in 1878. Add to this the ambiguity, idiosyncrasy and prolixity of Isnard's treatise. His definition and use of mathematical symbols is inconsistent and the essence of his arguments difficult to extract, nested as they are in a morass of other material that is neither very original nor very interesting. Such deficiencies were bound to handicap the recognition and acceptance of Isnard's contribution. In the final analysis, however, Isnard was simply a brilliant pioneer who wrote ahead of his time, and like so many other semi-tragic heroes of economic analysis (for example, Cournot and Gossen), he failed to receive his due until long after departing the scene.

Isnard suffered in his personal life even as his ideas suffered (by neglect) in economics. Hot-tempered, yet not given to the intrigues apparently required to advance in the engineering ranks of a quasi-military public service, Isnard spent most of his career in a subordinate capacity. After he finally received a post worthy of his talents, his wife died, leaving him to raise three motherless children. At that point Isnard left government service and struggled in penury for some time. Recalled by Napoleon for the Egyptian campaign in 1798, he was inexplicably left behind. Adding insult to injury, he was forced to take an oath of allegiance to the Republic even though he was an avowed royalist. He later became a member of the Tribunate under Napoleon and took an active part in the formation of public finance and conscription policies. But upon completing his term he resumed his engineer's career at Lyons, where he died soon after, 54 years to the day from his birth. Given his apparent influence on Walras, Theocharis (1983, p. 62) probably did not exaggerate much when he labelled Isnard's *Traité* 'one of the most important contributions in the history of the development of mathematical economics'.

Italy, Economics in

Massimo M. Augello and Marco E. L. Guidi

Abstract

The history of economics in Italy reflects an interaction between scientific–educational institutions and political power, which led economists to combine a theoretical approach and political commitment. During the Enlightenment a network of circles and public academies spawned the contributions of Beccaria, Genovesi, Galiani, Ortes and Verri. The institutionalization of economics in the 19th century prepared the success of the marginalist generation led by Pantaleoni, Pareto and Barone. In the interwar period, academic economists formed a bulwark against Fascism. The post-war political climate favoured the internationalization of economics, with the importation of Keynesianism and, later, other currents of thought.

This article examines the evolution of Italian economic thought from its origins to the post-Second World War years, when the professionalization and internationalization of economics reached maturity, sowing the seeds of the present vigorous state of economic studies. It offers an institutional history of political economy, distinguishing four epochs. The first epoch runs from the 16th to the 18th century. In this period, the alliances between

enlightened sovereigns and groups of intellectuals produced a wealth of original contributions to economics. The second epoch corresponds to the Napoleonic age and the Restoration. This was a period in which, despite political repression in Italy, Smithian political economy penetrated many circles and was debated in journals and academies. The third epoch runs from the unification of Italy in 1860 to the rise of the Fascist regime in 1922, and is referred to as the 'liberal age'. This period was crucial for the institutionalization of economics and for the prominent public role that was attributed to economists. Such a favourable environment was responsible for the high standard of scientific debate, which culminated in the generation of Pantaleoni and Pareto, when Italian economics, as Schumpeter wrote (1954, p. 855), 'was second to none'. Finally, the fourth epoch regroups the Fascist era and the post-war years. During the decades of Fascism, the regime's attempts to control economic debate produced a reaction of self-defence and isolation among neoclassical economists. After the war, the new climate of liberty encouraged economists to get back to their public role. The political debate on economic planning was responsible for the acceptance of Keynesianism in the 1950s. The success of Neo-Ricardianism in the 1960s and, later, of American-based mainstream economics marked the internationalization of Italian economics.

Public Happiness and Geometrical Method: From the Origins to the Enlightenment

Although in the Middle Ages theological debate over the 'just price' and the legitimacy of usury flourished in many parts of Italy, and Italian authors came to be respected throughout Europe, the beginnings of modern economic science in this country date from the 16th and early 17th centuries, when the formation of regional states generated a need to regulate public finances, trade and the circulation of money. Some traces of economic analysis can be found in the treatises on politics published by the humanist Niccolò Machiavelli (1469–1527) *(Discorsi sopra la prima deca di Tito Livio*, 1513–21) and the Jesuit Giovanni Botero (1544–1617) *(Della Ragion di Stato,* 1589). But the most original analyses were contained in some short treatises of a systematic and highly formalized character, based on a hedonistic framework, a coherent theory of value and an extensive use of mathematics. The theoretical framework they provided could be employed to interpret the monetary and commercial problems of the time. Of this kind are the *Discorso sulle monete* (1582) by the aristocrat Gaspare Scaruffi, the *Lezione delle monete* (1588) by the merchant and historian Bernardo Davanzati (1529–1606), the *Breve trattato delle cause che possono far abbondare li regni d'oro e d'argento, dove non sono miniere* (1613) by Antonio Serra, whose life is shrouded in mystery, and the *Trattato mercantile della moneta* (1683) by Geminiano Montanari (1633–87), a professor of mathematics and astronomy. These works were connected to the diffusion of the Catholic currents inspired by Platonism and hostile to Aristotelian scholasticism that were at the root of the Galilean revolution. The abstract nature of these texts can be explained by the fact that they were a product of the scientific academies created in this period under the aegis of the Italian princes – especially those in Florence – with a view to encouraging knowledge which could be useful in strengthening state power and countering the civil decay of the country, for which they blamed the political influence of the Church. The authors of these economic treatises were natural philosophers who acted as temporary consultants to government or were members of the state bureaucracy.

The long wave of Galilean and Platonic doctrines continued through the 18th century and had a recognizable impact on the theoretical structure of the economic discourse in the two circles that were at the centre of the Italian Enlightenment, combining in different ways with new ideas coming from France and Scotland and with ideas from other indigenous traditions. The first of these circles was the Accademia dei Pugni of Milan, which was run by Pietro Verri (1728–97), author of the *Meditazioni sull' economia política* (1771) and Cesare Beccaria (1738–94), known not only for his main work, *Dei*

delitti e delle pene (1764), but also for a series of theoretical articles on political economy published in the journal of the academy, *Il Caffè* (1764–6). The second group was that in Naples headed by Bartolomeo Intieri, whose discussions sparked both *Della moneta* (1751) by Ferdinando Galiani (1728–87) and *Lezioni di economia civile* (1766–7) by Antonio Genovesi (1713–69). These groups became involved in the economic reforms their monarchs were trying to bring about, as revealed by the public offices obtained by Verri, Beccaria and others. Also in other parts of the country, the academies were called upon to produce a science whose utility was measured in terms of greater dominion over nature and of the greater ability of governments to increase 'public happiness'. But it was the 1753 foundation of the Accademia Economico-Agraria dei Georgofili in Florence that sanctioned the scientific status of economics and its political role in the strategy of reform. Right up to the end of the 18th century, this academy was to be one of the main vehicles for the spread of Physiocratic and Smithian doctrines in Italy. Its journal was an example of the many agricultural periodicals that hosted economic debates, often of a practical kind, albeit open to the new science of political economy.

Collaboration between philosophers and princes ushered in the creation of the first teaching of political economy as part of a reform of university studies whose purpose was to bring them under the umbrella of the state, combating the control that religious orders and professional bodies had traditionally exerted over them. A chair of Commercio e meccanica was founded in Naples in 1754 on the initiative (and funding) of Intieri, and conferred on Genovesi. Another professorship of political economy, established at the Scuole Palatine, Milan, in 1768, was assigned to Cesare Beccaria. Similar chairs were created in Modena, Catania and Palermo. The aim of these chairs was twofold: they should instruct government bureaucrats in the art of governing economic and financial affairs, and stimulate the application of new agricultural techniques and agrarian laws.

From a theoretical point of view, the contribution of these authors – to whom one should add at least Giammaria Ortes (1713–90) and Gianbattista Vasco (1733–96) – is quite homogeneous. Their core approach is based on a natural law framework which turns around a static rather than dynamic notion of equilibrium, and suggests that there are forces in society that tend to restore equilibrium when natural disasters, changes in tastes, or political errors create unbalances. Another basic assumption is the sensationalist view that human beings are constantly under the guidance of pleasure and pain. The underlying methodology is still abstract and 'geometrical', as in the works of their predecessors. The focus of analysis is on problems of exchange rather than of production (although Beccaria gave the clearest definition of the division of labour before Adam Smith). Their main contributions concern the analysis of value, based on utility and scarcity: Ortes, Beccaria and Verri attempted a mathematical formulation of the law of demand and supply as a guide to the analysis of price adjustments. Another theme of inquiry is the theory of money, where Galiani, adopting metallist assumptions, expounded a clear distinction between short-run variations in the value of money and long-term effects, and between real and monetary effects. Finally, these authors shared a view of the sovereign as a reformer and supreme moral authority, who takes into account the feelings and needs of individuals and constructs a social order according to the dictates of reason and natural law. This order consists of an equilibrium of interests that generates 'public happiness' *(felicità pubblica).*

The Spread of Classical Economics in the Age of *Risorgimento* (1815–60)

Although the Napoleonic age is considered, in Europe as a whole, a period in which political economy was regarded with suspicion, in Italy the establishment of the Empire's satellite kingdoms favoured the discipline's development and its institutionalization. However, the content of teaching was radically modified: theoretical economics was reduced in order to make room for legal and statistical notions, which were considered more urgent for the training of public officials. Moreover, Napoleonic administrations

concentrated on the collection of detailed statistical information about the condition of their *départements*, in order not only to promote anti-feudal reforms but also to protect French interests. A new generation of government officials was assigned to this task: among them there was the most important economist of this period, Melchiorre Gioja (1767–1829), who published his main work, the *Nuovo prospetto delle scienze economiche,* between 1815 and 1817. Gioja examined Smith's and Say's theories with a critical eye, and his original analysis of cooperation, division of labour and machinery was acknowledged by Charles Babbage as an anticipation of his own theories. Regarding economic policy, Gioja was favourable towards state intervention in order to foster the development of agriculture and manufactures.

Another Napoleonic official was Pietro Custodi (1771–1842), who from 1803 to 1805 edited the 50 volumes of a collection titled *Scrittori classici italiani d'economia politica,* which reproduced most of the Italian texts on political economy from previous centuries. Custodi aimed at stimulating the patriotic spirit of his fellow citizens by encouraging them to improve their economic and statistical knowledge. This collection produced in the next generation of intellectuals of the *Risorgimento* era an exaggerated feeling of national pride, which nevertheless encouraged the study of economics.

Economics experienced its worst period after the Restoration in 1815. The reactionary governments of the Italian regional states considered the teaching of economics to be a vehicle for liberal and democratic ideas. As a consequence, all chairs of political economy were suppressed, except in Naples and Sicily, where they were put under strict political control. Only in the 1840s, in Piedmont and Tuscany, with the establishment of constitutional governments, was the teaching of political economy restored. Antonio Scialoja (1817–77), first, and then Francesco Ferrara (1810–1900) were appointed professors at the University of Turin, while other chairs of economics were created in Pisa and Siena.

In these conditions, discourse on political economy went on largely outside universities. This does not mean that it was clandestine, since it was developed in academies and associations which enjoyed an official status. But the political control over these institutions implied that public debate on controversial issues was sometimes tolerated and sometimes heavily repressed. Already in the Napoleonic age newly founded institutions, such as the Accademia Pontaniana of Naples or the Istituto Nazionale, established in Bologna and transferred to Milan in 1810, had included departments of moral and political sciences where political economy was discussed. Furthermore, the experiences of 18th-century agrarian academies had prompted the establishment of a network of provincial associations termed 'agrarian' or 'economic societies', which aimed at promoting the development of local economies. These associations continued their activities even during the decades following the Restoration, expanding from Piedmont to Sicily. Despite their eminently practical goals, economic societies gave an important impetus towards the spread of British and French political economy and laissez-faire ideals.

Another means by which political economy spread through the Italian learned classes was the periodical press, despite the existence of censorship. In the early decades of the 19th century the heading 'political economy' appeared on a growing number of articles published in new journals of 'sciences, letters and arts', such as the *Biblioteca italiana,* founded in Milan in 1816, the *Antologia,* created in Florence in 1821, and *Il progresso delle scienze, delle lettere e delle arti,* first published in Naples in 1832, where it acted as the main point of convergence of liberal culture. Lively exchange of ideas was also found in journals of agriculture, especially the *Giornale agrario toscano,* founded in 1827, which together with the Accademia dei Georgofili promoted an original debate on sharecropping echoing Sismondi's remarks in *Tableau de l'agriculture toscane.*

The first signs of a trend towards specialization in economic disciplines came with the birth of several journals mainly devoted to statistical and economic themes, such as the *Annali universali di statistica* and the *Giornale di statistica.* The former was first published in Milan in 1822

and had among its contributors Gioja and Giandomenico Romagnosi (1761–1835). The latter was founded in Palermo in 1836 as the organ of the Central Statistical Office. Edited by Ferrara, it achieved immediate recognition as the premier forum for debate among Sicilian laissez-faire economists. Another interesting experiment was *Il Politecnico,* launched by Carlo Cattaneo (1801–69) in 1839. The majority of the essays were composed by Cattaneo himself, and dealt with various practical issues. However, in two remarkable articles Cattaneo focused on doctrinal questions, criticizing the protectionist theories of Friedrich List, and arguing that knowledge and motivation are the most important factors of economic development. But one should also mention a number of journals created in Naples in the 1840s, which arose against the backdrop of private law schools, established as an alternative to the more conservative form of instruction offered by the universities. These journals and institutions soon became a focal point for the new school of liberal economists, of which Scialoja was the main representative.

As this description makes clear, the political economy debated in these forums was that of Smith and Say. In northern Italy a key figure was Romagnosi, a legal philosopher who – taking inspiration from Giambattista Vico's philosophy of history – formulated a peculiar version of Smithian political economy, in which the notion of 'natural progress of opulence' was employed to argue that economic development depended on a framework of formal and informal institutions (so-called *incivilimento),* and that government-induced industrialization would result in social disaster. Romagnosi's 'institutionalist' approach influenced a whole generation of economists, stimulating interesting contributions on the relationships between law and economics. In the south of Italy, the penetration of classical economics was mediated by the influence of the French *idéologues,* which caused Say's work to be received enthusiastically. The most brilliant product of this environment was Scialoja's *I principj della economia sociale esposti in ordine ideologico* (1840), translated into French in 1844, which adopted Say's subjectivist approach to value and developed the analysis of the entrepreneur in a pre-Schumpeterian sense.

But the most acute and original economist of this age was Ferrara, who in his lecture notes of 1856–8 and in the prefaces to the *Biblioteca dell' economista* – a 'library' containing the Italian translation of a vast number of foreign works on economics, of which he was the editor – proposed a generalization of the cost of reproduction theory of value formulated by Henry Carey and John Rae. Ferrara's version of this theory took into consideration three different cases: that of 'physical reproduction' by direct labour, that of physical reproduction 'by way of exchange' and that of 'economic' reproduction by substitutes. In this way, the theory highlighted the fact that value is grounded on utility and subjective opportunity costs, clearly foreshadowing marginalist analysis.

The Institutionalization of Economics in the Liberal Age (1860–1922)

The epoch that followed the unification of the country in 1860 was decisive for the consolidation of economic studies. Chairs of political economy were introduced in the more than 20 law faculties that existed at the time. In 1876, new university regulations added the teaching of statistics and public finance. The latter was established as a compulsory course in 1885. Likewise in the 1880s, two Higher Schools of Commerce were created in Genoa and Bari, similar to the first institution of this kind, which had been founded in Venice in 1868. This expansion multiplied the opportunities for economists to obtain university positions, and well before the end of the 19th century the social identity of the economist could be largely identified with the academic profession. But a decisive stimulus to the professionalization of economics was provided in the mid-1870s by the explosion of the Italian counterpart of the *Methodenstreit*, the dispute over methods that divided German-speaking economics. All the major economists became involved in it, and opposition between different economic and political conceptions had an important impact on the professional and academic level. These

divisions induced economists to devote greater attention not only to the scientific aspects of the profession (training and specializations) but also to academic policy (increase in the number of academic chairs and control over recruitment procedures). This process resulted in a generational change within the ranks of academic staff, leading to a preponderance of the followers of *Kathedersozialismus* or 'socialism of the chair' in the German mould.

Another important element is represented by the increasing public role played by economists. The extension of civil liberties, coupled with the institution of a national representative system, gave them an extraordinary opportunity to spread economic knowledge and influence policymaking. Many economists became columnists for newspapers and weekly magazines, while others were active in the foundation of associations of interests, chambers of commerce, saving banks or cooperatives. Lastly, virtually all the leading economists of this age – more than 30 – became members of parliament. And although some of them were involved in parliamentary activities that bore little relation even to the broadest view of the scope of political economy, in the central debates on tariffs and trade, fiscal policies, credit, education, and in inquiries on the condition of agriculture and industry the voice of economists became a typical feature of public life. Some economists were also appointed ministers, while three of them – Paolo Boselli (1838–1932), Luigi Luzzatti (1841–1927), and Francesco Saverio Nitti (1868–1953) – became prime ministers.

On the whole, these activities strengthened the scientific and social identity of economists.

The growing professionalization of economists was also reflected in the creation of new societies in which they played a central role. After the first experiments in Turin in the 1850s and early 1860s under the guidance of Ferrara, the Società di Economia Politica Italiana was established in 1868 on the initiative of the economist Francesco Protonotari, who was the editor of the most important scientific and literary journal of the time, the *Nuova Antologia.* These associations attracted the great majority of academic economists and many representatives of the political elites. The constitution of the Società di Economia Politica significantly opened with the statement that the Society's mission was to 'promote and disseminate economic studies'. However, very soon its activities were dominated by more practical discussions on parliamentary debates and government economic policy. Conflicts concerning the new orientation of the society's purposes led to a gradual slowdown in the pace of activities.

It was against this backcloth that the *Methodenstreit* arose, breeding the projects of two rival associations. The former, dubbed Società Adamo Smith, was set up in Florence in 1874 on the initiative of Ferrara and several laissez-faire economists and politicians belonging to the group of the so-called 'Tuscan moderates'. The aim of the Society was that of 'promoting, developing and defending the doctrine of economic liberties', and of assuming the character of a scientific body, excluding from debate all that could be more properly described as political. The latter society, called Associazione per il Progresso degli Studi Economici, was created in January 1875 by a group headed by Luigi Cossa (1831–96), a powerful academic of the university of Pavia, Fedele Lampertico (1833–1906), an influential senator of the Venetian area, and by Luzzatti and Scialoja. Responding to Ferrara's splinter-group tendency, these economists had drawn up a document, known as the 'Padua circular', which marked the start of the counteroffensive by 'socialists of the chair'. The society set itself the task of promoting social studies, to be accomplished partly through extension of its organizational structure to different parts of Italy.

Both associations proved to be short-lived, but the overall effect of their activities over roughly a 30-year period was that of ushering in a profound change in the institutional set-up of economic studies, reinforcing the academic and public background of the economists' activities. This new condition was reflected in the world of publishing. To begin with, while scientific–literary journals continued in their tradition of hosting writings on economic themes, more specialized journals were established. Characteristically, in the 1870s almost all of the economic journals exhibited very close

links with one or the other of the conflicting schools of economic thought. Thus, orthodox liberals used as their mouthpiece the journal *L'Economista,* created in 1874, whereas 'socialists of the chair' founded one year later the *Giornale degli economisti*. Rather than a genuine forum for scientific debate, however, such journals tended to become tools with which to enter the political fray. This characteristic was to a lesser extent replicated by the new journals that appeared in the 1890s, despite their more scientific and academic nature: the most important among them were the socialist periodical *Critica sociale,* directed by Filippo Turati (1857–1932), the *Rivista internazionale di scienze sociali e discipline ausiliarie,* edited by the Catholic economist Giuseppe Toniolo (1845–1918), and *Riforma sociale* (1894–1935), edited at first by Nitti, and later by Luigi Einaudi (1874–1961). Perhaps the first journal of economics in the modern sense may be considered the new series of the *Giornale degli economisti,* started in 1890 and managed by Maffeo Pantaleoni (1857–1924), Antonio De Viti de Marco (1858–1943) and Ugo Mazzola (1863–99). This journal voiced the radical laissez-faire approach of its editors, while becoming the forum of academic research and the main vehicle of penetration of marginalist theory in Italy.

Even outside the world of journals, greater attention began to be paid to the promotion of economic studies. For instance, after the first two series of the *Biblioteca dell' economista,* edited by Ferrara and published in the 1850s and 1860s, a third series was entrusted to Gerolamo Boccardo (1829–1904) in the 1870s, and a fourth and fifth series were continued by Salvatore Cognetti de Martiis (1844–1901) and Pasquale Jannaccone (1872–1959) up to 1922. With its 71 volumes containing more than 150 classics of economics, the *Biblioteca* was extremely successful and became a unique tool for those who wanted to update their knowledge in this field. Economists also popularized their doctrines through dictionaries and encyclopaedias; the most important of them was the *Dizionario della economia politica e del commercio,* published in 1857–61 by Boccardo, who was also the editor of the *Nuova enciclopedia italiana* (1875–88).

Undoubtedly the main instrument for the spread and institutionalization of political economy was the large number of treatises, manuals and popularizations that were published during this period. The authors of these texts were both major economists and a host of lesser-known scholars, philanthropists and schoolteachers interested in the popularization of political economy. The number of works published – almost 300 from 1840 to 1920 – reveals that there was a pervasive 'need' for political economy, considered as a discipline that could educate the younger generations of administrators and politicians, instruct public opinion and enlighten the working classes. To judge from the number of editions, the most popular manuals were Cossa's *Primi elementi di economia politica* (1875, 17 re-editions), Emilio Nazzani's *Sunto di economia politica* (1873, 16), Boccardo's *Trattato teoricopratico di economia politica* (1853, nine), Camillo Supino's *Principii di economia politica* (1904, nine), Achille Loria's *Corso completo di economia politica* (1909, seven), and Augusto Graziani's *Istituzioni di economia politica* (1904, six).

At the same time, the scientific quality of the work was high. Italian economists rapidly assimilated international economic debates, and in some cases they became important protagonists. The quantitative approach to statistics initiated by A. Quetelet and E. Engel was largely accepted in the mid-1860s thanks to the contributions of Angelo Messedaglia (1820–1901), whose methodological works influenced a whole generation of economists, Emilio Morpurgo (1836–1885), and Luigi Bodio (1840–1920), who organized the Central Statistical Office and was elected secretary of the International Institute of Statistics on its foundation in 1885. Some years later, Cossa, Lampertico and Luzzatti were instrumental in familiarizing Italian scholars with the methodology of the German Historical School and the social views of socialism of the chair. These economists promoted a renewal of economic studies along inductivist and quantitative lines, and adopted a critical stance vis-à-vis economic liberalism in matters of social policy. They were called the 'Lombard–Venetian School' since most of them taught at the universities of Pavia and Padua.

An even more vigorous and original response to outside stimuli was represented by the penetration of marginalism. Pantaleoni's *Principii di economia pura* – a work largely inspired by Jevons, Edgeworth and Marshall – dated from 1889, but the same author had already published in 1883 a work on public finance based on marginalist notions. Pantaleoni encouraged Vilfredo Pareto's (1848–1923) conversion to the new approach some years later. In 1893, the latter succeeded Walras at the chair of economics in Lausanne. In his *Cours d'économie politique* (1896–7), and more radically in *Manuale di economia politica* (1906), he revolutionized utility theory, laying the foundations of modern microeconomic analysis. A third representative of Italian marginalism was Enrico Barone (1859–1924), whose article on 'The Ministry of Production in the Collectivist State' (1908) was included by Hayek in his 1935 anthology on economic planning. Interesting applications to public finance were also provided by Barone himself and by De Viti and Mazzola. Their contributions lay the foundation of an original school of thought whose analysis of taxes, public expenditure, and of the political context in which fiscal structures operate, has been recognized by James Buchanan as the starting point of the development of modern public finance theory. A distinctive feature of Italian marginalist economists was their practical and ideological commitment: they engaged themselves in political and editorial activities, staunchly defending a radical laissez-faire view. The socialists Arturo Labriola (1873–1959) and Enrico Leone (1875–1940) attempted to find a compromise between marginalism and Marxism. In the first decade of the 20th century, neoclassical economics had already become the orthodox approach.

Less vigorous, albeit no less original, was the Italian contribution to Marxist revisionism. In *La rendita fondiaria e la sua elisione naturale* (1880), Loria (1857–43) attempted to explain the functioning of a capitalist economy as a result of the structure and evolution of landed property. The historical and theoretical weaknesses of Loria's approach were then attacked at the end of the century by the Marxist philosopher Antonio Labriola (1843–1904), but his efforts to convince Benedetto Croce (1866–1952) to join his camp resulted in a relaunching of revisionism: Croce considered Marx's notion of surplus value as a simple 'mental abstraction' which could not explain the essence of capitalist production. On the other hand, Antonio Graziadei (1873–1953) argued that the labour theory of value was useless to explain the genesis of surplus value and the formation of market prices.

From Corporatism to Keynesianism and Neo-Ricardianism

After an early phase of authoritarian laissez-faire policy delegated by Mussolini to the economist and minister of finance Alberto De' Stefani (1879–1969), a turn towards a corporatist organization of the economy was accomplished in 1926. The introduction of corporatism was the result of political decisions rather than of scientific debate, although corporatist currents of Catholic and socialist ascendancy had existed since the late 19th century. The fascist regime organized two national conferences in 1930 and 1932 to stimulate a debate on corporatist economics, but they ended up with the defeat of those intellectuals who stood for a more radical transformation of economic relationships along corporatist lines.

On the whole, only from 1925 to 1934 did corporatist economics enjoy some popularity. Its partisans proclaimed that the *homo corporativus* should replace the individualist *homo oeconomicus*, but they failed to produce significant achievements in economic theory. Orthodox economists like Einaudi and Jannaccone, initially forced into a tactical retreat, took back the lead in debate after 1934. Most academic economists – Gustavo Del Vecchio (1883–1972), Marco Fanno (1878–1965), Costantino Bresciani Turroni (1882–1963), Giovanni Demaria (1899–1998), and others – put aside their laissez-faire beliefs and attempted to interpret corporatist economy from a marginalist viewpoint. Corporatism was thus reduced to a case of economic policy, which did not modify the content of pure theory. A characteristic that distinguished these and other economists was their firm attachment to

Paretian general equilibrium analysis, which they developed in a dynamic sense elaborating some suggestions derived from Pantaleoni's writings and from Pareto's sociology. At the same time, forced to defend orthodoxy against ideological attacks, these economists largely ignored or misunderstood the nature of the Keynesian revolution.

This success of orthodoxy can be mostly explained by institutional factors. The Fascist government tried to reform the organization of university studies, in 1935 transforming the teaching of economics into that of 'corporatist political economy'. However, orthodox economists jealously defended their academic autonomy, and the younger generation they recruited was composed of disciples whose career was generally not obstructed by political intrusions. The efforts of the Fascist regime concentrated on the creation of special schools and research institutions – such as the School of Corporatist Sciences of the University of Pisa, directed by Giuseppe Bottai (1896–1979), the Labour School of Florence, headed by Gino Arias (1879–1942), and the National Institute of Agrarian Economics, directed by Arrigo Serpieri (1877–1960).

Likewise, the major publishing houses – in particular Einaudi in Turin and Laterza in Bari – actively supported orthodox economics. The publisher that more actively sponsored corporatist economics was Sansoni in Milan, which issued a series connected to the Pisa Corporatist School, containing works on corporatism and economic planning. The lobbying activity of liberal economists also succeeded in modifying the editorial project of the *Nuova collana di economisti stranieri ed italiani* (1932–7), originally conceived as a sequel of the *Biblioteca dell'economista* and as the seal of Fascist economic culture. As a matter of fact this collection was open to recent international literature (Pigou, Sraffa, Hicks, Frisch, Hayek, Robertson and Keynes), and made no room for corporatist economics. Even the major cultural enterprise of the Fascist regime, the *Enciclopedia Italiana* edited by Giovanni Gentile, was quite impartial in the choice of authors for its economic entries.

Conversely, Mussolini's government was able to impose a considerable control over the periodical press. On the one hand, it created its own ideological mouthpieces – such as *Gerarchia* and *Critica Fascista* – and favoured the rise of economic journals – such as *Economia,* founded in 1923, and *Nuovi studi di diritto, economia e politica,* started in 1927 – that stimulated a considerable debate around the implications of corporatist economics. On the other hand, it extended its repression of journals of the liberal camp. Both *La Riforma sociale* and the *Giornale degli economisti* were discontinued for political reasons, in 1935 and 1942 respectively.

One of the costs of the Fascist years was a limited but significant 'brain drain': among those who were forced to emigrate were Bresciani Turroni, Umberto Ricci (1879–1946), Piero Sraffa (1898–1983), and the young Franco Modigliani (1918–2003).

The evolution of the economics profession in the post-war period was substantially influenced by the restoration of liberal-democratic institutions. First and foremost, the recovered political freedom favoured the rise of a network of centres of research and advanced studies (the Centre of Specialisation and Economic–Agrarian Research of Portici, the Svimez in Naples, the Istao in Ancona, the Research Department of the Bank of Italy in Rome) and of university departments.

Scholarships were granted to young scholars who wanted to continue their studies abroad, encouraging the opening of frontiers to international debate after the relative isolation of the Fascist period. The main economic journals were restructured and new specialized periodicals emerged, adopting international standards. Another crucial event was the creation in 1951 of the Società Italiana degli Economisti, whose constitution stipulated a full economics professorship as a criterion for admission.

The new political context soon stimulated many economists to return to their traditional public vocation. Einaudi, Labriola and Nitti sat in the Constitutional Assembly (1946) with other economists of the younger generation, including Epicarmo Corbino (1890–1984), Amintore Fanfani (1908–1999), Antonio Pesenti (1910–

1973), Paolo Emilio Taviani (1912–2001) and Ezio Vanoni (1903–1956). A special Commission on economic and social affairs nominated by the government was chaired by Demaria and composed of the most eminent amongst his colleagues.

It was mostly from the political side that Keynesianism made its entry into the Italian debate in the early 1950s, despite the persisting reluctance of economists to accept its theoretical underpinnings. Some Catholic economists engaged in politics, such as Fanfani and Giorgio La Pira (1904–77) declared themselves to have been inspired by Keynes when, as members of the cabinet, they introduced a plan for subsidized housing to reduce unemployment. But a Keynesian flavour could also be discerned in the 'Plan for labour' propounded in 1948 by the CGIL, the communist and socialist trade union. Likewise, the 'Scheme for the growth of employment and income in Italy in the decade 1955–1964' presented by Vanoni was explicitly inspired by Harrod's growth model. Finally, the debate of the 1960s on economic planning, in which Ferdinando di Fenizio (1906–74), Pasquale Saraceno (1903–1991), Giorgio Fuà (1919–2000), Paolo Sylos Labini (1920–2005) and Federico Caffè (1914–1987) participated, was clearly dominated by Keynesian assumptions. This does not mean that Keynes's theory was not present in more academic debates. The second edition of di Fenizio's *Lezioni di teoria economica* (1948) reflected the neoclassical synthesis arguing that the Keynesian approach was complementary rather than alternative to classical theory. Also Caffè and Vittorio Marrama (1914–82) published a series of theoretical contributions on Keynesian economic policies. Finally, Keynesianism exerted a considerable influence on the Italian public finance tradition, especially thanks to the works of Sergio Steve (1915–2006).

The 1960s were also marked by the impact on Italian economics of works of Sraffa, who since the 1920s had migrated to Cambridge. His article on 'The Laws of Return under Competitive Conditions' (1926) – preceded by a paper published in 1925 in the *Giornale degli economisti* – had criticized Marshall's equilibrium analysis and paved the way for research in imperfect competition. In *Production of Commodities by Means of Commodities* (1960) Sraffa expounded an alternative to general equilibrium analysis based on a reformulation of the classical and Marxian notion of surplus. This work originated a school of thought, the neo-Ricardians, that exerted a powerful influence on international scientific debates and on Italian academic life for a couple of decades. Among its main representatives one should count Pierangelo Garegnani and Luigi Pasinetti.

The strength of neo-Ricardian economics has probably been the last distinctive feature of Italian economics, at least in its most theoretical departments. In recent decades, the growing internationalization of this discipline has caused Italian economics to move towards the American-based mainstream of economics, with its typical formalistic and quantitative features. This change has been symbolized by the move to English as *lingua franca* not only of economic discussion but also of Italian journals, conferences and Ph.D. programmes.
